Reaction 13.12: ATP-dependent phosphofructokinase (PFK)

Reaction 13.13: Fructose-1,6-bisphosphatase (FBPase)

Reaction 13.14: Pyrophosphate-dependent phosphofructokinase (PFP)

PFK catalyzes the C-1 phosphorylation of fructose 6-phosphate, an essentially irreversible reaction under cellular conditions. It is a glycolytic enzyme, working in the opposite direction to the flux during sucrose synthesis. The enzyme

FIGURE 13.24 Interconversion of fructose 6-phosphate and fructose 1,6-bisphosphate by ATP-dependent phosphofructokinase (PFK), PP_i -dependent phosphofructokinase (PFP), and fructose-1,6-bisphosphatase. PEP, phosphoenolpyruvate; F2,6bP, fructose 2,6-bisphosphate.

has been studied in detail in systems other than plants, and it is viewed as a principal regulated step controlling the glycolytic flux.

In plants, both plastid and cytosolic PFK isoenzymes are strongly activated by P_i and inhibited by phosphoenolpyruvate and other 3-carbon metabolites of the glycolytic pathway. Consequently, this early step in glycolysis is sensitive to energy demand (indicated by P_i levels) and to negative feedback from downstream intermediates in the pathway (Fig. 13.24). During photosynthesis, free phosphate levels are low due to photophosphorylation and metabolite buildup in the chloroplast, while carbon export from the chloroplast as triose phosphate is high. Thus, the cytosol is supplied with ample substrates for the reactions of glycolysis, resulting in PFK inhibition. In contrast, at night and in nonphotosynthetic tissues, P_i levels are higher and carbon supply is primarily in the form of hexose phosphates derived from starch or sucrose metabolism; thus, PFK is activated to meet respiratory and biosynthetic demands.

FBPase catalyzes the hydrolytic cleavage of phosphate from the C-1 position of fructose 1,6-bisphosphate to form fructose 6-phosphate and P_i . This gluconeogenic enzyme supports the flux of carbohydrate from the triose phosphate pool to the hexose phosphate pool in the cytosol. An isoenzyme is also present in chloroplasts, where it is part of the Calvin–Benson cycle, but it is typically absent in nonphotosynthetic plastids. FBPase is also included as a reaction of the oxidative pentose phosphate cycle (see Section 13.9).

Cytosolic FBPase is strongly inhibited by **fructose 2,6-bisphosphate**, as is the enzyme from animals. In plants, the concentration of cytosolic fructose 2,6-bisphosphate is controlled in part by the status of the triose phosphate pool, and in part by the status of the hexose phosphate pool. Consequently, the level of this inhibitor, and hence cytosolic FBPase activity, is sensitive to carbon supply from the chloroplast and the utilization of hexose phosphates for biosynthesis (see Section 13.6.2). In contrast, the plastid FBPase is regulated differently, via a redox mechanism linking its activity to the light reactions of photosynthesis (see Chapter 12).

The third enzyme, PFP, is something of an enigma. Animals and most other eukaryotes do not have it and, in contrast to PFK and FBPase, PFP catalyzes a readily reversible reaction. In many tissues, PFP is present at higher activities than PFK.

Although many roles have been postulated for PFP, none has been conclusively verified (see Box 13.1). PFP is powerfully activated in the direction of fructose 1,6-bisphosphate formation by fructose 2,6-bisphosphate, the same **signal metabolite** that inhibits cytosolic FBPase (Fig. 13.25).

13.6.2 Fructose-2,6-bisphosphate is a signal metabolite that regulates the partitioning between sucrose and starch synthesis

Knowledge of the kinetics and regulation of the enzymes described in the preceding sections has allowed the development of a model explaining how starch synthesis might serve as an overflow mechanism that allows storage of any excess carbohydrate produced during photosynthesis. This is needed when sucrose synthesis starts to exceed the capacity of the leaf to export or store it. Carbon stored as starch can then be utilized to support respiration and continued sucrose biosynthesis during darkness, when photosynthesis cannot occur. Some plants, such as tobacco (*Nicotiana tabacum*), store a large fraction of photoassimilate as starch. Almost half of the total sucrose export from the leaf occurs during the night and is derived from starch synthesized during the preceding day. Other species, such as pea (*Pisum sativum*), synthesize less starch and store more sucrose in the vacuole.

Partitioning between sucrose and starch is not a binary on/off mechanism; rather, it represents continuous monitoring of the status of the various pools of metabolites in the cytosol and chloroplast. Central to this model is fructose-2,6-bisphosphate, which is found only in the cytosol and inhibits the activity of cytosolic FBPase (see Section 13.6.1). Fructose-2,6-bisphosphate is a signal metabolite. It is not part of a part biochemical pathway or cycle, but is synthesized from fructose 6-phosphate by **fructose-6-phosphate 2-kinase** and converted back to fructose 6-phosphate by **fructose-2,6-bisphosphatase** (Fig. 13.26). The inhibitory effect on cytosolic FBPase means that changes in the concentration of fructose 2,6-bisphosphate have a powerful effect on the flow of carbon from triose phosphates into the hexose phosphate pool. Thus, to understand partitioning between sucrose and starch, it is essential to understand the factors that control fructose-2,6-bisphosphate levels (Fig. 13.27).

Fructose-6-phosphate 2-kinase is activated by P_i and strongly inhibited by triose phosphates; in contrast, fructose-2,6-bisphosphatase is inhibited by P_i . Hence, the concentration of fructose-2,6-bisphosphate is in part controlled by the increase in the triose phosphate to P_i ratio occurring during photosynthesis. The levels of these regulators are communicated between the stroma and cytosol via the strict counter exchange mechanism of the TPT, linking the production of triose phosphates in the chloroplast and their consumption in the cytosol, with P_i release in the cytosol and reincorporation by photophosphorylation.

The concentration of fructose-2,6-bisphosphate is also affected by the hexose phosphate pool which, in mature leaves, primarily reflects the status of sugar export from

FIGURE 13.25 Structures of fructose 1,6-bisphosphate and fructose 2,6-bisphosphate. The regulatory metabolite and the metabolic intermediate differ in the position of one phosphate group.

FIGURE 13.26 Formation and degradation of fructose 2,6-bisphosphate by fructose-6-phosphate 2-kinase and fructose-2,6-bisphosphatase. Regulation by inorganic phosphate (P_i), triose phosphates, and fructose 6-phosphate is indicated.

the leaf. When sucrose production exceeds export, sucrose accumulates and its synthesis is inhibited (possibly by inhibition of SPS, Fig. 13.13), and the hexose phosphate concentration increases. One of the hexose phosphates, fructose 6-phosphate, is also a regulator of fructose-2,6-bisphosphate levels; it activates fructose-6-phosphate 2-kinase and inhibits fructose-2,6-bisphosphatase, thereby increasing the fructose 2,6-bisphosphate concentrations (see Fig. 13.26). Hence, the concentration of fructose 2,6-bisphosphate integrates both a feedforward signal (the supply of photosynthate from the chloroplast) and a feedback signal (demand for substrates for sucrose biosynthesis) to control the capacity for gluconeogenic flux.

Triose phosphate concentrations not only influence the formation of fructose 2,6-bisphosphate, but also determine the concentration of fructose 1,6-bisphosphate available as substrate for FBPase. Under standard conditions, at pH 7.0, the equilibrium position of the aldolase reaction favors the formation of fructose 1,6-bisphosphate. The equilibrium position is defined by Equation 13.1:

$$K_{\text{eq}} = \frac{[\text{glyceraldehyde 3-phosphate}][\text{dihydroxyacetone phosphate}]}{[\text{fructose 1,6-bisphosphate}]} \quad (\text{Eq. 13.1})$$

Because the two triose phosphates are rapidly interconverted by triose-phosphate isomerase, this equation shows that the concentration of fructose 1,6-bisphosphate is determined by the square of the triose phosphate concentration ($[\text{triose phosphate}]^2$), making the aldolase reaction very sensitive to the triose phosphate concentration. That is, the concentration of fructose 1,6-bisphosphate increases exponentially

with a linear increase in triose phosphate concentrations. Thus, the equilibrium of the aldolase reaction and the regulation of the fructose 2,6-bisphosphate concentration by triose phosphates and P_i are complementary mechanisms to relate the rate of sucrose synthesis to the amount of photosynthate exported from the chloroplast (Fig. 13.27).

13.6.3 Sucrose synthesis coordinates with photosynthate supply at the start of the day

At the start of the light period, photosynthesis begins and triose phosphates accumulate in the chloroplast. This causes the TPT to exchange triose phosphate for P_i . Triose phosphates accumulate in the cytosol, while P_i concentrations decline. Consequently, fructose-6-phosphate 2-kinase is rapidly inhibited, and fructose-2,6-bisphosphatase is activated. As a result, fructose 2,6-bisphosphate concentrations quickly decline, relieving the inhibition of fructose-1,6-bisphosphatase. This, combined with the impact of the equilibrium effect of the aldolase reaction, allows the carbon to flow into the cytosolic hexose phosphate pool, once the concentration of triose phosphate reaches a threshold value. In turn, the increased concentration of glucose 6-phosphate activates sucrose-phosphate synthase, allowing the synthesis of sucrose (see Fig. 13.13). Enhancing this effect will be the stabilization of sucrose-phosphate synthase in the active, nonphosphorylated state by the low concentration of phosphate and the high concentration of glucose 6-phosphate (Fig. 13.13). Hence, these two feed-forward mechanisms activate the flow of photosynthate

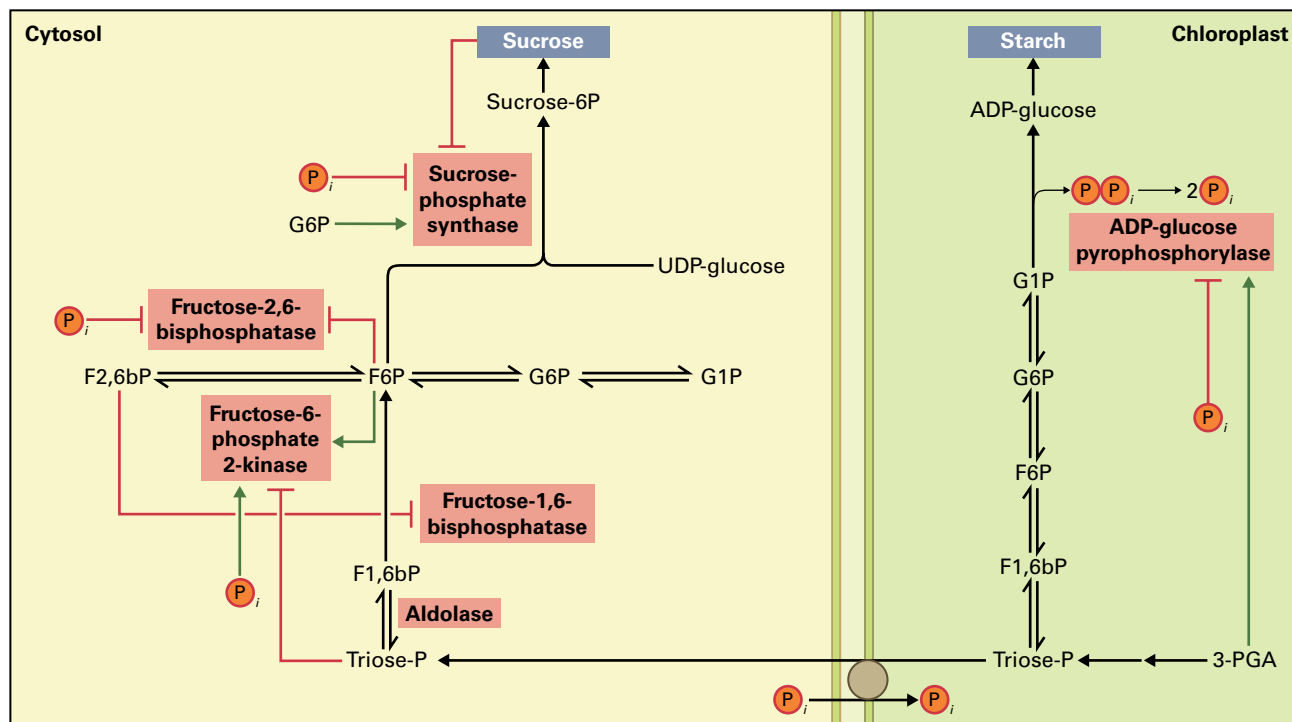

FIGURE 13.27 Regulation of the interconversion of starch and sucrose. This interconversion provides an example of how metabolite levels are constantly monitored in the leaf cell, and how pathways are both activated and inhibited to keep them balanced. Early daylight: The onset of photosynthesis causes the accumulation of triose phosphates in the chloroplast. These triose phosphates are exported to the cytosol in exchange for inorganic phosphate (P_i). The triose phosphates inhibit fructose-6-phosphate 2-kinase, while the removal of cytosolic P_i weakens the activation of this enzyme and relieves inhibition of fructose-2,6-bisphosphatase and sucrose-phosphate synthase. As a result, fructose 2,6-bisphosphate (F2,6bP) concentration drops, inhibition of cytosolic fructose-1,6-bisphosphatase is relieved, and carbon flows into the hexose phosphate pool. The increasing concentration of glucose 6-phosphate (G6P) activates sucrose-phosphate synthase, resulting in sucrose synthesis. Midday: the model postulates that sucrose-phosphate synthase is deactivated by negative feedback from sucrose accumulation, but this has not been confirmed. In any case, diminished sucrose-phosphate synthase activity results in accumulation of its substrate fructose 6-phosphate (F6P), which inhibits fructose-2,6-bisphosphatase and activates fructose-6-phosphate 2 kinase. The resulting increase in the concentration of F2,6bP leads to inhibition of fructose 1,6-bisphosphatase. Because the aldolase reaction is reversible, triose phosphates accumulate in the cytosol, preventing export of triose phosphates from the chloroplast. This results in accumulation of 3-phosphoglycerate (3-PGA), which activates ADP-glucose pyrophosphorylase and promotes starch synthesis. Onset of darkness: As the light intensity falls during the evening, photosynthesis progressively declines. The synthesis of 3-PGA stops, activation of ADP-glucose pyrophosphorylase is lost, and starch synthesis declines. P_i accumulates in the chloroplast, further inhibiting ADP-glucose pyrophosphorylase, which also becomes deactivated through oxidation. Although this presents the situation in the leaf as a series of distinct events, metabolite levels are constantly monitored to adjust the rates of starch and sucrose syntheses, which are kept in step with the rate of photosynthesis at all times.

to sucrose once the threshold level of triose phosphate is reached (Fig. 13.27).

13.6.4 Partitioning shifts towards starch when sucrose synthesis exceeds sucrose export

At midday, under high light conditions, the rate at which chloroplasts supply **photosynthate** may exceed either the demand for sucrose in sink tissues or the ability of the leaf to export it. Under these conditions, starch is synthesized from the excess carbon.

When sucrose accumulates in the leaf cell, it reduces the rate of its synthesis, which increases the size of the hexose

phosphate pool. The inhibition of sucrose synthesis is probably due to inhibition of sucrose-phosphate synthase, although the mechanism by which this happens is still unclear. The increase in fructose 6-phosphate both activates fructose-6-phosphate 2-kinase and inhibits fructose-2,6-bisphosphatase (see Fig. 13.26), and this dual action overrides the feedforward effect of triose phosphates. As the concentration of fructose 2,6-bisphosphate increases, it inhibits fructose-1,6-bisphosphatase and slows the flow of carbon into the hexose phosphate pool. As cytosolic triose phosphate levels increase, their export from the chloroplast is inhibited. The increase of triose phosphate in the chloroplast, in turn, causes an increase in the plastid concentrations of 3-phosphoglycerate, which activates ADP-glucose pyrophosphorylase (see Fig. 13.21). Hence, carbon flow is diverted from sucrose to starch (Fig. 13.27).

This mechanism for controlling the flow of carbon into sucrose reflects both the supply of and demand for photosynthate. Central to this mechanism are the TPT and P_i . The TPT controls carbon flow between the chloroplast and the cytosol, communicating the changes in one compartment to the other. P_i plays a major role in the fine regulation of this overflow mechanism by affecting a number of the key regulated enzymes, usually in an antagonistic way to one of the phosphorylated metabolic intermediates (i.e., components of the hexose phosphate and triose phosphate pools). As P_i levels generally change in a reciprocal manner to these intermediates, small changes in absolute amounts represent a larger change in the ratio of the effectors, with a more pronounced regulatory impact on enzyme activity. This mechanism monitors constantly the status of the various metabolic pools so that the partitioning between sucrose and starch is optimized for the particular environmental conditions of the plant.

13.6.5 The overflow model for leaf starch synthesis cannot fully explain assimilate partitioning

Plants have a way of making even the most elegant model seem inadequate. For example, the overflow model described above suggests that, on a cloudy day when the light intensity is low, the rate of photosynthesis should never meet the demand for sucrose, so no starch should be made. In reality, however, some starch is made under these conditions, albeit in lower amounts. This suggests the presence of an underlying mechanism that ensures some carbon assimilated during the day is stored in preparation for the coming night. Furthermore, partitioning responds to the **photoperiod**, such that in short days a greater proportion of assimilated carbon is stored as starch. This change is controlled—either directly or indirectly—by the **circadian clock**, which allows the plant to predict that a long night accompanies a short day, hence the need for additional starch. The rate of starch degradation is also controlled at night such that the starch reserves are depleted gradually and last the entire night (Fig. 13.28).

Studies of mutant plants also revealed a surprisingly high degree of adaptability in the pathways of photosynthetic carbon metabolism. Some naturally occurring mutants of the Florida weed “Yellowtop” (*Flaveria linearis*) have no detectable cytosolic FBPase, although the chloroplast enzyme is present. Similar laboratory-generated *Arabidopsis* plants have also been produced that grow more or less normally and produce sucrose and starch in their leaves with near-normal efficiency. Furthermore, potato (*Solanum tuberosum*), tobacco (*Nicotiana tabacum*), and *Arabidopsis* plants lacking the TPT have also been generated, which also grow well in the laboratory.

How can plants survive without these proteins, which are supposedly central to photosynthetic carbon metabolism? The answer appears to be that these atypical plants first make starch in their chloroplasts, but break it down simultaneously

FIGURE 13.28 Pattern of starch accumulation and utilization in *Arabidopsis* leaves during different diurnal regimes. The black line represents the near-symmetrical pattern observed under 12 h light/12 h dark conditions. The rates of starch synthesis and starch degradation respond in complementary ways to short day (red) or long day (green) conditions.

during the day, generating free sugars maltose and glucose (wild-type plants only break down starch at night). Consequently, carbon is not exported from the chloroplasts of these mutants as triose phosphate. Separate transporter proteins exist for both glucose and maltose, which can be metabolized in the cytosol to form hexose phosphates (see Section 13.7.3). This alternative pathway circumvents the need for the TPT and the cytosolic FBPase steps. Plants of this type demonstrate the remarkable flexibility of plant metabolism (Box 13.5).

13.6.6 At night, leaf starch reserves are broken down to support respiration and metabolism

At dusk, light intensity declines, and the supply of photosynthate decreases and eventually ceases. Many processes in plant metabolism continue, however, fueled by the remobilization of stored reserves, such as starch; energy and reducing power are provided by the respiratory pathways (**glycolysis**, the **citric acid cycle**, and the **oxidative pentose phosphate pathway**).

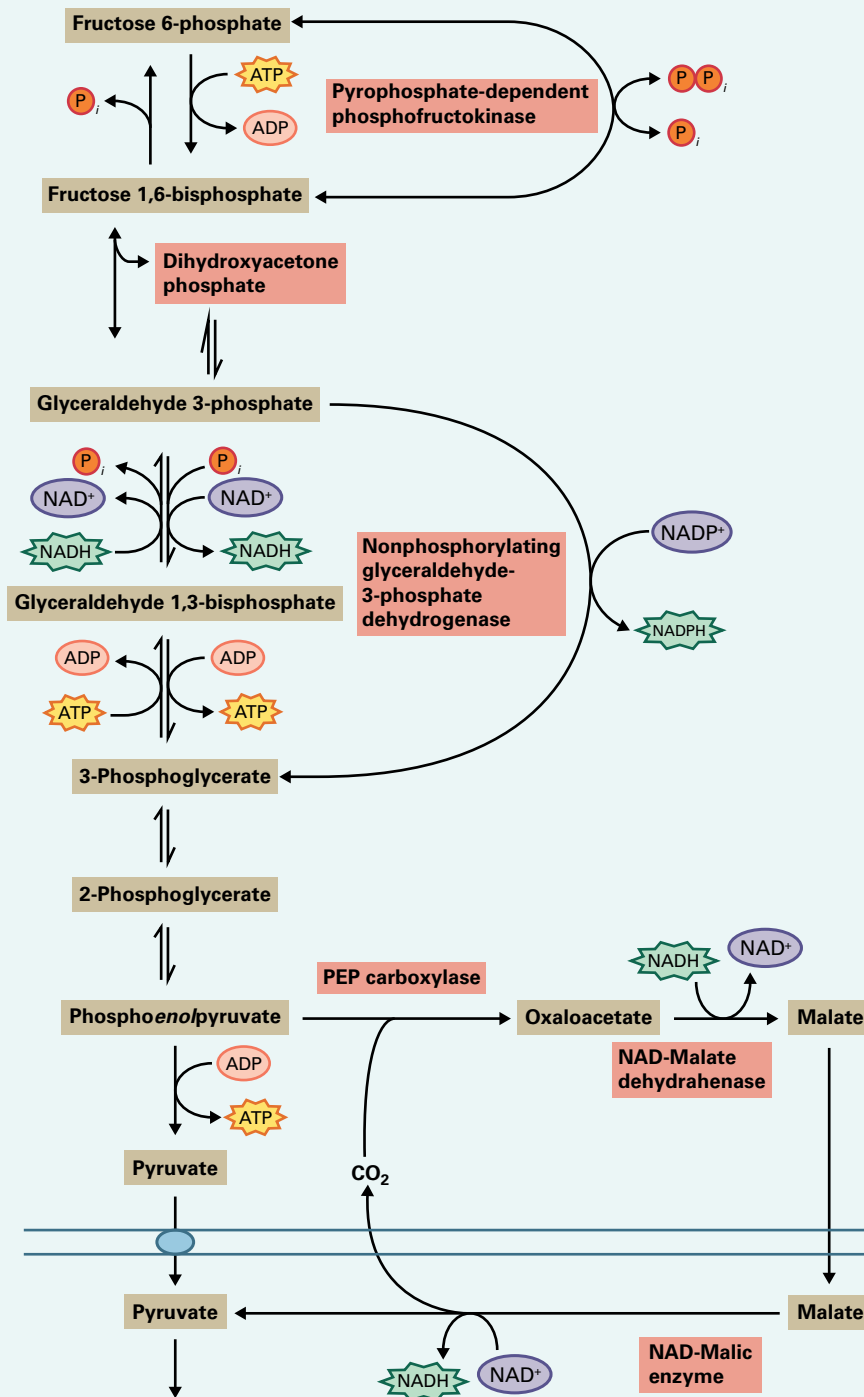

Under artificial, laboratory growth conditions, abruptly turning off the lights can cause a rapid drop in leaf sucrose levels; sucrose synthesis stops, while its export and metabolism continue. Then, after a short delay, starch degradation

Bypass reactions give plants metabolic flexibility

Because they are sessile, plants are subjected to whatever the environment has to offer. To survive, they have developed a flexible metabolism that helps them accommodate to environmental changes (for example, plants often have more than one enzyme capable of catalyzing a specific reaction).

Some enzymes of plant carbohydrate metabolism are not found in animals or in most other eukaryotic organisms. Examples include PFP, which bypasses the reaction catalyzed by fructose-1,6-bisphosphatase, and the nonphosphorylating glyceraldehyde-3-phosphate

dehydrogenase that produces only NADPH and 3-phosphoglycerate. The function of these bypasses is not fully understood. They may provide the plant with an ability to withstand phosphate starvation, a common condition. Indeed, in some plants, PFP activity increases when plants are starved of phosphate. Under these conditions, concentrations of adenylate nucleotides (ATP and ADP) are reduced, and reactions requiring them may be inhibited. PFP uses pyrophosphate, an alternative energy source, thereby conserving ATP. The nonphosphorylating glyceraldehyde-3-phosphate

dehydrogenase also bypasses reactions that require ADP as a substrate, thereby allowing carbon to pass through glycolysis without the need for ATP synthesis.

Such flexibility in plant metabolism is frequently illustrated when genetic engineering is used to knock out supposedly critical enzyme activities. For example, transgenic tobacco (*Nicotiana tabacum*) plants lacking cytosolic pyruvate kinase in their leaves appear nearly normal, whereas in other organisms, the lack of this enzyme retards growth. However, it appears that reactions bypassing pyruvate kinase (e.g., a combination of phosphoenolpyruvate carboxylase, malate dehydrogenase (see Chapter 14), and malic enzyme) can convert sufficient phosphoenolpyruvate to pyruvate to

maintain growth. A second example is plants lacking the TPT, which is required for the export of triose phosphates produced during photosynthesis; these plants reroute metabolism, synthesizing and degrading starch simultaneously to generate glucose and maltose that can be exported to the cytosol via distinct transporters. Plants lacking pyruvate kinase or the TPT, while growing relatively well in the laboratory, would almost certainly be at a disadvantage compared to their wild-type counterparts in their native habitats. The loss of some of their metabolic flexibility would take its toll. The continued study of performance of such plants may help scientists understand why plant metabolism is configured as it is.

begins and sucrose levels rise again. Under natural conditions (which can be simulated in the laboratory using a sinusoidal light regime), the changes in light intensity are more gradual, and plant metabolism can adapt.

As light intensity and photosynthesis decline, the rates of sucrose and starch synthesis also decline, and as a result, sucrose export exceeds the rate of sucrose synthesis. The associated decrease in the concentrations of hexose phosphates results in a decreased concentration of fructose 2,6-bisphosphate, relieving fructose-1,6-bisphosphatase inhibition. This, then, allows free flow from triose phosphate to the hexose phosphate pool in the cytosol. Triose phosphate is exported from the chloroplast in exchange for P_i , so the activation of ADP-glucose pyrophosphorylase by 3-phosphoglycerate is lost, while P_i inhibits it. Thus, as photosynthesis slows, partitioning is shifted away from starch in favor of sucrose synthesis. Gradually, however, the carbon assimilation rate drops below the rate necessary to support sucrose biosynthesis, and eventually it stops altogether. During this time, starch degradation is triggered, allowing sucrose synthesis to continue into the night. Much progress has been made in the last decade in understanding the pathway of starch degradation in leaves, although the trigger to initiate it and the way the rate is controlled are still not fully understood.

13.7 Starch degradation

Starch is the most widespread storage carbohydrate in plants, and it accumulates in many different tissues and organs, including the chloroplasts of leaf cells. However, it is more typically associated with plant storage organs, such as seeds, roots, and tubers, which represent staple crops. Much knowledge about **starch degradation** has been derived from biochemical analyses done on germinating cereal grain, such as barley (*Hordeum vulgare*) and wheat (*Triticum aestivum*), and this thirst for knowledge was driven by the importance

of starch breakdown in the production of malt and flour for industry. It led to the discovery of hydrolytic enzymes known as amylases, several different types of which are now known.

The remobilization of starch from the endosperm of cereal grain is, however, an unusual example of starch breakdown in plants (see Box 13.6). In developing cereal grain, starch is made in the amyloplasts of the endosperm cells, which die upon seed maturation. This leaves a large starch-rich matrix surrounded by a specialized outer layer of living endosperm cells, the aleurone layer. After germination, degradative enzymes are secreted from the aleurone layer and the embryo, and starch degradation occurs extracellularly within the endosperm. This pathway differs in several important ways with the process that occurs inside chloroplasts.

13.7.1 Glucan phosphorylation modifies the starch granule surface

The semi-crystalline lamellar structure of the starch granule, which results from the packing of the double helices of adjacent amylopectin chains (see Fig. 13.18), represents a difficult structure for the enzymes of starch degradation to attack. The first step in starch degradation inside chloroplasts is the phosphorylation of a small proportion of the glucosyl residues of amylopectin by two enzymes: **glucan, water dikinase** (GWD) and **phosphoglucan, water dikinase** (PWD). GWD binds to the surface of the starch granule and introduces phosphate groups at the C-6 position of glucosyl residues (Reaction 13.15). PWD then binds to the prephosphorylated starch and introduces phosphate groups at the C-3 position of another glucosyl residue (Reaction 13.16).

Reaction 13.15: Glucan, water dikinase

BOX
13.6

Starch degradation in the endosperm a germinating cereal grain is an unusual example of starch breakdown in plants

The starch-rich cereal grains represent a cornerstone of human nutrition. In addition, they have been used for thousands of years to brew beer, because fermentable sugars are generated in large amounts from the starch upon germination.

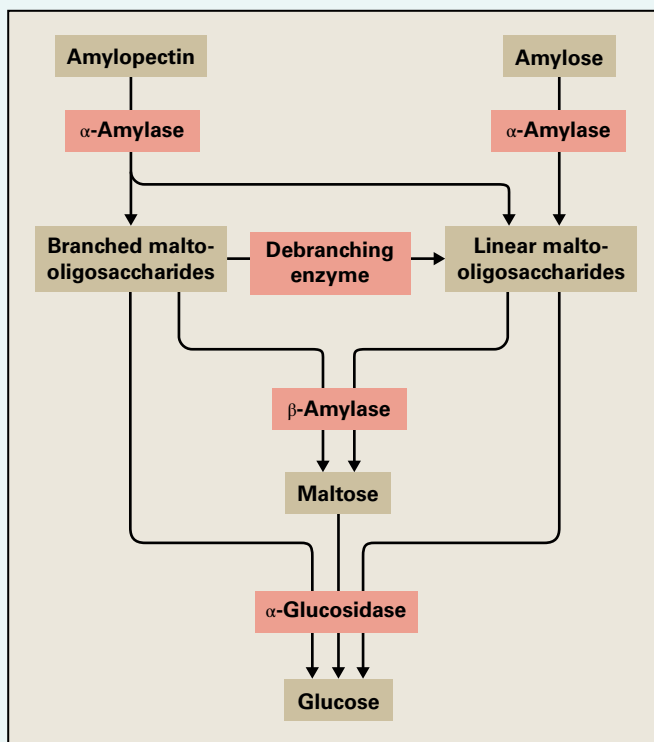

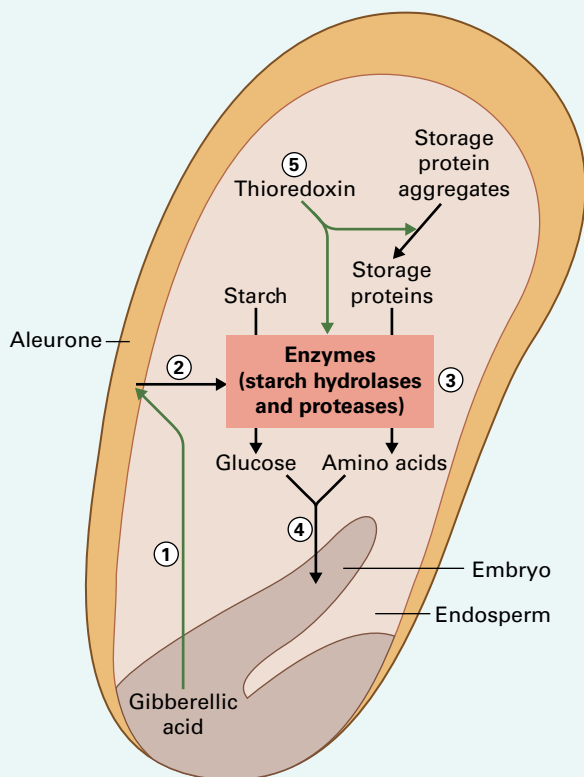

The embryo represents only a small fraction of the cereal grain volume; the rest is mostly occupied by the starch-rich endosperm. The starchy endosperm cells die upon seed maturation and desiccation, but the tissue retains the capacity for some metabolic processes, including a redox system that is important for germination.

During germination, the release of the hormone gibberellic acid from the embryo (1) triggers the secretion of enzymes from the living aleurone layer surrounding the starchy endosperm (2) and from the scutellum (the specialized cotyledon of the embryo). Three types of starch-degrading enzymes are released: α -amylase, the debranching enzyme limit dextrinase, and α -glucosidase (also called maltase). Proteases for degrading storage proteins are also secreted. In addition, secreted proteases activate a preformed β -amylase stored within the endosperm through limited proteolysis of its carboxyl terminus. Together, these enzymes hydrolyze the starch to glucose and the proteins to free amino acids (3), all of

which are taken up by the embryo (4) to support seedling establishment and growth.

There is no evidence that the enzymes involved in chloroplast starch degradation, such as glucan water dikinase and phosphoglucan phosphatases, are involved in the breakdown of endosperm starch. Rather, α -amylase is thought to initiate granule degradation, acting at specific sites (pores in the starch granule surface) and leading to a characteristic 'pitting' of the granule. The combination of limit dextrinase and β -amylase can degrade the branched and linear oligosaccharides released by α -amylase to maltose and maltotriose, both of which can be hydrolyzed to the constituent glucose monomers by α -glucosidase. The glucose liberated by starch breakdown in the endosperm can be taken up by the scutellum, phosphorylated by hexokinase and converted to sucrose for transport within the germinated seedling.

The endosperm also contains an h-type thioredoxin (Trx h) (see Chapter 12), which is reduced by NADPH and NADP-thioredoxin reductase (see Chapter 14). In turn, Trx h reduces critical disulfide (S-S) groups of enzyme inhibitor proteins and storage proteins of the endosperm (5), facilitating the breakdown of starch and stored

protein to nourish the developing seedling. Following reduction to SH, the storage proteins become more soluble and susceptible to endogenous proteases, enhancing the formation of nitrogen-containing nutrients. Furthermore, the proteins with disulfide bonds that inhibit the enzymes degrading starch and storage protein

are inactivated by reduction, allowing the degradative enzymes to become active and function during seedling establishment. Though not fully understood, Trx h also appears to serve as a means by which the embryo and aleurone sense the redox state of the endosperm during germination.

FIGURE 13.29 Pathway of starch degradation in chloroplasts. Maltose and malto-oligosaccharides are released from the surface of the insoluble starch granule during degradation. Malto-oligosaccharides are metabolized in the stroma, and maltose and glucose are exported to the cytosol. Estimated fluxes are indicated by relative arrow size, with dashed arrows representing minor steps in *Arabidopsis*. Inset is a model depicting the role of phosphorylation by glucan, water dikinase (GWD) and phosphoglucan, water dikinase (PWD) in disrupting the packing of amylopectin double helices (gray boxes). This allows the release of maltose and malto-oligosaccharides (blue lines) by β -amylases (BAM) and debranching enzymes (DBE). Phosphate (red dots) is released concomitantly by phosphoglucan phosphatases (PGPs) to allow complete degradation.

Reaction 13.16: Phosphoglucan, water dikinase

Phosphorylation alters the properties of the granule surface. The hydrophilic phosphate groups disrupt the packing of the double helices, perhaps even destabilizing the double helices themselves. This renders the exposed glucan chains more susceptible to the set of enzymes that can degrade the glucosidic bonds. The key role of glucan phosphorylation is illustrated by the phenotypes of GWD-deficient mutant or transgenic plants. The phosphate content of the starch is reduced and starch degradation is inhibited leading to the accumulation of high levels of leaf starch, a starch-excess (*sex*) phenotype.

13.7.2 Starch degradation yields maltose, glucose, and glucose 1-phosphate in chloroplasts

A number of enzymes participate in the subsequent degradation of starch, including β -amylase, debranching enzymes, **phosphoglucan phosphatases**, α -amylase, **disproportionating enzyme**, and starch phosphorylase. This results in a network of reactions rather than a linear pathway (Fig. 13.29). Some steps appear to be more impactful than others, as judged by the severity of the starch-excess phenotype resulting when the respective gene is mutated in *Arabidopsis*.

The linear chains of amylopectin and amylose are degraded primarily to maltose by β -amylase, which catalyzes a hydrolysis reaction that is irreversible under cellular conditions. β -Amylase gets its name from the fact that after hydrolysis, the hydroxyl group at the reducing end of the liberated maltose is in its β -anomeric form (Reaction 13.17). β -Amylase is an **exoamylase**, which acts processively from the nonreducing ends of the glucan chains until its progression is blocked by an α -1,6-branch point or a phosphate group. At branch points, β -amylase leaves short residual chains, two or three glucose residues in length. These are removed, again via an irreversible hydrolysis reaction, by one of two debranching enzymes (**isoamylase 3** or **limit dextrinase**; see Reaction 13.11). These enzymes are distinct from the **isoamylase 1-type debranching enzyme** that helps to achieve the correct structure of amylopectin (see Section 13.5.4). When β -amylase progression is blocked by a phosphate group, the phosphate is removed by one of two phosphoglucan phosphatases (Reaction 13.18). Thus, glucan phosphorylation and dephosphorylation proceed concurrently with glucan degradation.

Reaction 13.17: β -Amylase

Reaction 13.18: Phosphoglucan phosphatase

Chloroplasts also contain α -amylase, an **endoamylase** capable of hydrolyzing exposed internal α -1,4-glucosidic bonds (Reaction 13.19). α -Amylase can release a spectrum of linear and branched **malto-oligosaccharides** from the granule surface.

Reaction 13.19: α -Amylase

Thus, during starch degradation, the combined actions of α -amylase, β -amylase, and debranching enzymes can generate maltose and a mixture of short linear and branched malto-oligosaccharides in the chloroplast stroma (Fig. 13.29). Branched malto-oligosaccharides can be debranched in the stroma by debranching enzymes, and malto-oligosaccharides longer than three glucosyl residues (maltotriose) are further degraded by β -amylase. However, maltotriose is too short to be a substrate for β -amylase; it is metabolized by an α -1,4-glucanotransferase reaction catalyzed by disproportionating enzyme (D-enzyme, DPE1; Reaction 13.20). This versatile enzyme takes a part of a donor malto-oligosaccharide and transfers it to an acceptor molecule. For example, when acting on two maltotriose molecules, it transfers a maltosyl moiety from one to the other, generating glucose and maltopentaose (a chain of five glucose residues). The longer chains that it generates can again be attacked by

β -amylase so, when working together, these two enzymes effectively form a cycle that converts maltotriose to maltose and glucose. Interestingly, DPE1 does not use or generate maltose, which means that any maltose generated is exported to the cytosol.

Reaction 13.20: α -1,4-Glucanotransferase (D-enzyme DPE1)

Maltose and, to a lesser extent, glucose are the major products of starch breakdown inside chloroplasts. This is supported by analyses of the sugars exported from isolated chloroplasts incubated in the dark, and by genetic evidence (i.e., considering the severity of the starch-excess phenotypes of mutants lacking the aforementioned enzymes). Both maltose and glucose can be exported to the cytosol via distinct transporters in the chloroplast inner envelope that facilitate their diffusion across the membrane. However, chloroplasts also possess **α -glucan phosphorylase** (also called **starch phosphorylase**), an enzyme that cleaves individual glucose residues from the nonreducing end of glucan chains by phosphorylation, generating glucose 1-phosphate (Reaction 13.21).

Several enzymes functional in starch degradation in chloroplasts are activated by reduced Trx—namely, glucan-water dikinase, phosphoglucan phosphatase (SEX4), β -amylase1, and α -amylase3. The implication of these findings is not understood, since starch degradation takes place primarily at night, when chloroplast Trxs are mainly in an oxidized state (see Chapter 12). Moreover, Trx is considered to deactivate, rather than activate, enzymes of carbohydrate degradation. It is possible that, in this case, NTRC, which can be reduced at night by NADPH, is involved in the regulation of the enzymes (see Section 13.5.2).

Starch phosphorylase is homologous to glycogen phosphorylase, an important enzyme of glycogen degradation in animals. The animal enzyme is subject to complex allosteric and posttranslational regulation important in the control of glucose metabolism. By contrast, the precise role of phosphorylase in starch metabolism is unclear. The reaction it catalyzes is reversible and, given a glucan substrate, the net reaction direction depends on the respective concentrations of glucose 1-phosphate and P_i . Generally, estimates of these concentrations for the plastid stroma favor glucan degradation, particularly at night, when P_i levels rise and hexose phosphate levels decline. Unlike maltose and glucose released by hydrolysis, however, the glucose 1-phosphate liberated by starch phosphorylase probably serves to support plastid metabolism (i.e., the plastid oxidative pentose phosphate pathway and glycolysis). Alternative roles for starch phosphorylase have been proposed, such as the production of malto-oligosaccharides to prime starch synthesis, but conclusive genetic evidence is missing and further research is needed.

Reaction 13.21: α -Glucan phosphorylase

13.7.3 Maltose and glucose are metabolized in the cytosol to produce hexose phosphates

Maltose metabolism in the cytosol at night is only partially understood. A second **disproportionating enzyme** (DPE2; Reaction 13.22) catalyzes a glucosyl transferase reaction, releasing glucose and transferring the other glucosyl moiety to an acceptor molecule, the nature of which is poorly defined (Fig. 13.30). It is suspected to be a soluble heteroglycan, a polymer of relatively low abundance that contains mixed sugar residues, including arabinose, galactose, rhamnose, and glucose. The glucosyl residues transferred onto the heteroglycan by DPE2 can be removed again by a cytosolic isoform of α -glucan phosphorylase (see Reaction 13.21), which is encoded by a separate gene and has properties distinct from the plastid isoform.

Little is known about the structure, biosynthesis, and functional significance of this heteroglycan pool. It may represent a transient buffer that accommodates fluctuations in the rate of carbon supply from the chloroplast at night with its utilization in the cytosol. The combined actions of DPE2 and cytosolic α -glucan phosphorylase convert half the carbon in maltose to glucose 1-phosphate, which can equilibrate with other components of the hexose phosphate pool. The other half is released as free glucose which, together with that exported directly from the chloroplast, is phosphorylated via the action of the cytosolic hexokinase (Reaction 13.23).

Reaction 13.22: α -1,4-Glucosyltransferase (D-enzyme DPE2)

Reaction 13.23: Hexokinase

There is also little understanding of how the enzymes in the pathway of starch degradation are regulated, despite good

FIGURE 13.30 Maltose and glucose metabolism in the cytosol. The disproportionating enzyme DPE2 transfers one glucosyl moiety from maltose to an acceptor molecule, probably a cytosolic heteroglycan, the exact nature of which is not known.

evidence that the overall rate of degradation is carefully controlled (e.g., it lasts the length of the night in different photoperiods; see Fig. 13.28). In plants that accumulate a lot of starch in their leaves, precise control of starch turnover is important. Premature depletion of starch reserves would result in starvation during the night, while incomplete utilization of starch would mean that assimilates that could have been exported for new root, shoot or seed production languishes unused in the chloroplast. The apparent importance of glucan phosphorylation and dephosphorylation in facilitating leaf starch degradation suggests that regulation might be applied to these enzymes, rather than the downstream hydrolytic enzymes.

Many other tissues in which starch is degraded have received far less attention than either leaves or the cereal endosperm. It is likely that in nonphotosynthetic tissues such as roots and tubers, where starch is degraded in amyloplasts, a pathway similar to that described for the chloroplast operates, although the relative importance of the different steps might not be the same as in *Arabidopsis* leaves. However, in other tissues, such as the cotyledon of pea (*Pisum sativum*), a terminal and senescing tissue, there are indications that amyloplast integrity is lost and starch degradation occurs in the cytosol or in the vacuole. It is also possible that under conditions such as carbon starvation, starch may be degraded together with other cellular components via autophagy. In such cases, one can only speculate as to the exact pathway and enzymes involved.

13.8 The pentose phosphate/triose phosphate pool

Earlier in this chapter, triose phosphates were only considered as products of the Calvin-Benson cycle and intermediates in the synthesis of the major products of photosynthesis: sucrose in the cytosol and starch in the chloroplast stroma. However, triose phosphates are, in fact, part of a larger pool of interconvertible metabolites often referred to as the **triose phosphate/pentose phosphate pool**. This pool includes a diverse set of sugar intermediates: **ribulose 5-phosphate, ribose 5-phosphate, xylulose 5-phosphate, dihydroxyacetone phosphate, glyceraldehyde 3-phosphate, sedoheptulose 7-phosphate, erythrose 4-phosphate, and fructose 1,6-bisphosphate**. Fructose 6-phosphate, usually considered part of the hexose phosphate pool, is also linked to this pool, as it is a substrate for the enzymes **transaldolase** and **transketolase** (Fig. 13.31).

13.8.1 The pentose phosphate/triose phosphate pool integrates several key biosynthetic pathways

These sugar phosphates are components of metabolite pools that participate in several different pathways, and this emphasizes the fact that each pathway is actually a route within a

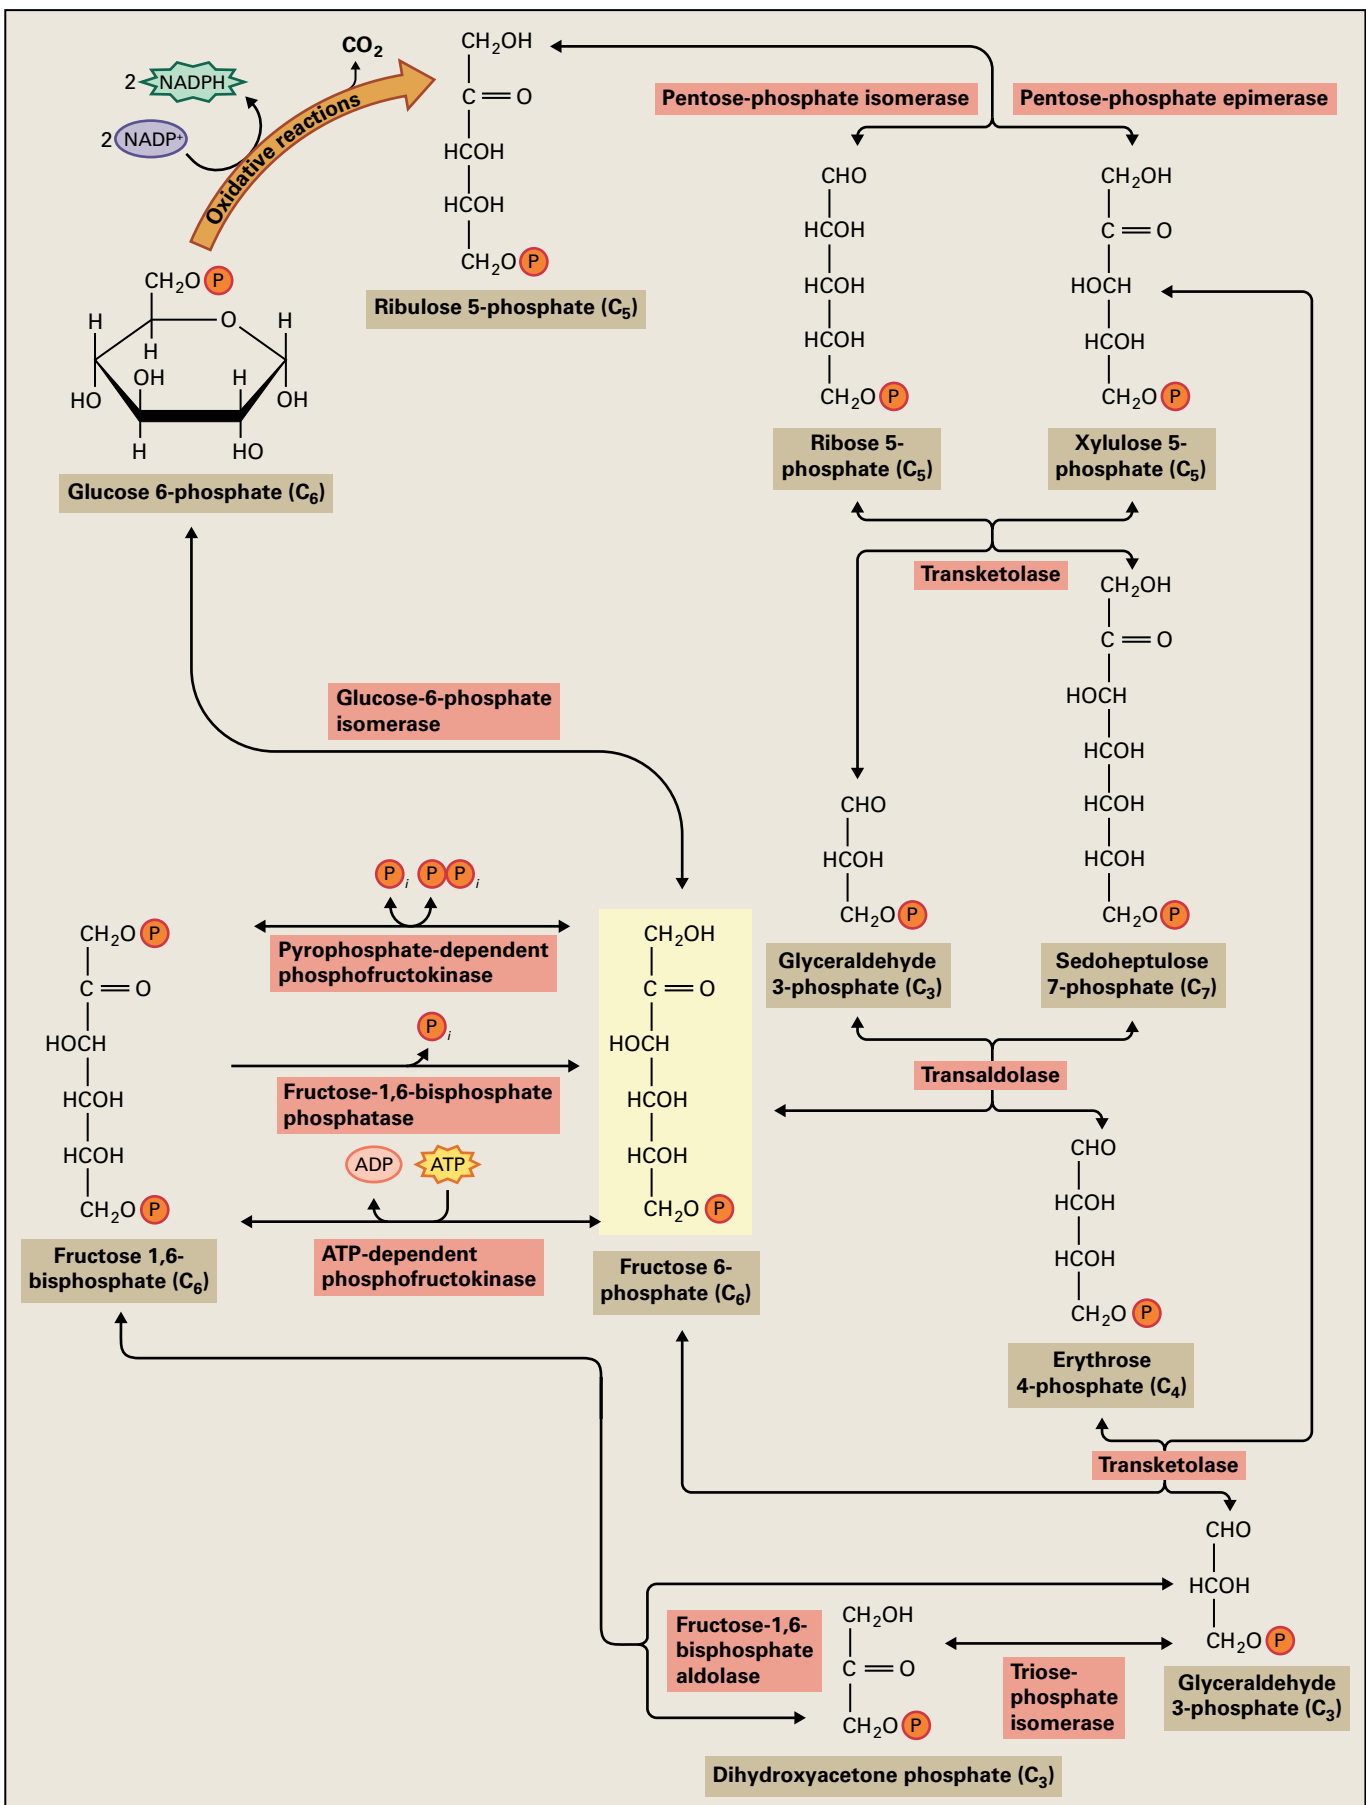

FIGURE 13.31 The pentose phosphate pathway consists of irreversible oxidative reactions that generate NADPH and reversible reactions that equilibrate intermediates of the pentose phosphate/triose phosphate pool. In some tissues, the principal function of this pathway is to generate NADPH to be used in synthetic pathways such as fatty acid synthesis. In this case, the product of the NADPH-generating reactions, ribulose 5-phosphate, can be converted back to glucose 6-phosphate by a series of reversible reactions. In the majority of tissues, this pathway also provides carbon intermediates for several pathways (see Figure 13.32).

much larger metabolic network. Glycolysis is usually depicted as a linear sequence of reactions that starts with hexose phosphate and ends with pyruvate (see Fig. 13.1), yielding a small net gain in ATP and NADH (most is supplied by the tricarboxylic acid cycle and electron transport in the mitochondrion). Similarly, the oxidative pentose phosphate pathway is depicted as a cyclic process in which glucose 6-phosphate is oxidized to ribulose 5-phosphate, with the concomitant formation of NADPH for use in biosynthesis, and the subsequent multistep regeneration of glucose 6-phosphate (see Section 13.9). In plant cells, however, these two pathways are actually linked by their shared intermediates, and both pathways operate interactively.

The various sugar phosphates of the glycolytic and pentose phosphate pathways occur both in plastids and in the cytosol, and there is communication between the pathways across the plastid envelope (see Fig. 13.4). Furthermore, plants use both pathways not only to produce energy-rich cofactors, but also to generate carbon skeletons required for biosynthetic reactions. In short, glycolysis, the pentose

phosphate pathway, and various biosynthetic pathways are integrated by their relationship to the pentose phosphate/triose phosphate pool.

Thus, fluxes through the routes in metabolism differ considerably, depending on the prevailing conditions. For example, the direction of flux through the sugar phosphate pools in a leaf mesophyll cell differs when it is illuminated and engaged in light-driven biosynthetic processes, and when it is darkened and generating its energy and reducing power via respiratory pathways. Fluxes within cells also differ, depending on the major metabolic activities; a heterotrophic starch-storing cell has lower fluxes through the triose phosphate pool than a heterotrophic lipid-storing cell. This is because all the acetyl-CoA needed for lipid synthesis is derived from the triose-phosphate pool, whereas the carbon for starch synthesis is taken from the hexose phosphate pool. Measurement of such fluxes is arguably one of the most important, yet most difficult undertakings in the study of plant carbohydrate metabolism (see Box 13.7).

BOX
13-7**Metabolic fluxes tell the truth about metabolism**

Modern research into **metabolism** has an impressive array of tools: **transcriptome** and **proteome** profiling to give a system-wide overview, methods for selective gene silencing or upregulation to investigate the importance of an enzyme *in vivo*, the recombinant expression of enzymes to study their properties *in vitro*. Methods have also been developed for **metabolomics**—the simultaneous measurement of many metabolites—that are based on techniques such as gas or liquid chromatography linked with mass spectrometry, and on nuclear magnetic resonance. This has improved the capacity for the acquisition of large metabolite datasets. Challenges remain because metabolites have different chemical properties to each other, are present in different quantities, and in some cases are sometimes unstable. Thus, even with a range of extraction and analytical methods, it can still be difficult to measure every metabolite in a pathway, even in major pathway such as the Calvin–Benson cycle.

However, even metabolomics and the large metabolite datasets it yields do not give a complete picture of metabolism, because metabolite levels do not necessarily reflect fluxes. Hypothetically, when the flux through a pathway increases, the levels of metabolites in that pathway might be expected to increase. However, this does not always happen. Furthermore, increases in the same metabolites could also occur if a reaction at the end of the pathway is downregulated, which would decrease the pathway flux. Thus, metabolite levels

should be regarded with caution, and fluxes should be regarded as the truth about metabolism.

In some cases, measuring fluxes is relatively simple (e.g., nutrient uptake by the root, net carbon fixation during photosynthesis, or the accumulation of an end product like starch). However, in the heart of carbohydrate metabolism, fluxes are difficult to measure and require integrated approaches that employ theoretical, experimental, and analytical methods.

Defining the pathways in a metabolic network is a prerequisite to measuring fluxes. This theoretical step can be aided or refined using genome sequence information and transcriptome data to define the enzymes within a given plant tissue. As a starting point, networks allow the modeling of metabolism, which can then be directly tested by experimentation. Experiments typically involve supplying an isotopically labeled compound (e.g., ^{13}C - or ^{14}C -labeled CO_2 to photosynthesizing leaves; ^{13}C -labeled glucose to heterotrophic cell cultures). There are different ways in which distribution of the isotope throughout metabolism can then be measured over time. Together with the network model, this redistribution can be used to calculate flux maps or compared against the theoretical metabolic models. While research in this area is experiencing a renaissance, the complexity of plant metabolism, the duplication and subcellular compartmentalization of pathways, and the presence of multiple cell types in plant organs means there is much to learn.

13.8.2 Pentose phosphate/triose phosphate pool metabolites are kept at equilibrium by numerous reversible enzymatic reactions

In glycolysis, after the conversion of fructose 6-phosphate to fructose 1,6-bisphosphate, the reactions catalyzed by fructose-1,6-bisphosphate aldolase and triose-phosphate isomerase are reversible. Similarly, apart from the initial oxidative reactions, the steps of the pentose phosphate pathway catalyzed by ribulose-5-phosphate epimerase, ribose-5-phosphate isomerase, transketolase, and transaldolase are also reversible. This keeps the cytosolic and plastid-localized triose phosphate/pentose phosphate pool metabolites in equilibrium (Fig. 13.31).

There are three major drains on the triose phosphate/pentose phosphate pool of metabolites (Fig. 13.32). First, the triose phosphates are utilized in the reactions of the energy-conserving reactions of glycolysis (see Section 13.9). These compounds can also be transported across the envelope of the plastid by the TPT. Second, the **shikimate pathway** uses **erythrose 4-phosphate** for the formation of lignin, polyphenols, and amino acids (see Chapters 8 and 24). Third, **ribose 5-phosphate** is required for nucleic acid synthesis. As metabolites are drained from this pool, the reversible reactions adjust to allow production of the metabolite that is being depleted. Because the reactions are reversible, metabolites can flow in either direction. The oxidative reactions of the pentose phosphate pathway, which are not reversible, are regulated and operate only when reducing power (i.e., NADPH) is needed (see Section 13.9).

Fructose-1,6-bisphosphate aldolase has already been mentioned in the context of sucrose synthesis (see Section 13.6.2).

FIGURE 13.32 Three metabolic pathways, both anabolic and catabolic, drain the pentose phosphate/triose phosphate pool. Glycolysis partially oxidizes triose phosphates to organic acids. Ribose is utilized in nucleotide synthesis. Erythrose 4-phosphate enters the shikimate pathway and contributes to the production of lignin, polyphenols, and some amino acids.

It catalyzes the reversible aldol cleavage of fructose 1,6-bisphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate (Reaction 13.24). The standard free energy change of this reaction indicates the equilibrium favors fructose 1,6-bisphosphate; the actual equilibrium position, however, is determined by the concentrations of all three reactants. Fructose 1,6-bisphosphate accumulates only when its cleavage products achieve a threshold concentration. Aldolases occur in nature as two distinct forms: Class I (in plants and animals) and Class II (in fungi and prokaryotes), resulting from convergent evolution. In plants, the gene family encoding Class I aldolase can be subdivided into two groups, one containing cytosolic isoenzymes, and the other containing plastid isoenzymes.

Reaction 13.24: Fructose-1,6-bisphosphate aldolase

Triose-phosphate isomerase, isoenzymes of which occur in both the cytosol and plastids, catalyzes the interconversion of glyceraldehyde 3-phosphate and dihydroxyacetone phosphate and is one of the most active enzymes known (Reaction 13.25). The reaction it catalyzes is readily reversible, although the equilibrium favors dihydroxyacetone phosphate by $\approx 14:1$, making this compound the principal triose phosphate in the cell. The effect of both the aldolase and triose-phosphate isomerase equilibria is to keep the concentration of glyceraldehyde 3-phosphate low. However, the glycolytic reactions that consume glyceraldehyde 3-phosphate can proceed because they are energetically favorable and

shift aldolase and triose-phosphate isomerase equilibriums toward glyceraldehyde 3-phosphate production (see Section 13.8).

Reaction 13.25: Triose-phosphate isomerase

Glyceraldehyde 3-phosphate \leftrightarrow Dihydroxyacetone phosphate

The enzymes ribulose-5-phosphate epimerase, ribose-5-phosphate isomerase, transketolase, and transaldolase all catalyze reversible reactions that keep the sugar phosphates of the pentose phosphate pathway close to equilibrium.

Reaction 13.26: Ribulose-5-phosphate epimerase

Xylose 5-phosphate \leftrightarrow Ribulose 5-phosphate

Reaction 13.27: Ribose-5-phosphate isomerase

Ribulose 5-phosphate \leftrightarrow Ribose 5-phosphate

Reaction 13.28: Transketolase

Sedoheptulose 7-phosphate + glyceraldehyde 3-phosphate \leftrightarrow
Xylulose 5-phosphate + ribose 5-phosphate

Reaction 13.29: Transaldolase

Glyceraldehyde 3-phosphate + sedoheptulose 7-phosphate \leftrightarrow
Erythrose 4-phosphate + fructose 6-phosphate

These enzymes occur in various types of plastids, but studies on different plants and tissues have yielded conflicting reports about their presence in the cytosol. Genome sequence information now suggests that some enzymes, notably transketolase and transaldolase, may be absent from the cytosol in most plants, while genes predicted to encode cytosolic forms of ribulose-5-phosphate epimerase and ribose-5-phosphate isomerase are present. The absence of some cytosolic enzymes for the reversible reactions of the pentose phosphate pathway is accommodated by the presence of transporters in the plastid inner envelope that are capable of transporting pentose and triose phosphates and, in some cases, hexose phosphates in exchange for P_i (see Fig. 13.4). Furthermore, this exchange of metabolites means that NADPH production and the withdrawal of precursors for biosynthesis can occur independently in each compartment (see Section 13.9).

13.9 Energy and reducing power for biosynthesis

In photosynthetic cells, light can supply much of the energy and reducing power needed for the biosynthetic reactions. However, in the dark and in nonphotosynthetic cells, light

energy cannot be used and plants need to respire. Reducing power in the form of NADPH is produced by two oxidative reactions of the pentose phosphate pathway. Most of the ATP is produced by aerobic respiration of pyruvate in the mitochondrion (via the citric acid cycle; see Chapter 14), but some is also produced in energy-conserving reactions of glycolysis as hexose phosphates are converted to pyruvate.

13.9.1 Two pentose phosphate pathway enzymes oxidize glucose 6-phosphate to ribulose 5-phosphate and NADPH

Glucose-6-phosphate dehydrogenase catalyzes the oxidation of glucose 6-phosphate to 6-phosphoglucono-D-lactone, with the concomitant formation of NADPH from $NADP^+$ (Reaction 13.30 and Fig. 13.33). The plant enzymes cannot use NAD^+ as an electron acceptor.

Reaction 13.30: Glucose-6-phosphate dehydrogenase

Glucose 6-phosphate + $NADP^+$ \rightarrow
6-Phosphoglucono-D-lactone + NADPH + H^+

High activities of glucose-6-phosphate dehydrogenase have been found in all plant materials studied, and genome analyses reveal multiple genes encoding cytosolic and plastid-localized isoenzymes. Although reduction of the product 6-phosphoglucono-D-lactone is thermodynamically feasible, the lactone is unstable and spontaneously decomposes to form 6-phosphogluconate, making the oxidative reaction essentially irreversible. A **lactonase**, again with isoenzymes encoded by multiple genes, further increases the rate of 6-phosphogluconate formation.

The cytosolic isoenzyme of glucose-6-phosphate dehydrogenase has no allosteric regulatory properties, which is surprising considering its important role in supplying NADPH. However, the enzyme is strongly inhibited by one of its products, NADPH, consistent with the idea that the function of the enzyme is to provide NADPH for biosynthetic reactions. In contrast, the plastid isoenzymes are regulated and can occur in reduced and oxidized forms, the latter being the active form. The dithiol–disulphide interconversion between two highly conserved regulatory cysteine residues relates the enzyme's activity to the redox state of the Trx pool and the availability of light. During photosynthesis, $NADP^+$ can be reduced by the photosynthetic electron transport chain (see Chapter 12), which makes the oxidative steps of the pentose phosphate pathway superfluous. Under these conditions, plastid-localized glucose-6-phosphate dehydrogenase is deactivated by photoreduced Trx, rendering the complete pathway inoperative.

Phosphogluconate dehydrogenase (Reaction 13.31) catalyzes the irreversible oxidative decarboxylation of 6-phosphogluconate to ribulose 5-phosphate and carbon dioxide, with the concomitant reduction of $NADP^+$ (see Fig. 13.33).

FIGURE 13.33 The oxidative reactions of the pentose phosphate pathway convert glucose 6-phosphate to ribulose 5-phosphate, generating NADPH in the process.

Reaction 13.31: 6-Phosphogluconate dehydrogenase

As with the preceding enzymes, plants have several distinct cytosolic and plastid isoforms of this enzyme. No regulatory properties of the enzyme have been described, and its activity is probably determined by the availability of 6-phosphogluconate generated by glucose-6-phosphate dehydrogenase.

13.9.2 The reactions in the lower half of glycolysis conserve energy

In the reactions of the lower half of glycolysis, triose phosphate molecules are oxidized to form pyruvate and energy is conserved in high-energy phosphate compounds that can be used to synthesize ATP from ADP. These high-energy compounds are generated by two enzymes, **glyceraldehyde-3-phosphate dehydrogenase**, which forms the mixed acid anhydride **1,3-bisphosphoglycerate** (Reaction 13.32), and **enolase**, which generates a phosphate ester linked to the enol form of pyruvic acid, phosphoenolpyruvate (Fig. 13.34; see also Section 13.9.3). Because the instability of the enol form of pyruvate gives the phosphate ester a high negative free energy of hydrolysis, the phosphate group can be transferred to ADP, yielding ATP.

Glyceraldehyde-3-phosphate dehydrogenase (Reaction 13.32) catalyzes a reaction in which the oxidation of the substrate (**glyceraldehyde 3-phosphate**) is linked directly to its phosphorylation and to the reduction of **NAD⁺** to **NADH**. The product, 1,3-bisphosphoglycerate, is a high-energy compound capable of donating its C-1 phosphate to ADP. This example of substrate-level phosphorylation was considered the model for all cellular ATP formation until the chemiosmotic scheme for ATP synthesis was accepted (see Chapters 3, 12, and 14).

Reaction 13.32: Glyceraldehyde-3-phosphate dehydrogenase

The glyceraldehyde-3-phosphate dehydrogenase reaction is readily reversible, although the equilibrium position favors glyceraldehyde 3-phosphate over 1,3-bisphosphoglycerate by approximately 10:1. The subsequent phosphoglycerate kinase reaction pulls the glyceraldehyde-3-phosphate dehydrogenase reaction in favor of the products. In the cell, the equilibrium position is also determined by the **NAD⁺:NADH** ratio, because these molecules bind competitively to the enzyme. The concentration of **NAD⁺** in the cell is generally around 10 times the concentration of **NADH**, again favoring 1,3-bisphosphoglycerate formation.

During the glyceraldehyde-3-phosphate dehydrogenase reaction, glyceraldehyde 3-phosphate oxidation is concomitant with the reduction of **NAD⁺**. The 3-phosphoglyceric

FIGURE 13.34 Oxidative and ATP-forming reactions of the glycolytic pathway, showing the relationship between the oxidation of the three-carbon molecules of the lower half of glycolysis and the creation of phosphate compounds with high negative free energies of hydrolysis (\sim).

FIGURE 13.35 Substrate-level phosphorylation by glyceraldehyde-3-phosphate dehydrogenase. In this reaction, a thioester bond is formed between a phosphoglyceric acid (derived from GAP) and a cysteine residue in the enzyme. The phosphorolysis of this bond in which the phosphate forms a mixed acid anhydride with phosphoglyceric acid (i.e., 1,3-bisphosphoglyceric acid) is accompanied by a high release of free energy. Like the thioester, the mixed acid anhydride bond is reflective of a high negative free energy of hydrolysis and is designated by a tilde (\sim). In the subsequent reaction catalyzed by phosphoglycerate kinase (not shown), this phosphate group is transferred to ADP to form ATP.

acid formed remains covalently bound to the enzyme through an energy-rich thioester bond to an active site cysteine residue. Hence, the energy made available by the oxidation of glyceraldehyde 3-phosphate is conserved, both through the formation of NADH from NAD⁺ and the formation of the thioester bond. In the second half of the reaction,

P_i binds to the active site and is transferred to the 3-phosphoglyceric acid moiety. This phosphorolysis reaction yields 1,3-bisphosphoglycerate (Fig. 13.35).

Three distinct forms of glyceraldehyde-3-phosphate dehydrogenase exist in plants. In addition to the cytosolic NAD⁺-dependent enzyme, there is a related NADP⁺-dependent

isoform in the chloroplast that is involved in photosynthesis (see Chapter 12). The third enzyme has a different evolutionary origin and is a nonphosphorylating, NADP⁺-dependent glyceraldehyde-3-phosphate dehydrogenase. It is present in the cytosol and generates 3-phosphoglyceric acid instead of 1,3-bisphosphoglycerate. Thus, the enzyme does not conserve as much energy as the other isoforms and catalyzes an essentially irreversible reaction in the cell. The nonphosphorylating enzyme is upregulated during phosphate starvation in *Arabidopsis* and has been proposed to allow carbon flow through the pathway to continue when the concentrations of ADP are too low for the synthesis of ATP from 1,3-bisphosphoglycerate to proceed (see Box 13.5). It has also been proposed that the enzyme works in conjunction with the TPT and the reductive reactions of the Calvin-Benson cycle to indirectly export NADPH from the chloroplast to the cytosol.

Phosphoglycerate kinase (Reaction 13.33) catalyzes the formation of 3-phosphoglycerate from 1,3-bisphosphoglycerate, transferring the phosphate group from the 1-position to ADP, forming ATP. Both cytosolic and plastid forms of this enzyme exist, and both have properties similar to those from other organisms.

Reaction 13.33: 3-Phosphoglycerate kinase

The equilibrium strongly favors the products of the reaction, because the mixed acid anhydride bond of 1,3-bisphosphoglycerate is unstable and has a high free energy of hydrolysis. Consequently ATP is generated during glycolysis. At a high ATP:ADP ratio, however, the reverse reaction can occur. For example, during photosynthesis, the enzyme is involved in the reductive reactions of the Calvin-Benson cycle, using ATP derived from photophosphorylation.

13.9.3 Phosphoglyceromutase and enolase are present in the cytosol and in heterotrophic plastids

Phosphoglyceromutase catalyzes the interconversion of 3-phosphoglycerate and 2-phosphoglycerate—a readily reversible reaction (Reaction 13.34). The enzyme moves the phosphate group from the 3-position to the 2-position, such that subsequent dehydration by enolase produces a high-energy compound, phosphoenolpyruvate (Reaction 13.35).

Reaction 13.34: Phosphoglyceromutase

Reaction 13.35: Enolase

The dehydration of 2-phosphoglycerate generates phosphopyruvate in the enol configuration. Because this configuration is unstable, the phosphate attached to the 2-position of pyruvate has a high free energy of hydrolysis, allowing transfer of the phosphate group to ADP in the subsequent reaction catalyzed by pyruvate kinase.

Although plastid-targeted isoforms of phosphoglyceromutase and enolase are encoded in the genomes of plants, the enzymes appear to be absent in chloroplasts. This may be because 3-phosphoglycerate is the initial product of CO₂ fixation in the Calvin-Benson cycle, and the presence of these enzymes would draw carbon from this cycle into plastid glycolysis. The enzymes are present in colorless plastids from seeds and roots, where their activities are generally positively correlated with the level of biosynthetic activity of the tissue.

13.9.4 Pyruvate kinase produces ATP in the cytosol and the plastid

Pyruvate kinase (Reaction 13.36) catalyzes the transfer of the phosphate group from phosphoenolpyruvate to ADP with the formation of ATP and pyruvate. The reaction is virtually irreversible because the initial product of the reaction is the enol form of pyruvate (see Fig. 13.34). In phosphoenolpyruvate, the enol form is stabilized by the phosphoester bond. Removal of the phosphate group allows the resulting enol form of pyruvate to convert to the more stable keto form, removing a product from the reaction and driving the reaction forward.

Reaction 13.36: Pyruvate kinase

Several related isoenzymes of pyruvate kinase exist in both the plastid and cytosol. In *Arabidopsis*, for example, 14 genes encode pyruvate kinase proteins. Unlike other enzymes of glycolysis, the plastid form is present in all plant tissues studied thus far. The enzyme has been reported to occur as a homo- or heteromultimer of related subunits. Interestingly, pyruvate kinase from several sources is inhibited by amino acids, such as glutamate and glutamine (Fig. 13.36). This couples the activity of the enzyme to the supply of carbon skeletons for nitrogen assimilation and amino acid biosynthesis. This form of regulation of the enzyme is related to the autotrophic nature of plants, which requires that a large amount of carbon be directed into biosynthetic activity. Furthermore, pyruvate kinase is activated by metabolites such as dihydroxyacetone phosphate (Fig. 13.36), which signals a supply of substrates.

Plant pyruvate kinases, however, appear not to share the regulatory properties of the well-studied mammalian liver enzyme. Specific sites on this enzyme are subject to phosphorylation and dephosphorylation; the phosphorylated enzyme is inactive. None of the plant enzymes appear to undergo comparable phosphorylation. Pyruvate kinase in animals and most other organisms is also allosterically activated by

FIGURE 13.36 Regulation of cytosolic pyruvate kinase and its relationship to nitrogen assimilation in the chloroplast. Pyruvate kinase activity in the cytosol is inhibited by amino acids such as glutamate. It is proposed that this influences the rate of production of synthesis of α -ketoglutarate (α -KG), an intermediate of the citric acid cycle, but also the carbon skeleton used in nitrogen fixation in the chloroplast. Gln, glutamine; Glu, glutamate; DHAP, dihydroxyacetone phosphate; PEP, phosphoenolpyruvate.

FIGURE 13.37 Regulation of glycolysis in plant and animal cells. In animals there is a “top-down” regulation through the activation of the PFK, producing fructose 1,6-bisphosphate (F1,6bP). This activation does not occur in plants. Instead there is a “bottom-up” regulation through the inhibition of PFK by phosphoenolpyruvate (PEP). Pyruvate kinase is differently regulated, reflecting the autotrophic nature of plants.

fructose 1,6-bisphosphate (Fig. 13.37), linking its activity to that of PFK by a feedforward loop. Although sequences similar to the fructose 1,6-bisphosphate activation site do occur in the plant enzyme, no evidence has been found for any feedforward regulation. Rather, plant glycolysis appears to be regulated upstream, through the inhibition of PFK (Fig. 13.37; see also Section 13.6).

13.9.5 Carbon import and plastid respiration support biosynthesis in nongreen plastids

The plastid enzymes of the oxidative pentose phosphate pathway and lower part of glycolysis are important in the supply of both carbon skeletons and cofactors for biosynthesis, especially in nonphotosynthetic plastids. Plastid-localized anabolic pathways, such as starch synthesis, fatty acid synthesis, and aromatic amino acid synthesis, can consume large amounts of energy (in the form of ATP) and reducing power (in the form of reduced Fdx and NAD(P)H). Chloroplasts can produce the cofactors needed via photosynthesis, but in nonphotosynthetic plastids, the cofactors must be generated another way.

Plastids do have an adenylate transport system that exchanges ATP for ADP, and this is particularly important for starch biosynthesis in potato (*Solanum tuberosum*) tuber amyloplasts. Although no known transport system exists for the direct import of NADH or NADPH, reducing equivalents can be imported or exported by one or more shuttle systems (see Fig. 13.5). For example, in castor seed (*Ricinus communis*) endosperm, a tissue that synthesizes large amounts of storage lipids, the most effective substrate for fatty acid biosynthesis (by isolated colorless plastids) is malate, which is produced in the cytosol by PEP carboxylase and malate dehydrogenase and then imported into the plastid. Within the plastid, it is oxidatively decarboxylated by **malic enzyme** (Reaction 13.37), generating NADPH and pyruvate. The subsequent oxidative decarboxylation of pyruvate by a plastid-localized pyruvate dehydrogenase complex generates acetyl-CoA for fatty acid biosynthesis and the reducing agent NADH.

FIGURE 13.38 Use of photoassimilate by lipid-storing seeds to generate cofactors for fatty acid synthesis in a lipid-synthesizing plastid. In a colorless plastid, glycolytic enzymes, NADP-dependent malic enzyme, and the pyruvate dehydrogenase complex not only provide carbon for fatty acid biosynthesis, but also cofactors such as ATP and NADPH required for this biosynthetic pathway. G6P, glucose 6-phosphate; F6P, fructose 6-phosphate; PEP, phosphoenolpyruvate.

Reaction 13.37: Malic enzyme

In most plastids, cofactors can also be generated within the organelle by respiration. In other oilseeds, such as rapeseed (canola, *Brassica napus*), isolated plastids import hexose phosphates and phosphoenolpyruvate. These plastids have the glycolytic and the oxidative pentose phosphate pathway enzymes to metabolize hexose phosphate. The latter pathway generates significant amounts of NADPH, which are required for fatty acid chain elongation. The operation of pyruvate kinase supplies ATP as it converts the imported phosphoenolpyruvate to pyruvate for acetyl-CoA production. Hence, both the cofactors and the acetyl CoA substrate consumed in fatty acid biosynthesis are generated within the organelle (Fig. 13.38). Because all biosynthetic pathways require reducing power and energy, respiratory pathways are needed to provide cofactors, whether the principal product of the plastid is amino acids or secondary metabolites, rather than fatty acids.

In some species, including rapeseed (*Brassica napus*), the fatty acid-synthesizing plastids are actually green and capable of limited photosynthesis via the light that filters through the wall of the seed pod. Interestingly, these plastids also contain active Rubisco. However, in this tissue the enzyme is not part

of the Calvin-Benson cycle. Instead, it is supplied with substrates through the nonoxidative reactions of the pentose phosphate pathway, and its activity captures some of the CO_2 lost from pyruvate upon acetyl-CoA production. When coupled with energy derived from photosynthesis, this pathway makes the process of fatty acid biosynthesis more carbon efficient.

13.10 Sugar-regulated gene expression

Metabolites can act as allosteric regulators of enzyme activities. In addition to their role in metabolism and metabolic regulation, sugars can also act as signals, controlling cellular activities such as gene transcription, protein stability, and protein kinase activity. This is important for coupling cell or organ growth with metabolism and carbohydrate availability.

Sugar sensing has been extensively studied in simpler biological systems. For example, in *E. coli*, the presence of lactose in the growth medium results in the expression of genes required for lactose metabolism. In the yeast *Saccharomyces cerevisiae*, the presence of glucose in the growth medium represses the expression of genes required for the metabolism of other carbon sources. In plants, the situation is more

complicated, as sugars are generated internally through photosynthesis. Consequently, it is not only growth in developing tissues, but also photosynthesis in mature tissues that must respond to sugar availability.

13.10.1 Photosynthesis is regulated by sugars, with hexokinase 1 serving as a glucose sensor

Early studies of sugar sensing in plants focused on the repression of photosynthesis by excess sugars. Supplying exogenous sugars, or preventing the export of photosynthate, causes sugar accumulation in fully expanded source leaves. This results in a decrease in chlorophyll content and a reduction in the activities of the Calvin–Benson cycle enzymes, but also an accumulation of starch. Analysis of gene expression revealed that as photosynthetic genes were repressed by high sugars, genes involved in carbon storage were induced. Subsequent genome-wide studies have revealed that changes in sugar levels play a major role in regulating thousands of genes. Several sugar-sensing mechanisms have now been proposed, although much remains to be discovered about the sugar receptors and the subsequent signal transduction pathways. One major difficulty when researching sugar sensing is the fact that primary signaling events (that is, the sensing of changing levels of a particular sugar) can be confused with the metabolic consequences of altered sugar levels, which might also affect cellular activities via other downstream mechanisms. Ideally, these two different effects need to be dissociated from each other.

One approach has been to use the responses of *Arabidopsis* to high levels of exogenous sugars as the basis for genetic screens. For example, high levels of glucose repress seedling development after germination. The isolation of glucose-insensitive (*gin*) or glucose oversensitive (*glo*) mutants, having reduced or enhanced growth repression respectively, helped identify proteins involved in sugar perception and signal transduction (Fig. 13.39). These screens have also emphasized the degree of integration between sugar signaling and plant hormone signaling (e.g., auxin, ABA and ethylene; see Chapter 17), as several hormone response mutants also show altered responsiveness to sugars.

A good candidate for direct glucose perception is hexokinase 1 (HXK1), whose enzymatic function is to phosphorylate glucose and fructose using ATP (see Reaction 13.23). Mutants lacking HXK1 have a *gin* phenotype which could either result from the loss of signaling, or from the loss of the ability to metabolize glucose. However, three pieces of evidence suggest that HXK1 is a genuine signaling protein. First, *hxx1* mutants still have hexokinase activity provided by other isoenzymes. Second, the introduction of a catalytically inactive *hxx1* forms into the *hxx1* mutant restores glucose sensitivity, showing that glucose sensitivity and glucose phosphorylation can be uncoupled. Third, a small proportion of HXK1 protein can be found ‘moonlighting’ in the

FIGURE 13.39 Use of exogenous sugars to discover sugar-sensing mechanisms. Supplying 6% glucose to *Arabidopsis* seedlings causes a developmental arrest after germination and cotyledons fail to green (left). Using this phenotype as the basis of a genetic screen led to the discovery of glucose-insensitive (*gin*) mutants that still develop green cotyledons in the presence of 6% glucose. The *gin2* mutant lacks hexokinase 1 (HXK1), the enzyme that uses ATP to phosphorylate glucose to glucose 6-phosphate. Transforming the *gin2* mutant with the wild-type HXK1 proteins or mutant versions of the protein that lack catalytic activity, restores glucose sensitivity. This shows that the protein itself, rather than its catalytic activity is responsible for glucose signaling. Mannitol cannot be used by seedlings and thus served as a control. Source: Adapted from Moore et al. (2003). *Science* 300:332–336.

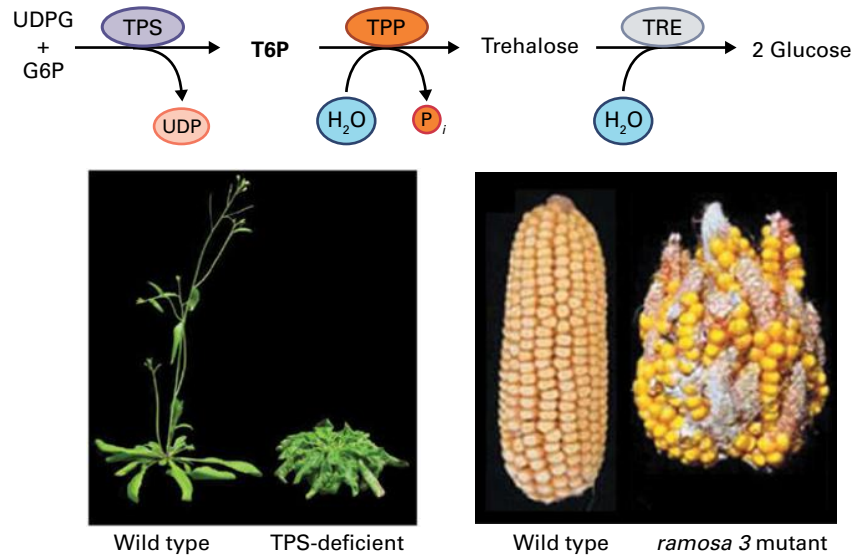

nucleus, associated in a multiprotein complex with transcriptional regulators.

There is evidence that sugars other than glucose are sensed in plants (sucrose and fructose, for instance), as are different nutrients and metabolite classes. Furthermore, multiple signaling mechanisms may exist for a specific sugar, as indicated by that fact that HXK1-signaling cannot explain all of the responses to glucose. Besides hexokinase, other types of proteins have been proposed as candidate receptors for **sugar signaling**. These include other enzymes, membrane receptors and specialized sugar transporters localized at the plasma membrane that activate cytosolic signaling pathways. Nuclear proteins containing both DNA-binding domains and enzyme-like domains have also been proposed to control gene expression directly in response to sugars (see Box 13.2).

13.10.2 Trehalose 6-phosphate is a signal metabolite involved in growth control

Sucrose may be sensed directly, but also indirectly through the synthesis of the signal metabolite **trehalose 6-phosphate** (Fig. 13.40). Trehalose, a disaccharide of α -1,1-linked glucosyl moieties (see Fig. 13.10), is widespread in nature, being a major sugar in many bacteria, fungi, and invertebrates. In plants, trehalose biosynthesis was initially thought to be restricted to a limited number of xerophytic species, where its

FIGURE 13.40 Trehalose metabolism and signaling in plants. Trehalose is synthesized from UDP-glucose and glucose 6-phosphate via the enzymes trehalose-phosphate synthase (TPS) and trehalose-phosphate phosphatase (TPP). Trehalose can be hydrolyzed back to its constituent glucose monomers by trehalase (TRE). In recent years, evidence has mounted that trehalose 6-phosphate is an important signal affecting plant development, exemplified by the inflorescence phenotype of the *ramosa 3* mutant of maize (*Zea mays*), which lacks a TPP isoform (bottom right), and the late-flowering phenotype of *Arabidopsis* plants deficient in TPS activity (bottom left). Source: Adapted from Ponnu et al. (2011). *Frontiers Plant Sci.* 2:70; Satoh-Nagasawa et al. (2006). *Nature* 441:227–230.

accumulation to high levels helps to confer anhydrobiosis, the ability to withstand prolonged periods of desiccation. However, it is now clear that many if not all plants have the ability to synthesize and degrade trehalose, and that the biosynthetic intermediate trehalose 6-phosphate rather than trehalose itself is the biologically active signaling compound.

The pathway of trehalose synthesis is similar to that of sucrose synthesis (Fig. 13.40) in that it occurs in the cytosol and utilizes UDP-glucose and hexose phosphate as substrates (glucose 6-phosphate rather than fructose 6-phosphate used for sucrose biosynthesis). The enzyme **trehalose phosphate synthase** produces trehalose 6-phosphate, which is then dephosphorylated by **trehalose phosphate phosphatase**. Trehalose can be hydrolyzed back to glucose by trehalase. In most plant tissues studied, trehalose 6-phosphate levels are very low, but in general reflect sucrose levels, and may serve as a proxy for sucrose itself.

Disruption of trehalose metabolism has major impacts on plant growth and development. This is most clearly illustrated in *Arabidopsis tps1* mutants, which lack the ability to produce trehalose 6-phosphate. Seeds homozygous for *tps1* exhibit a developmental arrest in embryogenesis, despite ample carbohydrates available for growth. This phenotype can be rescued by expression of the *TPS1* gene on a chemical-inducible promoter, but removal of the inducer from the growing rosette

strongly affects growth and delays flowering (Fig 13.40). Another striking example is the effect of mutations at the *RAMOSA3* locus of maize (*Zea mays*), which encodes an isoenzyme of trehalose phosphate phosphatase. Mutant plants exhibit marked abnormalities in their inflorescence architecture when flowering (Fig. 13.40).

Researchers are still discovering the mechanisms by which trehalose 6-phosphate mediates its effects, but some may operate via inhibition of a conserved class of eukaryotic protein kinases. The SnRK1 protein kinase in plants is homologous to the Snf1 (Sucrose nonfermenting 1) protein kinase in yeast and the AMP-activated protein kinase (AMPK) in mammals, which are vital regulators of metabolism and energy homeostasis. In plants, SnRK1 controls energy consuming processes by phosphorylating and deactivating enzymes of central metabolism (e.g., 3-hydroxymethyl-3-methylglutaryl-CoA reductase, sucrose phosphate synthase, and nitrate reductase). It also orchestrates transcriptional reprogramming to repress genes involved in biosynthetic reactions while inducing those involved in nutrient mobilization.

The area of sugar signaling, or nutrient sensing in general, continues to be at the front line of research and, in the coming years, will improve our appreciation of the links between photosynthesis, mineral nutrient acquisition, and growth.

Summary

Some of the complexities and unique aspects of plant carbohydrate metabolism are presented in this chapter, with emphasis on photosynthetic metabolism and its primary products, sucrose, and starch. Given the diversity of the plant kingdom, any such chapter will be incomplete. For example, the leaves of some plants do not make any starch in their chloroplasts, but instead

accumulate fructans in their vacuole. Unfortunately, not all pathways can be covered here.

A vital difference between carbohydrate metabolism in plants and that in other organisms stems from the fact that plants metabolize carbohydrates in both the cytosol and plastid, with most of the biosynthetic activity occurring in the latter compartment. This characteristic of

plant cells has a major impact on the organization and regulation of the carbohydrate metabolism pathways. That said, carbohydrate metabolism in the cytosol and plastid is connected by a series of metabolite transporters in the plastid envelope. Furthermore, while all plant tissues have plastids, they are themselves diverse in function, and each plastid type has a different metabolism and complement of membrane transporters, reflecting the nature of its biosynthetic activity. The overall regulation of carbohydrate metabolism is linked to the activity of these transporters. For example, the triose-phosphate translocator—the major protein of the chloroplast envelope, which catalyzes an enormous efflux of carbohydrate during photosynthesis—connects the cytosol with the plastid stroma in the middle of glycolysis. It is, therefore, not surprising that the regulation of glycolysis differs significantly in plants compared with animals.

Though metabolism is depicted as independent pathways, these pathways are intimately linked. Pools of metabolic intermediates are frequently shared by several pathways, and the direction of metabolite flow is determined by the needs of the cell, which can change dramatically (e.g., according to the availability of light in a leaf). There is also a tendency to regard plant tissues as homogeneous, whereas in fact they contain many distinct cell types, all of which differ metabolically. Perhaps only one third of the cells in a leaf are large photosynthetic palisade or spongy mesophyll cells, with most being

smaller cells in the vasculature and the epidermis. A nice example of the contrast possible from cell to cell is the starch metabolism in chloroplasts of palisade cells and of stomatal guard cells. In the palisade cells, starch is made during the day from assimilated carbon and degraded at night, whereas in the chloroplasts of the guard cell the reverse is true: Starch is degraded during the day to provide solutes to increase cell turgor and help open the stomatal pore. Later, starch is made again, which may help to sequester these solutes and aid stomatal closure.

Another key feature of plant metabolism is its degree of flexibility—something that can sometimes make plant metabolism research difficult and perplexing, but ultimately fascinating. A major driver in the evolution of this flexibility is the fact that plants are sessile and must withstand extreme changes in the external environment. This might explain why several different enzymes sometimes catalyze a single step in a pathway and why plants can bypass some of the principal reactions of carbohydrate metabolism.

Considerable opportunities for future discovery await those who read this chapter and wish to pursue a better understanding of plant carbohydrate metabolism, its regulation, and metabolic signaling pathways. The possibilities today to study plants using combinations of genetic, biochemical, cell-biological and systems-level methods will tell us how plants make the products on which society depends.

Respiration and Photorespiration

*A. Harvey Millar, James N. Siedow,
and David Day*

Introduction

Chapters 12 and 13 described how plants use light energy to assimilate carbon into sugars and starch, and how these molecules are subsequently broken down and converted into organic acids and other compounds. In this chapter, we address aerobic respiration—the further oxidation of these compounds to carbon dioxide (CO_2) and water (H_2O) in the mitochondrion—and review the mechanisms by which the energy released during respiration is conserved as ATP, a process called oxidative phosphorylation. We examine how plants can minimize ATP production while maintaining respiration rates, a mitochondrial attribute that may affect plant responses to environmental stress. We also describe how mitochondria and other cellular compartments interact by means of substrate shuttles across the inner mitochondrial membrane.

In addition to aerobic respiration, another respiratory process takes place in the leaves of many plants. This process, photorespiration, is the light-dependent uptake of O_2 and release of CO_2 . The O_2 uptake occurs in the chloroplast as a result of the oxygenase reaction of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), which leads to production of phosphoglycolate. Metabolism of phosphoglycolate involves a complex interaction among chloroplasts, peroxisomes, and mitochondria and leads to release of CO_2 . Although photorespiration drains carbon from plants and

adversely affects growth, it seems to be an unavoidable side reaction of CO_2 fixation in most plants. Some plants, however, have evolved anatomical and biochemical features that minimize the oxygenase reaction. These C_4 plants and Crassulacean acid metabolism (CAM) plants (see Chapter 12) demonstrate very low rates of photorespiration.

14.1 Overview of respiration

Aerobic respiration, a process common to almost all eukaryotic organisms, involves the controlled oxidation of reduced organic substrates to CO_2 and H_2O . Numerous compounds can serve as substrates for respiration, including carbohydrates, lipids, proteins, amino acids, and organic acids. Respiration releases a large amount of free energy, which is conserved in ATP molecules. This chemical bond energy can be used to drive metabolic reactions involved in the growth, development, and maintenance of the plant. In addition, the primary pathways of respiration provide metabolic intermediates that serve as substrates for the synthesis of nucleic acids, amino acids, fatty acids, and many secondary metabolites. Although the general process of respiration in plants is the same as in other eukaryotes, several features are unique to plants. These modifications apparently evolved to cope with the environmental and metabolic circumstances commonly faced by plants.

14.1.1 Plant mitochondria contain an outer and an inner membrane that separate the organelle into four functional compartments

The **mitochondrion** is the principal organelle of eukaryotic respiration. In electron micrographs, plant mitochondria appear as spherical or rod-shaped entities 0.5–1.0 μm in diameter and 1–3 μm in length, but in live cells fluorescently tagged mitochondria often appear as 10 μm or longer structures that frequently undergo fusion and fission as a discontinuous network (Fig. 14.1A). The number of mitochondria per plant cell varies and is related primarily to the metabolic activity of the tissue. The concentration of mitochondria per unit volume of cytoplasm, however, usually remains similar during different developmental stages of the same cell type. For example, the small cells of the root cap of maize seedlings contain approximately 200 mitochondria each, whereas the much larger mature root tip cells may have 2,000 or so mitochondria per cell. In very active cells such as phloem companion cells, secretory cells, and transfer cells, up to 20% of the volume of the cytoplasm may be occupied by mitochondria. On the other hand, some unicellular algae such as *Chlamydomonas* contain only a few mitochondria

per cell. With a few exceptions (e.g., the very active cell types mentioned above), the density of mitochondria in plant cells is lower than in animal cells, but the respiratory rates of isolated plant mitochondria are generally higher than in those isolated from animals.

Mitochondria contain two sets of membranes that divide the organelle into four compartments: the **outer membrane**, the region between the two membranes (**intermembrane space**), a highly invaginated **inner membrane**, and the aqueous phase contained within the inner membrane (mitochondrial **matrix**) (Fig. 14.1B). Invaginations of the inner membrane give rise to **cristae**, which appear as sac-like structures under the electron microscope (Fig. 14.1C). The membranes of cristae (cristal membranes) are specialized in their structure and protein composition; points of contact with the rest of the inner membrane are referred to as junction points (Fig. 14.1D). The marked impermeability of the inner membrane necessitates the presence of carriers to facilitate the movement of metabolites between the cytosol, the intercrystal space, and the mitochondrial matrix. By contrast, the outer membrane is permeable to solutes of molecular mass less than 10 kDa. This permeability is associated with the presence of pore-forming proteins known as **porins**. In some species, porin channels are gated by voltage and termed voltage-gated anion channels (VDAC) (see Chapter 3).

(B) Diagram of the membrane organization of a plant mitochondrion. The outer membrane is permeable to molecules of 10 kDa or less because it contains a pore-forming protein called porin. The highly invaginated inner membrane, which contains the components of the mitochondrial electron transport chain and ATP synthase, serves as the primary permeability barrier for the organelle. The space between the two membranes is called the intermembrane space. The mitochondrial matrix, the region bounded by the inner membrane, contains the mitochondrial genome, the enzymes associated with the citric acid cycle, and the machinery required for mitochondrial protein synthesis. FIGURE 14.2 Redox reactions of respiration. The oxidation of carbohydrate to carbon dioxide (CO_2) is coupled to the reduction of oxygen (O_2) to water (H_2O). The free energy released during this process is linked to the synthesis of ATP.

FIGURE 14.3 Structure and redox chemistry of nicotinamide adenine dinucleotide (NAD^+) and nicotinamide adenine dinucleotide phosphate (NADP^+). The nicotinamide moiety of the oxidized species NAD^+ gains two electrons and a proton to produce the reduced species NADH . The related coenzyme NADP^+ differs from NAD^+ by the addition of a phosphate group attached to the 2'-hydroxyl of the ribose sugar moiety (variable group R in the diagram).

The evolutionary origins of mitochondria, their semiautonomous status as organelles possessing DNA genomes and synthesizing some of their constituent proteins, and mitochondrial division are discussed in Chapter 1.

14.1.2 The principal products of respiration are CO_2 , H_2O , and free energy conserved as ATP

Although respiration can oxidize many compounds, the principal substrates provided by photosynthesis for plant respiration are sucrose and starch. Using sucrose as an example of a respiratory substrate, one can represent the overall process of aerobic respiration as follows:

Reaction 14.1: Aerobic respiration of sucrose

This reaction scheme is the reverse of photosynthesis, and it represents a coupled pair of redox reactions in which sucrose is completely oxidized to CO_2 , while O_2 , the terminal electron acceptor, is reduced to H_2O (Fig. 14.2). The standard free energy change (ΔG°) for this exergonic reaction, $-5764 \text{ kJ mol}^{-1}$, provides the thermodynamic driving force for the production of ATP.

The three stages of respiration—**glycolysis**, the **citric acid cycle**, and **electron transfer/oxidative phosphorylation**—take place in different subcellular locations. Glycolysis involves a series of soluble cytosolic enzymes that oxidize sugars to organic acids. In the reaction above, one sucrose molecule is broken into two hexoses, which are then converted by glycolysis to four molecules of the three-carbon (C_3) compound pyruvate. This partial oxidation of sucrose also produces the reduced cofactor NADH (Fig. 14.3), as well as 65 ATP. The reactions of the citric acid cycle occur within the mitochondrial matrix and can completely oxidize pyruvate to CO_2 ; the electrons are transferred to NAD^+ and another cofactor, FAD

FIGURE 14.4 Structure and redox chemistry of the flavin coenzymes, flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). FAD and FMN differ in the nature of the substituent R-groups attached to the redox-active isoalloxazine ring system common to both coenzymes. The fully oxidized form (FAD or FMN) gains one electron plus one proton in each of two sequential reactions, forming first a semiquinone (FADH[•] or FMNH[•]) and then the fully reduced species (FADH₂ or FMNH₂).

(Fig. 14.4), yielding NADH and FADH₂. The citric acid cycle also phosphorylates ADP directly (Fig. 14.5 and Table 14.1). Finally, in the inner mitochondrial membrane, the reduced cofactors generated during glycolysis and the citric acid cycle are oxidized by a set of electron transfer proteins that ultimately donate the electrons to O₂, producing H₂O. The large amount of free energy released during this electron transfer is used to drive the formation of a proton gradient across the inner mitochondrial membrane, and the energy stored in this electrochemical gradient subsequently drives the conversion of ADP and P_i to ATP by a process known as oxidative phosphorylation (Fig. 14.5 and Table 14.1). Not every molecule of sucrose or C₆ unit of starch metabolized via glycolysis and the citric acid cycle, however, is completely oxidized in this manner; many intermediates from these two pathways are diverted along the way to provide the primary carbon building blocks for other important cellular compounds (Fig. 14.6).

14.2 Citric acid cycle

Known by several names, including the tricarboxylic acid cycle and Krebs cycle (after its discoverer, Hans Krebs), the citric acid cycle oxidizes organic acids to produce CO₂ and

transfers the resulting electrons to reduce the redox cofactors NAD⁺ and FAD, forming NADH and FADH₂.

14.2.1 Cytosolic reactions generate products that are transported into the mitochondria to feed the citric acid cycle

The nature of the end product of the glycolytic reactions in the cytosol of plants is determined by the relative activities of the three enzymes that can utilize phosphoenolpyruvate (PEP) as a substrate. Both pyruvate kinase and PEP phosphatase form pyruvate; PEP carboxylase generates oxaloacetate (OAA) (Fig. 14.7). Pyruvate is transported directly into the mitochondrion. OAA is either transported directly into the mitochondrion or first reduced to malate by cytosolic malate dehydrogenase. The reduction of OAA in the cytosol can provide an extramitochondrial, nonfermentative mechanism for oxidizing NADH formed by glyceraldehyde-3-phosphate dehydrogenase during glycolysis (see Chapter 13).

The mitochondrial inner membrane contains separate carriers by which malate and pyruvate are taken into the mitochondrial matrix (see Section 14.7.1). Once in the

FIGURE 14.5 General mechanism of oxidative phosphorylation in mitochondria. Electrons released during the oxidative steps of glycolysis and the citric acid cycle produce 20 molecules of NADH and 4 molecules of FADH₂. These reduced coenzymes are subsequently oxidized by the mitochondrial electron transport chain. The free energy released during mitochondrial electron transfer is coupled to the translocation of protons across the inner mitochondrial membrane (from the matrix into the intermembrane space), which generates a proton electrochemical gradient ($\Delta\mu_{H^+}$) across the inner membrane. As protons move back across the inner membrane through the F₀ proton channel of the ATP synthase complex, the free energy released is used by the complex's F₁ component to catalyze conversion of ADP and P_i to ATP in the mitochondrial matrix. The efficiency of net H⁺ transfer and ATP synthesis can vary (n), see Table 14.1 and Section 14.4.3 for details.

TABLE 14.1 Net stoichiometry of sucrose oxidation.

Metabolic pathway	Substrates	Products	ATP yield, number of molecules
Glycolysis			
	1 Sucrose	4 Pyruvate	
	4 ADP + 4 P _i	4 ATP	4
	4 NAD ⁺ (cytosolic)	4 NADH (cytosolic)	
Citric acid cycle			
	4 Pyruvate	12 CO ₂	
	4 ADP + 4 P _i	4 ATP	4
	16 NAD ⁺ (mitochondrial)	16 NADH (mitochondrial)	
	4 FAD	4 FADH ₂	
Oxidative phosphorylation			
	12 O ₂	24 H ₂ O	
	4 NADH (cytosolic)	4 NAD ⁺ (cytosolic or mitochondrial) ^a	6–10* [†]
	16 NADH (mitochondrial)	16 NAD ⁺ (mitochondrial)	40 [†]
	4 FADH ₂	4 FAD	6 [†]
Cumulative ATP yield			60–64* [†]

*Oxidation of cytosolic NADH by external NADH dehydrogenase (see Section 14.3.4) supports the same level of ATP synthesis as oxidation of mitochondrial FADH₂. However, if cytosolic NADH is imported into the mitochondrion via the malate–aspartate shuttle (see Fig. 14.36), it can support the same level of ATP synthesis as oxidation of mitochondrial NADH.

[†]Assuming oxidation of 1 mitochondrial NADH supports the synthesis of 2.5 ATP and that oxidation of FADH₂ supports the synthesis of 1.5 ATP (see Section 14.4.3).

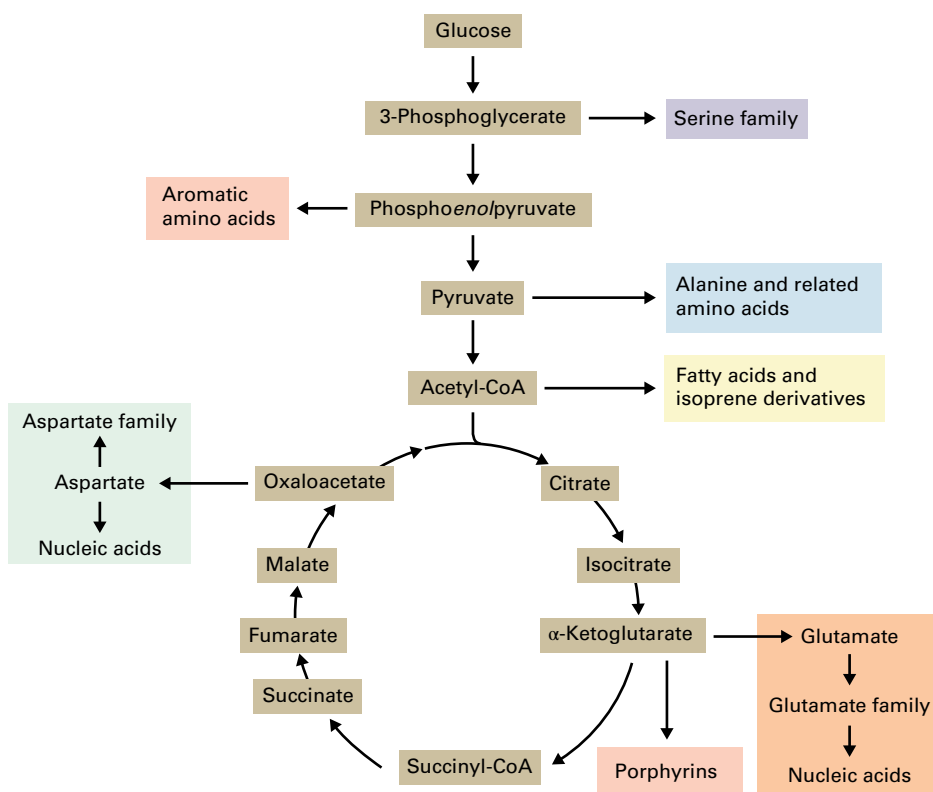

FIGURE 14.6 Intermediates produced during the reactions of glycolysis and the citric acid cycle serve as substrates for numerous plant biosynthetic pathways. The primary intermediates for the production of amino acids, lipids, nucleic acids, cell wall sugars, and many other essential components of the plant cell are derived from compounds that originate from glycolysis or the citric acid cycle.

FIGURE 14.7 Conversion of phosphoenolpyruvate (PEP) to pyruvate or malate during plant respiration. The conversion of PEP to pyruvate by the enzyme pyruvate kinase is coupled to phosphorylation of ADP. PEP phosphatase can bypass this ATP synthesis step, releasing P_i . Alternatively, PEP can react with bicarbonate ion (HCO_3^-) via the enzyme PEP carboxylase, releasing P_i and producing the C_4 product, oxaloacetate (OAA). OAA is commonly reduced to malate by NADH through the action of malate dehydrogenase. Both pyruvate and malate can be readily transported into mitochondria via carriers located in the inner mitochondrial membrane (see Fig. 14.36).

matrix, malate can be oxidized by either of two enzymes: a mitochondrial isoenzyme of malate dehydrogenase that yields OAA and NADH, or an NAD⁺-linked malic enzyme that generates pyruvate, CO₂, and NADH (Fig. 14.8). Therefore, uptake of malate from the cytosol effectively transfers reducing equivalents into the mitochondrion. The operation of both malate dehydrogenase and NAD⁺-linked malic enzyme increases metabolic flexibility, allowing plants to regulate specific portions of the citric acid cycle in different tissues.

14.2.2 Pyruvate enters the citric acid cycle through the action of the pyruvate dehydrogenase complex

Before entering the citric acid cycle proper, pyruvate is oxidized and decarboxylated by the pyruvate dehydrogenase complex to form CO₂, acetyl-CoA, and NADH. The pyruvate dehydrogenase enzyme complex, which requires the bound cofactors thiamine pyrophosphate (TPP), lipoic acid, and FAD as well as free coenzyme A (CoASH) and NAD⁺, links glycolysis to the citric acid cycle. The complex contains three separate enzymes: pyruvate dehydrogenase, dihydrolipoil transacetylase, and dihydrolipoil dehydrogenase (Fig. 14.9).

FIGURE 14.8 Alternative routes for the oxidation of malate in plant mitochondria. Once transported into the mitochondrion, malate can be acted on by malate dehydrogenase, which couples the oxidation of malate to the reduction of NAD⁺ to produce OAA and NADH, or by NAD⁺-malic enzyme, which catalyzes the oxidative decarboxylation of malate to pyruvate and CO₂ and the concomitant reduction of NAD⁺ to NADH. Both enzymes are located in the mitochondrial matrix.

FIGURE 14.9 Reaction sequence catalyzed by the pyruvate dehydrogenase complex. The overall reaction catalyzed by this complex involves the oxidative decarboxylation of pyruvate and leads to the formation of acetyl-CoA, CO₂, and NADH. The enzyme pyruvate dehydrogenase (E₁) initially catalyzes the decarboxylation of pyruvate to produce acetaldehyde, a C₂ product that reacts with bound thiamine pyrophosphate (TPP) to form hydroxyethyl-TPP. The hydroxyethyl derivative is transferred to the oxidized lipoamide group of dihydrolipoyl transacetylase (E₂), forming the acetyl thioester of reduced lipoic acid. E₂ then transfers the acetyl unit to the thiol moiety of coenzyme A (CoASH) to give acetyl-CoA and a fully reduced lipoamide group on the dihydrolipoyl transacetylase. Dihydrolipoyl dehydrogenase (E₃) then catalyzes the transfer of two electrons and two protons from the reduced lipoamide group of E₂ to the bound FAD of E₃, oxidizing the lipoamide and producing FADH₂. In the final reaction of the series, E₃ transfers two electrons and a proton to NAD⁺, yielding NADH.

Sophisticated regulatory mechanisms control the activity of the pyruvate dehydrogenase complex. In addition to feedback inhibition by its products, NADH and acetyl-CoA, pyruvate dehydrogenase activity is regulated by a kinase/phosphatase couple. ATP-dependent phosphorylation catalyzed by pyruvate dehydrogenase kinase inhibits the complex, and removal of the phosphate by pyruvate dehydrogenase phosphatase restores activity (Fig. 14.10). Pyruvate inhibits the kinase, ensuring that the dehydrogenase is active when substrate is plentiful. Ammonium ions (NH₄⁺) activate the kinase (see Section 14.7.6).

14.2.3 The citric acid cycle generates reducing equivalents, CO₂, and ATP

As the citric acid cycle proper begins, acetyl-CoA and OAA condense to form the C₆ molecule citrate and free CoASH (Fig. 14.11) in a reaction catalyzed by citrate synthase. Aconitase then isomerizes citrate to isocitrate. Next, NAD⁺-linked isocitrate dehydrogenase oxidatively decarboxylates isocitrate to form CO₂, α-ketoglutarate, and NADH. The α-ketoglutarate is oxidized further to succinyl-CoA, CO₂, and

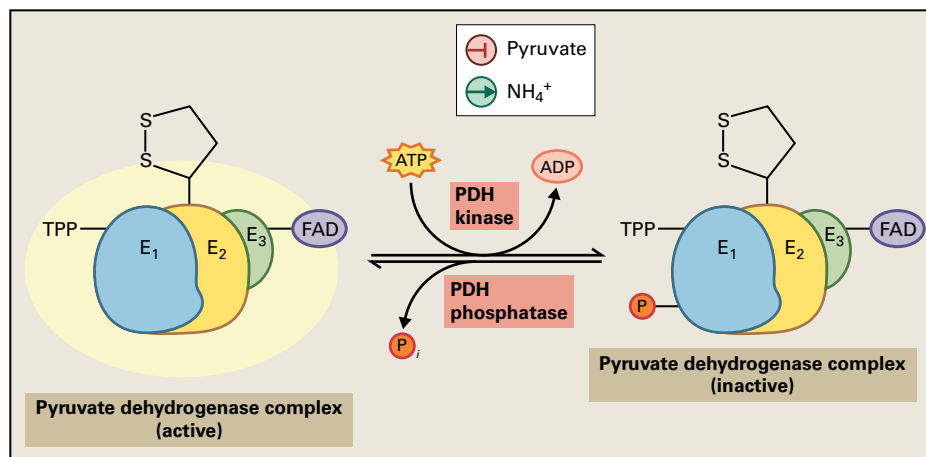

FIGURE 14.10 Regulation of the pyruvate dehydrogenase (PDH) complex by phosphorylation/dephosphorylation. PDH kinase inactivates the PDH complex by catalyzing the phosphorylation of E_1 . Reactivation involves subsequent dephosphorylation by a PDH phosphatase. Pyruvate and ammonium ions (NH_4^+) are allosteric modifiers that regulate the activity of PDH kinase.

NADH in a reaction catalyzed by the α -ketoglutarate dehydrogenase enzyme complex. The structure of this enzyme complex is similar to that of the pyruvate dehydrogenase complex, and the reaction catalyzed is chemically analogous to the formation of acetyl-CoA from pyruvate (see Fig. 14.9). The reaction mechanisms are very similar: for example, lipoamide participates in the α -ketoglutarate dehydrogenase reaction, and dihydrolipoamide dehydrogenase is the same in both complexes.

Succinyl-CoA synthetase catalyzes the conversion of succinyl-CoA to succinate, with the concomitant phosphorylation of ADP to ATP; this is the only citric acid cycle reaction that conserves energy directly by forming ATP. In plants, this enzyme differs from its animal counterpart in being specific for ADP rather than GDP. Succinate dehydrogenase, which catalyzes the oxidation of succinate to fumarate, is the only membrane-associated enzyme of the citric acid cycle and represents the catalytic component of complex II of the respiratory electron transport chain (see Section 14.3.2).

Fumarate reversibly hydrates fumarate to form malate, and malate dehydrogenase catalyzes the final step of the citric acid cycle, oxidizing malate to OAA and producing NADH. The reaction is freely reversible, but the equilibrium in vitro strongly favors the reduction of OAA. In vivo, however, the products are consumed rapidly; OAA condenses with acetyl-CoA to produce citrate, and NADH is oxidized by the respiratory electron transport chain. This shifts the malate dehydrogenase steady state toward product formation. Malate dehydrogenase is inhibited by its product, NADH, and by acetyl-CoA.

Whereas most citric acid cycle enzymes are NAD^+ -linked, NADP^+ -dependent isoforms of isocitrate dehydrogenase and malate dehydrogenase also exist. The NADPH produced by these enzymes has many possible fates. The electron transport chains of plant mitochondria can oxidize matrix NADPH (see Section 14.3.5), and several mitochondrial reactions use NADPH as an electron donor. These include reduction of dihydrofolate to tetrahydrofolate, a substrate for

the C_2 photorespiratory cycle (see Section 14.9); production of reduced glutathione, which protects against reactive oxygen species (ROS) generated during mitochondrial electron transfer (see Section 14.3.7); and reduction of thioredoxin (see Section 14.3.6).

Overall, during the pyruvate dehydrogenase reaction and one subsequent turn of the citric acid cycle proper, the three carbon atoms of pyruvate are released as CO_2 , one molecule of ATP is formed directly, and four NADH and one FADH_2 molecules are produced (Fig. 14.11). This stoichiometry assumes the NADP^+ -dependent isoforms of isocitrate and malate dehydrogenase do not participate in the reaction.

14.2.4 The citric acid cycle can oxidize amino acids, but fatty acid oxidation normally occurs in the peroxisome

Pyruvate, malate, and OAA from glycolysis are typically the most prevalent mitochondrial substrates in vivo, especially in the dark or in nonphotosynthetic tissues. However, other compounds are also metabolized in the mitochondrial matrix and interact with the citric acid cycle. Glycine produced during photorespiration is a special case, discussed later in detail (see Section 14.9.2), but other amino acids also serve as substrates for mitochondrial respiration in some tissues, particularly in seeds rich in stored protein. Amino acid oxidation may be preceded by a transamination reaction that generates a citric acid cycle intermediate, or the oxidation may occur directly. One example of direct oxidation within the mitochondrion involves glutamate dehydrogenase, which catalyzes a reversible reaction:

Reaction 14.2: Glutamate dehydrogenase

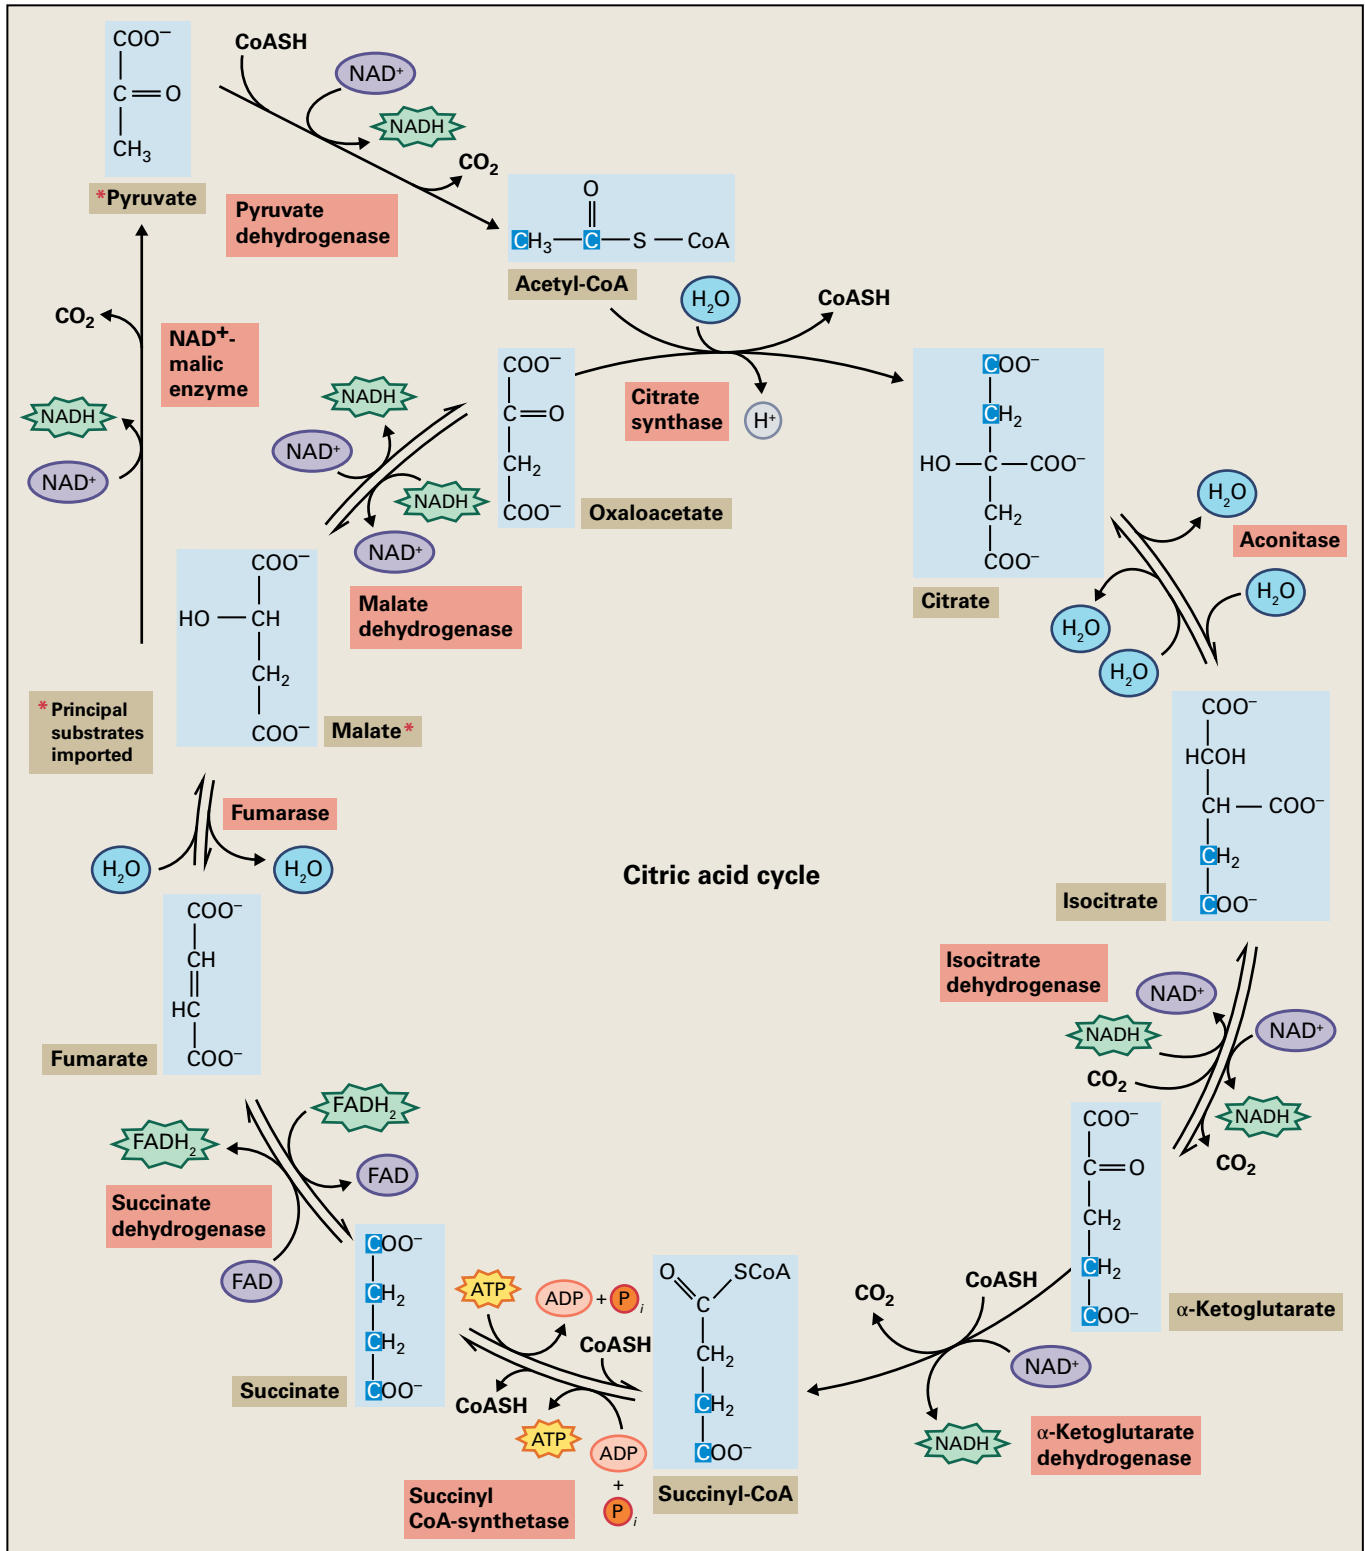

FIGURE 14.11 Reaction sequence of the citric acid cycle. In a reaction catalyzed by citrate synthase, acetyl-CoA formed by the pyruvate dehydrogenase complex combines with OAA to produce the C_6 tricarboxylic acid citrate. In the overall cycle, the citrate is oxidized to produce two molecules of CO_2 in a series of reactions that leads to the formation of one OAA, three NADH , one FADH_2 , and one ATP . The resulting OAA reacts with another molecule of acetyl-CoA to continue the cycle. The oxidative decarboxylation of pyruvate yields an additional CO_2 and NADH . Thus the citric acid cycle brings about the complete oxidation of pyruvate to 3CO_2 plus 10 electrons, which are stored temporarily as 4 NADH and 1 FADH_2 . Malate, which can be an alternative product of glycolysis in plants (see Fig. 14.7), is converted to pyruvate, CO_2 , and NADH by the action of NAD^+ -malic enzyme. The irreversible reactions of the cycle are identified with solid arrows. The two carbons donated by acetyl-CoA are highlighted through the first symmetrical intermediate, succinate, at which point they become randomized and can no longer be traced.

The role of this enzyme is not apparent in all plant tissues. In cotyledons of some legumes (e.g., pea and soybean), glutamate dehydrogenase and mitochondrial aspartate aminotransferase participate in the degradation of stored protein, oxidizing glutamate as a source of energy. The NH_4^+ released by this catabolic reaction is typically reassimilated (see Chapter 7). In leaves, glutamate dehydrogenase has been proposed to operate in the reverse direction as an ancillary enzyme in the reassimilation of NH_4^+ released during photorespiration, although screens for photorespiratory mutants of barley (*Hordeum vulgare*) and *Arabidopsis* did not identify plants deficient in glutamate dehydrogenase (see Chapter 7).

β -Oxidation of fatty acids to acetyl-CoA occurs in animal mitochondria; however, most fatty acid oxidation in plants takes place in peroxisomes (see Chapter 9). Mitochondria do participate in gluconeogenesis, a specialized interaction that enables plants to convert lipids to sugars (see Section 14.7.4), whereas animals lack this synthetic capability.

14.3 Plant mitochondrial electron transport

The mitochondrial electron transport chain conserved among eukaryotes consists of four membrane-bound, multiple-subunit protein complexes, commonly referred to as complexes I–IV (Fig. 14.12). These protein complexes catalyze the

multistep transfer of electrons from NADH and FADH_2 to O_2 , forming H_2O and translocating protons from the matrix to the intermembrane space. In this way, an **endergonic** (energy-consuming) reaction—proton pumping—is driven by the **exergonic** (energy-releasing) transfer of electrons from strong reducing agents to a strong oxidant. The reduction of $\frac{1}{2}\text{O}_2$ by two electrons from NADH involves a reduction potential difference (ΔE°) of 1.14 V (Fig. 14.13). This translates to 219.2 kJ of free energy released for every mole of NADH oxidized. If NADH or FADH_2 reduced O_2 directly, the heat released would not be biologically useful. The electron transport chain facilitates several modestly exergonic redox reactions, rather than a single explosive one, and conserves energy through proton translocation. The F_0F_1 -ATP synthase (sometimes called complex V) does not have electron transfer activity, but it provides a path for proton diffusion into the matrix and uses the free energy released by this spontaneous diffusion to drive the phosphorylation of ADP.

14.3.1 The electron transport chain contains both peripheral and integral membrane proteins and a lipid-soluble quinone

The standard electron transport chain conserved among all aerobic eukaryotes is also sometimes called the cytochrome pathway, and contains four complexes (complexes I–IV) with

FIGURE 14.12 Organization of the plant mitochondrial electron transport chain and ATP synthase in the inner mitochondrial membrane. Electron transfer complexes I–IV, ATP synthase, alternative NAD(P)H dehydrogenases, and the alternative oxidase (AOX) are diagrammed, incorporating what is currently known about their topological orientation in the inner membrane. Red lines indicate electron transfer pathways. A large pool of oxidized ubiquinone (UQ) and reduced ubiquinol (UQH_2) freely diffuses within the inner membrane and transfers electrons derived from the dehydrogenases to either complex III or the AOX. Blue arrows designate the direction of proton translocation at complexes I, III, and IV. Transmembrane proton movement generates a proton electrochemical gradient that drives the synthesis of ATP from ADP and P_i via the ATP synthase.

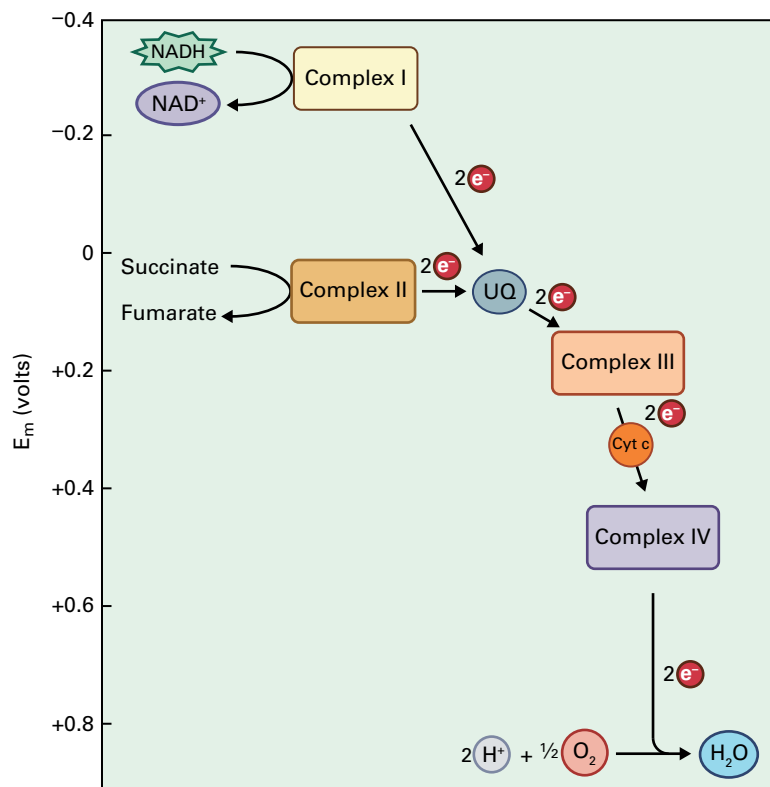

FIGURE 14.13 Approximate positions of the components of the respiratory chain on the redox potential scale. Release of energy drives proton translocation at three sites on the chain: between complex I and ubiquinone (UQ); between UQ and cytochrome *c*; and between cytochrome *c* and complex IV.

multiple protein subunits, as mentioned above. Some of these protein subunits are encoded by mitochondrial genes, and others by nuclear genes. Complex I is an NADH dehydrogenase that oxidizes the NADH generated in the mitochondrial matrix by citric acid cycle activity, regenerating NAD⁺. Complex II (succinate dehydrogenase), which is also a component enzyme of the citric acid cycle, oxidizes succinate to fumarate. Both complex I and complex II transfer electrons to ubiquinone, an abundant, mobile electron transfer cofactor that consists of a substituted *p*-benzoquinone head group and a C₄₅ to C₅₀ prenyl side chain (Fig. 14.14). Ubiquinone can carry one or two electrons. Both fully oxidized ubiquinone and fully reduced ubiquinol molecules are highly hydrophobic and capable of transverse and lateral movement within the inner membrane. A free pool of ubiquinone, present at concentrations far in excess of the proteins with which it interacts, shuttles electrons from complexes I and II to complex III.

Complex III transfers electrons from ubiquinol to cytochrome *c*, the only protein in the electron transport chain not tightly associated with an integral membrane protein complex (see Fig. 14.12). Cytochrome *c*, a small (12.5 kDa), peripheral membrane protein located on the outer surface of the inner membrane and exposed to the intermembrane space, carries one electron at a time from complex III to complex IV (cytochrome-*c* oxidase), the terminal electron carrier in the electron transport chain. For every four molecules of cytochrome *c* oxidized, one molecule of O₂ is reduced to two molecules of H₂O.

Numerous electron transport cofactors are associated with the proteins of the electron transport chain. These

include bound FAD and FMN molecules (see Fig. 14.6), hemes (Fig. 14.15), iron–sulfur (Fe–S) centers (Fig. 14.16), and copper atoms.

Proteomic analysis using peptide mass spectrometry has revealed the electron transfer complexes of the cytochrome pathway in plants include unique proteins. While 85% of the proteins in these complexes are clear homologs of proteins found in the same complexes in most other eukaryotes, approximately 15% of the proteins are either plant specific or are shared among plants and algae but are absent from yeast and animals. The roles of most of these unique proteins have not yet been clarified.

In addition to the cytochrome pathway, plant mitochondria also possess dehydrogenases on each face of the inner membrane that can oxidize NAD(P)H, and an alternative oxidase that can reduce O₂ without pumping protons (see Fig. 14.12). The free energy released as electrons flow through them is lost as heat, however, and cannot be used for ATP synthesis.

14.3.2 Three of the four respiratory complexes located in the inner mitochondrial membrane participate in proton translocation

Complex I is a large multisubunit complex of approximately 45 polypeptides. Depending on the species, the plant mitochondrial genome may encode as many as nine complex I components. The plant mitochondrial complex I is similar to

FIGURE 14.14 Structure and redox reactions of ubiquinone. Reduction of oxidized ubiquinone (UQ) with one electron forms the ubisemiquinone anion ($\text{UQ}^{\bullet-}$). The second reduction step involves the addition of an electron and two protons to give the fully reduced ubiquinol (UQH_2). The hydrophobic prenyl side chain, which in plants commonly contains 45 or 50 carbons, retains UQ near the center of the inner membrane, between adjacent leaflets of the phospholipid bilayer.

the mammalian and fungal NADH dehydrogenase complexes, but it contains a number of plant-specific components. Electron microscopic analysis of purified complex I from *Arabidopsis* indicates the complex has a pronounced L-shape, just like the complex in the bread mold *Neurospora crassa* and bovine heart and the X-ray structure of the bacterial enzyme (Fig. 14.17B).

Complex I oxidizes NADH produced by the reactions of the citric acid cycle and by other NAD^+ -linked enzymes in the matrix. The transfer of electrons from NADH to UQ by complex I leads to long-range conformational changes in four antiporter domains in the membrane arm of the complex that propagate the translocation of protons across the membrane (Fig. 14.17A). Complex I is inhibited specifically by the plant-derived flavonoid rotenone (a rat poison) and its analogs, which appear to act at or near the site of ubiquinone reduction (Fig. 14.18).

Complex II, the smallest of the four electron transfer complexes, consists of four proteins of sizes 70, 27, 15, and 13.5 kDa (Fig. 14.19A,B). In gymnosperms and angiosperms, complex II contains no mitochondrial products, making this the only respiratory complex encoded entirely by nuclear genes. However, the mitochondria of the liverwort *Marchantia polymorpha* encode the two smaller polypeptides, and in the red alga *Chondrus crispus*, only the largest subunit is encoded in the nucleus. Unlike complex I, complex II does not translocate protons, so succinate oxidation is linked to the synthesis of less ATP than is NADH oxidation. Malonate, an analog of succinate, is a strong competitive inhibitor of succinate dehydrogenase activity (see Fig. 14.18). The crystal structure of porcine heart complex II shows the protein environments around prosthetic groups with their unique midpoint redox potentials; two ubiquinone binding sites have been identified by inhibitor binding (Fig. 14.19).

Complex III, also known as the cytochrome bc_1 complex, includes a 42-kDa cytochrome with two b -type hemes (named b_{566} and b_{560} for the wavelengths of their α -band absorbance peaks), a 31-kDa cytochrome c_1 , a 27-kDa Rieske-type Fe-S protein, and five additional polypeptides (Fig. 14.20). The largest polypeptides in complex III are known as core proteins; in the plant complex these range in size from 51 to 55 kDa. Complex III has two quinone-binding sites, one that oxidizes ubiquinol (Center P) and one that reduces ubiquinone (Center N). These binding sites and the electron transport cofactors described above participate in a proton translocation mechanism known as the Q cycle (see Section 14.3.3). The widely utilized inhibitor antimycin A binds to Center N to block reduction of ubiquinone, and myxothiazol, another commonly used inhibitor of complex III in mitochondria, blocks the oxidation of ubiquinol at Center P (see Fig. 14.18).

The final complex of the standard respiratory chain is complex IV, cytochrome- c oxidase. As its name implies, this complex accepts an electron from reduced cytochrome c on the cytosolic side of the inner membrane and eventually donates it to O_2 on the matrix side of the membrane. The complex contains 13 polypeptides in animals and at least as many in plants, the largest three of which are encoded by the mitochondrial genome in most plants. The redox-active species of complex IV include two a -type hemes and two copper-containing centers. All four redox centers are located within mitochondrion-encoded subunits I and II (Fig. 14.21A). The elucidation of a high-resolution crystal structure for the mammalian cytochrome- c oxidase has confirmed many predictions of the structure-function features of this complex (Fig. 14.21B). Like complex I, cytochrome- c oxidase translocates protons across the inner membrane during electron transfer, but while the crystal structure has highlighted several routes that could facilitate the passage of protons across the membrane, it has not yet revealed the proton-pumping mechanism. Inhibitors of complex IV, which include cyanide (CN^-), azide (N_3^-), carbon monoxide (CO), and nitric oxide (NO), compete with O_2 for electrons (see Fig. 14.18).

Direct inhibition of mitochondrial function with inhibitors of the cytochrome pathway, such as antimycin A (an inhibitor

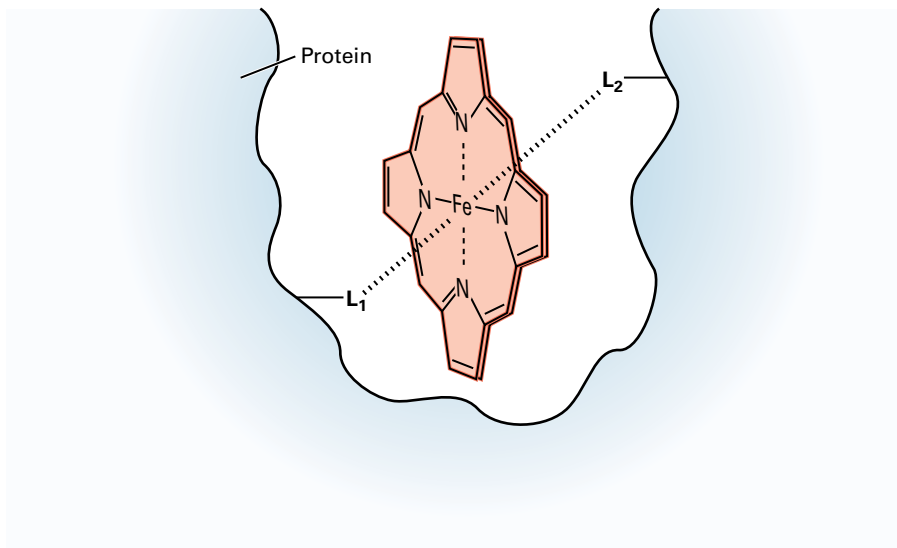

FIGURE 14.15 Structure of the heme prosthetic groups found in cytochromes. These porphyrin prosthetic groups contain four pyrrole rings linked in a macrocyclic ring system surrounding a central iron atom coordinated to the four pyrrole nitrogen (N) atoms. Both *b*-type (A) and *c*-type (B) cytochromes contain iron protoporphyrin IX, with the iron–porphyrin complex bound to the protein through iron-binding “axial” ligands on either side of the plane of the porphyrin ring system (C). In *c*-type cytochromes, in addition to the axial ligands, the porphyrin is covalently bound to the protein via thioether bonds between the vinyl ($-\text{CH}=\text{CH}_2$) side chains of the porphyrin and one or two cysteine residues of the protein. The *a*-type cytochromes contain heme A (D), which has a C_{15} isoprenoid tail attached to one of the pyrrole rings and is noncovalently bound to the protein through one or two axial ligands. The cytochromes are located in complexes of the mitochondrial inner membrane: complex III (*b*- and *c*-types) and complex IV (*a*-type).

FIGURE 14.16 Structure of the metal clusters found in iron-sulfur (Fe-S) proteins. Fe-S proteins associated with complexes I and II of the mitochondrial electron transport chain contain both 2Fe-2S clusters and 4Fe-4S clusters. A Rieske Fe-S protein is located in complex III. Four cysteine residues serve as ligands to the Fe atoms of the low-redox potential 2Fe-2S centers (A), whereas the high-redox potential Rieske 2Fe-2S centers are attached to the protein by two cysteine residues and two histidine residues (B). The irons in the 4Fe-4S centers also are bound to the protein through four cysteine ligands (C).

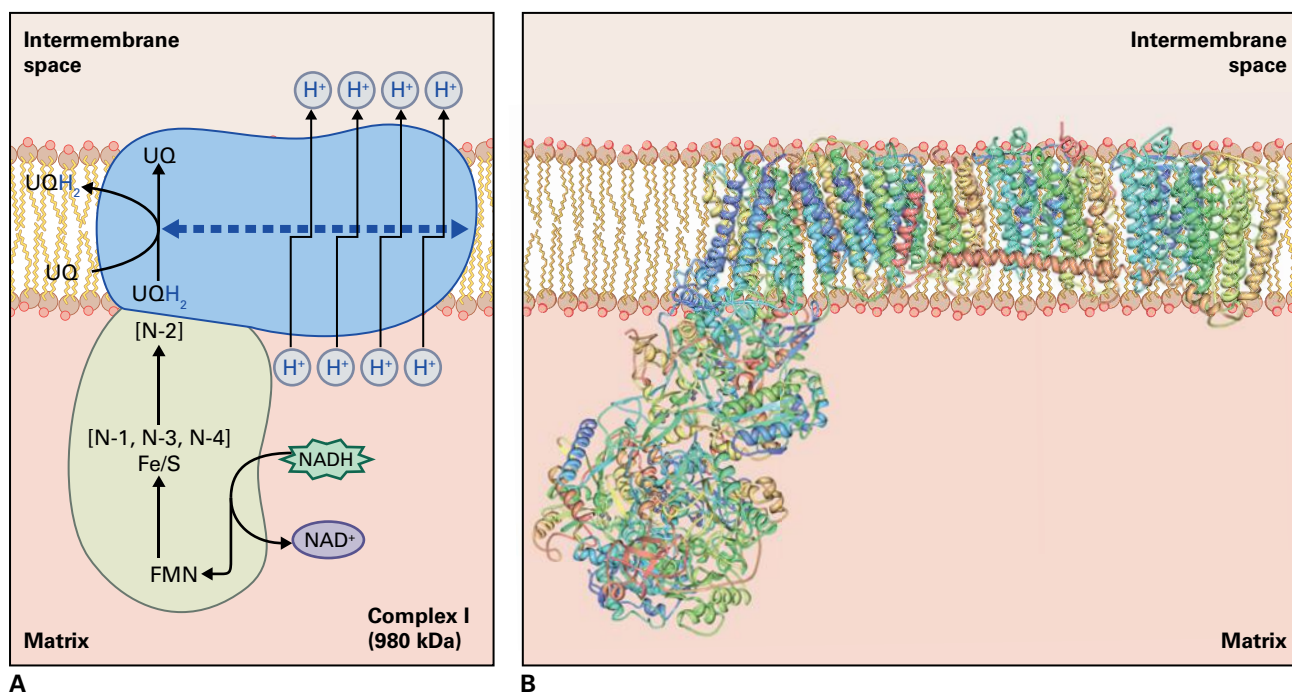

FIGURE 14.17 Proposed structure and membrane topography of mitochondrial complex I (NADH:UQ oxidoreductase). (A) Complex I transfers electrons from matrix NADH to ubiquinone. This transfer involves FMN and four Fe-S centers (N1-N4). The $H^+/2e^-$ ratio is four, with each H^+ taken across the inner membrane by an antiporter domain in the membrane arm. The complex is readily broken into two smaller complexes, one of which (blue) is very hydrophobic and contains almost all of subunits encoded in the mitochondrion and the antiporter domains. The other arm of the complex (green) protrudes into the matrix and is composed mainly of nucleus-encoded subunits. (B) Structure of the complete complex I from *Thermus thermophilus* based on PDB entry 4HEA.

of complex III) and rotenone (an inhibitor of complex I), causes changes in gene expression similar to those seen during aluminum and cadmium stress, viral infection, and cell death induced by H_2O_2 treatment. This indicates the plant stress response is at least in part mediated by mitochondria through mitochondrial-nuclear communication pathways.

14.3.3 Proton pumping at complex III is accomplished by the Q cycle

At complex III, transfer of one electron pair from ubiquinol to cytochrome *c* is accompanied by the translocation of four protons across the inner membrane (Fig. 14.22). This

**Complex****Inhibitor****Substrate**

FIGURE 14.18 Inhibitors of the mitochondrial electron transport chain and ATP synthase. Specific inhibitors of each of the mitochondrial complexes are shown, as are the substrates with which the inhibitors are thought to compete.

mechanism, called the Q cycle, presents the best case in which proton translocation by the electron transport chain is largely understood. During the Q cycle, ubiquinone is reduced to ubiquinol on the matrix side of the inner membrane. Three electron transport chain sites can reduce ubiquinone: one each at complexes I and II, and one at Center N on complex III (see Figs. 14.17, 14.19, and 14.20). The reduction is accompanied by the uptake of two protons from the mitochondrial matrix, regardless of which ubiquinone reduction site is utilized. Ubiquinol then diffuses to the outer face of the membrane and binds to Center P, the ubiquinol oxidation site on complex III (Fig. 14.22). Once

bound to Center P, the ubiquinol is oxidized; one electron reduces the Rieske Fe–S center, the other reduces cytochrome b_{566} , and two protons are released into the intermembrane space. The electron on the Rieske Fe–S center is subsequently transferred to cytochrome c_1 and then to cytochrome c . The electron residing on cytochrome b_{566} is transferred to cytochrome b_{560} , which donates electrons to ubiquinone at Center N.

During operation of the Q cycle, two protons are translocated across the inner membrane for each electron that reduces cytochrome c . This stoichiometry occurs because every two ubiquinols oxidized at Center P release four protons

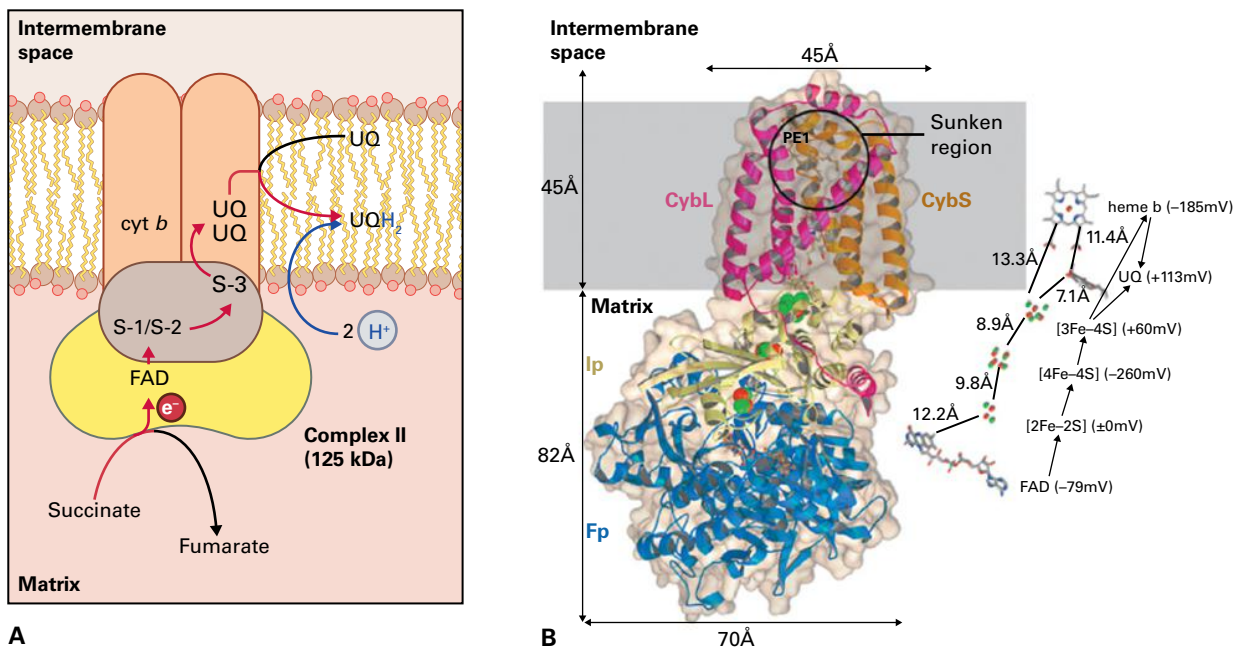

FIGURE 14.19 Proposed structure and membrane topography of mitochondrial complex II (succinate:ubiquinone oxidoreductase). (A) The two large hydrophilic peripheral subunits that make up succinate dehydrogenase— F_p (flavin protein, yellow), which covalently binds FAD, and I_p (iron protein, brown), which covalently binds Fe-S clusters S-1, S-2, and S-3—are attached to the inner membrane through two small, hydrophobic membrane-spanning subunits (orange) that contain one b-type cytochrome and a ubiquinone (UQ) pair, the exact locations of which are uncertain. The proposed path of electron flow is succinate \rightarrow FAD \rightarrow S-1/S-2 \rightarrow S-3 \rightarrow cyt b \rightarrow the UQ pair \rightarrow a UQ molecule from the mitochondrial UQ pool. (B) Ribbon diagram of mitochondrial respiratory complex II based on the crystal structure PDB entry 1ZP0. F_p is shown in blue, iron-sulfur protein (I_p) is shown in cream. The putative membrane region is shaded in gray. On the right side, the prosthetic groups constituting the electron transfer pathway (FAD, [2Fe-2S], [4Fe-4S], [3Fe-4S], and heme b) are shown together with ubiquinone (UQ), along with their edge-to-edge distances and midpoint redox potentials. The electron transfer flow at the Qp site is indicated by arrows.

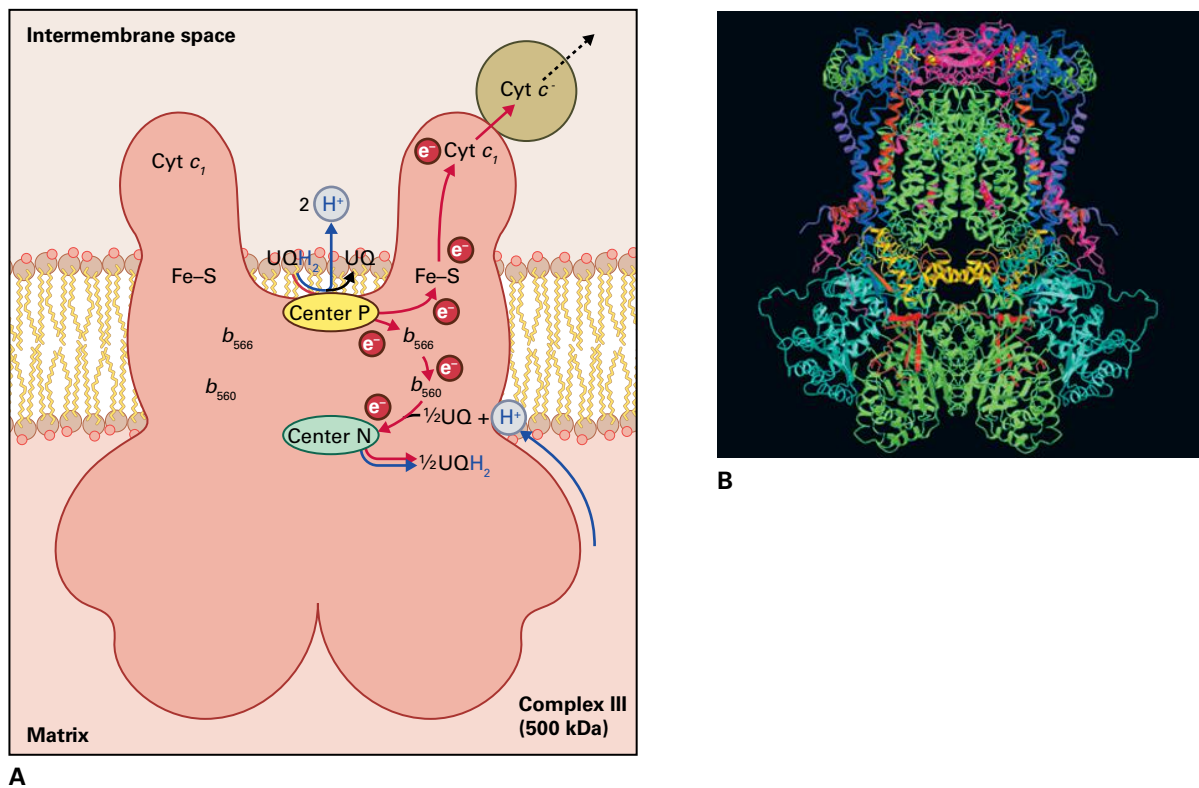

FIGURE 14.20 Proposed structure and membrane topography of mitochondrial complex III, the cytochrome bc_1 complex (ubiquinol:cytochrome-c oxidoreductase). (A) The complex is a dimer, with each monomer containing multiple subunits. Ubiquinol (UQH₂) is oxidized at Center P, while ubiquinone (UQ) is reduced at Center N in a two-step process (see Section 14.3.3). The two electrons from UQH₂ take divergent paths, one being transferred to mobile cytochrome c via a Rieske Fe-S center and cytochrome c_1 , the other reaching Center N via two b-type cytochromes. The inhibitory sites of antimycin and myxothiazol are at Centers N and P, respectively. (B) Crystal structure of a dimeric mammalian cytochrome bc_1 complex based on PDB entry 1BGY.

A

FIGURE 14.21 Proposed structure and membrane topography of mitochondrial complex IV (cytochrome-c oxidase). (A) The electron transfer center that initially oxidizes reduced cytochrome c , Cu_A , contains two copper atoms and resides in subunit II of the complex. All other electron carriers in cytochrome-c oxidase are found on subunit I. From cytochrome c , electrons flow initially to Cu_A , and then sequentially to cytochrome a and the coupled binuclear metal center formed by cytochrome a_3 and Cu_B . The a_3 - Cu_B center is the site of O_2 reduction; inhibitors of cytochrome-c oxidase, such as cyanide, also act at this site. The pathway for proton translocation is an active research area and may differ between the bacterial and eukaryotic enzyme, the Zn atom can affect the entry and the exit pathways for protons in the enzyme. (B) Cytosolic view of the crystal structure of the cytochrome-c oxidase from bovine heart based on PDB entry 1OCC.

B

into the intermembrane space, but only two of the four electrons proceed down the electron transport chain to reduce cytochrome c . The other two electrons are recycled through the b -type hemes to re-reduce one ubiquinone to ubiquinol at Center N (Fig. 14.22).

14.3.4 The electron transport chain is physically organized in supercomplexes of respiratory complexes

Dissolving the mitochondrial membrane using mild detergents has revealed that the respiratory complexes can form higher order supercomplexes, also called **respirasomes**. The tightest binding members of the respirasome in plants are a monomer of complex I with a dimer of complex III, forming a 1.5-megadalton (MDa) supercomplex; however, there is also strong evidence for other supercomplexes exceeding 1.5 MDa in size that contain complexes I, III, and IV. This higher-order structure may facilitate metabolic channeling during respiratory activity and could help establish and maintain the stable stoichiometries among respiratory complexes that are usually observed in animal and plant mitochondria (Fig. 14.23).

14.3.5 Plant mitochondria contain alternative NAD(P)H dehydrogenases that can oxidize NAD(P)H at both faces of the inner membrane

In addition to the NADH dehydrogenase activity associated with complex I, plants contain external and matrix-oriented NAD(P)H dehydrogenases (Fig. 14.24; see also Fig. 14.12). These NAD(P)H dehydrogenases can be distinguished from complex I by their insensitivity to the inhibitor rotenone, and they are often referred to collectively as the alternative or rotenone-insensitive bypass. This bypass transfers electrons from NAD(P)H to the ubiquinone pool, but it does not translocate protons across the inner membrane and so does not contribute to oxidative phosphorylation. As a result of the bypass, addition of rotenone does not fully inhibit oxidation of NAD(P) $^+$ -linked substrates by isolated plant mitochondria, but it does lower the ADP/O values associated with substrate oxidation, that is, the theoretical number of ADP molecules phosphorylated per atom of oxygen reduced (Fig. 14.25). This bypass has substantially less affinity for NADH than does complex I and consequently operates only when matrix concentrations of NADH are high.

A First UQH_2 oxidized

B Second UQH_2 oxidized

FIGURE 14.22 Operation of the Q-cycle during electron transfer through complex III. (A) Ubiquinol (UQH_2) binds at Center P in a pocket formed by cytochrome b and the Rieske Fe-S protein. Initially, one electron is transferred to the Rieske protein, and two protons are released into the intermembrane space. The resulting ubiquinone (UQ^-) transfers the remaining electron to the low-potential cytochrome b_{566} . The electron transferred to the Rieske protein is subsequently transferred to cytochrome c_1 , and then onto cytochrome c. The electron on cytochrome b_{566} is transferred to the high-potential cytochrome b_{560} , which is oriented toward the matrix side of the inner membrane and is associated with a second UQ binding site in complex III, Center N. Oxidized ubiquinone (UQ) binds to Center N and is reduced by one electron, forming a relatively stable ubiquinone anion (UQ^-). (B) After a second round of electron transfer from cytochrome b_{566} to cytochrome b_{560} , the UQ^- is further reduced to UQH_2 in a reaction that includes the uptake of two protons from the mitochondrial matrix. This UQH_2 dissociates from Center N, enters the UQ pool in the inner mitochondrial membrane, and diffuses across the membrane to Center P to initiate the reaction sequence again. As a result of the Q-cycle, four protons are translocated from the matrix to the intermembrane space for every two electrons transferred from complex III to cytochrome c.

FIGURE 14.23 Model of the mitochondrial oxidative phosphorylation system incorporating the classical model (A), the newly described respiratory supercomplexes (B), and an integrated model of the system (C). Abbreviations: M, matrix; IM, inner mitochondrial membrane; IMS, mitochondrial intermembrane space.

In vitro activity of the external dehydrogenases depends strongly on the presence of calcium, but their regulation has not been elucidated in vivo. However, these dehydrogenases have the potential to influence the redox balance of the cytosolic pyridine nucleotide pools—that is, the ratio of NAD(P)^+ to NAD(P)H —and therefore may influence many cytosolic reactions.

14.3.6 Plant mitochondria have an alternative, cyanide-resistant oxidase that transfers electrons to O_2

In addition to nonphosphorylating pathways for oxidation of NAD(P)H , plant mitochondria contain a pathway for transfer of electrons from ubiquinol to O_2 that bypasses

cytochrome *c* oxidase (Fig. 14.12). This nuclear-encoded alternative oxidase (AOX) is found in plants, many algae and fungi, and some protozoa. Electron flow through the AOX is insensitive to classic inhibitors of cytochrome *c* oxidase (CN^- , N_3^- , CO , and NO) and of complex III (antimycin-A, myxothiazol); however, the AOX can be specifically inhibited by salicylhydroxamic acid (SHAM) and *n*-propylgallate (Fig. 14.26). All plant species examined to date possess genes for the AOX; however, AOX activity in any given tissue varies, depending on the level of gene expression and the activation status of the oxidase (see below). Often, AOX expression is greatly enhanced in response to an environmental stress. The AOX is tightly bound to the inner membrane and diverts electrons from the standard electron transport chain at the level of the ubiquinol pool, transferring electrons from ubiquinol to O_2 and generating H_2O as the product.

BOX
14.1

Some electron transport chain components in the mitochondria resemble comparable complexes in the chloroplast

The mitochondrial electron transport chain shares several striking structural similarities with the photosynthetic electron transport chain. In the thylakoid membranes of the chloroplast (see Chapter 12), three large multisubunit protein complexes (Photosystem II, the cytochrome b_6f complex, and Photosystem I) are linked by a membrane-associated quinone (plastoquinone) and a small mobile protein (plastocyanin). Although the photosystems perform a light-harvesting function that has no mitochondrial parallel, the electron transport cofactors of the cytochrome b_6f complex mirror those of complex III: two b -type cytochromes, a c -type cytochrome (cytochrome f), and a Rieske Fe-S protein. The cytochrome b_6f complex interacts with plastoquinone in a Q cycle that translocates protons from the stroma to the thylakoid lumen. Furthermore,

both plastocyanin and cytochrome c are membrane-associated soluble metalloproteins that can be reduced by a cytochrome complex and carry one electron. The redox active metal that gives plastocyanin its name and blue color is copper, not iron, but some algae grown in copper-limiting medium can replace plastocyanin with a soluble c -type cytochrome. The similarity of the electron transport chains and ATP synthases present in these organelles may derive from a common prokaryotic heritage.

Both organelles also contain alternative respiratory enzymes, notably the single polypeptide quinol oxidase, IMMUTANS, in plastids that participates in chlororespiration and cyclic electron transport, and the alternative oxidase in mitochondria that participates in nonphosphorylating respiration.

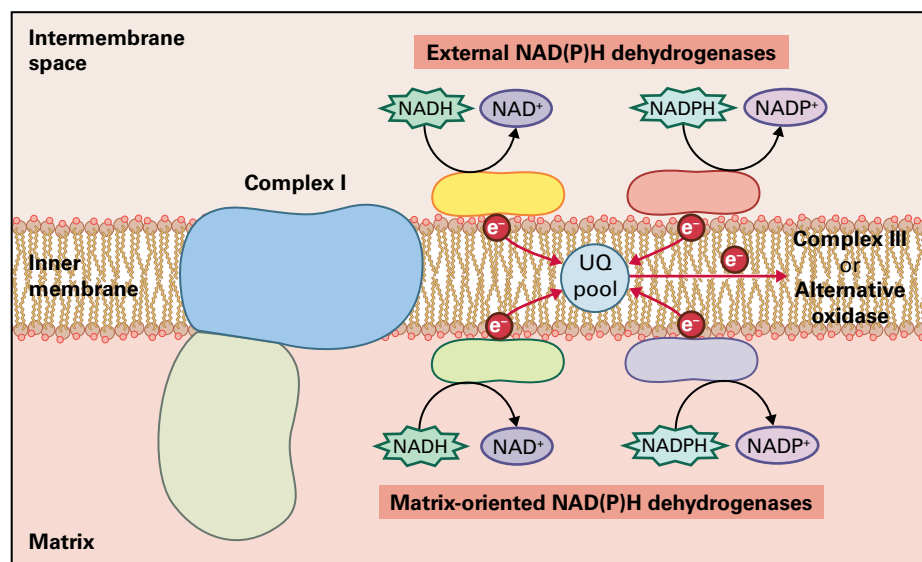

FIGURE 14.24 Alternative NADH and NADPH dehydrogenases of the inner mitochondrial membrane. In addition to complex I, plant mitochondria possess simpler (single polypeptide) dehydrogenases on both surfaces of the mitochondrial inner membrane. These do not pump protons and are insensitive to complex I inhibitors such as rotenone. In *Arabidopsis*, seven genes encoding putative alternative dehydrogenases have been identified; however, only four activities have been described in isolated mitochondria. The two external dehydrogenases are thought to oxidize cytosolic NAD(P)H and feed electrons into the UQ pool. The two matrix-oriented enzymes provide additional routes for oxidation of the NADH and NADPH formed in the matrix.

Reaction 14.3: Alternative oxidase

AOX oxidises O_2 to H_2O using four electrons by binding and oxidising two molecules of UQH_2 in succession, first to form an AOX-ubiquinone radical and release one molecule of H_2O and then reduce a second UQH_2 to yield a second H_2O and regenerate the AOX active site ready for a new catalytic cycle.

Because no proton pumping results from the electron transfer between ubiquinol and O_2 , all the free energy released

FIGURE 14.25 Operation of the rotenone-insensitive bypass of complex I in plant mitochondria. The diagram shows an oxygen electrode recording obtained with isolated mitochondria oxidizing malate in a reaction medium containing an excess of inorganic phosphate. Oxidation of the malate within the matrix generates NADH, which, in turn, is oxidized by the respiratory chain, leading to O₂ consumption. Addition of a small amount of ADP stimulates the rate of O₂ uptake by allowing the ATP synthase to operate, dissipating the proton motive force across the inner mitochondrial membrane. When all added ADP has been phosphorylated, O₂ uptake reverts to a slow resting rate. These rate changes allow researchers to calculate an **ADP/O ratio** (the amount of ADP phosphorylated per oxygen atom consumed), which is an indication of the number of proton-translocating sites. The ratio before addition of rotenone was >2, indicating operation of three translocation sites. Addition of rotenone blocks electron flow through complex I and redirects electrons to the alternative NADH dehydrogenase on the inner surface of the inner membrane; this enzyme does not pump protons, and the ADP/O ratio decreases accordingly. Note the resting rate of O₂ consumption is a little higher when electrons bypass proton-pumping complex I.

FIGURE 14.26 Structures of salicylhydroxamic acid (SHAM) and *n*-propylgallate, inhibitors of the AOX. SHAM is thought to act as a competitive inhibitor of ubiquinol (UQH₂).

FIGURE 14.27 Structure and membrane topography of the AOX dimer in plants, as deduced from the structure defined in a protozoan with the plant specific N-terminal extensions added that contain the regulatory cysteines. The AOX exists as a dimer partially embedded in the membrane. The dimeric structure is maintained by protein-protein interactions regardless of whether the intermolecular disulfide bond is oxidized. Each monomer is anchored to the inner mitochondrial membrane by the embedding of two α -helices. Two large hydrophilic domains flank the embedded helices and extend into the mitochondrial matrix. The amino acids that make up the di-iron center are located in the hydrophilic domain.

during electron flow through the AOX is lost as heat and cannot be used for ATP synthesis. Thus, when electrons from NADH oxidation flow through the AOX, at least two of the three sites of proton translocation are bypassed, the resulting proton motive force is diminished, and fewer molecules of ATP are synthesized (see Section 14.4.1).

A structure for the AOX has been obtained from a protozoan and the conservation of key residues in cDNA sequences from numerous plants and fungi show that it is a good model for this enzyme across species (Fig. 14.27). The enzyme exists in the inner mitochondrial membrane as a homodimer in which two 32 kDa monomers interact non-covalently to form a dimer. In plants and fungi, an extra extension on the monomers exists which contains a conserved cysteine that undergoes reversible intermolecular disulfide bonding via thioredoxin (Trx) that is reduced by NADPH via NADP⁺-thioredoxin reductase (Reaction 14.4).

Reaction 14.4: NADP⁺-thioredoxin reductase

The AOX active site in each monomer contains a di-iron metal center with a hydroxo-bridge. AOX shares structural features with other di-iron proteins like ribonucleotide

reductase, but the iron atoms are coordinated by carboxylates from amino acid residues in AOX, which is unusual for a di-iron protein. It is noteworthy that both ribonucleotide reductase and many of the AOXs interact with reduced thioredoxin, which serves as a substrate for ribonucleotide reduction by the former enzyme and as an activator of the latter (see Section 14.6.1).

14.3.7 An antioxidant defense system removes reactive oxygen species generated by the electron transport chain

The mitochondrial electron transport chain generates superoxide ($O_2^{\cdot-}$) mainly as a result of the reaction of O_2 with components of the electron transport chain. Detoxification of $O_2^{\cdot-}$ is essential to avoid peroxidation of lipid membranes or oxidation of mitochondrial proteins and nucleic acids. A manganese-dependent superoxide dismutase in the mitochondrial matrix converts $O_2^{\cdot-}$ to hydrogen peroxide (H_2O_2), which is degraded to H_2O via a series of mitochondrial reactions that can be catalyzed by Trx-dependent peroxidases, the ascorbate-glutathione cycle (see Fig. 20.37), or glutathione-dependent peroxidases that have been reported in plant mitochondria from some species.

14.4 Plant mitochondrial ATP synthesis

The mitochondrial electron transport chain translocates protons from the matrix side of the inner membrane to the cytosolic side, concentrating them in the intermembrane space. Protons diffuse back into the matrix through the F_0F_1 -ATP synthase complex, which catalyzes the conversion of ADP and P_i to ATP. Numerous inner membrane transporters facilitate this process.

14.4.1 The electron transport chain couples oxidation of reducing equivalents to formation of a proton electrochemical gradient

As its name suggests, the proton electrochemical gradient ($\Delta\mu_{H^+}$) formed by the action of the electron transport chain comprises two potentials, one electrical and the other chemical (see Chapter 3). This difference in free energy, which can also be calculated in volts as proton motive force (Δp), represents the sum of the electrical component ($\Delta\psi$, negative inside the mitochondrial matrix) and the chemical component (ΔpH):

Equation 14.1: Proton electrochemical gradient

$$\Delta\mu_{H^+} = \Delta\psi + \Delta pH$$

Equation 14.2: Proton motive force

$$\Delta p = \Delta\mu_{H^+} / 96.5 \text{ kJ V}^{-1} \text{ mol}^{-1}$$

The concept of coupling two reactions through a proton electrochemical gradient forms the basis of the chemiosmotic theory. In mitochondria, including those from plants, the principal contributor to $\Delta\mu_{H^+}$ is $\Delta\psi$ (-150 to -200 mV); the intermembrane space pH is only 0.2 to 0.5 units lower than that of the matrix. Typical $\Delta\mu_{H^+}$ values for plant mitochondria are -200 to -240 mV in the resting state (i.e., in the absence of ADP). In chloroplasts, by contrast, ΔpH represents most of the total $\Delta\mu_{H^+}$ because chloroplasts are more permeable to some ions and contain gated ion channels that are not present in mitochondria.

14.4.2 The F_0F_1 -ATP synthase complex couples dissipation of the proton electrochemical gradient with ATP formation

F_0F_1 -ATP synthase is a multisubunit complex that spans the inner membrane. Although mitochondrial function is commonly associated with proton diffusion coupled to ATP synthesis, in some circumstances the F_0F_1 complex can hydrolyze ATP to ADP and P_i and drive proton translocation from the matrix into the intermembrane space.

F_0F_1 -ATP synthase is composed of two major components (Fig. 3.5). The integral membrane protein complex, F_0 , functions as a proton pathway through the inner membrane and consists of as many as eight or nine separate polypeptides, with three primary subunits in a ratio of $a_1b_2c_{10-12}$. The peripheral membrane protein complex, F_1 , extends into the matrix space on a stalk anchored at its base to the F_0 complex (Fig. 14.28). The F_1 complex contains at least five separate polypeptides, α through ϵ , in a stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$. The catalytic sites for ATP synthesis are localized primarily on the β subunits. Four of the F_0 polypeptides (ATP4, ATP6, ATP8, ATP9) and one of the F_1 polypeptides (α subunit, ATP1) are commonly encoded by plant mitochondrial DNA. The F_1 stalk includes the γ -polypeptide and several other subunits, one of which is known as the oligomycin-sensitivity-conferring protein (OSCP) because it binds the antibiotic oligomycin. Binding of oligomycin to OSCP prevents proton translocation through the F_0 complex, inhibits ATP synthesis, and limits mitochondrial O_2 uptake (see Section 14.5.2).

In the “binding change” reaction mechanism proposed for ATP synthase, the free energy input from proton diffusion is not required to phosphorylate ADP directly, rather it induces a conformational change that releases tightly bound ATP

FIGURE 14.28 Mosaic structure of the F_0F_1 -ATPase from bovine mitochondria. The components of the structure were docked into a structure of the intact enzyme by electron cryomicroscopy. The extrinsic region consists of the spherical catalytic domain made up of three α subunits and three β subunits of the membrane shown in red and yellow, respectively. The γ -, δ - and ϵ subunits of the F_1 central stalk are shown in blue, purple and green, respectively. The central stalk and F_0 c-ring shown in brown constitute the rotor. The peripheral stalk (cyan) penetrates the membrane and links provide a connection to the catalytic domain. The complex is an integral membrane-spanning complex that acts as a proton channel, providing the pathway for movement of protons across the inner membrane into the matrix.

from one of the three F_1 active sites (see Chapter 3, Fig. 3.6). The $\alpha_3\beta_3$ subunit stoichiometry of the F_1 complex is consistent with this model, and the high-resolution crystal structure for the F_1 complex from mammalian mitochondria demonstrates structural and nucleotide (i.e., ATP and ADP) binding features that support this mechanistic scheme.

14.4.3 Movement of ATP, ADP, and phosphate into and out of plant mitochondria is also driven by the electrochemical proton gradient

The exact number of protons translocated per pair of electrons transferred from NADH to O_2 remains controversial, since the mechanisms that couple proton translocation to electron flow have not been clearly elucidated for complexes I and IV. However, measurements with isolated mitochondria from different sources give a value of 10 protons translocated per NADH oxidized by the cytochrome pathway. Given the free energy required for ATP synthesis and that available from the measured $\Delta\mu_{H^+}$, thermodynamic considerations indicate three protons are needed per ATP molecule synthesized. When the energy costs of transporting adenine nucleotide and phosphate across the inner membrane are taken into account,

however, the H^+/ATP ratio increases (Fig. 14.29). Unlike the chloroplast, where ATP synthesis and consumption both take place in the stroma, the mitochondrion must expend free energy to import ADP and inorganic phosphate (P_i) and export ATP across the inner membrane. One ATP^{4-} is exported from the mitochondrion in exchange for one ADP^{3-} from the cytosol, and one hydroxide ion (OH^-) from the mitochondrial matrix is exchanged for one cytosolic P_i . Hydroxyl transport equates to the net movement of one proton from the intermembrane space back into the matrix. Adding this proton to the three protons needed to synthesize one ATP from ADP and P_i at the measured values of $\Delta\mu_{H^+}$ gives a value of four protons translocated per ATP synthesized.

Including the energy cost of nucleotide and P_i transport in calculations of mitochondrial efficiency lowers the ADP/ O values associated with substrate oxidation. If four protons are needed to transport ADP and P_i into the mitochondrion and to synthesize ATP, then the ADP/ O ratio is 2.5, rather than the 3 previously assumed. In this context, careful measurement of ADP/ O ratios in isolated mitochondria often yields values close to 2.5 during oxidation of NAD^+ -linked substrates. Oxidation of succinate by the bound FAD of complex II or of NAD(P)H by the rotenone-insensitive dehydrogenases drives the synthesis of only 1.5 molecules of ATP per $\frac{1}{2}O_2$ reduced, because these reactions utilize only two of the three proton translocation sites.

FIGURE 14.29 The adenine nucleotide carrier and the phosphate carrier expend electron motive force to supply ATP synthase with substrate. The adenine nucleotide carrier catalyzes the electrogenic exchange of cytosolic ADP³⁻ for mitochondrial ATP⁴⁻. The net negative charge on the matrix side of the membrane ($\Delta\psi$) drives ATP export against a large concentration gradient and supports a high ATP/ADP ratio in the cytosol. In addition, the outer face of the carrier has a high affinity for ADP and therefore can import ADP to maintain oxidative phosphorylation even at low cytosolic ADP concentrations. The P_i carrier catalyzes an electroneutral exchange of negatively charged phosphate for OH⁻ and thus balances the electrogenic adenine nucleotide exchange by dissipating the equivalent amount of $\Delta\mu\text{H}$.

14.5 Regulation of the citric acid cycle and the cytochrome pathway

14.5.1 In vegetative tissues, expression of many respiratory enzymes is largely constitutive

Expression experiments comparing different stages of plant development and different tissues consistently show most genes for mitochondrial enzymes are expressed in most organs at relatively constitutive levels, but transcript abundance is dramatically enhanced in floral organs. Interestingly, genes encoding proteins of the cytochrome pathway and the citric acid cycle are remarkably nonresponsive to environmental stresses, though signals such as light, sucrose, and the nitrogen

status of the cell do affect the expression of components of the pyruvate dehydrogenase complex and the cytochrome pathway. Genes encoding the alternative oxidase (AOX) and some of the alternative NAD(P)H dehydrogenases, on the other hand, are very sensitive to environmental stress.

14.5.2 Regulation of respiratory activity in isolated mitochondria depends on availability of ADP and P_i

In isolated mitochondria, the rate of electron transfer and, therefore, the rate of O₂ uptake, are controlled primarily by the availability of ADP and P_i, a phenomenon described as **respiratory control**. In the absence of ADP or P_i, the F_o proton channel of the ATP synthase is blocked, and $\Delta\mu_{\text{H}^+}$ builds until it exerts a back pressure that restricts further proton translocation across the inner membrane. Because electron

FIGURE 14.30 Respiratory control and the impact of uncouplers on the ADP/O ratio. The rate of O_2 uptake is described by four respiratory states. State 1 occurs when no oxidizable substrate is present; O_2 consumption (O_2 nmol min^{-1} mg^{-1} of total mitochondrial protein) in state 1 is insignificant. Some O_2 is reduced (consumed) when substrate alone is added (state 2), but O_2 uptake is stimulated dramatically by adding ADP (state 3). When all ADP has been consumed, the O_2 uptake rate again decreases (state 4). The state 3 to state 4 ratio for rates of electron transfer, termed the **respiratory control ratio**, indicates how tightly ADP phosphorylation and electron transport are coupled. Chemical uncouplers collapse the proton gradient and release respiratory control, increasing O_2 consumption to state 3 rates.

transport is obligately linked to proton translocation, a large $\Delta\mu_{H^+}$ also restricts the rate of O_2 uptake (Fig. 14.30). In steady state, the rate of electron transfer is determined by the rate at which protons in the intermembrane space flow back into the matrix. When ADP and P_i are available, the back-flow of protons via the ATP synthase is rapid; in the absence of ADP or P_i , or both, the protons leak slowly across the inner membrane.

The proton leak can be dramatically stimulated by some compounds that act as protonophores (ion-binding, lipid-soluble molecules that allow protons to cross membranes) or proton channels. Such compounds are referred to as **uncouplers** since they disconnect electron transport from ATP synthesis by equilibrating the proton gradient across the membrane and dissipating the $\Delta\mu_{H^+}$ as heat. Uncouplers stimulate O_2 uptake, but because no $\Delta\mu_{H^+}$ is established, no ATP is formed. Mitochondria from both animals and plants contain uncoupling proteins that facilitate proton movement across the membrane in a regulated fashion. Certain plants take advantage of the heat released under conditions that do not yield ATP to promote flowering (Box 14.2). Interestingly, a similar phenomenon is observed in infants that use mitochondria rich in brown fat for warming. However, the primary role of uncoupling proteins in plants appears to be the maintenance of mitochondrial electron transport when

adenylate charge is high, thus preventing the over reduction of the ubiquinone pool that can lead to oxidative damage.

14.5.3 Substrate supply, organic acids, ADP, and matrix NAD(P)H may each serve to regulate respiratory metabolism in intact tissues

In vivo respiratory rates are generally accepted as being at least somewhat linked to the energy demands of the plant cell. However, the controlling factors may be dictated by tissue-specific and environmental factors and are difficult to ascertain. Mitochondria usually do not operate at full respiratory capacity in vivo. In many tissues, the respiration rate is controlled by the rate at which mitochondrial substrates are supplied, which slows if carbohydrate reserves are low or if glycolysis is downregulated by metabolic effectors (e.g., ATP). In tissues where substrate supply is plentiful, respiration can be limited by the rate of ATP turnover. In isolated mitochondria, the respiration rate is controlled by adding ADP. In vivo, respiration is also influenced by the cytosolic ATP/ADP ratio, which depends on both the concentration of ADP and the cellular rate of ATP utilization. The mechanisms of citric acid cycle regulation in plants have not yet been fully resolved, but current data suggest cycle activity is controlled by the energy status of the cell, through its impact on mitochondrial matrix concentrations of NADH, ATP and acetyl-CoA, which inhibit various dehydrogenases through binding to substrate and allosteric sites and with certain enzymes, through redox changes via thioredoxin. Therefore, the citric acid cycle turnover rate in vivo depends on the rate of NADH reoxidation by the respiratory electron transport chain and on the cellular rate of ATP utilization. The rate at which plastid and cytosolic pathways provide citric acid cycle substrates may also be important. For example, in some leaves, which undergo large diurnal shifts in carbohydrate content, respiratory rates are proportional to the concentration of carbon substrates in the leaf cells, being very low at the end of the night and increasing substantially during the day as photosynthesis replenishes carbon reserves.

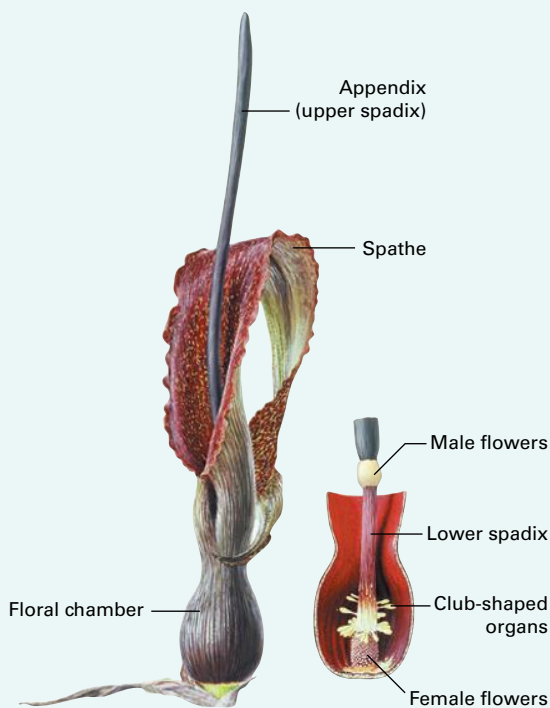

14.6 Integration of the cytochrome pathway and nonphosphorylating pathways

When nonphosphorylating respiratory pathways contribute to O_2 uptake, the extent to which respiration rates are regulated by the cytosolic ATP/ADP ratio is decreased. Because these enzymes are not involved in proton translocation across the inner mitochondrial membrane, they do not sense

BOX 14.2 The alternative oxidase and uncoupling proteins are active during thermogenesis in some flowers

The AOX and uncoupling proteins participate in thermogenesis during flowering in a few plants, mostly members of the family Araceae. These plants, which include skunk cabbage and voodoo lily, produce a club-like structure (called an appendix) on the developing floral apex. The outer layers of the appendix contain more mitochondria than most plant tissues. During anthesis (pollen release), mitochondria in the appendix use the AOX and uncoupling proteins to respire at very high rates. The free energy released as heat raises tissue temperatures 10°C to 25°C above ambient conditions and volatilizes odorous compounds that attract pollinators. In some cases, this mechanism can mimic the scent of rotting flesh and is used to deceive insects that lay their eggs.

It is unlikely that the AOX and uncoupling proteins promote thermogenesis in other plant tissues, because plants are not generally thermogenic. Observed rates of respiration in most plant organs are simply too low to generate significant amounts of heat, even if all electron flow were to be shunted through the AOX and even if uncoupling proteins completely prevented limitation of the electron transfer rate by dissipating the mitochondrial membrane potential.

Source: Benstead, Fife, Scotland, UK; previously unpublished.

the $\Delta\mu_{\text{H}^+}$ and, therefore, are not restricted by oxidative phosphorylation. This results in faster rates of respiration in the resting state. Given the ramifications of operating an energetically wasteful pathway in an organelle that functions primarily in energy conservation, it is important to understand how the nonphosphorylating NAD(P)⁺ dehydrogenases and AOX are regulated and how they interact with the cytochrome pathway.

14.6.1 Regulation of the alternative oxidase is complex

Both the expression and activity of the AOX are subject to regulatory controls. In most plants, two or more AOX proteins encoded by separate genetic loci are expressed in a tissue-specific manner. In soybean, for example, one isoform appears to be expressed mainly in photosynthetic tissues. In both soybean (*Glycine max*) and *Arabidopsis*, one out of several AOX isoforms is expressed strongly in response to environmental stresses. In many, but not all, plants tissues, AOX expression and activity are very low until a stress is applied.

FIGURE 14.31 Structure of an α -keto acid.

Factors that can induce AOX synthesis include low temperature, drought, generation of $\text{O}_2^{\cdot -}$ or H_2O_2 , certain herbicides, inhibitors of mitochondrial protein synthesis or electron transfer, and ripening in some fruits. In most cases, induction involves increased amounts of AOX mRNA. In cultured tobacco (*Nicotiana tabacum*) cells, addition of citrate to the growth medium also triggers AOX synthesis, suggesting a link between carbon metabolism and regulation of AOX gene transcription.

Research on mutants with elevated AOX protein levels and on plants under environmental stress has shown that regulation of AOX activity is complex and not just dependent on protein abundance. AOX activity is strongly enhanced by α -keto acids (Fig. 14.31), such as pyruvate and glyoxylate. In addition, the AOX is a target of thioredoxin (Fig. 14.32). When the intermolecular disulfide bond that can covalently link the two monomers is reduced to two sulfhydryl groups

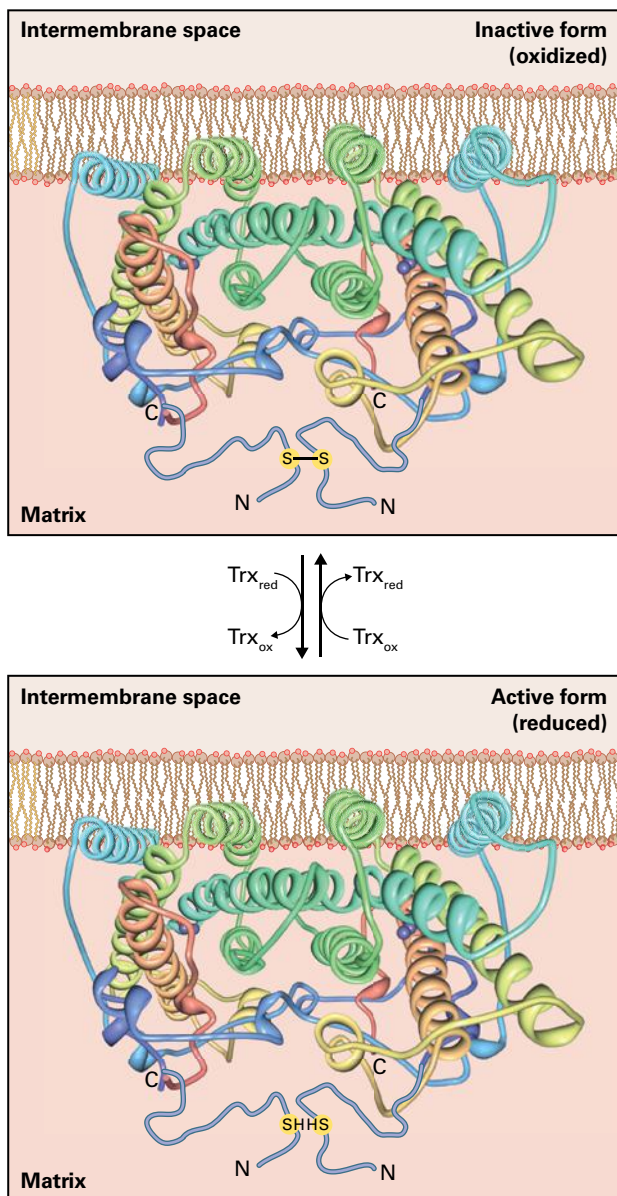

FIGURE 14.32 Proposed regulation of the AOX through action of a redox-active regulatory sulfhydryl/disulfide system. Reduction of an intermolecular disulfide bond increases the sensitivity of the AOX dimer to activation by α -keto acids. The reduced thioredoxin would be oxidized with O_2 possibly via a peroxiredoxin (see Chapter 12).

by thioredoxin, AOX activity significantly increases in the presence of pyruvate. In the oxidized, less active state, the AOX dimer is markedly less sensitive to stimulation by α -keto acids.

Reduction of the regulatory disulfide bond can be induced by applying citrate or isocitrate to isolated mitochondria and may involve NADPH generated in the matrix by NADP⁺-linked isocitrate dehydrogenase. This system seems to constitute a link between the redox poise of the mitochondrial matrix and the oxidation state of the regulatory cysteine residues in the AOX whose redox state is linked to NADH (see Reaction 14.4). Because citrate can also activate AOX expression, both

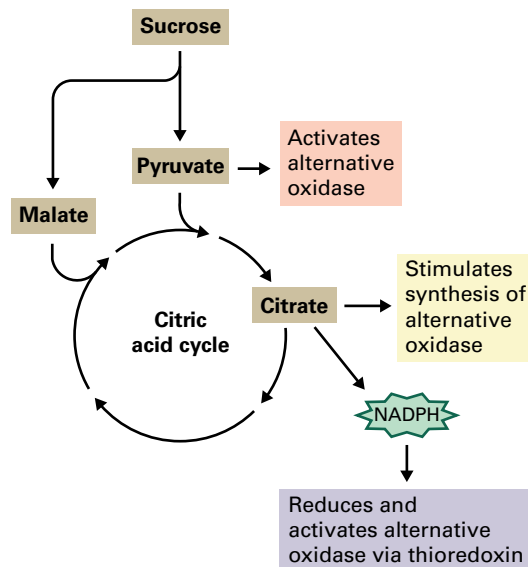

FIGURE 14.33 Impact of sugar metabolism on AOX activity. Activation and synthesis of the AOX are linked to the carbon status of the cell. When carbon flux to the mitochondrion exceeds the capacity of the electron transport chain to accept electrons, carbon intermediates such as pyruvate and citrate accumulate and the matrix NAD(P) pool becomes highly reduced. Accumulation of citrate leads to synthesis of more AOX protein, whereas accumulated pyruvate and NADPH activate the enzyme via thioredoxin. This feed-forward control ensures the potentially wasteful AOX is active only when the carbon supply in the cell is plentiful. Activation of AOX prevents overreduction of other respiratory chain components, thereby decreasing the production of harmful active oxygen intermediates.

the activity and synthesis of the AOX are integrated with the carbon and energy status of the cell (Fig. 14.33).

The impact of α -keto acids and disulfide bond reduction on AOX activity reveals a clearer picture of respiratory regulation. Several factors restrict electron flow through the cytochrome pathway, including increase in the cytosolic ATP/ADP ratio, decrease in cytosolic ADP concentration, and environmental stresses such as low temperature. These enhance the reduction state of the matrix NAD(P)⁺ pool to inhibit the rate of citric acid cycle activity, thereby increasing the concentration of mitochondrial pyruvate. Both responses may feed forward to activate the AOX: pyruvate activates AOX directly, and increased matrix NAD(P)H levels act indirectly by increasing the amount of reduced thioredoxin available. Once activated, the AOX could compete effectively with the cytochrome pathway for electrons from the ubiquinone pool, allowing the plant to maintain a greater rate of aerobic respiration than if the AOX were not present. This respiratory activity may prevent damage associated with the formation of ROS (see Section 14.3.7) or with fermentative metabolism (see Chapter 22). Finally, in addition to the mechanisms shown to control AOX abundance and activity in isolated mitochondria, other regulatory mechanisms may operate in intact tissues to regulate the partitioning of respiration between the two oxidases. The effect of altering respiratory efficiency on metabolism can be substantial, and sophisticated control is to be expected.

14.6.2 Alternative oxidase regulation and ubiquinone pool redox status influence electron flow through the cytochrome and alternative pathways

In the past, the AOX was believed to function simply in an electron overflow capacity. According to this scheme, AOX activity was significant only when >40–60% of the ubiquinone pool was reduced. With the cytochrome pathway at or near saturation, ubiquinol would divert electrons to the AOX. As a consequence, AOX activity was measured by the extent to which AOX inhibitors such as SHAM inhibited respiration. This approach assumed that the cytochrome pathway was already saturated and could not compensate for the inhibited alternative pathway. Thus, any observed decrease in the respiration rate would reflect how active the AOX had been in the absence of the inhibitor. This model is now considered out of date.

It is now understood that activation by α -keto acids and thioredoxin-mediated reduction allows the AOX to compete for electrons with the cytochrome pathway even when ubiquinol concentrations are low (Fig. 14.34). If the cytochrome pathway is unsaturated, increased electron flow through it can mask inhibition of the alternative pathway; therefore, respiration rates measured in the presence and absence of SHAM do not quantify AOX activity. Instead, researchers directly measure the respiratory rate of plant tissues and simultaneously

FIGURE 14.34 The ubiquinone pool kinetic model for engagement of Cyt pathway and AOX. A plot of the rate of electron transport (y-axis) as a function of the degree of UQ reduction (x-axis) describes the kinetics of both UQ-reducing pathways (complex I, SDH, and alternative NADH dehydrogenases) as well as the two UQ-oxidizing pathways (cytochrome chain and the AOX). For the UQ-reducing pathways, the maximum rate occurs when the UQ pool is oxidized, and the rate decreases as the UQ pool becomes more reduced (i.e. UQH_2 concentration increases). Alternatively, for the oxidizing pathways, the reaction rate is zero when the UQ pool is fully oxidized, but it increases as UQ is further reduced. The intersection of the UQ-reducing and -oxidizing kinetics indicates the steady-state UQ reduction state that occurs for the given electron transport chain rate. The plot demonstrates how the cytochrome pathway dominates electron flux at lower UQH_2 levels (red line), as well as how AOX becomes more dominant when UQH_2 level rises in response to either increases in UQ reducing potential or a blockage in the cytochrome pathway.

measure concentrations of ^{18}O consumed. Both plant mitochondrial respiratory oxidases discriminate against O_2 containing the ^{18}O isotope, so ^{18}O accumulates as a percentage of the O_2 in a closed respiring system over time. Owing to a measurable difference in the discrimination value of cytochrome oxidase and the AOX in plants, such measurements can be used to accurately determine the proportion of O_2 consumption by each oxidase in an intact plant tissue.

The ubiquinone pool kinetic model (Fig. 14.34) recognizes ubiquinone and ubiquinol as substrates or products of both the electron transport chain's ubiquinone-reducing enzymes (complexes I and II and the rotenone-insensitive bypass), and ubiquinol-oxidizing enzymes (complex III and the AOX). Partitioning between the cytochrome and nonphosphorylating pathways thus depends on both the ubiquinone redox poise and the kinetic properties of each of these enzymes.

14.6.3 Nonphosphorylating bypasses represent a unique aspect of plant respiratory metabolism, but their role is not well understood

The existence of the alternative NAD(P)H dehydrogenases and the AOX suggests respiring plant mitochondria might be able to shunt electrons solely through these nonphosphorylating bypasses and completely eliminate ATP synthesis, the function most commonly associated with mitochondria. It is unlikely a plant would experience this extreme state, but the presence of these non-energy-conserving bypasses raises obvious questions about the role they play in plant metabolism.

One hypothesis postulates enhanced bypass performance under unfavorable circumstances. Because the alternative NAD(P)H dehydrogenases and the AOX are far less complex than their proton-translocating counterparts, these simpler proteins might function more effectively under stress than the standard electron transport chain. If so, diversion of electrons through these bypasses in response to stress might maintain higher respiration rates than the cytochrome pathway could support. The alternative internal NAD(P)H dehydrogenases may also play a role in maintaining respiration rates during stress by modulating matrix concentrations of NAD(P)H and consequently influencing carbon flow through the citric acid cycle (see Section 14.5.3). Oxidation of cytosolic NADH by the alternative external NADH dehydrogenase would provide the NAD^+ required to maintain glycolysis, and the AOX would continue to support aerobic respiration. Although ATP production would be restricted, the plant could avoid shifting to fermentative metabolism.

Microarray studies have shown that expression of genes encoding the AOX and internal and external alternative NAD(P)H dehydrogenases is induced under various stresses. This lends support to the hypothesis that these alternative pathway components are important for avoiding or

minimizing generation of ROS by the electron transport chain when environmental conditions inhibit plant respiration. In animal mitochondria, if the mitochondrial quinone pool becomes highly reduced, O_2^- , H_2O_2 , and hydroxyl radical (OH^\cdot) are generated by the autoxidation of ubiquinol. Interestingly, O_2^- induces synthesis of AOX in fungal cells, as does H_2O_2 in plant cells.

If stress causes an inhibition of the plant mitochondrial electron transport chain at a site downstream from the ubiquinone pool, then pyruvate, citric acid cycle intermediates, and reduced pyridine nucleotides will accumulate and activate the AOX through thioredoxin (Fig. 14.32). This activation would attenuate the inhibitory effects of the stress on respiration and thereby prevent high levels of reduction of the ubiquinone pool to minimize production of ROS. Activation of the alternative NAD(P)H dehydrogenases may also help prevent ROS production at complex I, while allowing NAD(P)H turnover for maintenance of glycolysis and citric acid cycle activity.

Studies with transgenic tobacco (*Nicotiana tabacum*) cell cultures in which AOX has been repressed or overexpressed have confirmed that AOX helps minimize ROS production. Studies with *Arabidopsis* have shown plants lacking AOX are more sensitive to high temperature and high light conditions. These studies support the notion of an antioxidant role for AOX; by maintaining the ubiquinone pool in a relatively oxidized state, less ROS is produced. This helps prevent oxidative damage of the mitochondria and affects signaling pathways involved in coordination of other stress-related genes, perhaps explaining how AOX helps prevent programmed cell death in plant cells.

By modulating cellular redox poise and ROS levels, the alternative NAD(P)H dehydrogenases and the AOX aid the homeostasis of the cell.

14.7 Interactions between mitochondria and other cellular compartments

In addition to synthesizing ATP, plant mitochondria generate biosynthetic precursors and carry out reactions that are linked to other metabolic pathways, including gluconeogenesis during oil seed germination, C_4 photosynthesis, Crassulacean acid metabolism (CAM), and photorespiration (see Sections 14.8 to 14.10). These processes are facilitated by an extensive array of membrane transport proteins.

14.7.1 Movement of metabolites into and out of plant mitochondria is regulated by a series of specific transporters

The inner membrane of the mitochondrion is selectively permeable. Gases and H_2O move rapidly across the membrane, as do a few other uncharged molecules, such as the

protonated species of small or lipophilic organic acids (e.g., acetic acid). However, since mitochondrial chemiosmotic energy conservation is supported primarily by $\Delta\bar{\mu}_{H^+}$, movement of charged molecules across the inner membrane must be controlled so as to not dissipate the $\Delta\bar{\mu}_{H^+}$.

Charged compounds enter or leave the mitochondrion via selective carriers that are regulated by $\Delta\mu_{H^+}$. The types of movements that can occur are summarized in Figure 14.35. Transport can be linked to the membrane potential ($\Delta\psi$), the pH gradient (ΔpH), or both ($\Delta\bar{\mu}_{H^+}$); this last case applies when proton cotransport in one direction creates a charge imbalance in an exchange reaction. The $\Delta\bar{\mu}_{H^+}$ can drive transport directly or can be harnessed indirectly by coupling the transport of one species to another. **Electrogenic transport** involves the net movement of charge across the membrane, whereas **electroneutral transport** results in no net charge transfer. When an ion moves unaccompanied, the transport is termed uniport and is linked directly to $\Delta\psi$. Alternatively, one ion can move with another, either in the same direction (**symport**), or in exchange for an ion of like charge (**antiport**). Symport and antiport can be linked to either the ΔpH , if the other ion is H^+ or OH^- , or to $\Delta\psi$ if the combined transport is electrogenic. For example, the exchange of $ATP^{4-}_{out}/ADP^{3-}_{in}$ results in electrogenic movement of a negative charge out of the mitochondrion and is driven directly by $\Delta\psi$. The P_i and pyruvate carriers, on the other hand, catalyze electroneutral exchange of an anion for OH^- , utilizing ΔpH . Because transporters such as the dicarboxylate carrier exchange a dicarboxylate anion for P_i , they too are dependent on maintenance of a ΔpH across the inner membrane.

Plant mitochondria interact in many ways with a variety of cellular metabolic processes and, therefore, require numerous transporters that exchange metabolites across the inner mitochondrial membrane (Fig. 14.36). Transport proteins provide numerous paths by which carbon and cofactors can be shipped to and from the mitochondria. The dicarboxylate, pyruvate, and amino acid carriers import substrates to the mitochondria, whereas di- and tricarboxylate carriers may export citric acid cycle carbon intermediates (see Section 14.7.2).

Plant mitochondria also contain specific transporters for the net uptake of NAD^+ , CoASH, and TPP, all of which are essential cofactors for operation of the citric acid cycle. These transporters were discovered because isolated plant mitochondria lose these cofactors during prolonged storage and become unable to oxidize substrates such as malate and pyruvate. The carrier proteins were identified by complementation of yeast mutants lacking the transport of specific compounds with genes for plant carriers. Adding back these cofactors restores respiratory activity. Although slower than those involved in transport of other metabolites across the mitochondrial inner membrane, these transporters can facilitate accumulation of substantial cofactor concentrations. In vivo, they are presumably involved in mitochondrial biogenesis; organelle division would dilute and eventually deplete these cofactors if they were not imported.

FIGURE 14.35 The proton motive force ($\Delta\bar{\mu}_{H^+}$) established by proton pumping of the respiratory chain can drive ion transport across the inner mitochondrial membrane. Electrogenic transport involves the net movement of charge across the membrane; transport without net charge transfer is termed electroneutral. Inner membrane carriers that move only one ion (uniporters) are linked directly to $\Delta\psi$. Two chemical species may be cotransported in the same direction by symporters, or in opposite directions by antiporters. In the mitochondrial membrane, such coupled transport may be driven by the ΔpH , if one of the ions is H^+ or OH^- ; by $\Delta\psi$, if the combined transport is electrogenic; or by a combination of ΔpH and $\Delta\psi$ ($\Delta\bar{\mu}_{H^+}$).

14.7.2 Metabolite shuttles transfer carbon and reducing equivalents between mitochondria and other cellular compartments

One of the major challenges in plant mitochondrial research is developing an integrated view of mitochondria in the context of cell metabolism. Understanding how various carriers

of the inner membrane interact to supply substrates for both mitochondrial and cytosolic processes is a crucial step toward this goal.

The α -ketoglutarate carrier is thought to operate with the glutamate/aspartate carrier in a substrate cycle known as the malate/aspartate shuttle (Fig. 14.37A). This shuttle, which can be demonstrated in isolated plant mitochondria, imports cytosolic reducing equivalents (NADH) into the mitochondrion in the form of malate. Reducing equivalents imported

FIGURE 14.36 Carriers (substrate transporters) of the inner mitochondrial membrane. All of these secondary active transporters are indirectly linked to the $\Delta\bar{\mu}_{\text{H}^+}$ across the membrane and are capable of accumulating substrates inside the mitochondrial matrix. Uptake of pyruvate and P_i in exchange for OH^- is linked to the ΔpH . The resulting P_i gradient can then be used to drive uptake of dicarboxylate anions via exchange on the dicarboxylate carrier. Dicarboxylates in turn can exchange for α -ketoglutarate or tricarboxylates; in the latter exchange, electroneutrality is maintained by cotransport of a proton with the citrate. This is also true for the exchange catalyzed by the OAA transporter. Exchanges of ADP for ATP and glutamate for aspartate are electrogenic and driven by the $\Delta\psi$ across the inner membrane. Note that glutamate exchange is coupled to cotransport of a proton to cause a charge imbalance that is thought to be important for the operation of the malate/aspartate shuttle (see Fig. 14.37). Arginine transport is important for its degradation during germination. The uncoupling protein is activated under certain circumstances and can dissipate the $\Delta\psi$ across the inner membrane.

via the malate/aspartate shuttle can supply complex I, so oxidation of imported NADH is associated with greater ATP synthesis than is oxidation of cytosolic NAD(P)H by the nonphosphorylating external dehydrogenases of the respiratory chain. The glutamate/aspartate exchange is electrogenic in nature: glutamate and one proton are imported from the cytosol, and aspartate is exported from the matrix. Transporting a negative charge out of the mitochondrion ensures that this shuttle is unidirectional in respiring mitochondria, because the $\Delta\psi$ across the inner membrane (negative inside the matrix) drives aspartate out of the mitochondrion. However, the malate/aspartate shuttle can function only when the NADH/NAD $^+$ ratio is higher in the

cytosol than the matrix. The malate/aspartate shuttle may be involved in glyoxysome–mitochondrion interactions in oil seeds (see Section 14.7.4).

Plant mitochondria also possess an OAA carrier that exchanges malate or citrate for OAA. This simpler shuttle, which has been demonstrated in isolated mitochondria, is readily reversible and can transfer reducing equivalents into or out of the mitochondrion (Fig. 14.37B). The direction of the shuttle likely depends on the concentration of the participant metabolites on either side of the mitochondrial inner membrane. In leaves, the malate/OAA shuttle is thought to participate in the photorespiratory cycle. The reducing equivalents formed by glycine oxidation in the mitochondrial

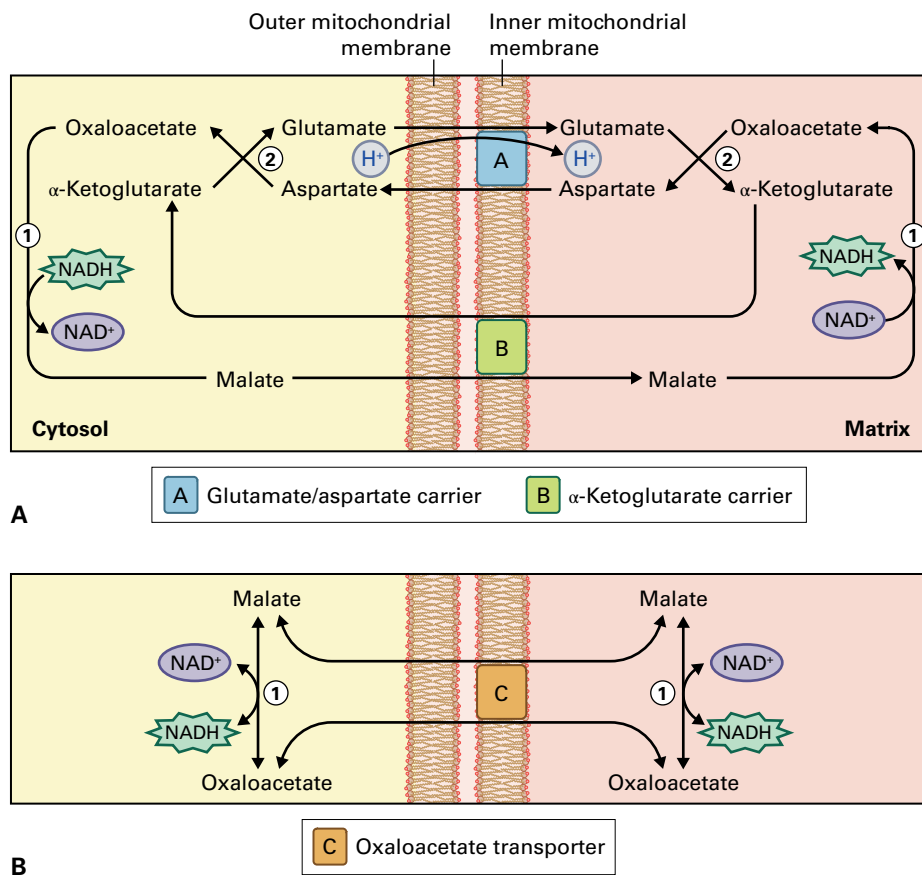

FIGURE 14.37 Examples of mitochondrial metabolite shuttles: substrate shuttles in plant mitochondria. Plants can transfer reducing equivalents from cytosolic NAD(P)H to the mitochondrial matrix by means of substrate shuttles across the inner membrane. Two such shuttles, which have been demonstrated in isolated mitochondria, are shown. (A) Malate/aspartate shuttle. Isoenzymes of malate dehydrogenase (MDH, 1) and aspartate aminotransferase (2) are found on both sides of the mitochondrial membrane. OAA reduction in the cytosol oxidizes NADH (or NADPH) and produces malate, which moves into the mitochondrion. In the mitochondrion, the reverse reaction occurs, liberating NADH that can be oxidized by the respiratory chain to drive ATP synthesis. Transamination of the OAA formed in the matrix prevents product inhibition of MDH. The aspartate and α -ketoglutarate formed are transported out of the mitochondrion in exchange for glutamate (carrier A) and malate (carrier B), respectively. Electrogenic glutamate/aspartate exchange is driven by $\Delta\bar{\mu}_{H^+}$, thereby providing directionality to the shuttle (i.e., reducing power is transferred into the mitochondrion only). (B) Malate/OAA shuttle. Here MDH isoforms on either side of the mitochondrial membrane are linked by malate/OAA exchange on the OAA carrier (carrier C). This shuttle is readily reversible in isolated mitochondria when sufficient MDH is added to the reaction medium.

matrix are exported as malate to the peroxisome, where malate oxidation provides NADH to reduce hydroxypyruvate (see Section 14.9.1).

14.7.3 The citric acid cycle provides carbon skeletons for ammonia assimilation and amino acid synthesis

An important ancillary function of mitochondria in all tissues is the production and export of α -ketoglutarate for ammonia assimilation or transamination reactions in the cytosol and plastids. Ammonia assimilation requires α -ketoglutarate (see Section 14.9.2 and Chapters 7 and 16); the only net source of this α -keto acid is the citric acid cycle. In addition, mitochondria in some roots may export citric

acid cycle intermediates such as malate and citrate, which are secreted into the rhizosphere to solubilize cations and facilitate plant uptake of Fe³⁺ and other mineral nutrients (see Chapter 23).

Export of citric acid cycle intermediates requires the mitochondrial import of substrates that can generate both acetyl-CoA and OAA. If pyruvate were provided as the only carbon source, export of citric acid cycle intermediates would prevent regeneration of OAA and bring the citric acid cycle to a halt. This need for anaplerotic reactions that replenish pools of citric acid cycle intermediates may explain why plant mitochondria possess relatively large amounts of NAD⁺-linked malic enzyme (see Fig. 14.8).

The α -ketoglutarate, OAA, and citrate carriers of the inner mitochondrial membrane may function in the export of α -ketoglutarate and citrate. Various schemes can be drawn for this carbon export, but it has not yet been determined which

pathway operates *in vivo*. For example, acting in concert with the pyruvate carrier, the OAA carrier may promote the uptake of OAA and pyruvate into the mitochondrial matrix, where they can be used to synthesize citrate for subsequent export (Fig. 14.38A). There is also a cytosolic isoform of isocitrate dehydrogenase, so the exported citrate can be used to generate α -ketoglutarate for ammonia assimilation or transamination. Alternatively, malate/ α -ketoglutarate exchange on the α -ketoglutarate carrier, or malate/citrate exchange on the tricarboxylate carrier, could be involved in a more complex scheme, in which NADH is transferred into the mitochondrion and more energy is generated from matrix NADH via the respiratory chain (Fig. 14.38B). When provided with the necessary extra-mitochondrial enzymes, isolated plant mitochondria are able to catalyze all of the exchanges required for both schemes.

14.7.4 Some plant tissues can convert lipids to sugars through gluconeogenesis

Most plant tissues store and respire carbohydrates. An important exception to this occurs in oil seeds, such as castor bean (*Ricinus communis*) and soybean (*Glycine max*), which store and respire lipids. Castor bean endosperm and soybean cotyledons contain substantial lipid reserves stored as triglycerides in specialized organelles called oil bodies (see Chapters 1 and 8). Utilization of these triglycerides involves their conversion to sucrose, which is then translocated to other organs in the growing seedling.

The interconversion process involves four cellular compartments: oil bodies, **peroxisomes** specialized in glyoxylate cycle and fatty acid β -oxidation (sometimes referred to as glyoxysomes) the cytosol, and mitochondria (Fig. 8.65). Triglycerides are hydrolyzed to glycerol and free fatty acids via lipases in the oil bodies (see Fig. 8.61). The glycerol is converted to triose phosphates used to synthesize sucrose in the cytosol (see Chapter 13). Fatty acids exported from the oil bodies undergo β -oxidation to NADH and acetyl-CoA (see Fig. 8.65) in the peroxisome. There, the acetyl-CoA is converted to succinate and malate by the glyoxylate cycle, in which two enzymes, isocitrate lyase and malate synthase, bypass the oxidative phase of the citric acid cycle. By preventing the complete oxidation of organic acids to CO_2 , the glyoxylate cycle diverts carbon skeletons toward sugar biosynthesis. Some of the malate exported by the peroxisomes is oxidized, decarboxylated, converted to fructose-1,6-bisphosphate by reversing the reactions of glycolysis, and ultimately used to make sucrose in the cytosol (Fig. 8.65).

Mitochondria participate in gluconeogenesis because peroxisomes lack the enzymes to process succinate, which is transported to the mitochondria and converted to OAA via the last two enzymes of the citric acid cycle. Furthermore, peroxisomes lack the mitochondrial electron transport chain, so NADH formed during fatty acid oxidation is transported to the mitochondria via the malate/aspartate shuttle. Thus, aspartate aminotransferase in the mitochondrion interconverts OAA and glutamate to aspartate and α -ketoglutarate, which are transported to the peroxisomes, where the reverse reactions occur to form OAA. Conversion of this OAA to

FIGURE 14.38 Export of organic acids from the mitochondrion for support of NH_3 assimilation in the plastid. Two possible substrate shuttles in the mitochondrion have been proposed: scheme A is the simpler of the two, but scheme B has the potential to generate more ATP because more NADH is generated in the matrix. The NADH/NAD^+ and $\text{NADPH}/\text{NADP}^+$ ratios in the cytosol may determine which scheme operates by regulating the activity of cytosolic MDH and NADP^+ -isocitrate dehydrogenase, respectively. (A) OAA and pyruvate enter the mitochondrion and are used to generate citrate, which is exported from the mitochondrion (in exchange for OAA) and is converted to α -ketoglutarate in the cytosol by NADP^+ -linked isocitrate dehydrogenase. (B) Two molecules of malate enter the mitochondrion and are oxidized via MDH and NAD^+ -linked malic enzyme to produce OAA and pyruvate in the matrix, which are subsequently converted to either citrate or α -ketoglutarate. The latter compounds exchange for malate via either the α -ketoglutarate or tricarboxylate carriers.

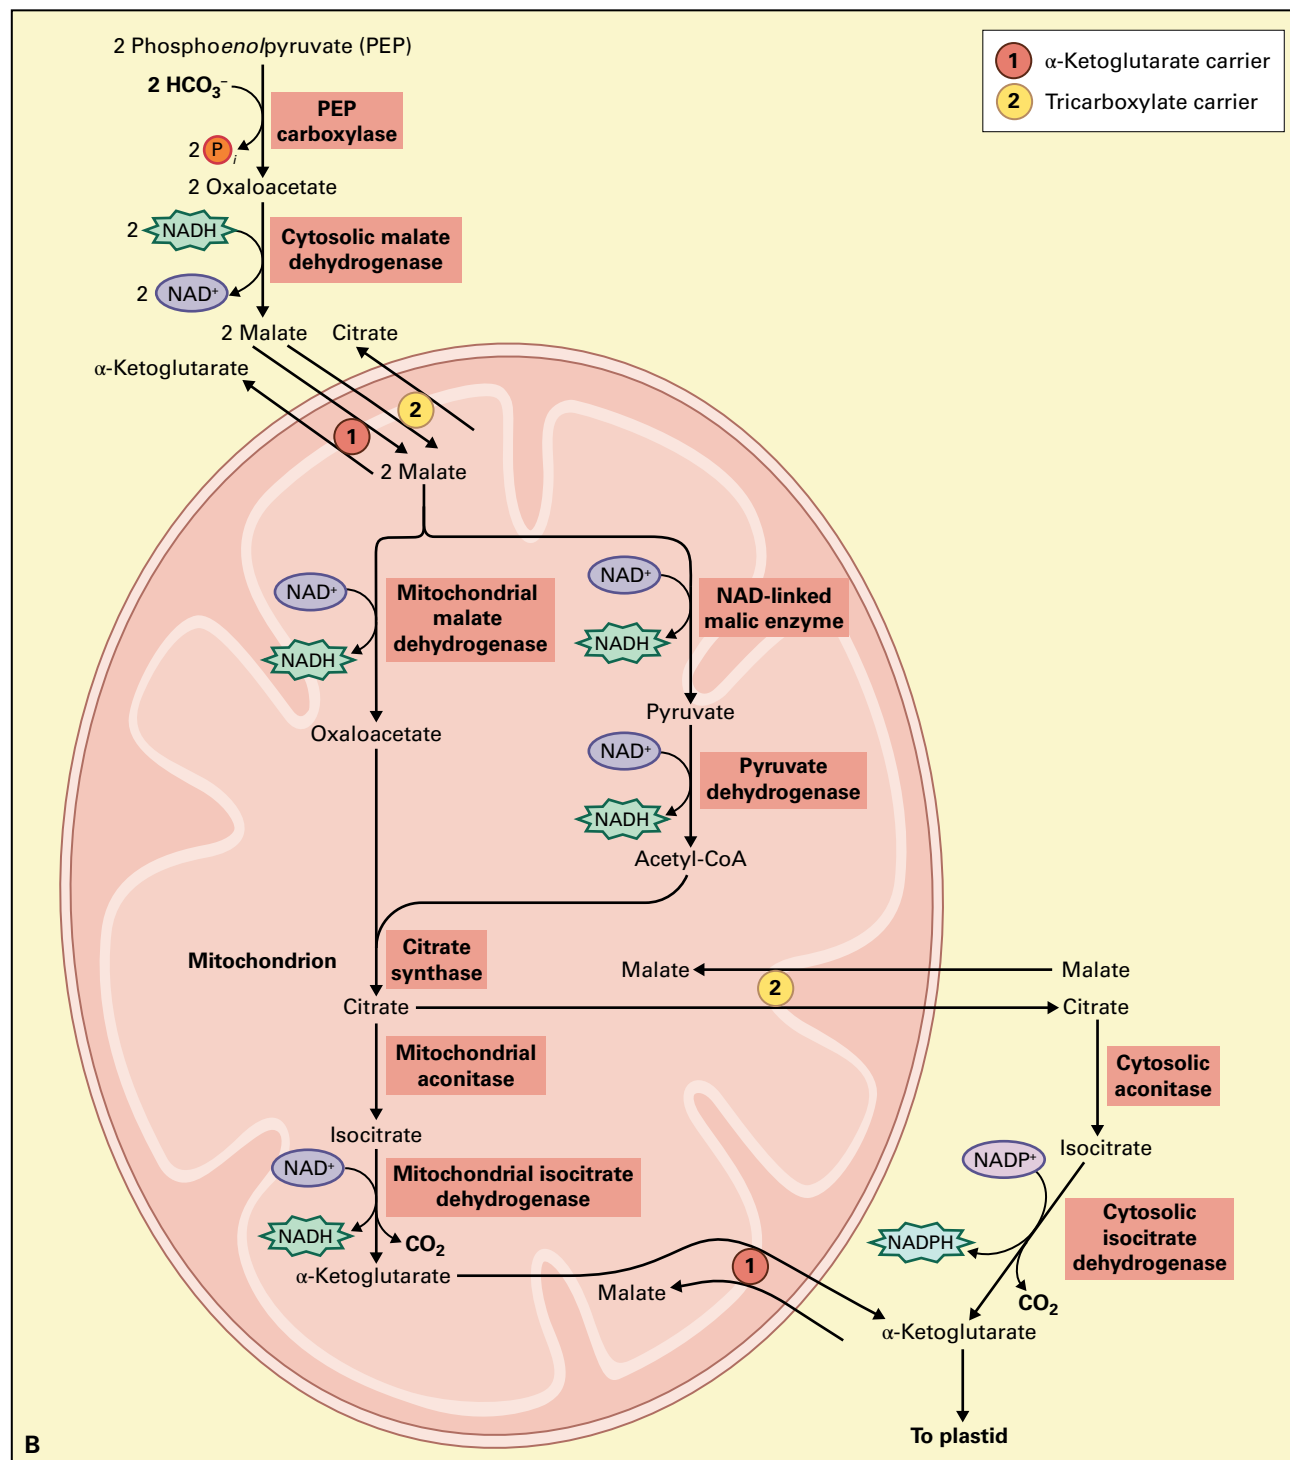

FIGURE 14.38 (Continued)

malate oxidizes the excess NADH in the peroxisome. The malate is recycled to the mitochondria to complete the shuttle, and the reducing equivalents released by mitochondrial malate oxidation drive ATP synthesis via the respiratory chain.

Operation of a malate/aspartate shuttle, rather than the simpler malate/OAA shuttle, has been proposed because isolated castor bean endosperm mitochondria do not transport OAA readily and the equilibrium of the malate dehydrogenase

reaction does not favor OAA formation. Amination of OAA, therefore, helps drive oxidation of malate in the mitochondria. During respiration, the driving force for malate oxidation would be provided by the demand by the citric acid cycle for OAA, but during gluconeogenesis, carbon must be returned to the peroxisome to provide substrate for further sugar production. The ATP needed for gluconeogenesis is provided by mitochondrial respiration (see Fig. 8.65).

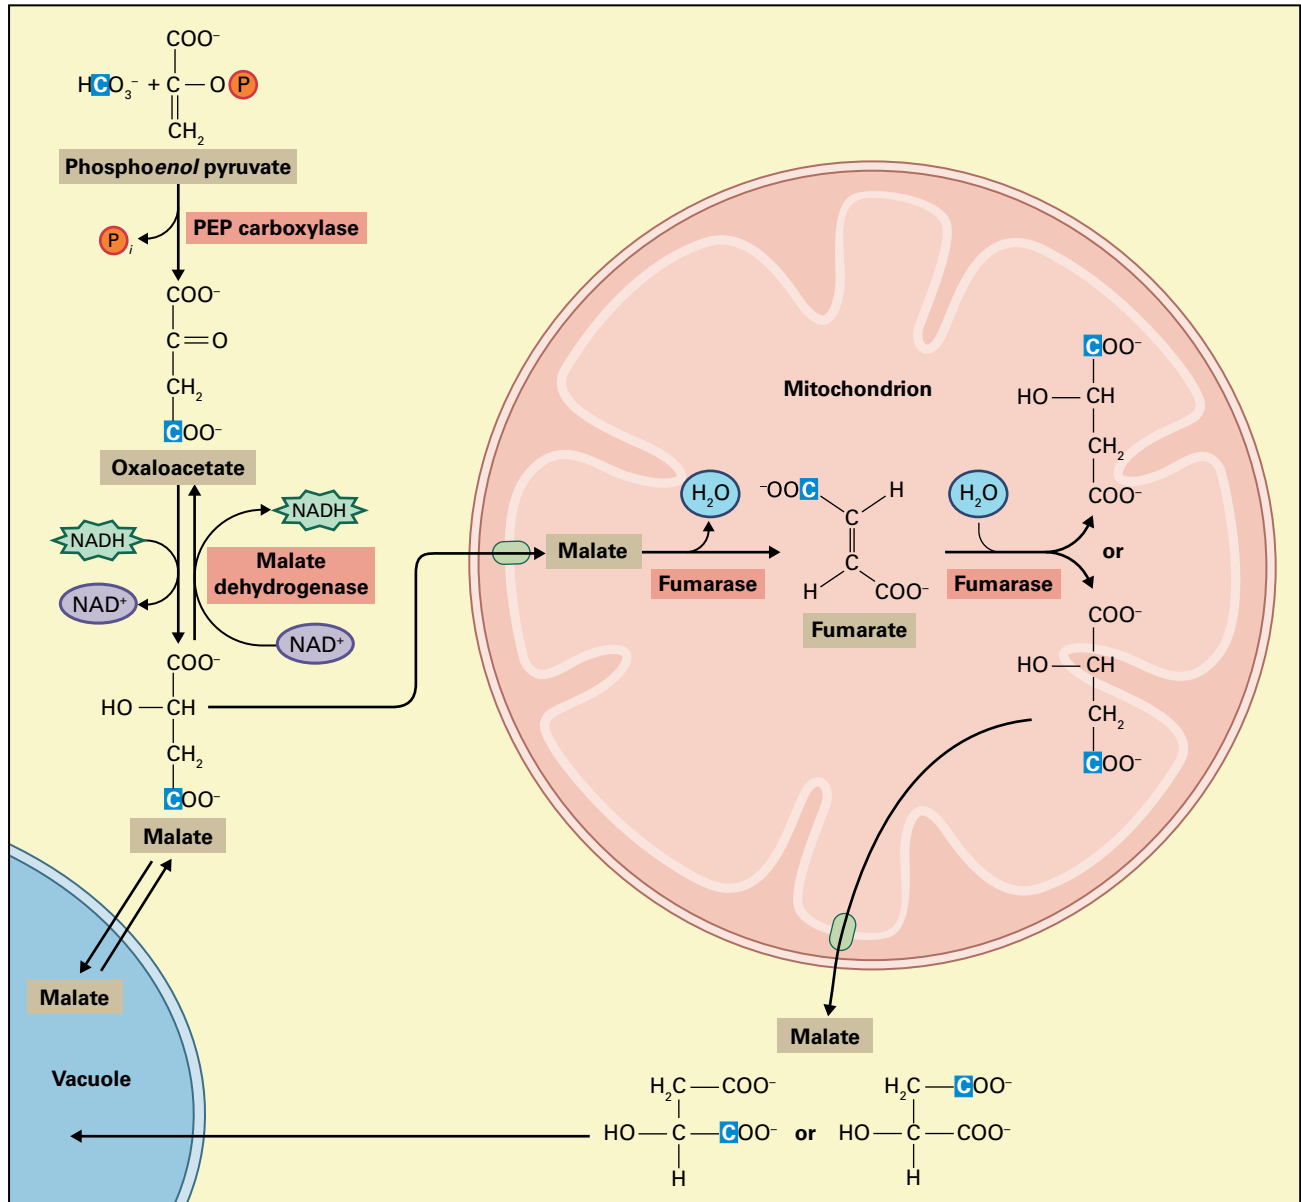

FIGURE 14.39 Randomization of label in PEP carboxykinase-type CAM plants suggests a considerable amount of flux through the mitochondria takes place at night after CO_2 uptake. The reaction of ^{13}C -labeled HCO_3^- with PEP catalyzed by PEP carboxylase results in malate labeled exclusively at the C-4 position, but the vacuole contains large amounts of malate labeled in the C-1 position, suggesting the malate moves through the mitochondria. The carbon atoms at the C-1 and C-4 positions of malate are scrambled by the action of the citric acid cycle enzyme fumarase, which converts malate to the symmetrical molecule fumarate. When the resulting fumarate is converted back to malate, fumarase is equally likely to hydroxylate C-2 or C-3; therefore, the labeled carbon (previously C-4) can be at either the C-1 or C-4 position in the resynthesized malate molecule.

14.7.5 Some C_4 and CAM plants use mitochondrial reactions to concentrate carbon dioxide for photosynthesis

Mitochondrial reactions are incorporated in the photosynthetic pathways of some C_4 plants and many species carrying out CAM. These reactions are unique to plant mitochondria and reflect the extent to which the central organelle of heterotrophic metabolism has evolved to support autotrophic carbon fixation.

The C_3 photosynthesis observed in most plants yields a three-carbon compound as its first stable product (see Section 14.8). C_4 photosynthesis (see Chapter 12) takes advantage of an aqueous equilibrium that favors bicarbonate ion (HCO_3^-) over CO_2 gas. In mesophyll cells, PEP carboxylase incorporates HCO_3^- into a four-carbon organic acid, which is then transported to bundle sheath cells, the site of CO_2 fixation by Rubisco. The C_4 acid is decarboxylated in the bundle sheath cells, thereby concentrating CO_2 and minimizing O_2 fixation by Rubisco.

The three different C_4 photosynthesis pathways—NADP⁺-malic enzyme, NAD⁺-malic enzyme, and PEP carboxykinase—

are each named for the bundle sheath enzyme that releases CO_2 (see Fig. 12.46). Whereas the NADP^+ -malic enzyme pathway does not require mitochondrial activity, the NAD^+ -malic enzyme and PEP carboxykinase C_4 pathways both utilize mitochondrial NAD^+ -malic enzyme to decarboxylate malate and, consequently, the bundle sheath mitochondria process an enormous amount of carbon to supply the chloroplast. The photosynthetic rates attained by NAD^+ -malic enzyme plants suggest carbon flux through the bundle sheath mitochondria is 10- to 20-fold greater than standard respiratory carbon flux, and several fold greater than the flux of glycine through mitochondria during photorespiration in C_3 plants.

In PEP carboxykinase plants, the situation is more complex. Although mitochondrial NAD^+ -malic enzyme is active in this pathway, cytosolic PEP carboxykinase is thought to provide most of the CO_2 fixed by Rubisco (see Fig. 12.46C). Why are both enzymes required? One possible role for NAD^+ -malic enzyme might involve oxidative phosphorylation. PEP carboxykinase converts OAA to PEP and CO_2 in a reaction that consumes one ATP. If the NADH generated by NAD^+ -malic enzyme is utilized for ATP synthesis, the predicted stoichiometry would be roughly two malate molecules oxidized per five molecules of PEP produced.

CAM, a variation on the C_4 theme, allows plants to conserve H_2O (see Chapter 12). In CAM plants, HCO_3^- uptake by PEP carboxylase takes place at night, while stomata are open. The resulting C_4 acid, typically malate, is stored in the vacuole. Malate decarboxylation and CO_2 fixation by Rubisco take place in the same cell during the next day, with the stomata closed to prevent H_2O vapor from escaping (see Fig. 12.45). As with C_4 plants, subtypes of CAM photosynthesis are named for the decarboxylating enzyme. Malic enzyme CAM plants use both cytosolic NADP^+ -malic and mitochondrial NAD^+ -malic enzyme to decarboxylate malate. By contrast, PEP carboxykinase CAM plants contain low concentrations of malic enzyme. This does not preclude mitochondrial participation in photosynthesis by PEP carboxykinase CAM plants, because respiration may still provide ATP for the PEP carboxykinase reaction in these plants. Furthermore, PEP carboxykinase CAM plants transfer a considerable amount of label from the C-4 to the C-1 position of malate after uptake of $^{13}\text{CO}_2$. This suggests a large flux of malate into and out of the mitochondria probably occurs during the dark period, because this redistribution of label requires interconversion of malate and the symmetrical compound fumarate, a reaction catalyzed by the citric acid cycle enzyme fumarase (Fig. 14.39).

14.7.6 In photosynthetic tissues, operation of the citric acid cycle is inhibited by light

Although plant mitochondria clearly participate in light-based metabolism (e.g., photorespiration, C_4 photosynthesis, CAM), the extent to which illuminated photosynthetic tissues engage in respiration remains unclear. It is extremely difficult to measure respiration in the light, because the large amount of O_2 release and CO_2 uptake by chloroplasts mask the opposite processes in mitochondria. Photorespiration further complicates

these measurements. Rates of aerobic respiration in darkened leaves are generally only 5–10% of maximum photosynthetic rates; however, all nonphotosynthetic tissues respire, and the entire plant respire during the night. Because of this, some plants may respire as much as 50–70% of carbon fixed daily by photosynthesis, depending on growth conditions.

It has long been thought that photosynthesis, particularly photophosphorylation, must poise the cytosolic ATP/ADP ratio at such high levels that respiratory control would restrict respiration severely. Indirect measurements of CO_2 output from intact leaves, combined with assessment of the external CO_2 concentration at which photosynthetic CO_2 uptake equals respiratory CO_2 release so that net photosynthetic CO_2 exchange is zero (the **CO_2 compensation point**) suggest nonphotorespiratory CO_2 release is inhibited in the light. This may indicate light slows the rate of carbon flux through the citric acid cycle by approximately 50%. The inhibitory mechanism is not known but may involve downregulation of pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and malic enzyme activities. Ammonia produced during photorespiration could stimulate PDH kinase, leading to inactivation of pyruvate dehydrogenase (see Fig. 14.10). Thioredoxin interacts with several enzymes of the citric acid cycle, but its effect on activity is yet to be determined.

On the other hand, the participation of glycolytic and citric acid cycle intermediates in many important biosynthetic pathways argues that some aerobic respiration must take place in illuminated green cells. Several observations indicate actively photosynthesizing tissues do respire. The nonphosphorylating pathways of mitochondrial electron transfer provide a mechanism by which plant mitochondria, at least in theory, can oxidize NADH without having to synthesize ATP and without being subject to respiratory control when cellular ADP concentrations are low (see Section 14.6.3). Furthermore, rapid fractionation of organelles from wheat leaf protoplasts has demonstrated cytosolic concentrations of ADP are no different in the light than in the dark, indicating photosynthesis does not appreciably deplete the pool of ADP available for oxidative phosphorylation. Mitochondrial ATP production appears necessary for maintaining high photosynthetic rates, probably because sucrose synthesis requires high amounts of cytosolic ATP.

14.8 Biochemical basis of photorespiration

14.8.1 Photorespiration is associated with light-dependent O_2 uptake and CO_2 evolution in green plant tissues

In the 1920s, the biochemist Otto Warburg (Nobel Laureate, 1931) discovered that increasing the external O_2 concentration inhibited photosynthesis in the green alga *Chlorella*. In most C_3 plants, photosynthetic rates decline as much as 50% when the O_2 concentration is doubled from the ambient value of 21%. Conversely, photosynthesis is stimulated as much as twofold by decreasing the O_2 concentration to <2%. The connection

FIGURE 14.40 Effect of CO_2 concentration on the CO_2 fixation rate. As the ambient concentration of CO_2 is increased in the presence of saturating light, net CO_2 uptake during photosynthesis increases in a roughly linear fashion, saturating at a relatively low CO_2 concentration ($150 \mu\text{L L}^{-1}$) in C_4 plants and only beginning to show signs of saturation at ambient CO_2 levels ($360\text{--}375 \mu\text{L L}^{-1}$) in C_3 plants. The concentration at which net change in CO_2 is 0 defines the CO_2 compensation point and reflects the CO_2 concentration at which the rate of gross photosynthetic CO_2 uptake exactly equals the respiration rate. The total respiration rate comprises both mitochondrial-linked (dark) respiration and photorespiration. That the CO_2 compensation point for C_3 plants ($20\text{--}50 \mu\text{L L}^{-1}$) is greater than for C_4 plants ($0\text{--}5 \mu\text{L L}^{-1}$) is associated with the presence of photorespiration in C_3 plants and its virtual absence in C_4 plants.

between O_2 concentration and photosynthesis was strengthened by the proportional relationship between the ambient O_2 concentration and the CO_2 compensation point (Fig. 14.40; see also Section 14.7.6). The CO_2 compensation point increases with increasing O_2 concentration, suggesting competition between O_2 and CO_2 during photosynthesis. In addition, actively photosynthesizing tissues release a burst of CO_2 immediately after illumination ceases. The amount of CO_2 evolved during this **post-illumination burst** is directly proportional to the external O_2 concentration. These observations ultimately revealed a novel pathway. Whereas almost all plants are capable of photosynthesis, in which light stimulates CO_2 uptake and O_2 evolution, most also perform **photorespiration**, a light-stimulated process that consumes O_2 and evolves CO_2 .

High rates of photorespiration are restricted to C_3 plants (see Chapter 12). The majority of plants fall into this category, although certain plants (i.e., C_4 and CAM plants) have evolved relatively sophisticated biochemical mechanisms that limit photorespiration by concentrating CO_2 at the site of carbon fixation. Many oxygenic photosynthetic organisms living in aquatic environments, including algae, cyanobacteria, and some plants, have also developed mechanisms for concentrating CO_2 or HCO_3^- in cells and transporting it to the chloroplast, thus minimizing the rate of photorespiration. Both photorespiration and its consequences for plants have been linked inextricably to changes in the ratio of CO_2 to O_2 in the earth's atmosphere that have taken place since life appeared. Since the beginning of the 20th century, large-scale anthropogenic CO_2 emissions have accompanied an increase in global

atmospheric CO_2 concentrations that might impact and inhibit photorespiration, thereby altering existing competitive relationships among many plant species.

14.8.2 Oxygenase activity of Rubisco catalyzes the initial step of photorespiration

The origin of photorespiration is found in the kinetic properties of Rubisco, the enzyme that catalyzes the carboxylation of ribulose 1,5-bisphosphate (RuBP) to form two molecules of 3-phosphoglycerate (3-PGA), the first stable intermediate in the C_3 reductive photosynthetic carbon cycle (see Chapter 12). However, Rubisco is also capable of catalyzing an oxygenase reaction, in which a molecule of O_2 reacts with RuBP to produce one molecule of 3-PGA plus one molecule of 2-phosphoglycolate.

The Rubisco reaction mechanism (Fig. 12.38) involves the initial binding of RuBP to the enzyme, followed by formation of a 2,3-enediolate intermediate. Either CO_2 or O_2 can react directly with this enediolate species, producing, respectively, an unstable C_6 or C_5 intermediate that breaks down to the final products rapidly and irreversibly. As a result of this mechanism, CO_2 and O_2 act as competitive substrates for Rubisco, with O_2 inhibiting RuBP carboxylation and CO_2 inhibiting RuBP oxygenation. The ratio of carboxylase to oxygenase activity is a function of the relative amounts of each gas present.

14.8.3 The relative carboxylase and oxygenase activities of Rubisco depend on kinetic properties of the enzyme

The ratio of RuBP carboxylase to RuBP oxygenase activity (v_c/v_o) is an important determinant of photosynthetic efficiency and can be expressed as a function of the kinetic parameters of the two competing reactions:

Equation 14.3: Ratio of carboxylase activity to oxygenase activity

$$v_c/v_o = \left(\frac{[V_c/K_c]}{[V_o/K_o]} \right) \cdot \frac{[\text{CO}_2]}{[\text{O}_2]}$$

where V_c and V_o are the maximal velocities (V_m), and K_c and K_o are the Michaelis–Menten constants (K_m), for the carboxylase and oxygenase reactions, respectively. This formula assumes CO_2 and O_2 are each present at a concentration lower than its apparent K_m . The ratio V_m/K_m defines the pseudo second-order rate constant for each reaction, so the set of kinetic constants $[V_c/K_c]/[V_o/K_o]$ constitutes a **specificity factor** that represents the ratio of the carboxylation and oxygenation rates when the two gaseous substrates are present in equal amounts. Among land plants, Rubisco demonstrates an average specificity factor of 100, with values ranging between 80 and 130. In today's atmosphere, the air-equilibrated concentrations of the two substrates are approximately $8 \mu\text{M CO}_2$

(0.038%) and $250 \mu\text{M O}_2$ (21%) at 25°C . Therefore, a specificity factor of 100 gives a v_c/v_o ratio of 3.2.

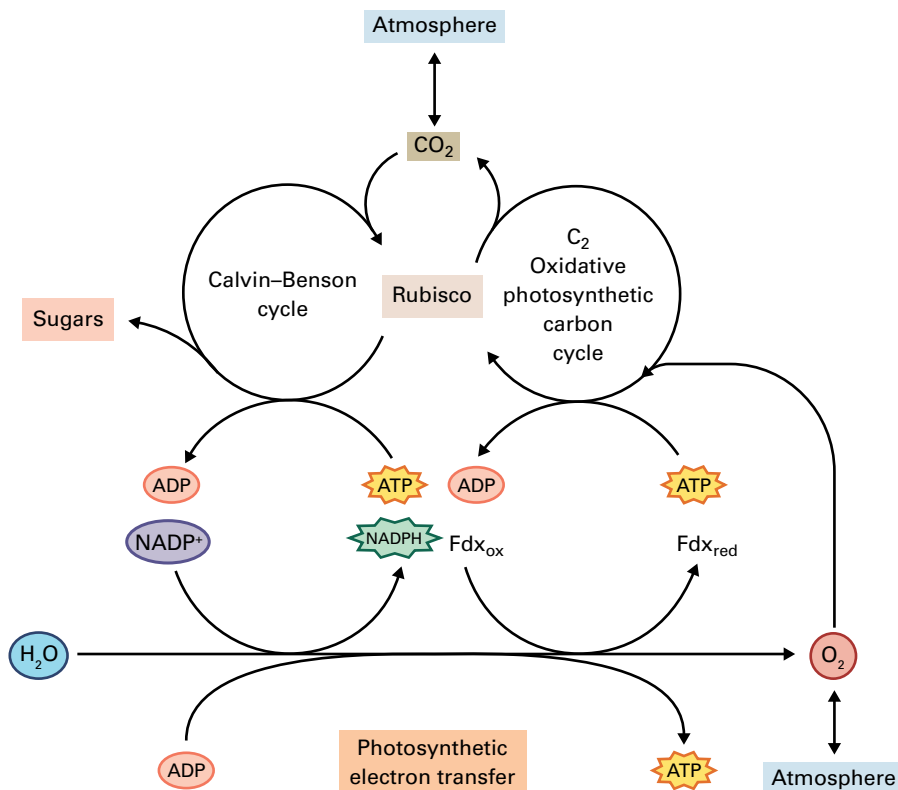

14.9 The photorespiratory pathway

Given a specificity factor of 100 for Rubisco, the ratio of carboxylase to oxygenase activity is approximately 3 to 1 under present atmospheric conditions. Therefore, an appreciable amount of RuBP is converted to 2-phosphoglycolate, a compound that cannot be utilized by the C_3 reductive photosynthetic carbon cycle (Calvin–Benson cycle). A second cycle, known as the C_2 **oxidative photosynthetic carbon cycle** or photorespiratory carbon oxidation cycle, salvages this carbon so it is not lost to photosynthetic metabolism. During the C_2 cycle, two molecules of phosphoglycolate are converted to one CO_2 and one molecule of 3-PGA, which can return to the C_3 cycle. The C_3 and C_2 cycles operate together in an integrated fashion (Fig. 14.41).

14.9.1 Photorespiratory reactions occur in three organelles: chloroplast, peroxisome, and mitochondrion

The C_2 cycle (Fig. 14.42) is initiated in the chloroplast with the formation of 2-phosphoglycolate, which is subsequently converted to glycolate and P_i by the action of phosphoglycolate

FIGURE 14.41 Diagram of the relationship between the reductive photosynthetic (C_3 or Calvin–Benson cycle) and the oxidative photosynthetic (C_2) carbon cycles. Rubisco initiates both the Calvin–Benson cycle and photorespiration (the C_2 cycle). In both cases, photosynthetic electron transport provides energy-rich substrates (ATP and NADPH for photosynthesis, ATP and reduced ferredoxin ($\text{Fd}_{x_{\text{red}}}$) for photorespiration and reassimilation of the resulting NH_3). One of the substrates of the C_3 cycle, CO_2 , is a product of the C_2 cycle; in turn, the substrate of the C_2 cycle, O_2 , is a product of C_3 photosynthesis. The same atmospheric pools provide gaseous substrates for and receive gaseous products from both processes.

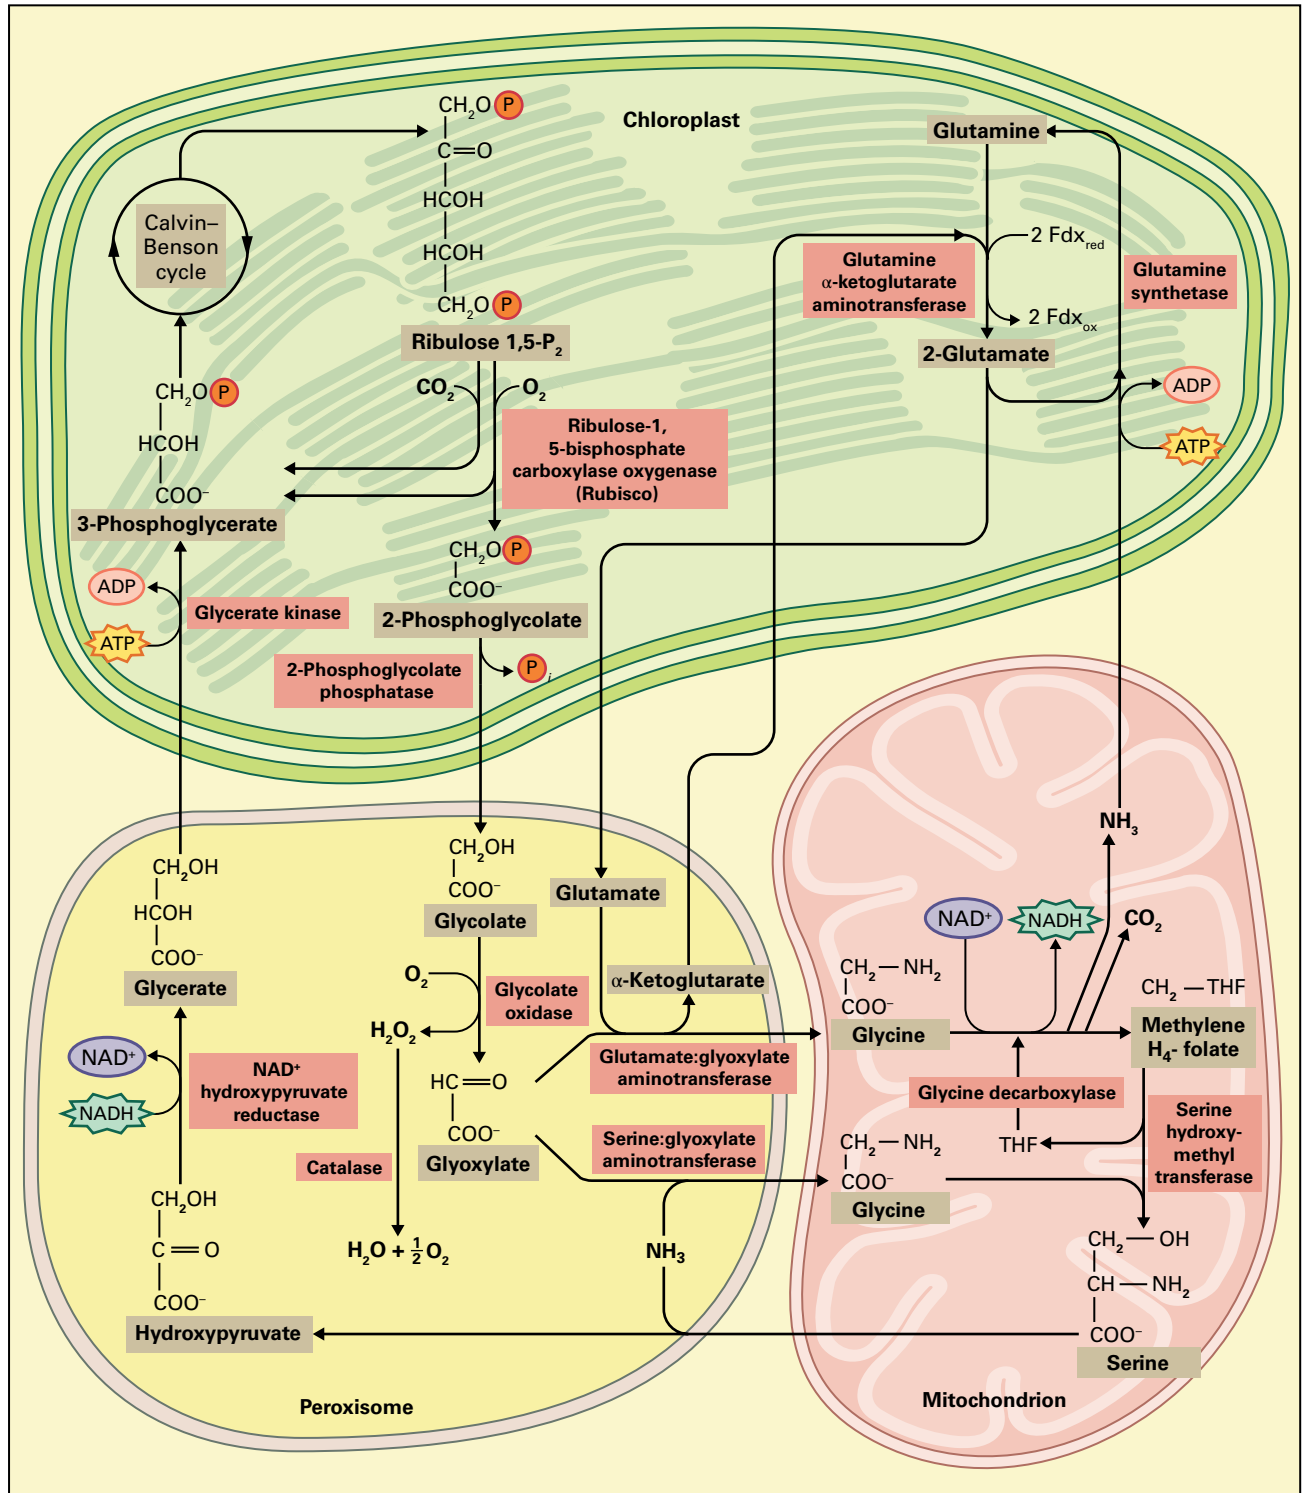

FIGURE 14.42 Operation of the oxidative photosynthetic carbon (C_2) pathway involves cooperative interaction among three separate subcellular organelles: chloroplasts, peroxisomes, and mitochondria. The pathway is initiated in the chloroplast when Rubisco catalyzes the oxygenation of ribulose 1,5-bisphosphate to produce one molecule of 3-phosphoglycerate (3-PGA) and one molecule of 2-phosphoglycolate. The reactions of the C_2 pathway bring about the metabolic interconversion of two molecules of 2-phosphoglycolate to salvage one molecule of 3-PGA, which can be used in the operation of the C_3 cycle. Additionally, conversion of two 2-phosphoglycolate to one molecule of 3-PGA requires uptake of a third molecule of O_2 and the release of one molecule of NH_3 . Reassimilation of the NH_3 requires the net input of two reducing equivalents (e.g., one molecule of NAD(P)H or two molecules of Fdx_{red}) plus one molecule of ATP . The final step in the formation of 3-phosphoglycerate also requires a molecule of ATP .

phosphatase. The glycolate exits the chloroplast through a glycolate transporter on the inner membrane of the chloroplast envelope and then enters a peroxisome, possibly by diffusion. In the peroxisome, glycolate reacts with O_2 to produce glyoxylate and H_2O_2 . This reaction is catalyzed by a peroxisomal flavin mononucleotide (FMN)-containing enzyme, glycolate oxidase. Two molecules of glyoxylate are aminated to form glycine in a peroxisomal reaction catalyzed by serine:glyoxylate aminotransferase and glutamate:glyoxylate aminotransferase. Both enzymes must function for the continued operation of the C_2 cycle (see Section 14.10.2). The H_2O_2 is removed by abundant catalase present in the peroxisome; two molecules of H_2O and one of O_2 are formed for every two molecules of phosphoglycolate that enter the C_2 cycle. As one O_2 enters the cycle, there is no net change in O_2 at this stage.

The glycine produced in the peroxisome then moves into the mitochondrion. Glycine decarboxylase, an abundant, complex enzyme with a reaction mechanism reminiscent of pyruvate dehydrogenase (see Fig. 14.9) and α -ketoglutarate dehydrogenase, catalyzes the oxidative decarboxylation of glycine to produce CO_2 , ammonia, NADH, and methylene tetrahydrofolate (Fig. 14.43). Serine hydroxymethyltransferase joins the methylene tetrahydrofolate to a second molecule of glycine, producing the C_3 amino acid serine in a reaction that requires pyridoxal phosphate as a cofactor. These enzymes are virtually absent from mitochondria of heterotrophic plant tissues. Leaves maintained in the dark demonstrate low activities of these two enzymes, but expression of the enzymes is stimulated on exposure to light to process the large flux of glycine that accompanies the onset of photorespiration.

For every two molecules of glycine that enter the mitochondrion, one molecule each of serine, CO_2 , and ammonia are produced, and one NAD^+ is reduced to NADH. This means one CO_2 is produced for every two molecules of O_2 taken up by the action of RuBP oxygenase.

The serine produced in the mitochondrion is transported back into the peroxisome, where it is deaminated by serine:glyoxylate aminotransferase to form hydroxypyruvate. Another peroxisomal enzyme, hydroxypyruvate reductase, catalyzes the reduction of hydroxypyruvate to glycerate, using NADH as an electron donor. The glycerate exits the peroxisome and is imported into the chloroplast by the same transporter that exports glycolate. Once inside the chloroplast stroma, glycerate is phosphorylated by ATP, yielding 3-PGA and ADP. This reaction, catalyzed by the enzyme glycerate kinase, completes the conversion of two molecules of phosphoglycolate to one of 3-PGA, which can now enter the C_3 cycle.

The phenotypes associated with mutations in genes that encode the C_2 cycle enzymes support the cycle's proposed function in recycling 2-phosphoglycolate produced by the oxygenase reaction. Such mutants die under normal atmospheric conditions that promote photorespiration (21% O_2 , 0.038% CO_2) but grow normally when placed in a high CO_2

atmosphere (>0.2%), where the oxygenase activity of Rubisco is minimal. An *Arabidopsis* mutant lacking phosphoglycolate phosphatase was among the first plants reported to demonstrate this phenotype, but additional mutations have now been found in peroxisomal catalase, serine:glyoxylate aminotransferase, glycine decarboxylase, serine hydroxymethyltransferase, and chloroplast-localized isoenzymes of glutamine synthetase and ferredoxin-dependent glutamine: α -ketoglutarate aminotransferase (see Section 14.9.2).

14.9.2 Production of ammonia during photorespiration requires an ancillary cycle for its efficient reassimilation

During operation of the C_2 cycle, glycine decarboxylation releases ammonia inside the mitochondrion. To avoid toxic ammonia accumulation while preventing N loss through volatilization, photorespiring plant cells must reassimilate this ammonia efficiently. Reassimilation takes place in the chloroplast through the sequential action of glutamine synthetase (GS) and glutamine:2-oxoglutarate aminotransferase (GOGAT; see Chapters 7 and 16).

Reaction 14.5: Net reaction of GS/GOGAT enzyme couple

The reducing equivalents for the GOGAT reaction are provided by the reduced ferredoxin (Fdx_{red}) formed during photosynthetic electron transfer, whereas the ATP consumed by the GS reaction is produced by photophosphorylation (see Chapter 12).

The need to reassimilate the ammonia produced during the operation of the C_2 cycle helps explain why two different aminotransferases are required in the peroxisome for the conversion of glyoxylate to glycine (see Fig. 14.42). For every two glyoxylates that pass through the C_2 cycle, only one serine is produced in the mitochondrion. The conversion of this serine to 3-PGA requires that serine:glyoxylate aminotransferase catalyze the deamination of the serine to produce hydroxypyruvate. This reaction aminates one of the two glyoxylates and generates glycine. Amination of the second glyoxylate is associated with reassimilation of photorespiratory ammonia. The molecule of glutamate formed during ammonia assimilation must be deaminated to regenerate the GOGAT substrate α -ketoglutarate. If glutamate is allowed to accumulate, ammonia assimilation will be inhibited by excess product and insufficient substrate. Glutamate:glyoxylate aminotransferase provides a mechanism for converting glutamate back to α -ketoglutarate. The photorespiratory N cycle and the two peroxisomal glyoxylate aminotransferases ensure that movement of N into and out of the C_2 cycle remains in balance.

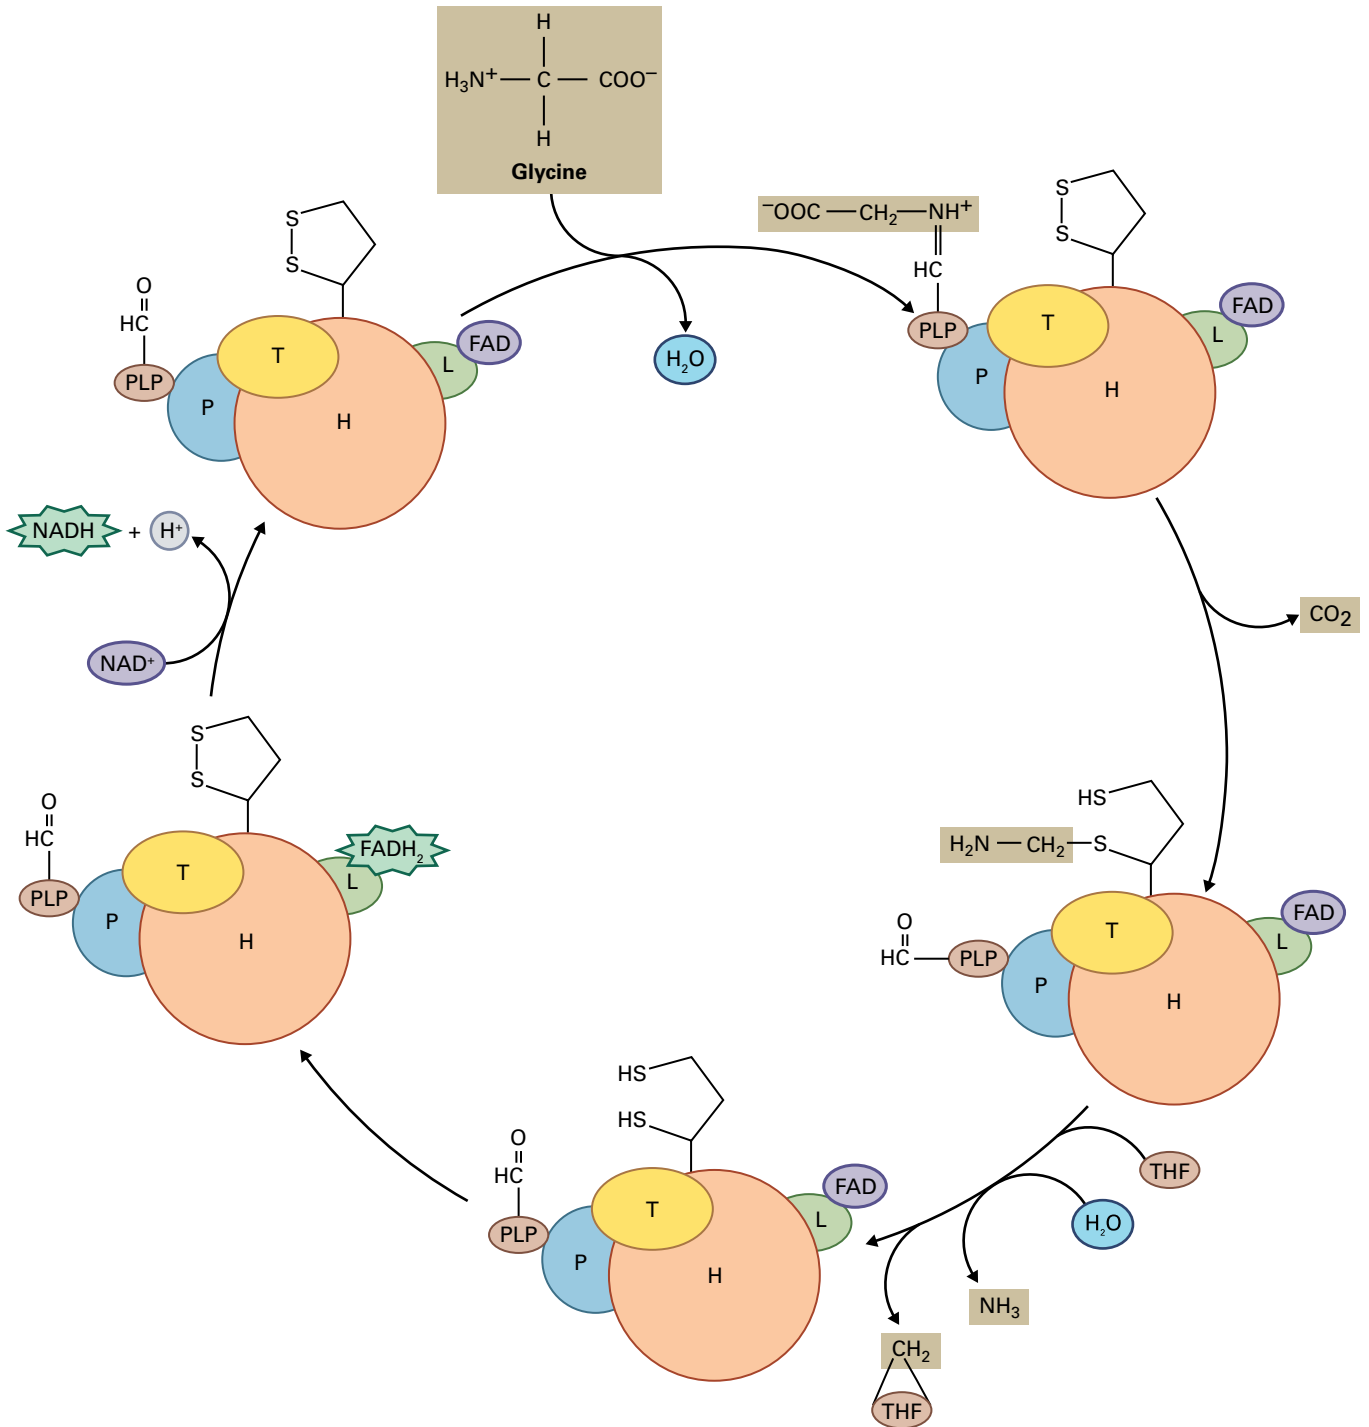

FIGURE 14.43 Reaction mechanism of the glycine decarboxylase complex. The complex consists of four enzymes, including a pyridoxal phosphate (PLP)-containing protein (P-protein), a lipoamide-containing protein (H-protein), a protein that interacts with tetrahydrofolate (T-protein), and an FAD-containing lipoamide dehydrogenase (L-protein). The reaction sequence is initiated by formation of a Schiff's base between glycine and the PLP on the P-protein. The P-protein catalyzes an oxidative decarboxylation of the glycine and transfers the reducing equivalents and the remaining methylamine to the lipoamide moiety on the H-protein. While not entirely the same, the remaining mechanistic features of the glycine decarboxylase resemble those found in the pyruvate dehydrogenase (see Fig. 14.9) and α -ketoglutarate dehydrogenase reactions of the citric acid cycle. The same L-protein is used in all three complexes.

14.9.3 Photorespiration increases the energy costs associated with photosynthesis

The stoichiometry associated with the C_2 cycle is not straightforward. Oxygenation of two RuBPs generates two molecules of 3-PGA and two molecules of 2-phosphoglycolate. The net reaction that converts the latter to one molecule of 3-PGA is:

Reaction 14.6: The C_2 cycle

In photosynthesis, the relationship of O_2 evolved to CO_2 taken up is 1:1. In photorespiration, by contrast, 3 O_2 are taken up for every CO_2 evolved. Salvaging phosphoglycolate by converting it to phosphoglycerate requires a net input of two Fdx_{red} (i.e., one NAD(P)H equivalent) and two ATPs. The reducing equivalents and one ATP molecule are consumed during photorespiratory ammonia reassimilation. The remaining ATP is used to phosphorylate glycerate. Whether this exact stoichiometry operates *in vivo* is less certain. No endogenous source of NADH exists in the peroxisome, so the reducing equivalents needed for hydroxypyruvate reductase reaction must be imported. This probably involves malate, which can generate NADH via the peroxisomal malate dehydrogenase, forming OAA as a product.

As discussed in Section 14.7.2, malate and OAA can be exchanged between the mitochondrial matrix and the cytosol through the operation of the OAA carrier. This malate/OAA shuttle provides a convenient mechanism for moving the NADH produced by mitochondrial glycine decarboxylase reaction to the peroxisome, where it can provide electrons for the reduction of hydroxypyruvate. If this mitochondrial shuttle operates, there is no need for the mitochondrial electron transport chain to function in conjunction with the C_2 cycle, and the stoichiometry cited above would hold. However, chloroplasts also possess an OAA transporter and may utilize a malate/OAA shuttle to transfer reducing equivalents to the peroxisome. If the chloroplast-localized malate/OAA shuttle is used and all the NADH produced during glycine decarboxylation is oxidized through the mitochondrial electron transport chain, operation of the C_2 cycle would consume two NAD(P)H equivalents and actually produce one ATP for every two CO_2 evolved.

If each NADH can produce 2.5 ATPs during oxidative phosphorylation (see Section 14.4.3), the net energy cost of the operation of the C_2 cycle per CO_2 evolved is 4.5 ATP equivalents, regardless of which pathway or combination thereof operates *in vivo*. The cost of converting the resulting 3-PGA to 0.6 RuBP via the C_3 reductive photosynthetic carbon cycle adds an additional 4 ATP equivalents (i.e., 1 NADPH + 1.5 ATP) to the total. However, operation of the C_2 cycle also leads to loss of one CO_2 , and the cost of refixing this CO_2 is another 8 ATP equivalents (i.e., 2 NADPH + 3 ATP). Assuming C_3 plants fix three molecules of CO_2 for

TABLE 14.2 Energy costs of photorespiration and photosynthesis.*

1 O_2 fixed by Rubisco	
C_2 cycle	2.25 ATP equivalents
Calvin–Benson cycle (regenerating RuBP from 3-PGA)	2 ATP equivalents
Recapturing 0.5 CO_2 released by C_2 cycle	4 ATP equivalents
Total	8.25 ATP equivalents
1 CO_2 fixed by Rubisco (C_3 plant)	
Calvin–Benson cycle	8 ATP equivalents
Total	8 ATP equivalents
1 HCO_3^- incorporated into C_4 acid (C_4 plant)	
C_4 cycle	2 or 3 ATP equivalents [†]
Calvin–Benson cycle	8 ATP equivalents
Total	10 or 11 ATP equivalents [†]

*Assuming a cost of 2.5 ATP per NAD(P)H oxidized.

[†]2 ATP equivalents for NAD⁺- or NADP⁺-malic enzyme plants, 3 ATP equivalents for PEP-carboxykinase plants.

every molecule of O_2 fixed by the C_2 cycle, the cost of fixing three molecules of CO_2 is 32.25 ATP equivalents in a C_3 plant—but only 30 ATP equivalents in many C_4 plants (Table 14.2).

The C_2 cycle clearly constitutes a major energy drain that lowers the efficiency of CO_2 uptake during C_3 photosynthesis. This point is emphasized when we consider that C_4 plants can make up for using additional ATP during photosynthesis by minimizing photorespiration. Plants that have evolved mechanisms to minimize photorespiration are thus at a definite advantage under recent atmospheric CO_2 concentrations, but anthropogenic CO_2 emissions may shift this advantage in the future (see Section 14.10.3).

14.10 Role of photorespiration in plants

14.10.1 The rate of photorespiration can represent an appreciable percentage of the photosynthetic rate

Under current atmospheric conditions, and given a specificity factor of 100, the rate of carboxylation to oxygenation should be approximately 3 to 1. Because each oxygenation reaction produces only 0.5 CO_2 , the rate of photorespiratory

CO₂ evolution should be equivalent to 16% of the rate of gross photosynthetic CO₂ uptake (i.e., 0.5 CO₂ released per oxygenation × 1 oxygenation per 3 carboxylations). Considering the number of carbon atoms metabolized through the C₂ cycle, the rate of carbon flux through the C₂ cycle at any given time can be estimated at approximately 65% of the photosynthetic rate (4 carbon atoms metabolized through the C₂ cycle per molecule of photorespiratory CO₂ evolved × 16% of photosynthetic CO₂ uptake). Experimental measurements using oxygen isotopes to discriminate between photosynthetic CO₂ uptake and photorespiratory CO₂ efflux indicate the rate of photorespiratory CO₂ release ranges from 18% to 27% of the photosynthetic carbon fixation rate. These data conform to the theoretical calculations above; in fact, the latter value suggests the flux of carbon through the C₂ cycle can exceed the rate of photosynthetic CO₂ fixation.

The values given above clearly illustrate the inhibitory effects of photorespiration on photosynthesis. However, the inhibition of photosynthesis by photorespiration is not associated solely with the evolution of CO₂ during the operation of the C₂ cycle. For every CO₂ released during the operation of the C₂ cycle, two molecules of O₂ react at the Rubisco active site and prevent CO₂ from being fixed. We can hypothesize, therefore, that if photorespiratory CO₂ flux equals 20% of the photosynthetic CO₂ uptake, then replacing these two oxygen molecules with CO₂ would increase the rate of photosynthesis by an additional 40% (see Fig. 14.42 and Reaction 14.5). Thus, abolishing RuBP oxygenation and the resulting C₂ cycle would enhance photosynthetic CO₂ fixation not by 20%, but by 60%. This premise is supported by experimental evidence: When net photosynthetic rates in C₃ plants are under 1% to 2% O₂, increases of 50% to 70% are commonly observed. Likewise, growth under high CO₂ or low O₂ (relative to that found in the normal atmosphere) enhances production of dry biomass, further demonstrating the energy costs of the C₂ cycle.

14.10.2 The oxygenase activity of Rubisco is consistent with the enzyme's anaerobic origins

The initial appearance of the enzyme Rubisco in ancient photoautotrophic bacteria is thought to have preceded the build up of free O₂ in the Earth's atmosphere by at least 10⁹ years. For a long time, therefore, the environment apparently did not select against the oxygenase activity inherent in Rubisco's catalytic mechanism. After the appearance of free atmospheric O₂, the selective pressure to minimize oxygenase activity must have been great, even though the early aerobic atmosphere contained less O₂ and more CO₂ than the air we breathe today. As recently as 100 million years ago, during the Cretaceous period, CO₂ accounted for approximately 0.3% of the atmosphere, almost an order of magnitude greater than the current CO₂ content.

The consequence of this selective pressure can be seen in the range of kinetic specificity factors (see Section 14.8.3)

displayed by different photosynthetic organisms. Specificity factor values as low as 15 are seen in bacteria that photosynthesize in anaerobic environments. These prokaryotes could not grow under current aerobic conditions: even if able to tolerate O₂, they would fix more O₂ than CO₂. Cyanobacteria have specificity factors of 50–60, but can augment this with transport systems that concentrate CO₂ at the site of fixation to minimize oxygenase activity. A specificity factor of 100, average for terrestrial plants, appears to reflect the best that evolutionary selective pressure can accomplish with Rubisco alone, given its oxygenase activity has been selected against for a very long time. The Ice Ages in particular must have penalized RuBP carboxylation—CO₂ concentrations dropped well below current levels (0.038%) to values less than 0.030%. It is noteworthy that, despite the costs of photosynthetic O₂ fixation, the Calvin–Benson pathway is the only CO₂ assimilation cycle that can function in today's atmosphere. The other five carbon cyclic pathways capable of supporting autotrophic growth are restricted to bacteria occurring in habitats with little or no O₂.

The deleterious impact of photorespiration apparently led to the evolution of C₄ plants, which developed complex biochemical pathways for concentrating CO₂ near Rubisco, in lieu of evolving a more efficient enzyme. The intricate biochemical, physiological, and structural relationships that make up C₄ photosynthesis suggest that photorespiration will not be overcome by manipulating one or even several genes. Whether genetic engineering of Rubisco can accomplish what more than a billion years of intense selection pressure have not remains to be seen. However, recent work in genetically engineering a recycling pathway for the products of ribulose-1,5-bisphosphate (RuBP) oxygenation within the chloroplast of C₃ plants shows that productivity gains can be made by reducing the losses and transport costs of the photorespiratory pathway.

14.10.3 Photorespiration has become an interdependent process in C₃ plant metabolism linked to a variety of benefits

Although photorespiration can restrict overall photosynthetic efficiency, it is strongly integrated with the leaf cell's carbon and nitrogen metabolic pathways and under certain conditions may be beneficial. Side reactions stemming from the photorespiration may help optimize metabolic function in C₃ plants. Most such benefits relate to nitrogen metabolism or stress tolerance. Photorespiration stimulates nitrate assimilation in C₃ plant roots, probably by increasing NADH availability in the cytosol. So, photorespiration can be positively correlated with growth under nitrogen limitation. Photorespiration is not a fully closed cycle: a small proportion of serine from photorespiratory flux is siphoned off for methionine and cysteine synthesis and is thus needed for optimal amino acid synthesis in C₃ plants. Photorespiration can enhance C₃ plant tolerance to drought, salinity and chilling. The mechanisms are still under investigation but may relate to the ability of photorespiration to dissipate

FIGURE 14.44 Effect of leaf temperature on quantum yield in C_3 and C_4 plants. In C_3 plants, the rate of photorespiration increases with increasing temperature to a greater extent than does the rate of gross photosynthesis. The enhanced relative operation of the C_2 cycle at higher temperatures leads to a greater energy cost per net CO_2 fixed, which is reflected in a decrease in the quantum yield (moles of CO_2 fixed per photon of light absorbed). When C_3 photosynthesis is carried out in the presence of decreased (1%) O_2 , photorespiration is effectively eliminated and the resulting quantum yield remains constant with increasing temperature. Plants having the C_4 pathway show a constant quantum yield with increasing temperature, thus reflecting the absence of photorespiration; instead, C_4 plants concentrate CO_2 at the site of CO_2 fixation in the bundle sheath cells. The lower quantum yield for C_4 plants than for C_3 plants in 1% O_2 reflects the fact that, although both lack photorespiration, C_4 plants retain the added energy cost (2 ATP per CO_2 fixed) needed to operate the C_4 pathway. At lower temperatures, C_3 plants have a higher quantum yield than C_4 plants even in normal air, reflecting the energy tradeoffs of having a lower rate of photorespiration but not incurring the cost of operating the C_4 pathway.

over-reduction of the chloroplast that leads to photoinhibition, and also to photorespiratory ROS production, stimulating stress signaling gene expression in C_3 plants.

14.10.4 Photorespiration may influence response of C_3 plants to future climatic events

As temperature rises, changes in Rubisco's kinetic constants decrease the value of the selectivity factor, increasing oxygenase activity relative to carboxylation. Increasing temperature also decreases the aqueous solubility of dissolved CO_2 more than it does that of dissolved O_2 , lowering the ratio of CO_2 to O_2 in air-equilibrated solution. Both of these effects enhance the rate of photorespiration relative to photosynthesis as the ambient temperature increases. As a result, in C_3 plants the quantum yield (see Chapter 12) for photosynthesis decreases continually as temperature increases, and the light-saturated optimum for net photosynthesis generally lies somewhere between 25°C

FIGURE 14.45 Effect of ambient temperature on CO_2 assimilation in C_3 and C_4 plants. In C_3 plants the increase in the relative contribution of photorespiration to net photosynthetic CO_2 uptake as temperature increases leads to a lower optimum temperature than that for C_4 plants, where the absence of photorespiration shifts the optimum temperature for net CO_2 fixation to higher temperatures. The steep decline in photosynthetic rates at temperatures above 40°C is common to both C_3 and C_4 plants and reflects an irreversible thermal denaturation of components of the photosynthetic apparatus at high temperatures.

and 35°C. In C_4 plants, which have a CO_2 -concentrating mechanism that effectively eliminates photorespiration, the relative quantum yield for photosynthesis remains roughly constant with increasing temperature, and temperature optima for photosynthesis are higher (30°C to 40°C) than those of most C_3 plants. When the atmospheric fraction of O_2 is low (<2%), the photosynthetic quantum yield for a typical C_3 plant is greater than that of a C_4 plant and remains constant with increasing temperature (Figs. 14.44 and 14.45).

The projected doubling of atmospheric CO_2 concentration sometime in this century could have significant consequences for photosynthesis. Given the direct competition between CO_2 and O_2 for Rubisco-bound RuBP, higher concentrations of CO_2 would enhance carboxylation over oxygenation, even when the overall rate of photosynthesis is not controlled by Rubisco or RuBP availability. The theoretical ratio of carboxylase to oxygenase activity could increase from present value of ≈ 3 to >10 , which should lead to an increase in net photosynthesis in C_3 plants. C_4 plants that lack measurable rates of photorespiration would not experience this photosynthetic enhancement and might be put at a selective disadvantage relative to C_3 neighbors. Such a change might assist agriculture because many of the world's most pernicious weeds are C_4 plants.

Although the efficiency of photosynthesis will increase with greater CO_2 concentrations, the absolute rate of photosynthesis may not. Numerous studies indicate that many plants acclimate to continuous exposure to high CO_2 , such

that their photosynthetic rates eventually resemble those of plants grown under current conditions. Reasons for this response include diminished amounts of Rubisco in plants grown in high-CO₂ and feedback inhibition of photosynthesis as a result of the inability to utilize all the additional

carbohydrate initially produced in high-CO₂ conditions. Regardless of this acclimation effect, increased atmospheric CO₂ may impact the balance of photosynthetic and photorespiratory reactions in many plants, with consequences that are at present unknown.

Summary

Aerobic respiration involves the controlled oxidation of reduced organic compounds to CO₂ and H₂O. Much of the free energy released during respiration is conserved in the formation of ATP. In glycolysis, the first stage of respiration, carbohydrates are oxidized to organic acids in the cytosol. The organic acids produced during glycolysis are completely oxidized to CO₂ in the mitochondrial matrix via the citric acid cycle. The electrons released during the operation of the citric acid cycle are transferred through a series of multiprotein complexes located in the inner mitochondrial membrane, ultimately reducing O₂ to H₂O. The free energy released during mitochondrial electron transfer is used to generate a proton electrochemical gradient across the inner membrane. The energy available in the proton gradient is subsequently used by another protein complex, ATP synthase, to synthesize ATP from ADP and P_i. Mitochondrial respiration is regulated by the availability of ADP and P_i and by the presence of additional electron transfer complexes that allow respiration to proceed without forming a proton gradient.

Plant mitochondria participate in several metabolic processes besides respiration, including providing reducing equivalents to other cellular compartments and carbon skeletons for amino acid biosynthesis. Plant mitochondria also participate in the biosynthesis of

sugars from lipids in some germinating seeds and in the decarboxylation reactions associated with photosynthesis in some C₄ and CAM plants. The movement of metabolites into and out of mitochondria requires specific transporters in the inner mitochondrial membrane, some of which are regulated by the proton gradient.

Photorespiration involves the light-dependent uptake of O₂ and evolution of CO₂ during photosynthesis in green plant tissues. The first step in photorespiration is associated with the oxygenase activity of the photosynthetic enzyme Rubisco. Phosphoglycolate formed during the oxygenase reaction is metabolized through the photorespiratory carbon cycle to save 75% of the carbon in the form of phosphoglycerate; the remaining 25% is lost as CO₂. The reactions of the photorespiratory carbon cycle occur in three organelles: chloroplasts, peroxisomes, and mitochondria. The loss of CO₂ during photorespiration can represent an appreciable percentage of the carbon fixed during photosynthesis, decreasing the overall efficiency of photosynthesis especially in C₃ species but it can positively influence aspects of nitrogen metabolism and stress tolerance in plants. Photorespiration reflects the evolutionary origin of Rubisco in an anaerobic environment and may influence the competitiveness of some plants in response to future changes in atmospheric CO₂ concentrations.

METABOLIC AND DEVELOPMENTAL INTEGRATION

Long-Distance Transport

*John W. Patrick, Stephen D. Tyerman,
and Aart J.E. van Bel*

Introduction

Long-distance transport systems are integral to successful functioning of land plants. Here we focus on angiosperms, in which these transport systems are most advanced evolutionarily. Vascular plants are characterized by vascular systems composed of two specialized tissues, xylem and phloem. Xylem and phloem occur together and extend throughout the entire plant body (Fig. 15.1). Xylem transports water and soil-borne nutrients from roots to transpiring leaves, where photosynthesis forms organic carbon compounds (photoassimilates). Phloem transports water, mineral elements, amino nitrogen compounds, and photoassimilates (resources) from fully expanded leaves or storage organs (sources, net resource exporters) to meet the nutrient (carbon, nitrogen, and mineral) requirements of heterotrophic growth or storage organs (sinks, net resource importers). Xylem transport is incapable of serving this function, as sink organ transpiration is too low to drive resource transport through xylem at sufficient rates to meet sink metabolic demand. In addition to transport of resources, xylem and phloem also conduct signals that coordinate defence responses as well as homeostatic and developmental functions between plant organs. Mechanisms responsible for transporting macromolecular signals have been hijacked by pathogens, in particular viruses, to aid their systemic spread throughout the plant body.

We begin with an analysis of long-distance transport by examining requirements for specialized cell designs to support high fluxes of resources. Short-distance transport through specialized parenchyma cells is interconnected with axial flows by loading and unloading the system. Short-distance

transport processes include transport across plasma membranes, tonoplasts, and through plasmodesma. Much progress has been achieved in discovering the biophysical principles of xylem transport, while more remains to be understood about mechanisms for xylem loading (repair) and phloem transport. Understanding mechanism provides the platform for discovering how flows of resources and signals are regulated as well as how transport of macromolecules, viruses, and bacteria occur. Such an exercise is at the very heart of the key principles governing whole plant productivity and concludes our review of long-distance transport. Boxes 15.1 and 15.2 provide a brief introduction to the biophysical and biochemical theory that underpins current understanding of long-distance transport.

15.1 Selection pressures and long-distance transport systems

15.1.1 Intercellular transport can occur along apoplastic, symplasmic, and transcellular routes

A number of options exist for intercellular transport between cells. The water-filled spaces of cell wall matrices (5–20 nm diameter) and lumens of xylem tracheary elements (10–300 μm diameters) are collectively referred to as the apoplast and provide one pathway for intercellular transport (pathway 1,

FIGURE 15.1 Diagram showing patterns of xylem and phloem transport. Movement in xylem is upwards from roots to mature leaves, primary sites of transpiration and photosynthesis. A very small amount of xylem transport (broken line) supplies growth sinks (e.g., expanding leaves) and even less is directed to shoot apices and storage sinks (e.g., developing fruit), both of which have low transpiration rates. Movement in the phloem proceeds from sites of photoassimilate production, primary mature leaves, to sites of utilization in growth or storage sinks. Phloem transport can be bidirectional within a single internode but is unidirectional within a given vascular bundle. In lower and upper internodes, movement tends to be unidirectional downward or upward respectively.

Fig. 15.2). In many instances, cells are highly interconnected by plasmodesmata (see Section 15.1.2), fine cytoplasmic threads that form a continuous cytosolic compartment through which intercellular transport may occur (pathway 2, Fig. 15.2). Such interconnected cytosols are referred to as symplasm (*sym* – joined together). In some cases, such as radial transport of water across roots, a transcellular pathway

may be followed. Here, for each cell layer, plasma membrane and tonoplast are crossed twice to enter and exit each cell and its vacuole (pathway 3, Fig. 15.2). It is difficult to quantify the contributions of transcellular and symplasmic pathways, so generally these are taken together as a cell-to-cell pathway for water movement.

15.1.2 Plasmodesmata form an interconnected symplasm to support intercellular transport

It has been 60 years since electron microscopy visualized plasmodesmata as plasma membrane-lined cytoplasmic canals, 20–50 nm in diameter interconnecting adjacent cells. The canals contain a rod of central endoplasmic reticulum (ER) that is continuous with ER strands on either side of the shared cell wall (Fig. 15.3). The ER rod is covered with spirally arranged macromolecules from which spokes extend to protein complexes associated with plasma membrane inside the plasmodesmal canal. Openings of plasmodesmata (orifices or cytoplasmic sleeves) often exhibit constrictions (neck regions), indicating a potential for plasmodesmal closure.

Originally, plasmodesmata were considered to act as intercellular passageways for small molecules, since microinjected fluorescent dye molecules greater than 1 kDa (≈ 0.5 – 1.0 nm in diameter) were excluded (Fig. 15.4). Subsequent studies found that molecular exclusion limits of plasmodesmata depended on developmental state, tissue type, and physiological conditions. For example, plasmodesmata between meristematic cells in roots allow passage of macromolecules up to about 65 kDa. Recently, a variety of proteins, including actin and myosin, involved in macromolecular trafficking have been detected inside the plasmodesmal canals.

Plasmodesmal numbers (densities) indicate a potential for intercellular trafficking. Whether symplasmic transport occurs depends on the open state of plasmodesmata. For instance, despite high plasmodesmal numbers located at bases of leaf hairs, a functional symplasmic barrier occurs due to plasmodesmal closure (Fig. 15.4). At symplasmic barriers (no plasmodesmata or all plasmodesmata closed), resources are released through plasma membranes into adjacent cell walls, diffuse through their aqueous pores (apoplastic transport), and are absorbed via the plasma membranes of adjoining cells.

15.1.3 Resource distribution in terrestrial environments requires long-distance transport

For multicellular plants to function effectively in terrestrial environments, a strong selection pressure existed for them to extract resources from both soil and air. Soil is the primary source for water and mineral nutrients, and light energy can be captured only from aerial environments at sufficient

BOX
15.1

Fundamentals of transport

Molecules and ions move down free energy gradients that reflect differences in concentration, temperature, pressure, voltage (for electrolytes), or combinations of these. The effective motive force for movement differs for different distance scales. Molecules dissolved in a solution are subject to bulk flow (convection) of solution driven by pressure gradients, and they can be carried along in the flow over large distances. Over short distances, molecular diffusion dominates. Total flux of a molecule (J_{total} , units: $\text{mol m}^{-2} \text{s}^{-1}$) is the combination of bulk flow and diffusion:

$$J_{total} = J_{bulk-flow} + J_{diffusion} = vc - D_i \Delta c / \Delta x \quad (\text{Eq. 15.B1})$$

Bulk-flow flux is given by concentration (c) times velocity (v). Diffusive flux is determined by concentration gradient ($\Delta c / \Delta x$) and diffusion coefficient (D).

Diffusion

Fick's first law of diffusion describes this movement as a flux (J , units: $\text{mol m}^{-2} \text{s}^{-1}$) of a population of molecules of type i (J_i) that is proportional to their concentration gradient ($\Delta c_i / \Delta x$):

$$J_i = -D_i \frac{\Delta c_i}{\Delta x} \quad (\text{Eq. 15.B2})$$

The *diffusion coefficient* (D , units: $\text{m}^2 \text{s}^{-1}$) is unique for each diffusing element and molecule and medium through which diffusion is occurring. Examples of D for solutes in water (25°C) are sucrose $0.52 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, and glucose $0.67 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (note increase with decrease in molecular size).

Diffusion theory predicts that diffusion time increases with the distance squared (x^2), and a useful relationship describes the time required for 37% of the initial concentration in a plane to spread a distance (x) as:

$$t_{37\%} = \frac{x^2}{4D_i} \quad (\text{Eq. 15.B3})$$

Bulk flow

Within xylem and phloem, flow is thought to be analogous to laminar flow along a pipe. Laminar flow is where a smooth parabolic profile of velocity occurs across a pipe's radius with higher velocities towards the center and slowed velocities adjacent to surfaces due to friction. Volume flow rate (J , units: $\text{m}^3 \text{ s}^{-1}$) of bulk flow in a pipe is derived explicitly from the Hagen–Poiseuille law as:

$$J = \frac{\pi r^4 \Delta P}{8\eta l} \quad (\text{Eq. 15.B4})$$

where ΔP is the pressure gradient over length l , r is pipe radius, and η is dynamic viscosity (units: Pa s). This equation can be arranged to give an effective resistance to fluid flow for a unit pressure gradient or to predict the pressure gradient ($\Delta P/l$) required for an observed volume flow rate (J). Resistance will increase 16-fold by halving pipe diameter.

Hydraulic conductance/conductivities

The volume flow rate (J) is proportional to pressure gradient times hydraulic conductance (L_o) derived from the Hagen–Poiseuille equation as:

$$L_o = \pi r^4 / 8\eta l \quad (\text{Eq. 15.B5})$$

Conductance depends on flow-path length, and to take this factor out for comparison between systems, conductance can be multiplied by path length to determine conductivity. Conductances and conductivities are normalized to various dimensions of particular flow pathways. For water transport across a surface (a cell or a root), conductance is generally normalized to surface area to give what is also termed hydraulic conductivity ($L_{p'}$, units: $\text{m s}^{-1} \text{ MPa}^{-1}$). Note velocity of flow equals L_p multiplied by pressure gradient, and for a pipe, velocity or volume flux (units: m s^{-1}) equals $r^2 \Delta P / 8\eta l$ (Equation 15.B1). Leaf hydraulic conductance is generally measured as flux (units: mmol s^{-1}) divided by water potential gradient and leaf surface area to give units of $\text{mmol m}^{-2} \text{ s}^{-1} \text{ MPa}^{-1}$.

Water potential and water potential gradients

In discussing flow properties above, driving force was simply considered as the pressure gradient or concentration difference (for diffusion). To encompass all driving forces, we consider total free energy gradient on water, quantified as water potential (Ψ_w , units of pressure) and comprising the additive potentials of pressure (Ψ_p), osmotic components (Ψ_π), matric components (Ψ_m), and gravitation (Ψ_g):

$$\Psi_w = \Psi_p + \Psi_\pi + \Psi_m + \Psi_g \quad (\text{Eq. 15.B6})$$

water potential is a measure of free energy per unit volume (units: Joules m^{-3} or Pa). Pressure potential (Ψ_p) is equivalent to hydrostatic pressure (P), and it should be noted that this can be negative. In a pipe or porous plant cell wall, water flow is driven only by differences in pressure potential. Gravitational potential accounts for changes in free energy with height (0.01 MPa m^{-1}). This term is not relevant for tissues or cells, but is significant for flow through xylem or phloem over tens of meters in trees. Differences in osmotic potential become effective in driving water flow across a membrane that is selectively more permeable for water. Dissolved solutes decrease

free energy of water (decreases Ψ_π component) and this is numerically equivalent to, though opposite in sign, to osmotic pressure (π) determined by total osmotic concentration of all dissolved solutes. Sometimes a matric component is identified to indicate lowering of free energy of water in a thin film adhering to a surface. This effect is more important in soil, and within a plant, the effect is incorporated within P and π components. Given the above considerations, Equation 15.B6 can be simplified as:

$$\Psi_w = \Psi_p + \Psi_\pi \text{ or } \Psi_w = P - \pi \quad (\text{Eq. 15.B7})$$

where P can be positive (hydrostatic pressure) or negative (tension) with the appropriate sign. The turgor pressure of a cell (TP) is the difference between inside hydrostatic pressure and outside hydrostatic pressure across the plasma membrane and cell wall, which at equilibrium (i.e., when inside $\Psi_w =$ outside Ψ_w) will equal the difference in internal minus external osmotic pressure: $TP = \pi_i - \pi_o$.

BOX 15.2

Intercellular transport across membranes and through plasmodesmata

Solute diffusion across a biological membrane may occur through the lipid phase or via specialized transmembrane proteins that speed diffusion (facilitated diffusion). Facilitated solute or water diffusion may occur through protein channels, or by solute interacting with a protein carrier to form a solute–protein complex that undergoes conformation change and in doing so transports the solute from one side to the other.

Diffusion across a membrane begins with the element or molecule partitioning from surrounding solution into the membrane, then diffusing across the membrane, and finally partitioning back out to solution on the other side. This may occur across both lipid and transmembrane proteins, the proportion depending on the type of element/molecule and specialized transmembrane proteins present. This process is embodied within the *permeability coefficient* (P_s , units: m s^{-1}). Thus, a diffusion flux (J_s , units: $\text{mol m}^{-2} \text{ s}^{-1}$) driven by a concentration gradient (ΔC_s) of an uncharged molecule (s), across a membrane is given by:

$$J_s = P_s \times \Delta C_s \quad (\text{Eq. 15.B8})$$

P_s is unique for a particular element/molecule in a particular membrane. Diffusion through membrane channels conforms to Equation 15.B8 except that P_s is much higher. For instance, P_s for water movement across a lipid membrane can increase 500 fold when water channels (aquaporins) are functioning.

For electrolytes, diffusion rates and direction are modified by membrane potential differences (for more details see Chapter 3).

Rates (R_v , units: mol s^{-1}) of facilitated diffusion mediated by a carrier across a membrane can be modeled as a solute-saturable component described by

Michaelis–Menten kinetics combined with a non-saturable component obeying first order kinetics as:

$$R_v = [V_{max} \cdot C / (K_m + C)] + kC \quad (\text{Eq. 15.B9})$$

where V_{max} (units: mol s^{-1}) is maximal velocity, K_m (mol m^{-3}), Michaelis–Menten constant, C , solute concentration, and k (units: $\text{m}^3 \text{ s}^{-1}$) a first order rate constant.

Work must be done to transport solutes across membranes against their chemical (nonelectrolytes) or electrochemical (electrolytes) gradients. In most cases (see Chapter 3) this is achieved by proton-coupled solute transport, organized in symport or antiport configuration, with protons returning down their electrochemical gradients (proton motive force, *pmf*, units: mV) given by:

$$pmf = (E_i - E_o) + 59(pH_o - pH_i) \quad (\text{Eq. 15.B10})$$

where $(E_i - E_o)$ is membrane potential difference, and $(pH_o - pH_i)$ the pH difference across the membrane.

Assuming a sucrose/ H^+ stoichiometry of one, a derivative of the Nernst equation predicts difference between intracellular (C_i) and external (C_o) sucrose concentrations at which sucrose/ H^+ symport reverses for a given *pmf* by:

$$\text{Log}_{10}(C_i) = \text{Log}_{10}(C_o) - [(E_i - E_o) + 59(pH_o - pH_i)] / 59 \quad (\text{Eq. 15.B11})$$

Plasmodesmal transport

A permeability coefficient can be derived for plasmodesmal transport (Equation 15.B8). The diffusion component is largely determined by plasmodesmal substructure (Equation 15.B2). Similar comment applies to bulk flow through plasmodesmata (Equation 15B.5).

FIGURE 15.2 Illustration of apoplast/symplast concept and transport pathways. Resources may move from cell-to-cell by way of: (1) Apoplastic transport through their cell walls (brown arrows). Alternatively, resources may enter a cell across the plasma membrane and then move from cell-to-cell by: (2) Symplasmic transport through interconnecting plasmodesmata (green arrows) or; (3) Transcellular transport via the vacuole across the tonoplast followed by exit across the plasma membrane before regaining entry to the adjacent cell through the plasma membrane (mainly for water; blue arrows).

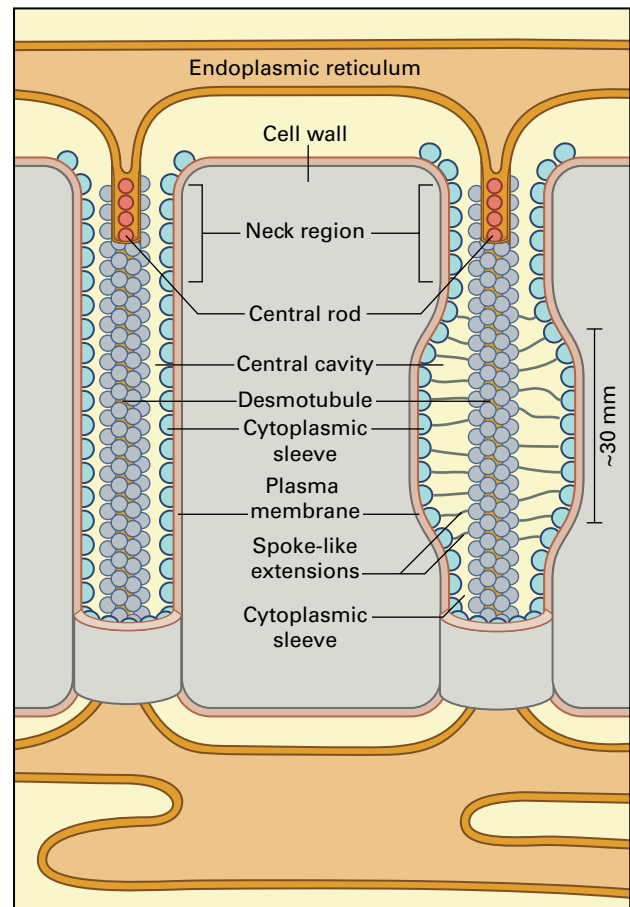

FIGURE 15.3 Substructure of plasmodesmata. (A) A digital false-color computer-enhanced image identifies outward (OPL) and inward (IPL) leaflets of plasma membrane traversing the cell wall, a protein layer attached to the IPL (violet), attached to IPL, from which protein spokes (P, red) arise to connect with proteins (W, violet ring delimited by the two lines) spirally arranged around a central ER rod (CRP) or desmotubule. (B) Electron micrograph (EM) of a transverse section of a plasmodesma demonstrating spokes (arrows) between the plasma membrane double-layer and desmotubule. (C) Models of plasmodesmata between young (left) and mature cells (right) based on EM-images (such as A, B). Plasma membrane and ER are continuous cell to cell, with the latter tightly furled to form the desmotubule. A sleeve of cytoplasm occupies the gap between plasma membrane and desmotubule. In the mature plasmodesma (right), the sleeve has been enlarged to form a cavity. Much of the cytoplasmic sleeve is occupied by proteinaceous particles partially embedded in the plasma membrane and desmotubule. Gaps between these particles evidently represent the physical basis for molecular sieving properties of symplasmic transport. Within the central cavity, spoke-like structures extend across the cytoplasmic sleeve; their presence in the neck region is still unclear. Source: (A) Botha et al. (1993). *Annals of Botany* 72:255–261. (B) R. Kollmann, University of Kiel, Germany.

energies to drive photosynthesis. A consequence is the spatial separation of two assimilatory organs (roots and leaves) that are resource interdependent. Hence, there is an obligatory requirement for long-distance transport of resources between roots and leaves (Fig. 15.1).

15.1.4 Diffusion constrains intercellular transport of resources over long distances

The simplest mechanism for intercellular transport is diffusion via an apoplastic or symplasmic pathway. As an example, applying diffusion theory (Equation 15.B3) to sucrose transport, with a diffusion coefficient in water of $0.52 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, predicts that 4.8 s is required for sucrose to reach 37% of its equilibrium concentration over 100 μm , a typical cell length. However, sucrose diffusion over a distance of 1 mm (about 10 cells arranged end-to-end and interconnected by plasmodesmata) takes 8 min, and raising this distance to 1 cm increases the time to 5.6 days. Thus, for distances exceeding 1 mm,

FIGURE 15.4 Mobile and immobile fluorescent probes in the *Abutilon nectary trichome* (for a drawing of the trichome, see Fig. 15.5). (A–C) *F-Glu* (536 Da) movement after injection into the tip cell. The frequently observed ‘stair-step’ distribution of fluorescence results from diffusion within cells being relatively more rapid when compared with cell-to-cell movement. (D) The slightly larger *F-Trp-Phe* (739 Da) shows no sign of movement after 60 seconds. Source: (A–D) Terry & Robards (1987). *Planta* 171:145–157.

sucrose movement by diffusion alone becomes increasingly problematic for supporting metabolic demands.

Constraints imposed by diffusion can be relieved partially by cytoplasmic streaming (i.e., bulk flow; see Box 15.1). This limits the rate of intercellular sucrose transport to diffusion through plasmodesmata, which nevertheless offers a higher transport capacity than transport through a transcellular pathway (Fig. 15.5). This does not necessarily pertain to water flow, where membrane transport has an extremely high capacity conferred by aquaporins.

A plasmodesmal sucrose flux of $2 \times 10^{-4} \text{ mol m}^{-2} \text{ s}^{-1}$ will satisfy the metabolic demand of heterotrophic cells. A sucrose concentration drop of 33 mM across each adjoining cell wall interface (predicted using Equation 15.B8) will generate this flux through plasmodesmata with maximum permeability coefficients of $6 \times 10^{-6} \text{ m s}^{-1}$. Assuming a 1 M sucrose concentration at the start of the transport pathway, this arrangement would support transport across a maximum of 30 cell walls arranged in series. For an average cell length of 100 μm , this translates into a transport distance of 3 mm before sucrose available for onward transport is depleted. Overall for land plants, this exercise demonstrates that a strong selection pressure existed to evolve a long-distance transport system to deliver sucrose and other resources at rates sufficient to support plant growth.

15.1.5 Harnessing bulk flow through low-resistance conduits removes constraints on plant size

In contrast to diffusion, bulk flow (Equation 15.B4) has a high capacity to transport resources over long distances. Gradients in pressure potential are generated through different means to drive bulk flow in opposite directions through xylem (tension) and phloem (hydrostatic pressure) (Fig. 15.6). Since plasmodesmata (see Fig. 15.4), membranes (plasma membranes and tonoplasts; see Fig. 15.2), and cell walls (see Fig. 15.5) are bottlenecks for intercellular transport, not surprisingly the

	Transport system (red indicates the transport interface)	Superiority factor ^a
A	<i>Abutilon</i> nectary trichome (nectary secretion rate)	1,600–16,000
B	C_4 mesophyll–bundle sheath interface (photosynthesis rate, which is dictated by transport rates of C_4 and C_3 acids)	100–1,000
C	C_3 bundle sheath–vascular tissue interface (translocation rate)	30–300

^aActual solute flux compared with the highest known fluxes for plant membranes (1 to $10 \times 10^{-8} \text{ mol m}^{-2} \text{ s}^{-1}$)

FIGURE 15.5 Fluxes of cell-to-cell nutrient movement across transport interfaces between cells are much higher than expected for transmembrane transport implicating plasmodesmata as the pathway for movement. In these three examples, the transport interface for movement measured is indicated in red. BS, bundle sheath; M, mesophyll.

FIGURE 15.6 Patterns of xylem and phloem transport and driving forces accounting for water flows in opposite directions in xylem and phloem during transpiration. (A) Diagram of water flows within and between longitudinal arrays of xylem tracheary elements (TE) and phloem sieve tubes (ST) interconnecting roots and fully-expanded leaves. Note that TEs (tracheids or vessel elements) in this diagram are simplified to represent the complete network. Water movement within TEs and STs is considered to be analogous to laminar flow where a smooth parabolic profile of velocity occurs across a pipe's radius with higher velocities towards the center and slowed velocities adjacent to surfaces due to friction (indicated by vertical arrows). A large component of the upward water flow from roots is lost through transpiration from leaves. (B) Xylem sets the water potential gradient of the pathway to shoots, and water approaches near equilibrium between adjacent xylem and phloem tissues. Hence their water potential (Ψ) gradients are essentially identical along axial vascular paths interconnecting roots and leaves. (C) Nutrient concentrations in TE saps are low, so TE sap osmotic pressure (π) is low and taken as constant with path length. In contrast, high sugar and nutrient concentrations present in ST saps generate high π that dominate ST sap Ψ . Osmotic pressure of ST sap decreases from leaf to root as a result of nutrient loss along the axial pathway. (D) Hydrostatic pressure (P) gradients are the sum of Ψ and π (Equation 15.B7). TE Ψ is determined by transpiration-induced tension (negative P) that drives bulk flow upwards from roots to leaves. In contrast water intake by STs, proportional to their osmotic content, creates a corresponding positive P gradient for leaf to root.

conducting elements of the phloem, sieve elements (SEs) and those of the xylem, tracheary elements (TEs), underwent considerable evolutionary change to enhance their conductances for bulk flow (Equation 15.B5). These changes included circumventing membrane transport and widening plasmodesmal pores to eventually give rise to sieve tubes (STs), or removing end cell walls and membranes to give rise to xylem vessels (see Section 15.2).

15.2 Cell biology of transport modules

15.2.1 Vascular cells arise from (pro) cambial progenitors

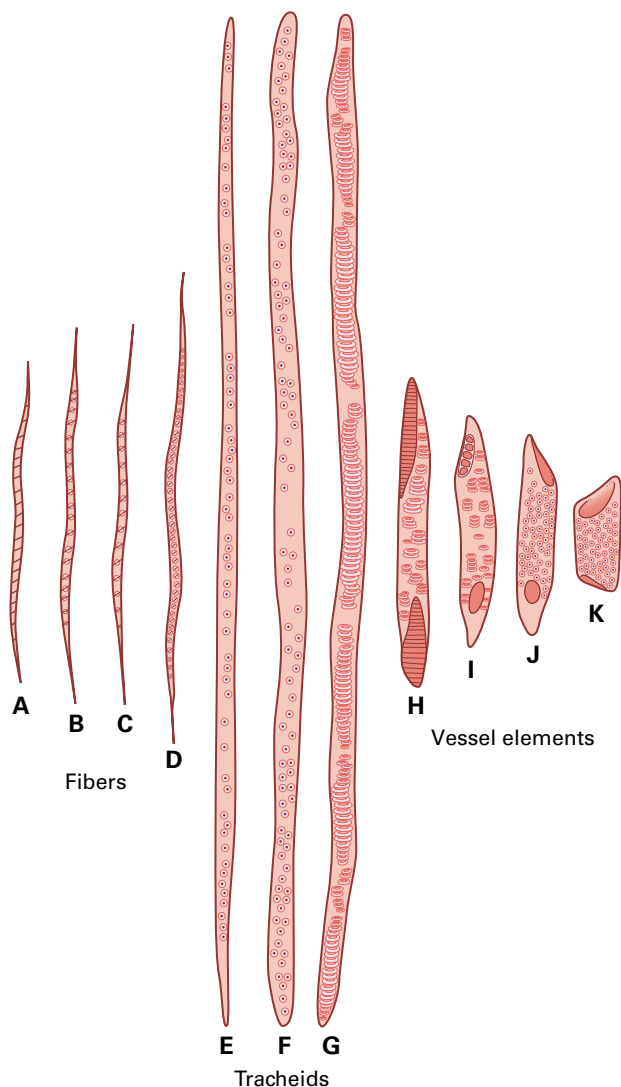

SEs function as a cellular complex with modified phloem parenchyma cells called companion cells (CCs). TEs, SE/CC complexes, and ancillary vascular cells each have specialized functions for loading, axial flow, and unloading of resources.

Primary phloem and primary xylem differentiate as bundles in procambial strands arising from stem cells located in root and shoot apical meristems. In eudicots, a circumferential strip of procambial cells remains undifferentiated between primary phloem and xylem to become a dividing meristematic layer (vascular cambium). In most eudicots, initials arising from divisions of vascular cambia produce secondary phloem to the outside and secondary xylem to the inside. In monocots, procambium strands completely differentiate into primary phloem and xylem without a vascular cambium.

15.2.2 Cell designs facilitate xylem transport functions

TEs are hollow tubes that have undergone elongation, secondary cell wall thickening, and lignification. Lignin is impermeable to water and solutes, and it is deposited by living protoplasts before programmed cell death and loss of plasma membrane (see Chapter 20). There are two kinds of TEs: vessel elements and tracheids (Fig. 15.7). Tracheids are the only TEs in almost all gymnosperms, while angiosperms may have both tracheids and vessel elements. A vessel is a series of vessel elements joined end-to-end. End walls between vessel elements, remnants of which are referred to as perforation plates, are dissolved to various degrees during late stages of cell maturation. Vessel elements evolved from tracheids in early angiosperms, and trends have been towards increased vessel width accompanied by decreased length, and opening of perforation plates.

The selective advantage of not having lipid membranes in TEs is illustrated by comparing the hydraulic conductance of a file of cells with and without membranes. For 10 cells end to end with dimensions of a typical xylem vessel element (200 μm long and inside diameter of 50 μm), hydraulic conductance (L_p , Equation 15.B6) is $7.7 \times 10^{-8} \text{ m}^3 \text{ s}^{-1} \text{ MPa}^{-1}$. Hydraulic resistance is the inverse of conductance at $1.3 \times 10^7 \text{ s MPa m}^{-3}$. For each membrane face, conductance of one circular piece of membrane (50 μm in diameter) with a high L_p of $3 \times 10^{-6} \text{ m s}^{-1} \text{ MPa}^{-1}$ (indicative of aquaporin activity) is $5.9 \times 10^{-15} \text{ m}^3 \text{ s}^{-1} \text{ MPa}^{-1}$ (hydraulic resistance $1.7 \times 10^{14} \text{ s MPa m}^{-3}$). Summing the 20 membrane faces in series gives a resistance for the file of cells of $3.4 \times 10^{15} \text{ s MPa m}^{-3}$, a value 260 million times the

L

M

FIGURE 15.7 Components of xylem tissue in angiosperms. Xylem fibers (A to D) are narrow elongated cells with very thick secondary cell walls specialized for support and provide strength to wood. Xylem tracheids (E, F, G) are highly elongated tapered cells that conduct water. Pits may be seen along cells where transfer of water occurs between tracheids. Xylem vessel elements (H to K) are less elongated but wider than tracheids. Their end cell walls (perforation plates) may be partially (H) or fully open (K). Vessel elements are connected end to end to form a xylem vessel. (L) Bordered pit pairs (bp) interconnect tracheary element (TE) lumens, and half bordered pits (hp) connect TE lumens to xylem parenchyma cells (XPC). A simple pit (sp) on the libriform fiber (lf) side, at the TE side is a small-bordered pit with an extended pit corridor. (M) Detail of bordered pit pair showing pit membrane (pm) in high magnification (length of pm is 3.7 μm). Source: (A–K) Bailey & Tupper (1918). (L, M) Micrograph provided by Dr J. Nijssse, Wageningen University; from De Boer and Volkov (2003). *Plant Cell Environ.* 26:87–101.

hydraulic resistance of the open tube. This means that to achieve the same flow rate with living cells, there would have to be a 260 million times greater pressure gradient!

Diameters of vessels between species range over an order of magnitude (15–300 μm), depending on age and location within a plant. This confers a much larger variation in resistance (Equation 15.B5). However, end walls account for 60–80% of the hydraulic resistance, suggesting vessel length is an important determinant of their water transport efficiency. Tracheids are generally of smaller diameter (10–50 μm) and longer (6–11 mm) than vessel elements (50–100 μm) such that both their smaller diameter and substantial increased end wall number per unit length contribute to their much lower water transport efficiency compared to vessels. Vessels, composed of many

vessel elements stacked end to end, can range from several centimeters to meters in length. Water flow occurs from one tracheid or vessel to another along aligned sections of adjacent cell walls over a relatively large portion of their lengths, and not just at their very ends. Here, water passes through small porous holes in their lignified cell walls called pits.

Dome-shaped pits are aligned (pit pairs) in secondary cell walls of adjacent tracheids or vessels (Fig. 15.7L,M). The compound middle lamella is exposed in pit pairs of adjacent conduits and consists of cellulose microfibrils and a pectin/hemicellulose matrix with countless small pores. This becomes a “membrane” in the sense that water and dissolved solutes can pass relatively unimpeded, but air entry is impeded because of the small pore diameters (5–20 nm in eudicots).

The pectin in pit membranes may respond like a hydrogel to alterations in ion concentrations of xylem fluid; higher K^+ concentrations increase hydraulic conductance, possibly by shrinking the hydrogel matrix and widening pores in pit membranes. This may be an important regulatory mechanism for diverting water flow to different plant organs and for diurnal changes in stem hydraulic conductances.

Lignification of the cell walls of TEs serves two purposes: to waterproof and strengthen the walls against collapse from the large tensions developed within. In elongating stems, spiral and hoop patterns of lignification allow stretching of vessels. TEs have been shown to collapse under excessive tension, and TEs of mutants defective in lignin synthesis have reduced mechanical strength. Cell wall thickness seems to be constrained by developmental processes – smaller diameters confer increased strength, resulting in an apparent conflict between strength versus conducting efficiency. In wood comprising vessels, tracheids, and fibers, vessels function as water conduits, with the structural role taken by tracheids and fibers. Fibers are highly lignified, thin elongated cells with a small ratio of diameter to cell wall thickness that provides high strength (Fig. 15.7A–D). Vessel diameter can, therefore, be larger with concomitant increase in hydraulic conductance.

Xylem parenchyma cells are living cells associated with TEs. They have the high metabolic activity required for loading and unloading water and nutrients from TEs as well as lignin polymerization, nutrient transfer between phloem and xylem, storage of carbohydrate, and repair of xylem. They have an analogous role to phloem CCs, except linkage to TEs is transmembrane rather than via plasmodesmata. Since TEs are lignified except at pit pores, transport of nutrients and water is essentially confined to small areas of half pits where plasma membranes of xylem parenchyma cells border TEs (Fig. 15.7L). Xylem parenchyma cells that border conduits often have cell wall invaginations under pit membranes that

increase the plasma membrane surface area for increased transport capacity. Transporters are highly active in xylem parenchyma cells (see Section 15.3.4).

15.2.3 Many aspects of conducting cell design enhance key phloem functions

During evolution, certain longitudinal cell arrays gradually lost their cell contents to evolve phloem conduits (Table 15.1). During SE ontogeny, the nucleus gradually disintegrates, as do the tonoplast and several other cellular components. What finally remains is the plasma membrane, a thin layer of parietal cytoplasm (mictoplasm) composed mostly of stacked ER, a few, often dilated, mitochondria, phloem-specific plastids, and SE proteins (Figs. 15.8 and 15.9).

Unequal longitudinal divisions of axial arrays of procambium cells produce SEs and CCs, and following division, the daughter cells are symplasmically isolated, probably to enable divergent differentiation to proceed (Fig. 15.8). After completing development, symplasmic contacts are restored via plasmodesmata (pore–plasmodesma units, PPU), with a single canal at the SE side and a branched canal at the CC side (Fig. 15.8E), to form a genetic and metabolic unit (SE/CC complex). Support of cellular functions by metabolically active CCs, via unique symplasmic interconnection offered by PPU, probably evolved as SEs lost their metabolic capability (Table 15.1).

A peculiarity of SEs and CCs is the structural diversity of their plasmodesmal connections. In (pro)cambial cells, all interfaces are connected by unbranched plasmodesmata (Fig. 15.8A–C). During differentiation into SE/CCs, plasmodesmata are transformed into sieve pores between SEs and into PPU at SE/CC interfaces, but they remain unchanged between CCs and phloem parenchyma cells (Fig. 15.8E).

TABLE 15.1 Ultrastructural features of sieve elements in groups of land plants reflecting their evolutionary development.

	Mosses	Vascular cryptogams	Conifers	Angiosperms
Plasma membrane	Present	Present	Present	Present

Golgi apparatus	Absent	Absent	Absent	Absent

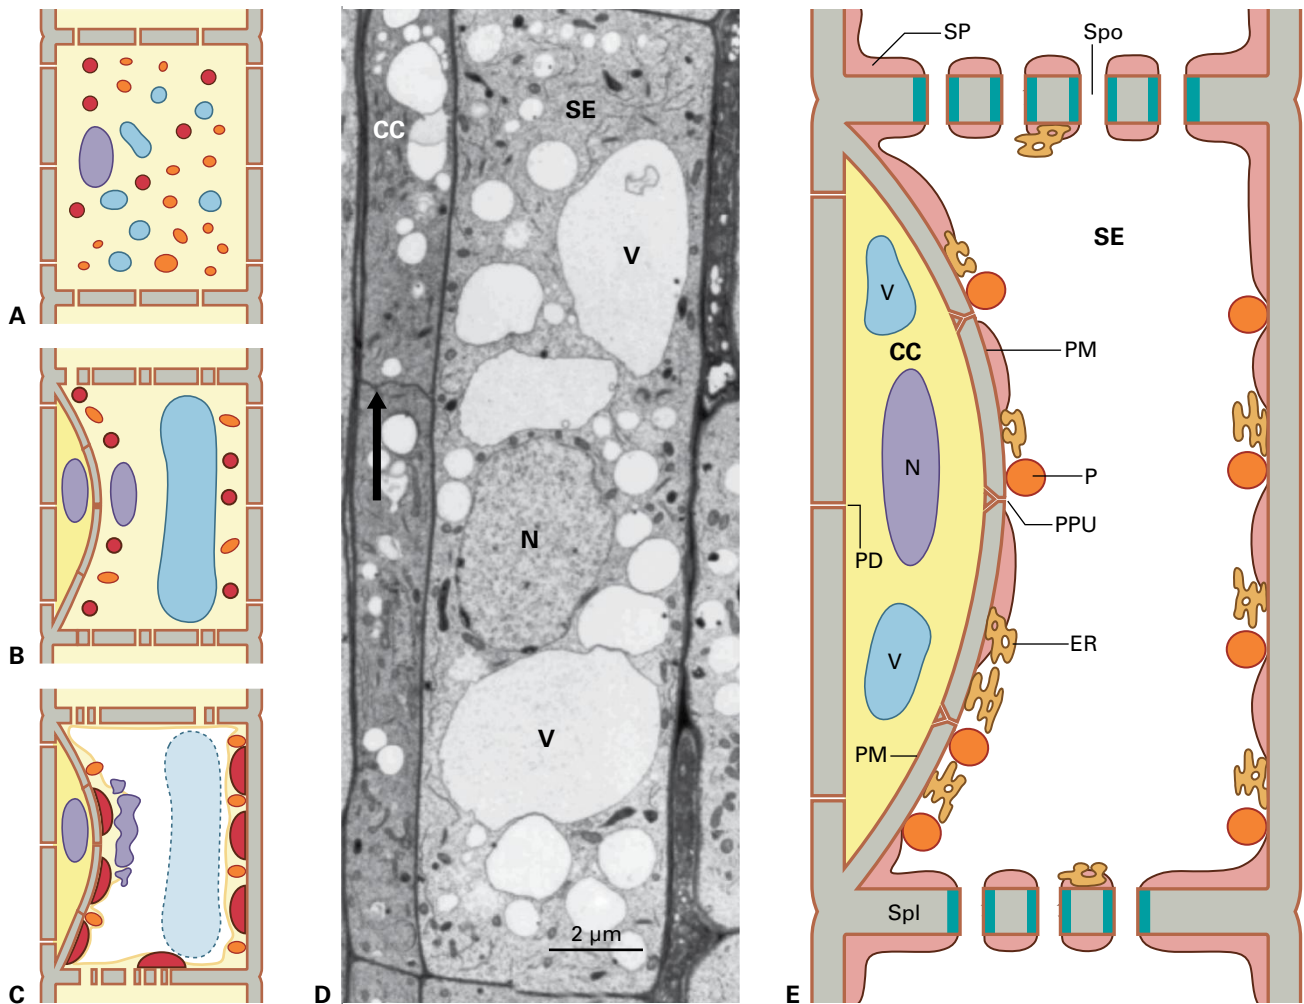

FIGURE 15.8 Ontogeny of a sieve element/companion cell (SE/CC) complex in the transport phloem. (A) Both cell types originate from the same (pro)cambial cell characterized by a dense cytoplasm and many simple plasmodesmata. (B) After a longitudinal division, the daughter cells follow different developmental patterns. A dense cytoplasm remains in the narrower CC while the SE forms a large central vacuole (blue) and conspicuous protein bodies (red) and plastids (orange) develop. (C) The nucleus (violet), ribosomes, Golgi apparatus and vacuole membrane (tonoplast) of the SE (shown in B) degrade. The developing CC often divides transversely. (D) Electron micrograph of a longitudinal section of a differentiating SE/CC complex from a *Ricinus communis* stem. SE is highly vacuolated (V), nucleus (N) is starting to disintegrate, and SE-protein bodies and plastids are beginning to appear. In the CC, the thin transverse wall (arrowhead) indicates a recently completed cell division and cytoplasm is much denser than in the SE. Sieve pores and pore-plasmodesma units (PPUs) are yet to form. (E) Following cell elongation, only a plasma membrane (PM), a parietal ER-net (light brown), SE plastids (P) and, in eudicots, phloem-specific, structural proteins (SP) remain in SEs. CCs retain their full complement of organelles. Their nuclei (N) lie in a dense cytoplasm, numerous vacuoles (V) are present and mitochondria possess many cristae (not shown). Plasmodesmata (PD) of young SE/CC complexes undergo specific changes depending on the particular cell interface. PDs at SE/CC interfaces transform into PPU that are branched on the CC side. PDs in longitudinal walls of SEs become truncated. PDs in transverse walls of SEs change into sieve pores (Spo, up to 1 µm in diameter) lined by callose deposits (aqua green) to form a sieve plate (Spl). Simple PDs connect CCs with adjacent phloem parenchyma cells. Note that for diagrammatic space-saving purposes the length of the SE/CC complexes has been strongly reduced compared to the width and the shared SE/CC wall is strongly curved into the SE. In reality, CCs “bulge” into the SEs to a lesser extent.

Source: (D) A Schulz, University of Copenhagen, Denmark.

Why did SEs retain a minimal cellular organization in contrast to dead TEs (see Section 15.2.2)? Complete removal of cell contents would have been more advantageous to optimize hydraulic conductivity (see Sections 15.1.5 and 15.2.2). Strong selection pressures must have led to partial retention of their cellular contents. The most important reason is that bulk flow through STs is driven by hydrostatic pressure differences generated and regulated by membrane transport (Fig. 15.6C,D);

consequently, plasma membrane integrity is essential for SE transport function.

The SE/ER may serve as a Ca^{2+} store for Ca^{2+} -dependent occlusion (see Section 15.6.4) and as a track for local movement of macromolecules (see Section 15.6.5). A principal function of structural SE proteins (Fig. 15.9D–G) may be Ca^{2+} -dependent occlusion of sieve pores (see Section 15.6.4). To prevent sieve pore occlusion by ER stacks, plastids,

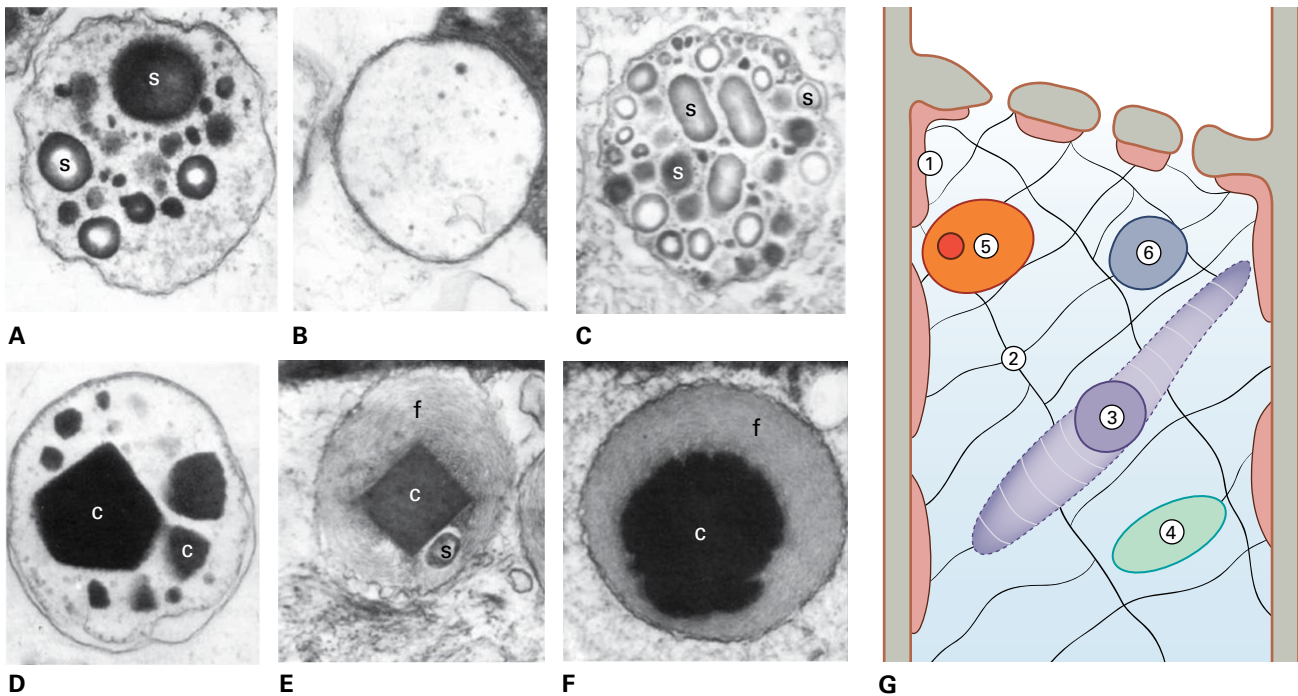

FIGURE 15.9 Sieve element plastids and phloem-specific protein bodies located in the SE parietal cytoplasm and tethered to the plasma membrane. mitochondria, and protein aggregates that could be dragged along by bulk flow, these components are anchored to each other and to the plasma membrane. Despite the ubiquitous occurrence of SE plastids in angiosperms (Fig. 15.9A–F), their roles are not known.

15.3 Short-distance transport events between xylem and nonvascular cells

15.3.1 Xylem delivers water, nutrients, and signals to shoots at variable rates

Water flow depends largely on transpiration. However, water derived from phloem unloading in root tips and fruits may be recycled via xylem. Some plants deliver sufficient nutrients to shoots without transpiration, relying only on root pressure to force sap to the shoot. Xylem flow velocity varies during the day and is lower at night, contrasting to more constant phloem sap velocity. Peak xylem flow velocities of 40 mm s^{-1} have been recorded in plants with large vessels, but typical velocities are 0.4–1.0 mm s^{-1} . Variable velocity means nutrients and signals may be delivered to shoots at different rates.

Most water is delivered to fully expanded leaves, yet these leaves have less demand for nutrients (e.g., calcium) compared to the growing shoot. This requires tuning the xylem loading of nutrients and water in roots to the resource requirements of shoots and the velocities of water flow. Transfer between xylem vessels in stems and between xylem vessels and phloem is important in this context.

15.3.2 Xylem loading of water and nutrients in roots involves multiple cellular pathways and transporters

Water moves radially across roots into xylem TE (Fig. 15.10). The stele is the central part of the root containing the pith (if present), vascular tissue, and pericycle, and occurs on the inside of the endodermis. At strategic locations (endodermis and sometimes exodermis), the root apoplast is blocked by Casparian bands composed of lignin deposited in cell walls. Some endodermal and exodermal cells have conspicuous absence of lignin and suberin lamellae and are referred to as passage cells.

Water movement through the root apoplast is driven only by pressure gradients, while transport across a membrane-delimited pathway (transcellular; see Section 15.1.1) involves pressure and osmotic gradients. During transpiration,

FIGURE 15.10 Pathways of xylem loading of nutrients and water. (A) Stylized transverse section of a root showing root hair, epidermis, cortex, endodermis (End.) and stele. Pathways of nutrient and water movement across the root are indicated as well as key transport steps through plasmodesmata and plasma membranes. At the endodermis, Casparian bands block apoplastic nutrient transport. Hence nutrient movement must cross plasma membranes of each endodermal cell (EC) and pass to the stele via the symplasm or transcellularly, or once effluxed from endodermal cells via the apoplast. (B) Xylem parenchyma cells (XPC) load xylem tracheary elements (TE) through half-bordered pits where there is a concentration of membrane transporters.

pressure gradients dominate due to large tensions in the xylem. When transpiration rate is reduced, osmotic flow may dominate because without large pressure-driven flow solutes actively loaded into the stele are not diluted, creating an osmotic gradient. Depending upon genotype and environmental conditions, 30–80% of water flow across roots occurs via the cell-to-cell pathway (symplasmic plus transcellular, Fig. 15.2). For example, apoplastic barriers tend to develop more in roots subjected to dry soil, where a greater proportion of flow occurs via the cell-to-cell pathway. Genotype comparisons show that wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*) roots have a greater degree of tension-driven flow via the cell-to-cell pathway than those of lupine (*Lupinus angustifolius* L. and *Lupinus luteus* L.). Furthermore, wheat roots take up most water near their apices, while lupine roots take up water along a greater proportion of the root.

In the radial flow pathway, water flow per unit area increases toward the stele, since the same volume of flow must occur at the outer surface of the root and surface of the stele (water is incompressible). This is compensated for by a progressive increase in membrane hydraulic conductivity,

probably due to greater activity of aquaporins (Fig. 15.11). At interfaces between xylem parenchyma cells and TEs, concentrated flows are linked with high expression levels of aquaporins (Fig. 15.11D,E). The central role of aquaporins in radial water transport is well illustrated by antisense suppression of *NtAQP1* expression in *Nicotiana tabacum*, which results in halving of root hydraulic conductivity.

Nutrients are taken up into the symplasm mostly at the root surface (root hairs and epidermal cells) and within the cortex. Endodermal cells retrieve nutrients swept along with water in the root apoplast (Fig. 15.10). Some nutrients and salt (NaCl) may leak around the apoplastic barriers (“bypass flow”) in the endodermis and are directly swept to the xylem. This can occur where apoplastic barriers are not well developed or where lateral roots emerging from the stele cause breaks in these barriers. Mutants compromised in endodermal barrier development have decreased ability to maintain potassium supply to the shoot.

Unloading of symplasmic nutrients occurs in the stele from endodermal or xylem parenchyma cells. Different transporters and channels are located in the stele compared to cortex and epidermis (Fig. 15.12). Whereas cortical and epidermal transporters take up nutrients at very dilute concentrations, those in xylem parenchyma cells need to release nutrients. An exception is where phloem delivers nutrients, such as K^+ , within the stele. These nutrients are taken up by xylem parenchyma cells, released into TEs, and transported back to the shoot. Amino-N and K^+ are recycled in this fashion, with about 30% of the K^+ delivered to the xylem originating from phloem. Another exception is the transport of sodium from the xylem to prevent excessive movement to the shoot. This can be the basis of salt tolerance in some plants.

In xylem parenchyma cells, anions such as NO_3^- and Cl^- are released passively into TEs by a variety of anion channels, while both highly selective and nonselective cation channels may release ions such as K^+ and Na^+ . The release of Na^+ and Cl^- into the xylem is a focus in salinity research because reduced xylem loading of both these ions could prevent salt damage to shoots. For both reabsorption and xylem loading of ions, the proton efflux pump (H^+ -ATPase) is critical (Fig. 15.12A). This pump establishes voltage and proton gradients that drive passive transport of ions (voltage gradients) and transport of other molecules and ions coupled to the flow of protons (see Box 15.2 and Chapter 3). TE sap pH also signals soil water stress to shoots.

Total osmolality of xylem sap is usually less than 40 mosmol kg^{-1} , or about -0.1 MPa osmotic potential, a relatively small component of total water potential. Nutrient concentrations of TE sap vary with soil nutrient composition, water flow rates, and plant nutritional status; for example, depending on conditions, NO_3^- may be reduced to organic N in parenchyma cells of roots or shoots, thus contributing to variable NO_3^- levels in xylem saps (Table 15.2).

In some cases, the roles of transporters in xylem loading have been established from gene silencing techniques. The SKOR protein is expressed in xylem parenchyma and pericycle cells and is a K^+ efflux channel (Fig. 15.12A). Knockout of the

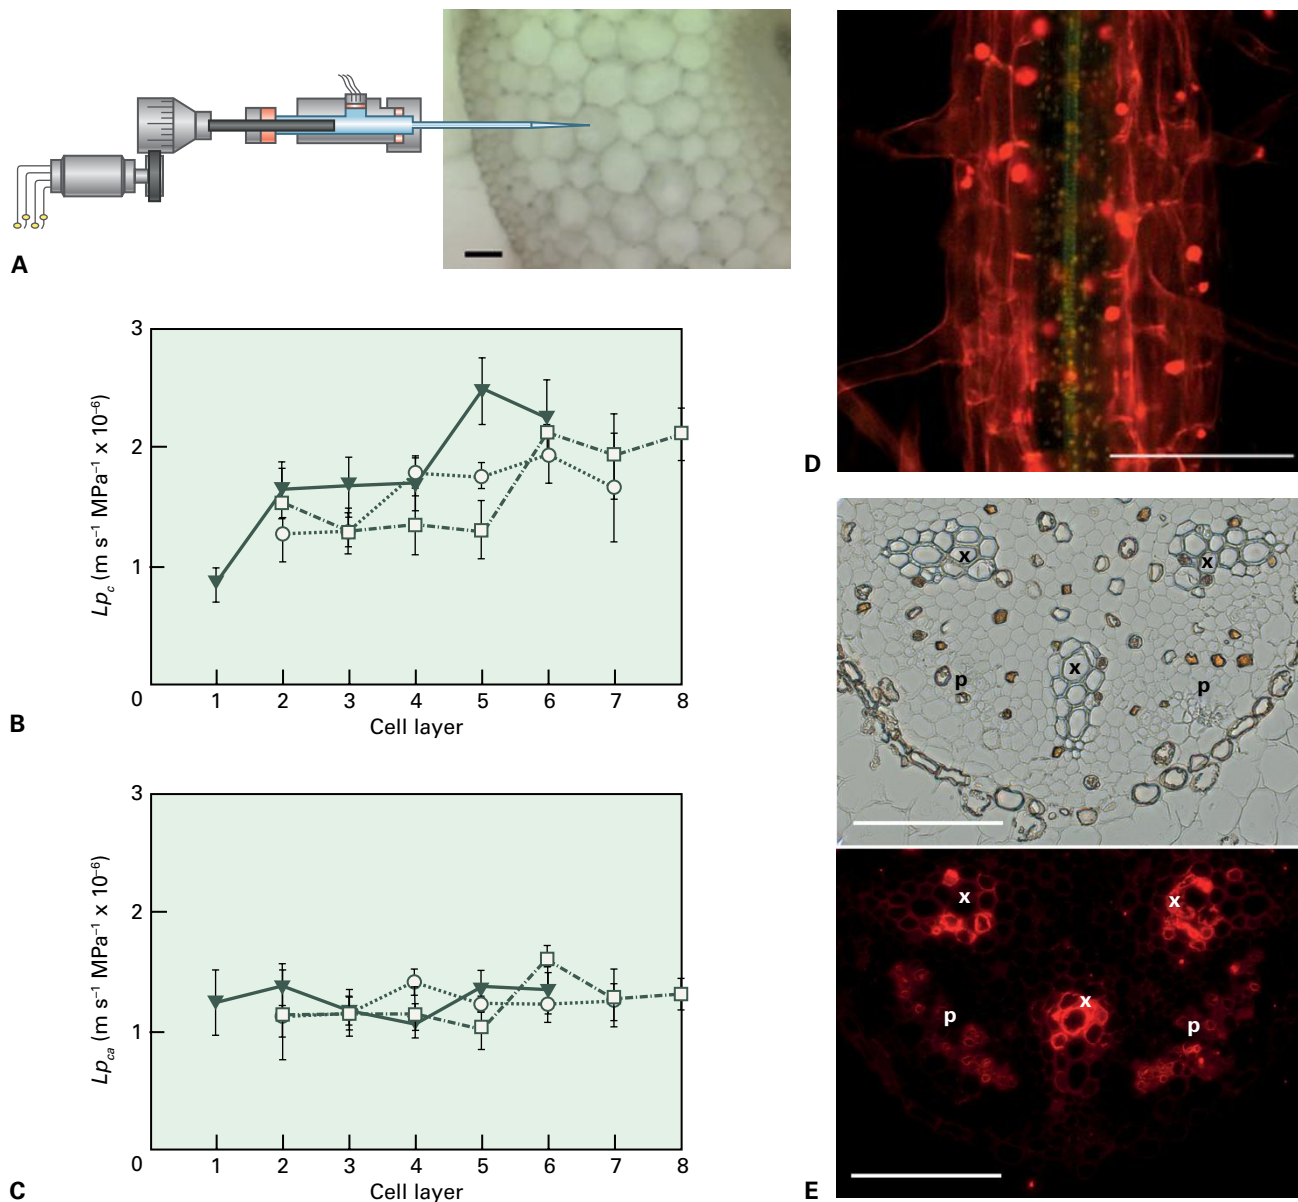

FIGURE 15.11 Water transport across roots and loading into xylem is characterized by an increased inward radial flux of transport towards the center of the root. (A) Cell pressure probe measuring hydraulic conductivities (L_p and see Box 15.2) of cells at different positions across the root. Scale bar = 50 μm . (B) For three contrasting plant species (indicated by different symbols) cell membrane L_p s are similar and increase radially towards the root center. (C) When cell $L_{p_{ca}}$ are scaled to the progressively reduced total cell membrane surface area across the root, effective L_p is constant across the respective cell layers. This indicates that L_p compensates for increased flux of water flow towards the root center. (D, E) In the stele, aquaporin expression is often highly concentrated around TEs to accommodate increased flux of water flow at this point. (D) Confocal micrograph of an Arabidopsis root from plants expressing a GFP-AtPIP2;3 construct stained with propidium iodide (cell walls red). Expression of the aquaporin AtPIP2;3 is closely associated with a TE and is visualized by the green signal from the GFP promoter fusion. (E) Immunolocalization of PIP1 protein in a grapevine (*Vitis vinifera*) root. Light micrograph of a stele cross-section (upper image) and fluorescent image below with intense (red) staining showing localization of PIP1 adjacent to xylem (X) and phloem (P) (in lower image). Scale bars = 100 μm . Source: (A–C) Bramley et al. (2009). *Plant Physiology*. 150(1):348–364. (D) Wang; (E, F) Vandeleur et al. (2008). *Plant Physiology*.

SKOR gene with a T-DNA insertion results in 50% decline in K^+ transport to shoots. Similarly, when zinc pumps HMA2 and HMA4 are knocked out, the double mutant accumulates zinc in roots and displays zinc deficiency in shoots. Transporter asymmetries across root cells indicate a highly directional nutrient transport. Rice silicon transporters Lsi1 and Lsi2 are located at different faces of epidermal and endodermal cells (Fig. 15.12B); Lsi1, which is related to aquaporins, acts as a passive channel

allowing silicon entry on the outside face of cells, while Lsi2 actively extrudes silicon from cells into the root apoplast.

Xylem loading is under control of hormones and other signals from shoots (Fig. 15.12A). Xylem loading of K^+ is related to shoot K^+ status, and phloem import of K^+ from shoots may function in this role. The plant hormone abscisic acid (ABA), recycled from shoots in the phloem, affects SKOR efflux activity and represses SKOR expression. ABA

FIGURE 15.12 Directional transport to the xylem occurs by a combination of specialized transporters in certain cells and different transporters on different sides of the same cell. (A) Directional transfer of K^+ to the xylem by different types of transporters located in epidermal/cortical versus xylem parenchyma cells. Common to all cells are H^+ -ATPases (green) that energize membranes for both nutrient uptake and xylem loading. In the stele, phloem unloads K^+ , a large proportion of which is reloaded into the xylem. K channels that load the TEs are also regulated by abscisic acid (ABA). (B) Directional transfer also is mediated by transporter asymmetry within a single cell type as illustrated by two silicon transporters (Lsi1 and Lsi2) in endodermal cells (EC), immunolocalized with antibodies raised against Lsi1 and Lsi2. Scale bars = 100 μ m. Source: De Boer and Volkov (2003). *Plant Cell and Environment* 26:87–101; De Boer (1999). *Plant Biology* 1:36–45.

also downregulates release of anions via an anion channel located in the stele. ABA accumulates under water stress, so that decreased xylem loading of ions allows roots to accumulate solutes under water stress, helping to maintain their

TABLE 15.2 Concentration of major solutes in the xylem sap of three plants.

Solute/Species	Concentration (mM)		
	Poplar	Banksia	Sunflower
NO_3^-	1–3	0.01	5–15

turgor pressure and growth (see Chapter 22). This analysis accounts for the independence of xylem loading of nutrients and delivery rate to shoots of water flow.

15.3.3 Concentrations of substances in the xylem are regulated during flow to their destination

In the axial pathway through roots/stems to transpiring leaves, water, nutrients, and hormones are able to exchange with xylem parenchyma cells to facilitate transfer between TEs, and between phloem and TEs. Concentrations of nutrients and toxic ions may be modified, depending on where TEs deliver their contents. Some plants can retrieve Na^+ from TE sap within their stems or woody trunks.

Nitrogen (N) in TE saps flowing to growing shoots is enriched by xylem-to-xylem transfer of organic N (amino acids) rather than NO_3^- between leaf traces in nodes. Similarly, xylem-to-phloem transfer enriches organic N content of phloem sap exported from leaves. This transfer diverts N supply from fully expanded leaves and enhances N delivery to growing regions.

15.3.4 Unloading of water and nutrients in leaves involves specific cellular pathways and transporters

A network of major and minor veins distributes water and nutrients to all parts of a leaf (see Section 15.4.3), such that any cell in a leaf is no more than a few cell layers from a minor vein. Minor veins are often encased in a layer of distinct cells referred to as a bundle sheath. Just as in roots, water and nutrients may flow from xylem to sites of evaporation via apoplastic or symplasmic pathways. Membrane-impermeant polar dyes loaded into petioles of transpiring leaves have shown that

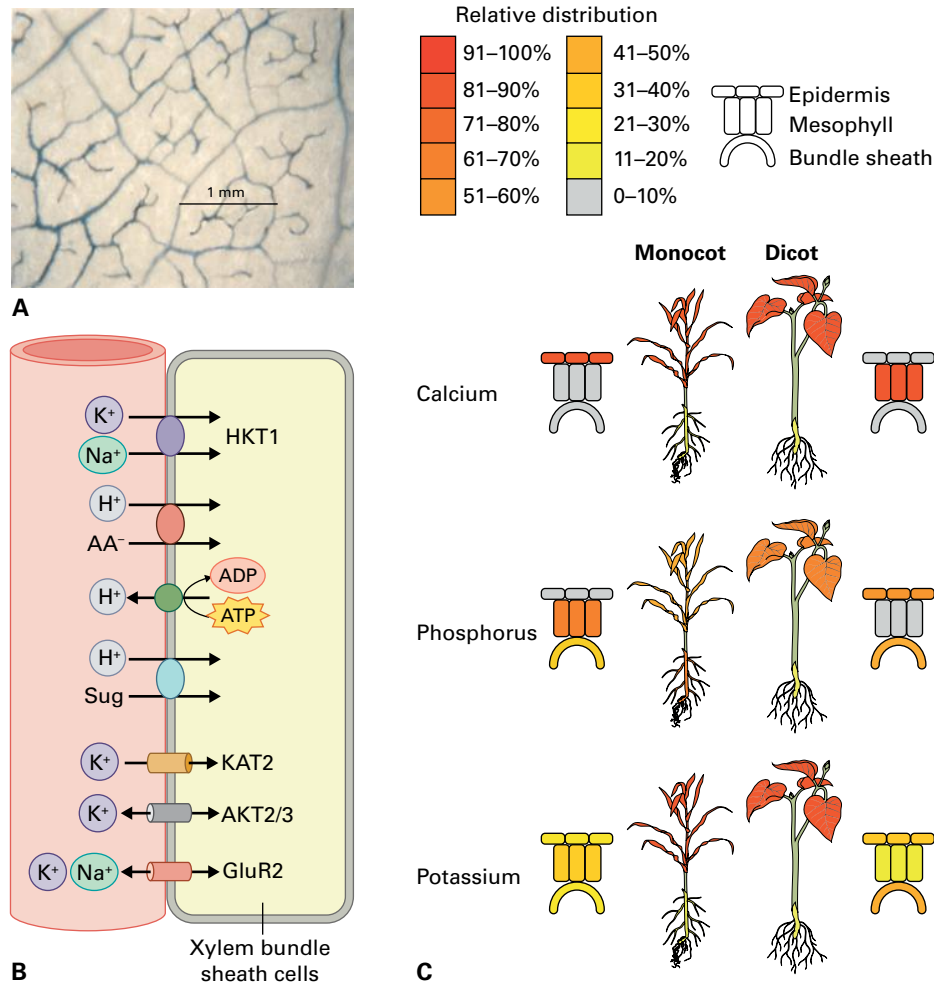

FIGURE 15.13 Xylem unloading in leaves involves symplasmic transport and directional membrane transport. (A) As the transpiration stream exits minor veins, xylem-borne solutes that are unable to move with water into the symplasm are left behind in the minor vein apoplast as shown by the distribution of Evans Blue introduced into the xylem transpiration stream of a detached castor bean (*Ricinus communis*) leaf. (B) Xylem bundle sheath cells have a variety of transporters that control unloading and redistribution of nutrients. Note that as for root loading, H^+ -ATPases energize membranes to run secondary active transporters [e.g., HKT1 Na^+ transporter, amino acid transporters (AA), sugar transporters (sug)] and channels (KAT2 and AKT2/3 K^+ channels and a nonselective GluR2 channel). This is only a small selection of transporters expected to function in xylem unloading. (C) Relative accumulation profiles of selected elements Ca, P, K at the organ level and cell-specific levels within the leaf. Model monocot (left side of each figure) and eudicot (right) shown with shoot and root concentrations. Stylized leaf cross-section shown for both monocot and eudicot represented as a heat map showing relative proportion of [ion] within the leaf. Note that the concentrations of Ca and P are reciprocal in the mesophyll and epidermis and have opposite profiles between monocots and eudicots, however there are exceptions to this allocation. The Ca distribution is positively associated with the distribution in different cell types of CAX type Ca transporters on the vacuolar membrane. Source: (A) D. Fisher, Washington State University, Pullman; previously unpublished.

apoplastic movement is blocked as soon as the dyes exit xylem vessels in minor veins at the bundle sheath interface (Fig. 15.13A). Thereafter, water and nutrients enter xylem parenchyma/bundle sheath cells to follow a symplasmic pathway. A membrane transport step in the water-unloading pathway is consistent with light-dependent hydraulic conductance of leaves correlating with aquaporin expression. An exception is Ca^{2+} , which moves predominately through the apoplast to the sites of storage in specific cell types in the leaf (see below).

Specific transporters are involved in xylem unloading (Fig. 15.13B). For example, AtHKT1, located in plasma membranes of leaf xylem parenchyma cells, protects leaves from Na^+ stress by recirculating Na^+ . Disrupting AtHKT1 expression increases Na^+ concentrations in TE sap and decreases

them in ST sap. An iron-nicotianamine transporter (AtYSL1) expressed in leaf xylem parenchyma cells is implicated in iron and nicotianamine (an iron chelate) redistribution. There are other examples of specific transporters located more or less exclusively to xylem parenchyma cells.

Nutrients are targeted to different cell types in leaves in phylogenetically distinct patterns of ion accumulation (Fig. 15.13C). For instance, Ca^{2+} accumulates in the epidermal cells but not mesophyll or bundle sheath cells of most grasses. In contrast, eudicots accumulate Ca^{2+} in palisade or spongy mesophyll, but not epidermal cells. Nutrient concentrations in leaf apoplasts also appear to be highly regulated and have been implicated in turgor pressure regulation of leaf cells and in stomatal control.

15.4 Short-distance transport events between phloem and nonvascular cells

15.4.1 Phloem can be divided into three sequential functional sectors

Angiosperm phloem comprises three sequential sectors, each of which has a specific function (Fig. 15.14). Photoassimilates produced by mesophyll cells, and minerals plus amino N compounds arriving in the transpiration stream from roots (see Section 15.3.4), together with water, are loaded into **collection phloem** (phloem loading) located within minor veins of fully expanded leaves (sources – net resource exporters). Loaded resources are translocated by the **transport phloem** through the main veins of source leaves, petioles, and ultimately stem and/or root axes (phloem transport) to be distributed between

FIGURE 15.14 Phloem includes three functional zones: collection, transport and release phloem. These functions may be associated with size ratios (oval insets represent cross-sections of SE/CCs with CC sections in yellow) between CCs and SEs that progressively decrease from source to sink. Uptake and release of photoassimilates (violet arrows) into/from SEs are accompanied by concurrent fluxes of water (blue arrows) along the phloem pathway. Influx and efflux of water are responsible for hydrostatic pressure (P) differences between ST ends in source (P_{so}) and sink (P_{si}) regions. Note that bulk flow continues into sink cells thus locating P_{si} at these sites. The blue gradient represents the presumptive hydrostatic pressure drop.

sinks (net resource importers). Resources delivered to **release phloem** are unloaded (phloem unloading) into expanding or storage cells of sink organs.

15.4.2 Collection phloem is the site of SE loading

Photosynthetic source leaves are the principal organs supporting phloem loading. **Phloem loading** includes all transport processes responsible for transferring resources from their cellular sites of acquisition and storage to SE/CC complexes. The ultimate step of resource transfer into SE/CCs is referred to as **SE loading** and may follow an apoplastic or symplasmic route (Fig. 15.15).

15.4.3 Nutrients move symplasmically from mesophyll to bundle sheath or phloem parenchyma cells of collection phloem located in minor veins

Functional leaf design, and in particular venation patterns, optimize photoassimilate transport from mesophyll cells to SE/CC complexes. In eudicots, vein systems are mostly reticulate, with branching extending from two to seven orders (Fig. 15.16A). Veins with the highest order of

FIGURE 15.15 Modes of phloem loading and associated terminology. Phloem loading comprises a series of transport processes within a phloem-loading zone. Loading into SE/CC complexes is called SE loading and is preceded by nutrient transport through a pre-SE pathway. If SE/CC complexes are symplasmically coupled to MCs and phloem loading is not reduced by membrane transport inhibitors (see Fig. 15.18B, C), SE loading is defined as being symplasmic. If SE/CC complexes are symplasmically isolated and phloem-loading rate is slowed by membrane-transport inhibitors (see Fig. 15.18D, E), SE loading is defined as being apoplastic. Various combinations of cell types can border the SE/CC complexes. MC, mesophyll cell; BSC, bundle sheath cell; PPC, phloem parenchyma cell; CC, companion cell; SE, sieve element. Paired horizontal lines represent plasmodesmata.

FIGURE 15.16 Leaf structure in relation to phloem loading and export. (A, B) Light micrographs of venation patterns in whole leaf segments bleached to remove chlorophyll and visualize their vasculatures. (A) Branched venation in the leaf of fava bean (*Vicia faba*); a eudicot. Phloem loading occurs into minor veins (MV), but small veins around leaf areoles (a) also may be involved. Lower-order (i.e., larger) veins export nutrients. (B) Parallel venation in the leaf of barley (*Hordeum vulgare*); a monocot. Parallel-oriented small (SLV), intermediate (ILV) and large (LLV) longitudinal veins are connected by transverse veins (TV). Phloem loading occurs into SLVs and ILVs, ILVs and LLVs export nutrients. (C, D) Cross-sections of a tomato (*Solanum esculentum*) and barley leaves. (C) Photoassimilates are transported (dashed arrows) symplasmically from palisade (PP) and spongy (SP) mesophyll cells through bundle sheath (BS) cells towards phloem parenchyma cells in minor veins (MV) where photoassimilates are loaded into the phloem. EP, epidermis. SE loading may occur symplasmically or apoplastically (see Fig. 15.15). (D) Photoassimilates are transported symplasmically (dashed arrows) from mesophyll cells (MC) through BS cells towards phloem parenchyma cells of small longitudinal veins (SLV). Sieve-element loading may occur symplasmically or apoplastically (see Fig. 15.15). Stomata (S) in epidermis (EP). Source: K. Ehlers, University of Giessen, Germany.

branching—minor veins—contain one or a few TEs and one or a few SE/CC complexes. Thus, by generating a large catchment area for photoassimilates in intimate contact with mesophyll cells, minor vein networks form the major site for phloem loading (Fig. 15.16A,C). Vein systems of monocot leaves comprise parallel small, intermediate, and large vascular bundles (Fig. 15.16B). Transverse veins interconnect longitudinal veins. Small and intermediate longitudinal veins (Fig. 15.16B,D) collect photoassimilates, while transverse veins transfer photoassimilates from small to large veins for export from leaves.

The densities of plasmodesmal interconnections infer photoassimilates move symplasmically from mesophyll to bundle sheath or phloem parenchyma cells of minor veins (Fig. 15.15; 15.16C,D). A *Z. mays* (maize) mutant (*sucrose export defective1—sxd1*) provides compelling evidence for symplasmic transport. The lesion results in structurally deformed plasmodesmata located between bundle sheath and

phloem parenchyma cells of small longitudinal veins, and this deformation causes a pronounced reduction in photoassimilate export.

15.4.4 Composition of sieve tube sap identifies compounds loaded into the phloem

A handicap in collecting ST sap for analysis is that STs occlude in response to damage (see Section 15.6.4). However, a few plant species continue exuding ST sap after excision. Included among these are *Ricinus communis*, many palms, some lilies, and several cucurbits. Given the restricted number of exuding species, alternative methods for ST sap collection have been designed. For example, Ca^{2+} chelators such as EDTA prolong exudation of ST sap by preventing Ca^{2+} -induced sieve-plate occlusion (see

Section 15.6.4), but a disadvantage of organ excision is the potential contamination by nonphloem sap compounds. The most sophisticated method is to collect ST exudates from cut aphid stylets inserted into STs. Damage inflicted by the thin (1 μm in diameter) stylet tips does not induce sieve plate occlusion (see Box 15.3), and pure phloem sap can exude for up to 24 hours in monocotyledons.

ST sap contains 10–12% dry matter and 88–90% water, rendering water the most abundant transported substance. Dissolved in ST sap are nonreducing sugars, amino N compounds, organic acids, inorganic ions, hormones, RNAs,

proteins, and a wide range of plant-specific secondary metabolites. These substances collectively buffer ST sap at pH 7.0–7.5 and generate high osmotic potentials (Ψ_{π} of -1.4 to -2.0 MPa; Table 15.3, Fig. 15.6C).

Sugars account for up to 80% of sap osmotic content. Most herbs translocate sucrose; two groups of plants have other sugar profiles in their ST sap, but both still contain a proportion of sucrose. One group translocates sugar alcohols or polyols (principally mannitol or sorbitol), and the other translocates sugars belonging to the raffinose family oligosaccharides (RFOs, Fig. 15.17).

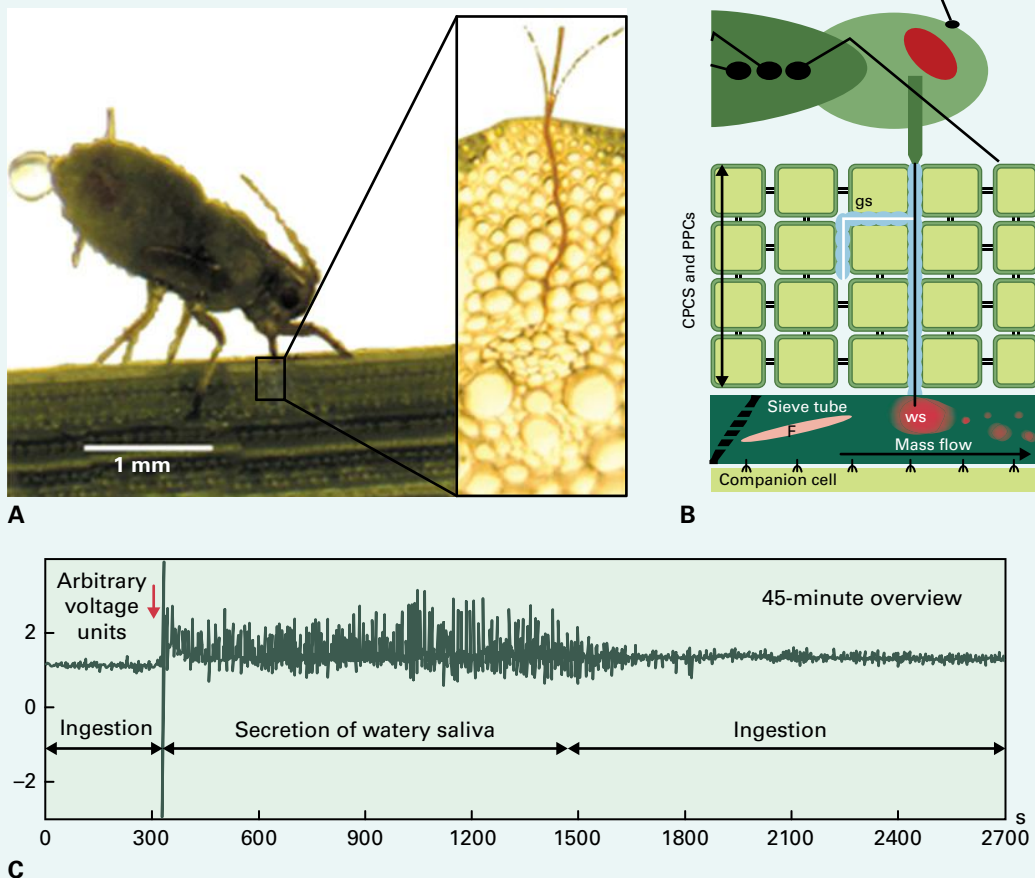

BOX 15.3

Aphid feeding and collection of ST exudates

Aphids feed from nutrient-rich ST content and have developed navigation mechanisms to track STs. Aphids insert their mouthparts (stylet) into shared cell walls between epidermal cells and steer them through cortex parenchyma (CPCs) and phloem parenchyma (PPCs) cells towards STs (A,B). It is almost certain that their navigation depends on continuously probing cell contents. During this stage, aphids excrete gel saliva (gs, B), which promptly hardens into a tubule through which

their soft and flexible stylet is driven forward (B). Tubules can be stained to visualize the stylet path (inset A).

Upon puncturing a SE, aphids change their behavior by suddenly secreting masses of watery saliva (ws, B). During this stage, stylets can be separated from the aphid body by microcautery. Hydrostatic pressure in STs propels phloem sap through cut stylets and drops of pure ST sap can be collected. However, stylets are often occluded by phloem-specific proteins, particularly in

eudicots. Hence, the method is mainly applied for collection of ST sap from monocots over relatively short periods (<24 hours).

Electropenetrogram studies record electrical currents produced by muscular movements of aphids and membrane potentials of impaled cells (C). They demonstrate that secretion of watery saliva is followed by a regular pattern coincident with alternating uptake of ST sap driven by pressure flow and delivery of small amounts of watery saliva.

One function of watery saliva was discovered recently. Burning (red arrow in C) a broad bean (*Vicia faba*) leaf of an intact plant triggers an electric potential wave along STs

initiating a massive Ca^{2+} influx into STs causing forisomes to disperse to block sieve pores (and see Section 15.6.6). Such an event deprives aphids of their food supply. As a response, aphids located several centimeters away on a main vein subjected to burning switch abruptly from ingestion to saliva secretion (C). After an extended period of secretion (≈ 20 min, C), the ingestion pattern is resumed. Coincidence between ST occlusion and intensified saliva secretion is interpreted as a mechanism to unblock the phloem pathway. Since ST occlusion is Ca^{2+} dependent, salivation could act to bind Ca^{2+} as it contains several Ca^{2+} binding proteins and other proteins that may be involved in detoxifying plant defense compounds.

TABLE 15.3 Sugar and amino acid concentrations in specified cellular compartments of leaves. Barley (monocot) and spinach (eudicot) transport sucrose as the principal sugar. In addition to sucrose, common plantain and celery transport the polyols, sorbitol and mannitol respectively.

Plant spp.	Transported compound	Concentration (mM) in		
		Mesophyll cytosol	Leaf apoplast	Phloem sap
Barley	Sucrose	232	1.5	1030
	Total amino acids	275	3.1	830
Spinach	Sucrose	53	1.3	830
	Total amino acids	86	3.24	192
Common plantain	Sorbitol	133	5.5	422
	Sucrose	12	0.3	645
Celery	Mannitol	100	6.7	732
	Sucrose	86	1.2	389

A broad spectrum of amino acids and other nitrogenous compounds (ureides, citrulline, allantoin, allantoic acid) are also present in ST saps. Abundance of amide/amino acid couples of glutamine/glutamate and asparagine/aspartate is particularly striking.

For inorganic compounds and elements, K^+ is the only species that makes a major contribution to osmotic potential of ST sap (60–100 mM). Mg^{2+} and H_2PO_4^- occur at considerably lower concentrations; concentrations of Na^+ , Fe^{2+} , Mn^{2+} , Cl^- , SO_4^{2-} and several microelements are even lower. NO_3^- and Ca^{2+} levels are present in the low nanomolar range.

Secondary metabolites are transported in STs including a range of terpenes, alkaloids and nitrogenous substances that act as deterrents or poisons against herbivores (see Section 15.4.10). Vitamins occur in appreciable concentrations. For instance, vitamin C (ascorbic acid) and glutathione play central roles in detoxifying oxygen radicals. Indeed, a complete antioxidative capacity exists in STs.

Signaling molecules, detected at physiological concentrations in ST sap, include fatty acids, hormones, putrescine, and cyclic AMP. A portion of phloem-specific proteins may be engaged in long-distance communication along with a cohort of RNA species (see Section 15.6.5).

15.4.5 SE loading requires an intricate interplay between cell structure and metabolism

Plants can be subdivided into groups depending on their principal form of translocated sugar (Fig. 15.17). This has a bearing on SE loading mechanisms for sugars as outlined below.

Plasmodesmal frequencies interconnecting SE/CCs to adjacent bundle sheath/phloem parenchyma cells and CC ultrastructure have been used to erect hypotheses for putative

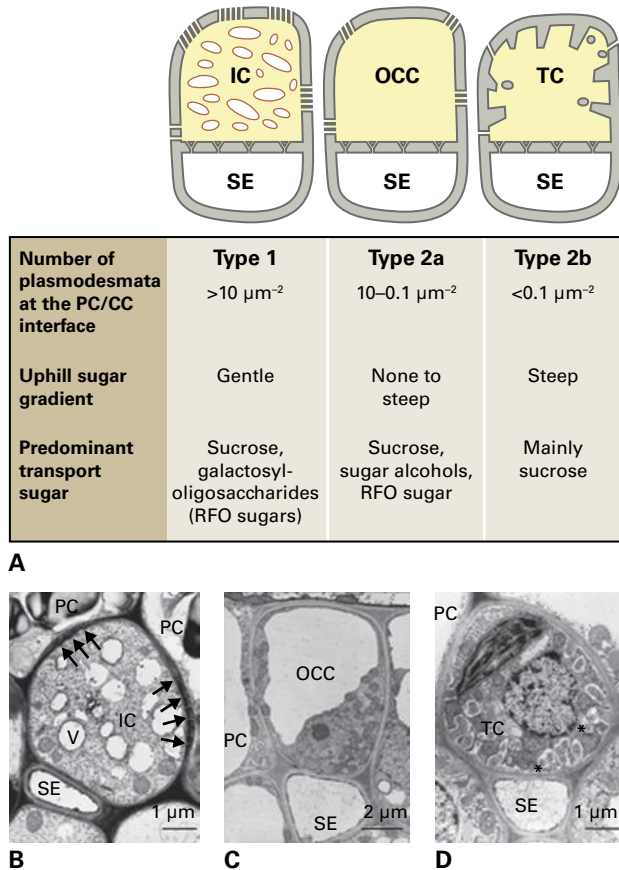

FIGURE 15.17 Relationship between minor vein CC ultrastructure and mode of phloem loading in eudicots. (A) Three types of CCs are distinguished by plasmodesmal (parallel groups of lines) densities interconnecting with phloem parenchyma (PC) or bundle sheath (BSC) cells, sugar gradient steepness from mesophyll cells (MC) to SE/CC complexes and transported sugar species. (B) Intermediary cells (ICs) characterized by numerous cytoplasmic vesicles (V) and many branched plasmodesmata at wall interfaces between PCs and ICs (arrows indicate plasmodesmal fields), load raffinose family oligosaccharides (RFOs) and sucrose. (C) Ordinary companion cells (OCCs) lack distinguishing structural features. This heterogeneous group exhibits varying densities of plasmodesmata at BSC/OCC or PC/OCC interfaces and loads a variety of sugars. (D) Companion cells modified with a transfer cell (TC) architecture, characterized by cell wall invaginations (asterisks) to increase their plasma membrane surface areas, have few plasmodesmata at PC/CC interfaces. Sucrose is the principal transported sugar. SE, sieve element. Source: (B, D) Oparka & Turgeon (1999). *Plant Cell* 11:739–750. (C) Reidel et al. (2009). *Plant Physiol.* 149:1601–1608.

pathways of SE loading (Fig. 15.17A). Minor vein configurations can be separated into two broad types based on apparent symplasmic continuities. Type 1 species, putative symplasmic loaders, have an “open” configuration with numerous plasmodesmal connections between CCs and bordering parenchyma cells. Their CCs invariably exhibit an intermediary cell ultrastructure (Fig. 15.17A,B). Type 2 species exhibit configurations with moderate to low PD densities between CCs and adjacent cells. They fall into two groups. The first group (Type 2A) possesses CCs lacking wall invaginations (Fig. 15.17C)

and may include both symplasmic and apoplastic loaders. The second group (Type 2B) exhibit a transfer cell morphology (Fig. 17.17D) and are exclusively apoplastic loaders.

A routine test for apoplastic SE loading is to determine the sensitivity of photoassimilate export to inhibition of plasma membrane transport (in general) with a membrane-impermeant sulfhydryl reagent, para-chloromercuribenzenesulfonic acid (PCMBs), and concurrently test for any confounding effect on leaf photosynthesis. Using these approaches, responses consistent with apoplastic SE loading of sucrose and polyols are found for a wide range of plant species with Type 2 minor vein configuration, particularly those with an herbaceous habit, including many crop species (Fig. 15.18).

PCMBs-insensitive export of photoassimilate from source leaves (Fig. 15.18B,C) indicates symplasmic phloem loading. SE/CC complexes of these responders exhibit plasmodesmal frequencies greater than $1 \mu\text{m}^{-2}$ (i.e., Type 1 and Type 2a—Fig. 15.17A–C). However, several species with Type 2a configuration function as apoplastic loaders, indicating that structure alone does not determine SE loading pathway. Moreover, vein anatomy and physiological evidence indicate that different loading paths can coexist; for instance, some Type 1 species also have CCs with or without wall ingrowths in the same minor veins (Fig. 15.19).

15.4.6 Apoplastic SE loading is determined by the cellular location and transport function of membrane-bound proteins

All apoplastic loaders verified to date translocate sucrose and/or polyols. Apoplastic loading includes two transmembrane steps: sugar release into the vein apoplast and subsequent uptake by SE/CC complexes (Fig. 15.15).

Until recently, membrane transport mechanism(s) responsible for sugar release to the vein apoplast eluded discovery. This gap in understanding was breached by cloning a novel class of sugar transporters, SWEETs (Sugar Will Eventually be Exported Transporters). These function as sugar facilitators capable of transporting sucrose and glucose in an efflux mode (see Chapter 3). Consistent with serving a major role in phloem loading, AtSWEET11 and 12 localize to the collection phloem and their double mutant caused carbohydrates accumulation in source leaves and photoassimilate export to be slowed.

The mode of sucrose uptake by SE/CC complexes is well understood. Here, a H^+ -symport mechanism loads sucrose or polyols into SE/CC complexes (Fig. 15.20 and Equation 15.B9; see also Chapter 3) to reach higher concentrations than in the surrounding leaf apoplast and mesophyll cytosol (Table 15.3). Several clades of sucrose/ H^+ symporters (SUTs or SUCs) localize to plasma membranes of minor vein SE/CCs to participate in apoplastic loading. High-affinity SUT1 isoforms (apparent K_m values of 0.5–2 mM; Equation 15.B9), depending upon plant species, are exclusively localized to SEs

FIGURE 15.18 Apoplastic and symplasmic phloem loading detected by exposing a leaf to a membrane-impermeant sulfhydryl reagent (PCMBS) that inactivates plasma membrane transporters. (A) PCMBS treatment of a leaf immediately slowed phloem export but had no effect on photosynthesis demonstrating that PCMBS had not entered leaf cells and had reacted exclusively with sulfhydryl groups on the outer surfaces of their plasma membrane. (B–E) Autoradiographic images of leaf discs of *Ipomea* (B, C) and *Pisum sativum* (pea) (D, E) floated on a solution containing [^{14}C]sucrose in the absence (B, D) or presence (C, E) of PCMBS. Without PCMBS, ^{14}C accumulated (white areas) by leaf discs was located in their collection phloem. In *Ipomea* leaves, phloem loading was unaffected by PCMBS (C) indicating a symplasmic loading pathway. In contrast, phloem loading was eliminated in pea leaves (E) exposed to PCMBS indicative of an apoplastic pathway of phloem loading. Source: (B, C) Madore & Lucas (1987). *Planta* 171:197–204; (D, E) Turgeon & Wimmers (1988). *Plant Physiol.* 87:179–182.

or CCs (Figs. 15.21 and 15.22B). Consistent with a mixed apoplastic and symplasmic loading system, a SUT1 localizes to SEs and OCCs but not to intermediary cells (ICs) of *Alonsoa meridionalis* leaves. Low-affinity SUT2 and SUT4 isoforms (apparent K_m values of ca. 10 mM) colocalize with SUT1 to minor vein SEs of solanaceous species. However, in other eudicot species SUT2 occurs in SEs and SUT1 localizes to CCs (Fig. 15.22B), while SUT4 targets to tonoplast of mesophyll cells. In leaves of *Plantago major*, two high-affinity

polyol/ H^+ transporters, PmPLT1 and PmLT2, colocalized to CCs of minor veins and concentrate polyols in SEs (Table 15.3).

Reverse genetics demonstrate that SUT1s play key roles in apoplastic SE loading, as shown by downregulated *SUT1* expression causing substantial reductions of photoassimilate export. In contrast, knockdown of plasma membrane localized SUT4 in potato elevated rates of photoassimilate export (Table 3.5) perhaps reflecting a post-translational control of SUT1 transporter activity. However, in those species where

FIGURE 15.19 Different SE/CC configurations occur in one minor vein indicating that phloem-loading modes operate in parallel in some species. Transverse EM sections show that (A) Minor veins of *Acanthus mollis* contain two SEs each flanked by an IC and one central SE accompanied by a TC. (B) Minor veins of *Coleus blumei* possess two SEs flanked by ICs and several central SEs accompanied by ordinary CCs. (C) Minor veins of *Cucumis sativus* show two IC/SE complexes at the bottom and a SE with an ordinary CC at the top. IC, intermediary cell; TC, companion cell modified to a transfer-cell morphology. Arrows and arrowheads point to pit fields of plasmodesmata.

FIGURE 15.20 Supplying sucrose causes a sharp depolarization of ST membrane potential suggesting a sucrose/ H^+ symport mechanism for phloem loading. An exuding aphid stylet was used to measure ST membrane potential in a strip of phloem from a willow (*Salix exigua*) branch. Introducing a 100 mM sucrose solution bathing the surface was followed several minutes later by a sucrose-free solution.

SUT4 localizes to the tonoplast, SUT4 knockdowns inhibited phloem loading consistent with SUT4 functioning to release vacuolar-stored sucrose to buffer cytoplasmic sucrose pools for export.

Sugar symporters colocalize with H^+ -ATPases in minor veins. The proton extrusion activities generate *pmfs* to drive sucrose/ H^+ symport into SE/CC complexes (Equation 15.B10 and Fig. 15.20). This function has been verified by suppressed expression of an H^+ -ATPase causing lowered sucrose content of ST exudates (Table 15.4).

Phloem loading of amino acids and amides depends upon a complex series of relationships. These include root/leaf localization of nitrate reductase (see Chapter 16), extent of xylem–phloem exchange along the transport phloem, and degree of leaf senescence (see Chapter 20), or exposure to abiotic stress (see Chapter 22), during which peptides also can be loaded. Comparison of amino acid concentrations in mesophyll cells and ST exudates (Table 15.3) demonstrates that an active phloem loading mechanism must operate. Based on expression and localization studies, a broad range of amino acid and amide transporters have been implicated in phloem

FIGURE 15.21 Diagram illustrating cellular localization of transporters responsible for apoplastic phloem loading. Sugars and amino acids are delivered symplasmically from mesophyll and released to the phloem apoplast from phloem parenchyma cells (PPCs) by an unknown set of transporters (question marks). Amino acids are delivered to the phloem apoplast directly from the xylem transpiration stream along with K^+ and water. Plasma membrane H^+ -ATPases, localized to CCs, generate a steep pmf used to drive proton co-transport of sucrose, polyols and amino acids into SE/CC complexes. K^+ channels retrieve K^+ and sustain SE/CC membrane potentials. Water flows into SE/CC via aquaporins.

Plant spp	Suppressed expression of:	Relative rate of photoassimilate export (% wild type)
Tobacco	<i>NtSUT1</i>	18
<i>Arabidopsis</i>	<i>AtSUT1</i>	51
Potato	<i>StSUT4</i>	306
Tobacco	<i>pma4</i>	38

loading including those functioning in release to the vein apoplast (e.g. *AtSIARS1*, *AtBAT1*) and uptake into SE/CC complexes (e.g. AAPs, *AtCAT6* and *9*, *AtProT1*; see Chapter 3). For instance, overexpressing *PsAAP1* targeted to SE/CC complexes in the collection phloem enhanced phloem loading in pea (*Pisum sativum*).

Ions are delivered to leaves in the transpiration stream (see Section 15.3.4) and can load directly from the vein apoplast into SE/CC complexes as illustrated for K^+ (Fig. 15.21). Inward rectifying K^+ channels, detected in protoplasts derived from CCs and SEs (Fig. 15.22), may account for loading of K^+ to high concentrations (60–100 mM). With an increasing interest in food quality, phloem transport of transition elements such as iron (Fe) and zinc (Zn) have received recent attention.

Intermediary	-4.4	0.2	334

A

B

FIGURE 15.23 Symplasmic loading of RFO sugars occurs in Type 1 minor vein configurations (Fig. 15.17A, C). (A) RFO sugar concentrations and osmotic potentials in mesophyll, bundle sheath and intermediary cells (ICs) of a cucurbit leaf. ND, no data. (B) ‘Polymer trap’ model for symplasmic phloem loading. Sucrose (and in some plants, galactinol) moves symplasmically into ICs and is used to synthesize RFOs, raffinose and stachyose. These sugars can diffuse from ICs into SEs through large-diameter PPUs but their molecular size excludes backward diffusion through small plasmodesmal orifices connecting ICs with bundle sheath cells.

15.4.7 During symplasmic SE loading, a trapping mechanism concentrates sugars in SEs

In view of an unlikely active transport through plasmodesmata, accumulating RFOs in SE/CC complexes (Fig. 15.23A) has presented a perplexing challenge. For these species, a “polymer trap” model accounts for this phenomenon, whereby sucrose, synthesized in mesophyll cells, diffuses down a concentration gradient via plasmodesmata to ICs in minor veins (Fig. 15.23B). There, sucrose is used to synthesize the larger RFO molecules raffinose and stachyose. Synthesis of these sugars maintains the concentration gradient to drive diffusion of sucrose from mesophyll cells to ICs. The larger size of RFOs prevents them from moving symplasmically back from ICs to mesophyll cells, but they can pass through the much larger PPUs to SEs. This model is consistent with RFO synthesis in ICs, where their concentrations are much higher than in mesophyll cells. In addition, suppression of RFO synthesis by downregulating two galactinol synthase genes reduced photoassimilate export from leaves.

In several Type 2A species, which translocate mostly non-RFO sugars, total osmotic concentrations are similar in mesophyll cells and minor vein SE/CC complexes. These observations suggest sugars move by bulk flow through an uninterrupted symplasm from mesophyll cells to STs. This phenomenon may be more ubiquitous than previously thought, especially in woody species. In these cases, phloem loading is passive and does not depend upon expenditure of metabolic energy.

15.4.8 In collection phloem, water flows accompany phloem loading of nutrients

Apoplasmic loading of sucrose and polyols and symplasmic loading of RFOs generate steep concentration and osmotic gradients between phloem parenchyma and SE/CC complexes. These gradients induce large water fluxes across the plasma membranes of SE/CC complexes in the range of $7 \times 10^{-10} \text{ m}^3 \text{ m}^{-2} \text{ s}^{-1}$, which require osmotic water permeability values of $40\text{--}200 \mu\text{m s}^{-1}$ corresponding to those expected for membranes containing high densities of aquaporins. Indeed, aquaporins have been detected in minor vein CCs. Water entering SE/CC complexes is drawn from minor vein apoplasts and replenished by the transpiration stream (Fig. 15.21). Simultaneous measurements of hydrostatic and osmotic pressures of ST sap sampled by stylectomy (Box 15.3) estimate ST sap water potentials to be -1.0 to -1.5 MPa (Table 15.5). These values are more negative than those of TE sap in hydrated transpiring leaves of herbaceous plants (≈ -0.5 MPa) and leaves entering incipient wilting (ca. -1.4 MPa). Thus, ST sap water potentials are more negative than those of the surrounding apoplasmic fluid, allowing phloem loading of water under most conditions. For those symplasmic loading species, in which total osmotic concentrations are similar in mesophyll cells and minor vein SE/CC complexes, water inflow would be expected to occur along the entire phloem-loading pathways.

TABLE 15.5 Minimum and maximum hydrostatic pressures (P) in, and sap osmotic potentials (π) of, sieve tubes.

Plant spp.	Water relation parameter	Potential (MPa)	
		Minimum value	Maximum value
Barley	Hydrostatic pressure	+0.8	+1.4
	Osmotic potential	-1.9	-2.6
	Water potential	-1.1	-1.2
Sow thistle	Hydrostatic pressure	+1.0	+1.5
	Osmotic potential	-2.0	-3.0
	Water potential	-1.0	-1.5

Measurements of well-watered barley and sow thistle plants using aphid stylectomy. Estimates of ST sap water potentials (Ψ) are derived from these measurements (see Equation 15.B7).

15.4.9 Transport phloem is an underestimated, but important transport player

Transport phloem translocates resources and signals from collection phloem to release phloem. Whereas collection and release phloem zones are commonly a few hundred microns long, transport phloem covers large distances from source leaves to root and shoot apices, distances of 0.1–3 m (small to large herbs; shrubs) up to 100 m (tall trees).

The impact of transport phloem on nutrient transport and distribution is much greater than has been attributed by the pressure flow hypothesis of phloem translocation, which treats the transport phloem as an inert and impermeable pipe. Emerging evidence shows that transport phloem sustains onward longitudinal flux by buffering ST sap concentrations (and hence hydrostatic pressures) to deliver resources and signals to adjacent nonvascular cells and exert a pronounced influence on ST sap composition. Such dynamic functions are attributable to SE-associated cells (CCs, phloem parenchyma cells), since SEs possess a limited metabolic capacity (see Section 15.2.3).

15.4.10 Transport phloem function relies in interaction between SEs, CCs, and phloem parenchyma cells

During their lifetime, which can last for 30 years, CCs remain functionally competent to produce or process metabolites needed by SEs. In addition to supplying energy substrates (Fig. 15.24), CCs probably execute turnover of structural macromolecular components channeled to SEs via their PPU (see Section 15.6.5). This intricate interrelationship between SEs and CCs hampers assessment of their individual contributions to their collective functioning, though future

studies using CC and SE protoplasts may discriminate between their individual functions.

Phloem parenchyma cells are probably of paramount importance for phloem physiology. Given their location, it is plausible they act as sites for temporary carbohydrate storage (Fig. 15.25A). In transport phloem, plasmodesmal frequency between CCs and adjacent phloem parenchyma cells is generally low, indicative of restricted capacity for lateral symplasmic exchange of molecules along transport phloem. ST-limited translocation of membrane-impermeant fluorochromes shows these plasmodesmata are closed under conditions in which sink demand exceeds source supply (source-limiting conditions) (Fig. 15.25B); when source supply exceeds sink demand, plasmodesmata at this interface gate open (Fig. 15.25C).

Phloem parenchyma cells also function in plant defense. For instance, in solanaceous plants, phloem parenchyma cells produce the protein prosystemin. In response to an unknown signal, polypeptide systemin is cleaved from prosystemin and released into SEs. Upon arrival in sink organs, systemin triggers production of proteinase inhibitors that block protein digestion by herbivorous insects. A spectacular example of interactive phloem cell biology is the division of labor between SE/CCs and phloem parenchyma cells in producing benzyloisoquinoline alkaloids abundant in laticifers of opium poppy (*Papaver somniferum*). The morphinian pathway enzymes are absent from latex but reside in SEs, with their transcripts localized to CCs. This suggests trafficking of transcripts and secondary metabolites via plasmodesmata and PPUs and subsequent transport to laticifers.

15.4.11 Lateral exchange of nutrients occurs from transport phloem

Release along transport phloem supplies nutrients for storage and supports secondary growth and cell maintenance. Mature petioles, stems, and roots (axial sinks) function as short-term

FIGURE 15.24 Sieve element function depends on genetic and metabolic contributions by companion cells. (A) Absence of metabolic machinery in SEs (Table 15.1) is compensated by high densities of mitochondria (dark areas indicated by arrowheads) in CCs. (B) Potential energy transfer between SEs and CCs. There are three potential ways to maintain sugar concentrations in SEs. (1) Sucrose (SUC) retrieved by sucrose/ H^+ -symporters energized by CC-generated pmf and transferred to SEs via PPU in their common cell wall (CW). (2) ATP produced by CC mitochondria moves via PPU to SEs and energizes proton pumps in energy-deficient SEs. The pmf drives sucrose symporters in SE plasma membranes. (3) Electrogenic potential generated by proton pumps in CC partly propagates via plasma membranes to SEs via PPU. There, the electrogenic potential contributes to pmf fuelling sucrose symporters in SEs. Deployment of sucrose/ H^+ -symporters on CC- or SE-plasma membranes can account for retrieval of sucrose. Not shown, the electrogenic component of the pmf, generated by the proton pump, can be augmented or replaced by K^+ release through AKT2 channels located on the SE/CC plasma membranes – the so-called K^+ battery. Source: (A) van Bel & Kempers (1991). *Planta* 183:69–76.

reservoirs for nutrients released from transport phloem that are ultimately reloaded and translocated to other (terminal) sinks (Fig. 15.25); residence times extend from seconds to months.

A high-turnover sucrose pool resides in the transport phloem apoplast, which is fed by large passive fluxes from SE/CC complexes that are driven by substantial outward gradients in sucrose concentrations across the plasma membranes. For instance, in bean (*P. vulgaris*) plants, STs lose 6% of photoassimilates per centimeter of stem, and two-thirds of this is retrieved. The phloem apoplastic pool buffers photoassimilate concentrations and, hence, hydrostatic pressures of STs through a continuous cycle of release and retrieval of photoassimilates by sugar/ H^+ symport (Figs. 15.24B, 15.25A).

Apoplastic sucrose concentrations in stems range from 3 to 70 mM. Consistent with this concentration range, retrieval by transport phloem involves a complex of low- and high-affinity sugar transporters localized to SE/CC complexes. In fact, qualitative profiles of SUT clades and their cellular localization in collection phloem (see Section 15.4.6) are reproduced

in transport phloem. This finding applies equally to amino N carriers and K^+ channels. Collectively these transporters function in retrieving nutrients leaked to phloem apoplast back into SE/CC complexes. However, competition for sugars leaked to phloem apoplast between SE/CC retrieval and allocation to lateral storage pools is likely as suggested by localization of a mannitol symporter to SEs, CCs, and phloem parenchyma cells of celery (*Apium graveolens*) petioles.

In some monocot stems a suberin band, deposited in walls of bundle sheath cells, blocks radial transport through the stem apoplast, and a symplasmic path is essential at least for this component of the unloading pathway. Indeed, the entire phloem-unloading pathway follows a symplasmic route in wheat and rice stems during storage product accumulation (Fig. 15.26A,C). Here, sucrose symporters located in SE/CC complexes (Fig. 15.26B,D) likely retrieve sucrose leaked to the phloem apoplast. Interestingly, a switch to an apoplastic loading step occurs at SE/CCs coincident with remobilization of stem reserves to support grain filling. Radial transport in eudicot stems also can switch reversibly between apoplastic and symplasmic routes (Fig. 15.25).

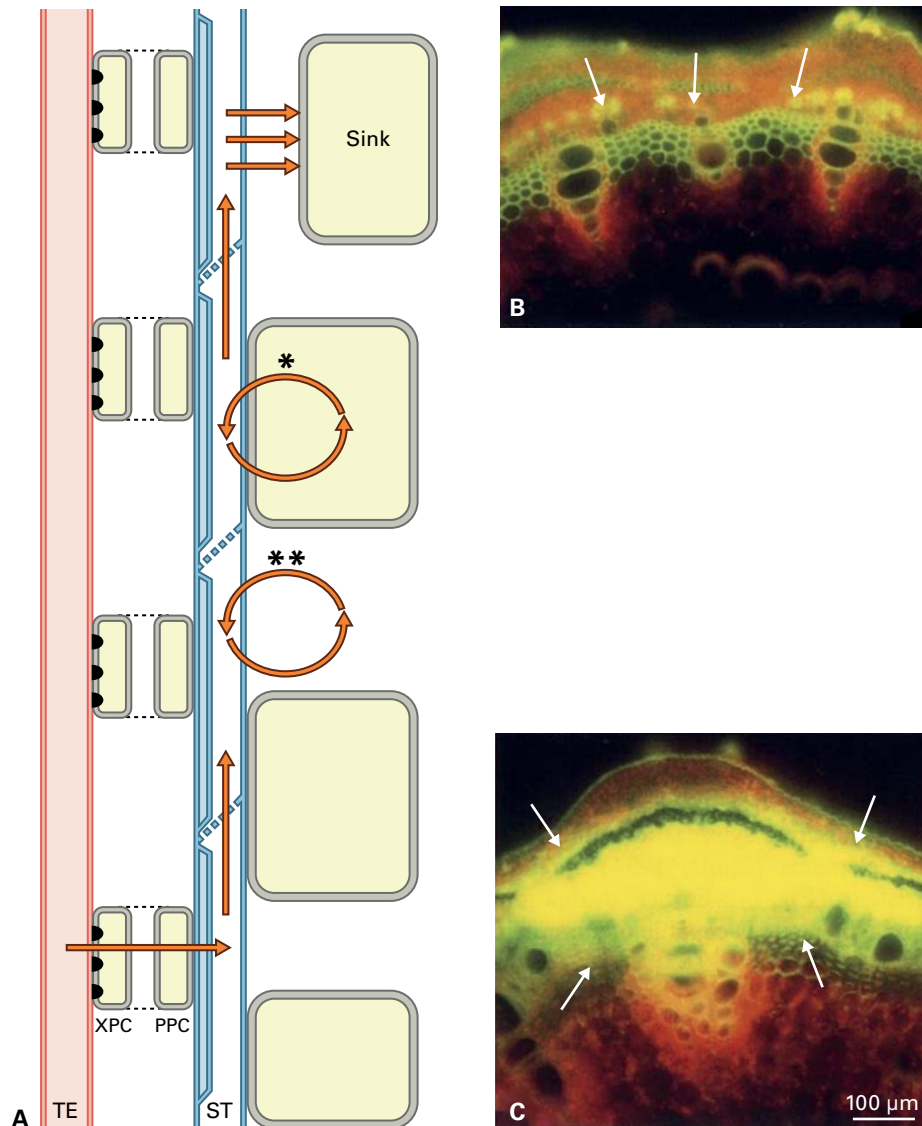

FIGURE 15.25 Nutrient exchange between transport phloem and surrounding tissues. (A) Diagrammatic representation of nutrient exchanges with transport phloem (P). Nutrients (amino N compounds and mineral elements), retrieved from TEs by xylem parenchyma cells (XPC, mostly with cell wall invaginations – black circles) are transported along a radial pathway (dashed lines) and loaded via phloem parenchyma cells (PPC) into STs for delivery to sinks. During movement through the transport phloem, nutrients are reversibly exchanged (circular arrows) with surrounding tissues into long-term (*) or short-term (**) storage pools. Long-term (days to months) storage of nutrients occurs in PPCs and nonvascular cells. Under lowered source/sink ratios, these substances are re-mobilized and loaded into the transport phloem. Short-term (minutes to hours) storage occurs in the axial apoplast. Rapid bi-directional exchanges of nutrients across plasma membranes of SE/CC complexes act to buffer their hydrostatic pressures and sap nutrient concentrations. (B–C) Source-sink ratios influence the cellular pathway of lateral nutrient exchange as indicated by distribution of a membrane-impermeant fluorescent dye, carboxyfluorescein (CF), loaded into source leaf phloem. (B) Fluorescent micrograph of a free-hand cross section of a bean (*P. vulgaris*) stem, pruned to a low source/sink ratio, showing CF (arrows; bright yellow fluorescence), restricted to SE/CC complexes of transport phloem demonstrating these are symplasmically isolated from surrounding cells. (C) Fluorescent micrograph of a free-hand cross section of a *P. vulgaris* stem, pruned to high source/sink ratio, showing CF has moved from SE/CC complexes into surrounding cells (arrows; bright yellow fluorescence) indicating symplasmic continuity between transport phloem and surrounding cells. 15.4.12 Release phloem mediates phloem unloading

Phloem unloading describes the intercellular transport of resources from SEs to sink cells. Components of this pathway include **SE unloading** arranged in series with subsequent

intercellular transport through vascular and nonvascular cells (**post-SE transport**) (Fig. 15.27). Resources may be unloaded from primary or secondary phloem (see Section 15.2.1) depending upon sink type. Unloading occurs from protophloem in **growth sinks** and from primary (metaphloem) or secondary phloem in **storage sinks**.

FIGURE 15.26 Transport phloem in stems of wheat (A, B) and rice (C, D) showing escape of fluorescent carboxyfluorescein from phloem (broken white outline) into surrounding ground tissues (A, C) illustrating presence of a symplasmic unloading route. Sucrose/ H^+ symporters were immunolocalized localized to SEs in wheat (B; arrows, strong fluorescence of a bound SUT1 antibody labeled with a fluorescent secondary antibody) and SE and CCs in rice (D; arrow, grey-blue immunocytochemical staining of cell walls catalyzed by a phosphatase conjugated secondary antibody labeling a bound SUT1 antibody). X = xylem.

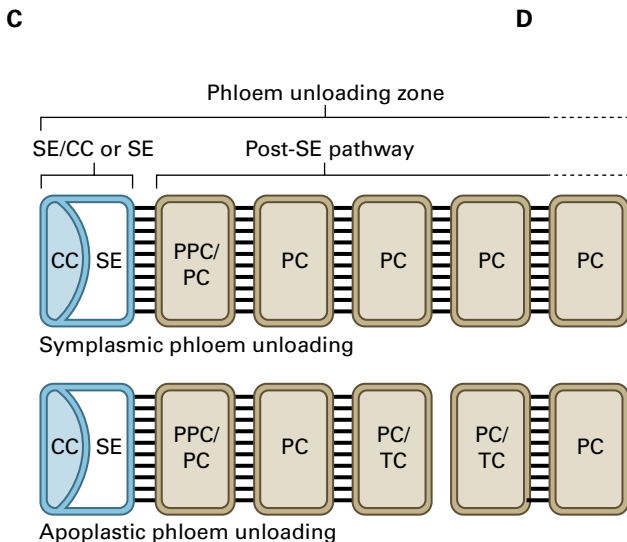

FIGURE 15.27 Phloem unloading comprises a series of transport processes located in an array of cells (SE with or without CC; PPC, phloem parenchyma cell; PC, parenchyma cell; TC, transfer cell) designated as the phloem-unloading zone. Phloem loading and unloading are defined by similar principles (see Fig. 15.18) with one modification. Phloem unloading is defined as apoplastic if an apoplastic step occurs in the post-SE unloading pathway (lower row). SE unloading is predominantly symplasmic (see Table 15.6).

15.4.13 Phloem sap exit from SEs is commonly symplasmic

For most sinks, SE unloading follows a symplasmic route, and only a small fraction of nutrients unloaded from SE are released directly to the phloem apoplast. Apoplastic routes are constrained by the limited plasma membrane surface areas of protophloem SEs and metaphloem SE/CC complexes and, hence, the transporter densities required to support efflux of nutrients (Table 15.6).

A major fraction of SE unloading likely occurs by bulk flow through plasmodesmata connecting SEs or SE/CC complexes with adjacent phloem parenchyma cells. The flow is driven by large hydrostatic pressure differences across this interface (Fig. 15.28). The canal diameters of these plasmodesmata could be as high as 8 nm, conferring a substantial increase (50- to 256-fold) in hydraulic conductivity over plasmodesmata of 2–3 nm in diameter (Equation 15.B5), which are found in other tissues. Thus, both hydrostatic pressure differences and plasmodesmal hydraulic conductances favor bulk flow (Equation 15.B4).

TABLE 15.6 Putative plasma membrane (10^{-8} mol m^{-2} membrane surface area s^{-1}) and plasmodesmal (10^{-4} mol m^{-2} plasmodesmal cross-sectional area s^{-1}) fluxes of sucrose from protophloem SEs or metaphloem SE/CCs in a selection of growth and storage sinks.

Sink	Potential plasma membrane flux		Plasmodesmal fluxes between:		
	Putative	% contribution	SE or SE/CC–PPC	PPC–PPC	PPCvNVC
Barely root protophloem (no CCs)	700	1.4	77	ND	ND
Elongating bean stem					
Protophloem	43	23	No PD connections with protophloem SEs		
Metaphloem	56	18	47	0.5	6
Mature bean stem	7	100	20	2	6
Developing seeds

Tomato fruit					
*Symplasmic	290	3.4	14	4	34
†Apoplasmic	11.3	89	0.1	0.2	660

Putative sucrose fluxes estimated from dry weight gains, accounting for respiratory losses, of each importing organ. In addition, each flux estimate is derived on the grounds that all sucrose moves through the specified membrane or interconnecting plasmodesmatal cross sectional areas measured from histological sections.

Percentage maximal contribution to total membrane flux capped by maximal capacity for facilitated membrane transport of 10×10^{-8} mol m^{-2} s^{-1} . For example, % contribution of the plasma membrane flux for barley root protophloem is $(10/700 \times 100) = 1.4\%$. In contrast, the putative plasma membrane flux across the phloem of a mature stem of 7×10^{-8} mol m^{-2} s^{-1} is within the maximal capacity for facilitated membrane transport of 10×10^{-8} mol m^{-2} s^{-1} and hence the contribution of membrane transport is 100%. Reported range of plasmodesmal sucrose fluxes – 2 to 84×10^{-4} m^{-2} plasmodesmal cross-sectional area per second.

PPC, phloem parenchyma cell; NVC, nonvascular cell; ND, no data.

*Pre-maximal phase of sugar accumulation.

†Maximal phase of sugar accumulation.

FIGURE 15.28 Hydrostatic pressures of symplasmic unloading routes. Measured (SEs in grain and roots; PCs, root ground cells) or estimated (PPC, phloem parenchyma cell of grain and roots; PCs, maternal cells of grain) hydrostatic pressures in root apices and coats of developing wheat grains respectively show pronounced pressure differences (1.0–1.3 MPa) between SEs and adjoining cells (PPC; PC). In contrast, intercellular hydrostatic pressure differences along post-SE unloading pathway (see Fig. 15.27) tend to be minimal. Arrows indicate anticipated flows of nutrients (brown) and water (blue).

15.4.14 For post-SE transport, a symplasmic route is the common but not universal pathway

Structural precedents exist for symplasmic unloading in all sink types, as indicated by plasmodesmata connecting SEs through to sink cells (Fig. 15.27). This pathway is characterized

by a putative symplasmic constriction (i.e., low plasmodesmal densities) located at SE/ or SE-CC/phloem parenchyma cell boundaries causing the steep osmotic gradients across these boundaries (Table 15.6). These interconnecting plasmodesmata are transport-capable, as shown by passage of phloem-imported, membrane-impermeant fluorochromes.

During development, shifts between apoplasmic and symplasmic routes occur in root apices, tubers, and fleshy fruits

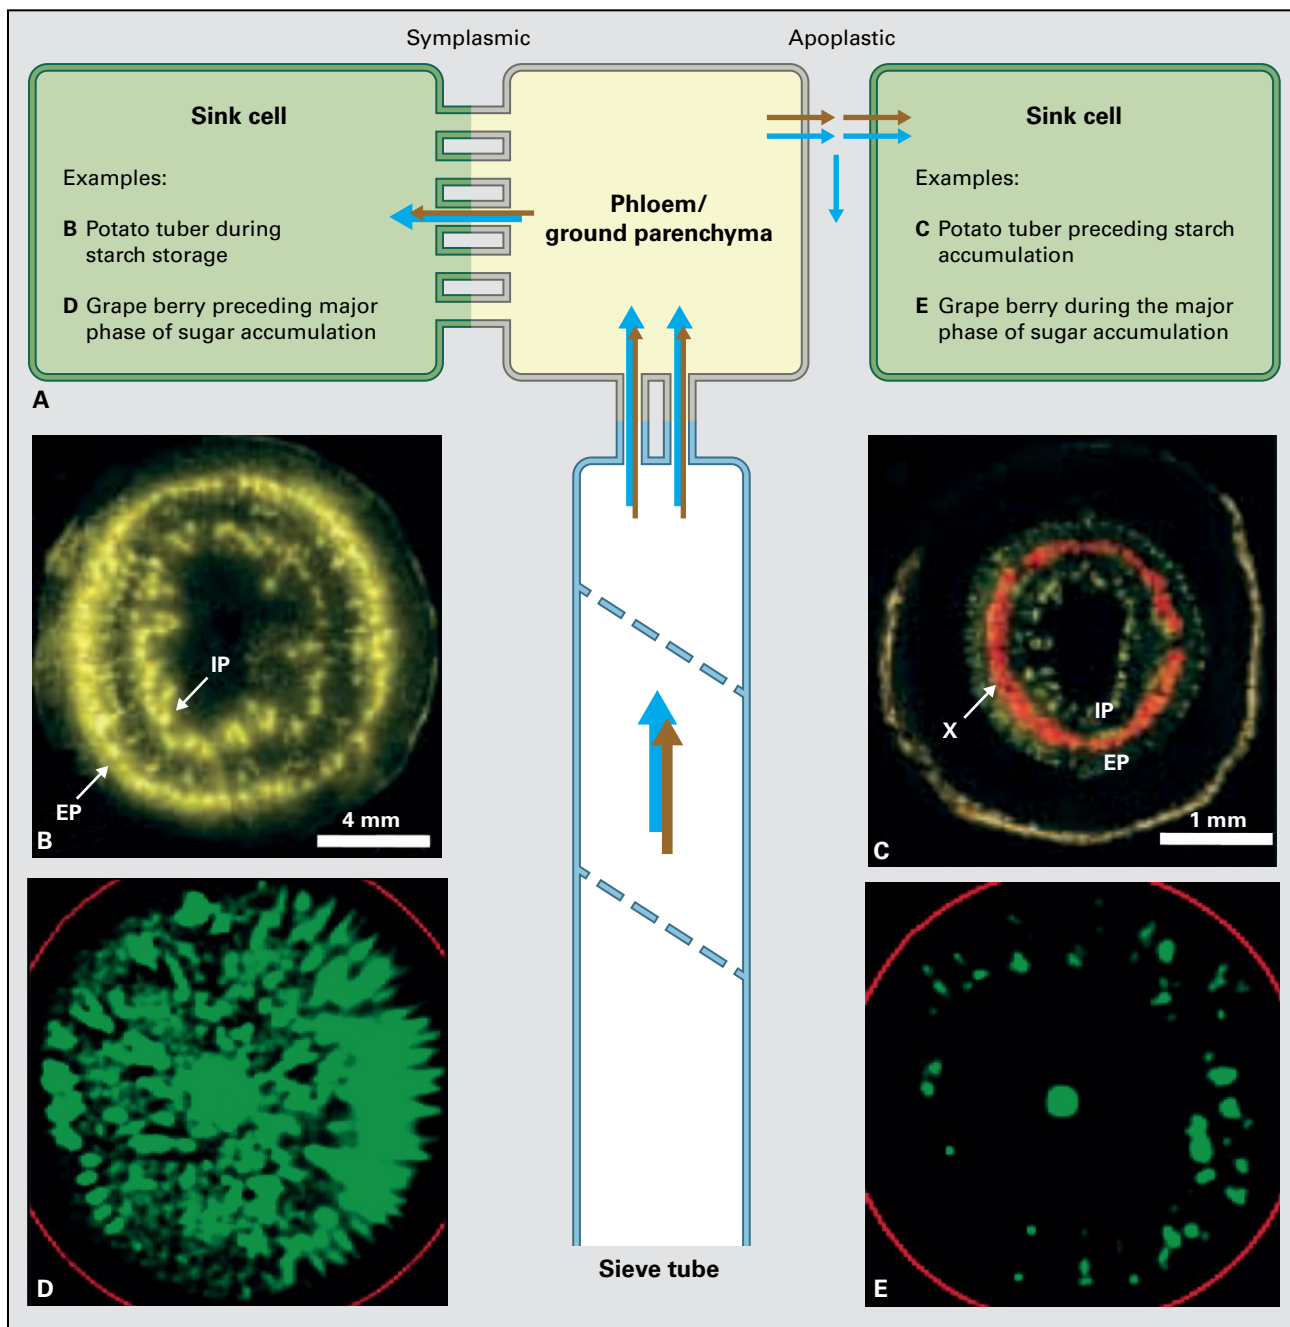

FIGURE 15.29 Developmentally programmed plasmodesmal gating in phloem unloading pathways. (A) Phloem-delivered water (blue arrows) and dissolved nutrients (brown arrows) are unloaded symplasmically from SEs into phloem parenchyma cells by bulk flow that may continue into ground parenchyma cells. Post-SE flows may be symplasmic (A, left) or include an apoplastic step (closed plasmodesmata) (A, right). Water may flow into expanding sink cells (horizontal blue arrow) or be re-cycled to the mature plant body through the xylem (vertical blue arrow). (B–E) Histological cross-sections showing distribution of phloem-imported carboxyfluorescein (CF) in: (B, C) Developing potato tubers prior to (C), and following (B), onset of starch accumulation during which time CF was restricted to (B), or disbursed from (C), internal (IP) and external (EP) phloem respectively. Xylem (X) is C stained with Texas Red dextran. (D, E) Developing grape berries (*Vitis vinifera*) prior to (D), and during (E), their major phase of sugar accumulation during which CF moved symplasmically from (D), or was retained by (E), berry vascular bundles. Source: (B, C) Viola et al. *Plant Cell* 13:385–396. (D, E) Zhang et al. (2006). *Plant Physiol.* 142:220–232.

(Fig. 15.29A). Before tuber initiation in potato stolons, plasmodesmata are closed and nutrient unloading from SE/CC complexes is apoplastic (Fig. 15.29C). Coincident with tuber swelling, internal and external phloem strands of tubers commence to unload symplasmically (Fig. 15.29B). Developing tomato (*Solanum lycopersicum*) fruit and grape (*Vitis vinifera*) berries exhibit a reverse behavior, with

phloem unloading switching from symplasmic to apoplastic pathways (Fig. 15.29D,E). Thus, symplasmic unloading is linked to polymer formation and apoplastic unloading with elevated intracellular sugar levels. Collectively, plasmodesmal gating along unloading pathways confers flexibility in regulating nutrient fluxes as sink function alters across development.

15.4.15 Nutrient movement occurs by a combination of diffusion and bulk flow through symplasmic pathways during post-SE unloading

A concentration gradient of a major osmotic solute translates into an osmotic pressure gradient. Thus, post-SE symplasmic unloading of nutrients includes diffusion and bulk flow components (Box 15.1). Their relative contributions depend upon the path conductances and driving forces for each transport mechanism.

Nutrient unloading by diffusion may be linked to sink cell metabolism and intracellular compartmentation, as these processes determine nutrient concentrations in the cytosol and concentration gradients from SEs to sink cells. A similar linkage is predicted for bulk flow in growth and polymer storage sinks, where metabolic interconversion to nonosmotic species maintains a low cell osmotic and hydrostatic pressure (Fig. 15.30A).

Consistent with diffusion contributing to unloading, photoassimilate import rates into root tips and stems immersed in sucrose solutions are inversely related to bath sucrose concentrations. Similarly, photoassimilate import responds inversely to alterations in sink cell hydrostatic pressures of developing seeds, root tips, and stems (Fig. 15.30B).

15.4.16 An apoplastic step occurs in certain post-SE unloading pathways

Nutrients traversing post-SE unloading pathways encounter symplasmic discontinuities at the interfaces between maternal seed coat and filial endosperm/embryo of developing seeds, in fleshy fruits, and in biotrophic relationships such as those formed between plant hosts and mycorrhizal or pathogenic fungi.

Once sugar accumulation commences in developing tomato fruit and grape berries, a symplasmic discontinuity develops at

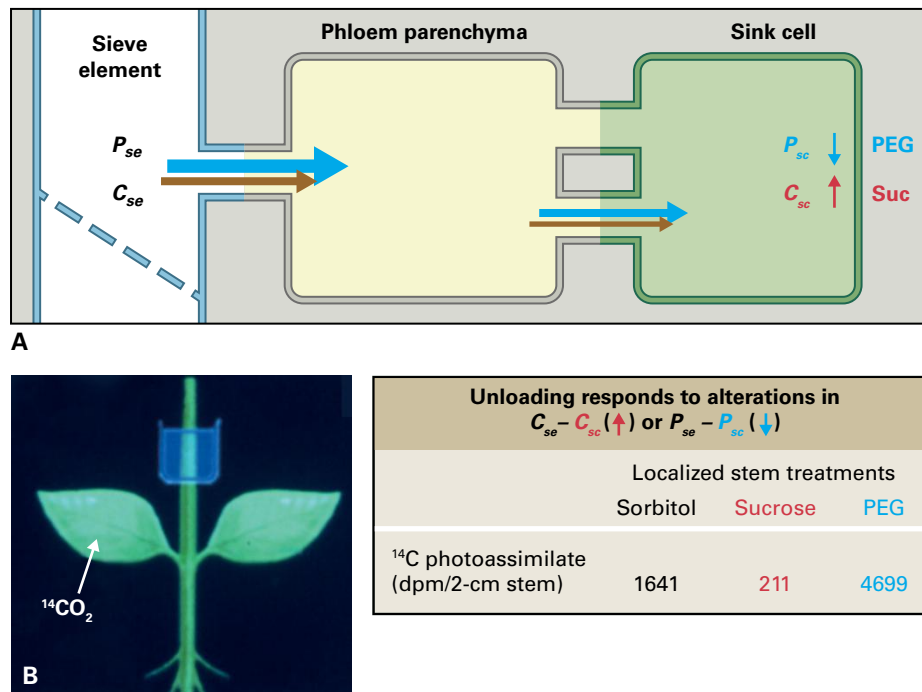

FIGURE 15.30 Symplasmic phloem unloading may be mediated by a combination of intercellular differences in hydrostatic pressure (bulk flow; $P_{se} - P_{sc}$) and/or sucrose concentrations (diffusion; $C_{se} - C_{sc}$ and see Equation 15.B1). (A) This proposition can be tested experimentally by increasing intracellular sucrose (C_{sc}) concentrations in, or lowering hydrostatic pressure (P_{sc}) of, sink cells by exposing these respectively and separately to solutions containing sorbitol, sucrose or polyethylene glycol (PEG; 8 kDa) at identical osmolalities. Sucrose is readily taken up thus increasing intracellular sucrose concentration in sink cells (C_{sc}) and hence lowering differences in sucrose concentration between SEs and sink cells ($C_{se} - C_{sc}$). A molecular size of 8 kDa prevents PEG from penetrating cell walls. Hence PEG exerts a local effect on the outermost cell layer by osmotically withdrawing cellular water. Consequently hydrostatic pressures (P_{sc}) are lowered thus increasing the hydrostatic pressure difference between SEs and sink cells (i.e., $P_{se} - P_{sc}$). A sorbitol solution of identical osmotic concentration is used to control for extracellular osmotic effects of sucrose. Both molecules permeate the stem apoplast resulting in no change in hydrostatic pressure difference between SEs and outermost cells (i.e., $P_{se} - P_{sc}$). Increasing C_{sc} would slow photoassimilate unloading by diffusion while decreasing P_{sc} would accelerate photoassimilate unloading by bulk flow. Arrows indicate movement of sucrose (brown) and water (blue) through a symplasmic unloading-pathway. (B) Experimental test of model proposed in (A) using accumulation of ^{14}C -labelled photoassimilates in bean (*Phaseolus vulgaris*) stems as a measure of phloem unloading. Bath solution containing sucrose, sorbitol or PEG held in wells positioned around the treated stems. Following several hours for equilibration with bath solutions, a source leaf is exposed to a pulse of $^{14}\text{CO}_2$ (left hand panel). Levels (dpm, disintegrations per minute) of ^{14}C -photoassimilates (i.e. primarily transported as sucrose) accumulated in treated stem portions provide measures of phloem unloading. The findings show increasing C_{sc} inhibits photoassimilate accumulation consistent with unloading by diffusion (cf. sorbitol treatment). In contrast, decreasing P_{sc} caused elevated photoassimilate accumulation (cf. sorbitol) indicating bulk flow drove unloading under these conditions.

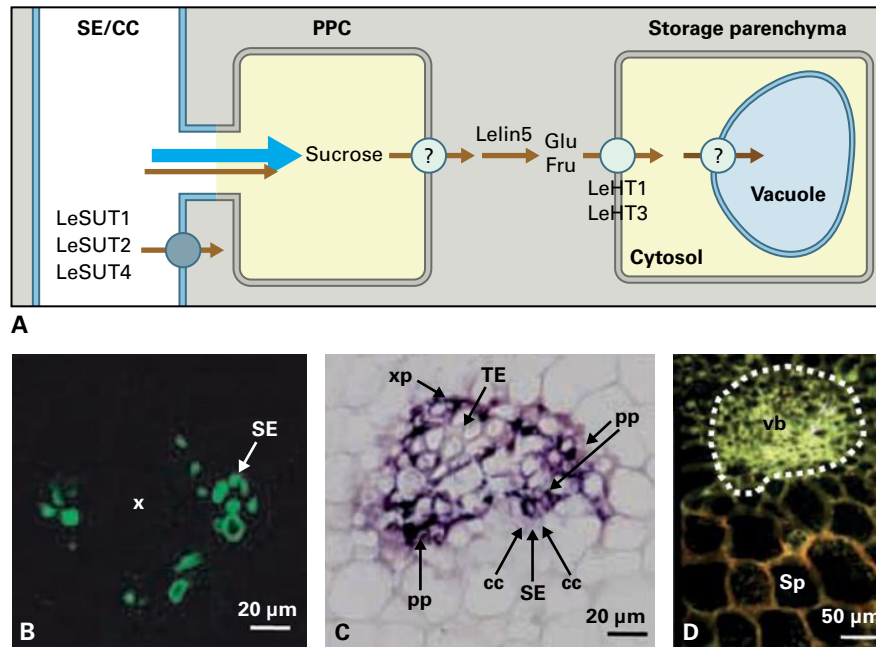

FIGURE 15.31 Pathway of phloem unloading and sugar transporter localization in developing tomato fruits. (A) Diagrammatic representation of the cellular pathway of phloem unloading. Sucrose efflux to fruit apoplast could occur by reversal of SUTs on SEs (see text) or through yet to be identified transporters in phloem parenchyma cells following symplasmic transport from SE/CC complexes by bulk flow (sucrose brown arrow; water blue arrow). An extracellular invertase (*LeLin5*) hydrolyzes released sucrose. Resulting hexoses are accumulated from the fruit apoplast into storage parenchyma cells by hexose/ H^+ symport mediated by *LeHT1* and *LeHT3*. Vacuolar compartmentation of hexoses is mediated by proton antiport across the tonoplast possibly by a tonoplast monosaccharide transporter. (B–D) Cellular localization of key sugar transport proteins and an extracellular invertase. (B) Immunolocalization of *LeSUT1* to SEs (green fluorescence). (C) In situ hybridization detected *LeLin5* transcript in phloem parenchyma cells (pp). xp, xylem parenchyma. (D) In situ hybridization detected *LeHT3* transcript colocalized to storage parenchyma cells (Sp and note orange signal) with H^+ -ATPase to create the pmf to drive hexose symport. These transporters were absent from vascular bundles (vb and delimited by a white broken line) suggesting nonenergized unloading of sugars to the fruit apoplast.

the vascular bundle/storage parenchyma interface in tomato (Fig. 15.31) and SE/CC complex/phloem parenchyma cells in grape (Fig. 15.29E). Symplasmic isolation of vascular and sink tissues ensures that elevated hydrostatic pressures or sugar concentrations in sink cells (e.g., 1 M hexoses in grape berries) do not compromise hydrostatic pressure or concentration differences driving photoassimilate import into these sinks. Dye-coupling experiments show that symplasmic continuity exists between importing SEs and nonphloem tissues in coats of developing seeds, but a symplasmic discontinuity exists at their coat/embryo interfaces (Fig. 15.32A). As a consequence in all examples described above, two plasma membrane transport steps are recruited: nutrient release into, followed by retrieval from the sink apoplast.

15.4.17 Nutrient release into and retrieval from the sink apoplast may occur during passage through post-SE unloading pathways

Simple diffusion, facilitated diffusion, and energy-coupled transport (see Box 15.2) have been proposed as mechanisms for nutrient release across efflux cell plasma membranes to sink apoplasts.

Predicted membrane fluxes by simple diffusion (Equation 15.B8) account for 50% of the observed sucrose flux direct from SE/CCs of tomato (*Solanum lycopersicon*) fruit, but less than 25% of the total membrane flux of sucrose from bean (*Phaseolus vulgaris*; *V. faba*) seed coats (Table 15.7). The unaccounted portion of these membrane fluxes must be facilitated (Equation 15.B9). In this context, SUTs and SUFs (sucrose facilitators) localize to efflux cells of fleshy fruits and inner coat cells of developing seeds (Figs. 15.31 and 15.32, respectively). If potential energy of the transmembrane sucrose concentration difference exceeds that of the pmf, sucrose/ H^+ symporters can function in an efflux mode (Equation 15.B11). For example, in developing seeds and fleshy fruit containing extracellular invertase activity (Figs. 15.31 and 15.32), sucrose concentrations in their apoplastic saps are 1 mM or less, and efflux cells have pmfs of -100 mV. Using these values in Equation 15.B11 predicts a cytosolic sucrose concentration of 48 mM, at which a SUT would reverse to facilitate sucrose efflux. Thus, under these conditions, SUT reversal is plausible as ST sap concentrations are an order of magnitude higher.

In sinks lacking extracellular invertase activity (e.g., storage phase grain legume and temperate cereal grain) or sinks importing polyols not hydrolyzed by invertase (e.g., apple fruit), sugar symporter reversal is an unlikely unloading mechanism. In these cases, predicted intracellular sugar

FIGURE 15.32 Nutrient movement to, and membrane transporters operating at, coat/embryo interface of developing legume seeds. (A) Diagrammatic representation of a broad bean (*Vicia faba*) seed showing chalazal (gray solid line) and smaller lateral (gray broken line) veins, continuous with the parental vasculature entering through the funiculus, forming a single vascular ring around the seed coat equatorial region. Phloem-imported nutrients are unloaded symplasmically and spread circumferentially around the seed coat (red broken line) before moving radially inward to the apoplastic space between seed coat and cotyledon (red arrows). (B) Diagram illustrating known membrane transporters (yellow symbols) responsible for exchanging phloem-imported nutrients from seed coat to cotyledons. Membrane transport to, and from, seed apoplastic space occurs in specialized cells that in some species exhibit transfer cell morphologies. Both maternal and filial transport cells are energized by H⁺-ATPases (purple symbols) that generate the pmf to drive sucrose/H⁺ antiport from seed coats, and proton-coupled symport of amino N compound and sugars into cotyledons. Sucrose facilitators are present in unloading cells of seed coats along with ion channels including ones exhibiting specificities for K⁺ (K outward rectified channel – KORC) and chloride as well as a nonselective channel (NSC) capable of transporting large molecular weight compounds. A nonselective cation channel (NSCC) occurs in cotyledon loading cells. An extracellular invertase (Inv) is only present during the pre-storage phase of seed fill.

TABLE 15.7 Predicted* and estimated† fluxes of sucrose across plasma membranes of putative unloading cells to the sink apoplast in developing seeds and fleshy fruit.

Sink organ and unloading cell types	Transmembrane concentration difference (mM)	*Predicted flux by simple diffusion (10 ⁻⁸ mol m ⁻² s ⁻¹)	†Estimated flux (10 ⁻⁸ mol m ⁻² s ⁻¹)

*Predicted sucrose flux by simple diffusion = membrane permeability coefficient × transmembrane concentration difference. Lipid membrane permeability coefficient for sucrose ≈ 10⁻¹⁰ m s⁻¹.

†Estimated membrane fluxes determined from measurements of total plasma membrane surface areas and rates of sucrose import computed from biomass gains and respiratory losses.

concentrations (Equation 15.B11) required to reverse symporter activity are nonphysiologically high. In this context, AtSWEET, 11, 12, and 15 sucrose effluxers account for a proportion of sucrose released from seed coats. The remaining sucrose flux might be energized by sucrose/proton antiport. In addition to sucrose, large quantities of mineral nutrients, notably K^+ and Cl^- , are released through membrane channels from legume seed coats to the seed apoplast (Fig. 15.32B).

Similar to apoplastic phloem loading (see Section 15.4.6), much more is known about nutrient retrieval from sink apoplastic spaces. In developing seeds, high densities of membrane transporters, together with H^+ -ATPases, colocalize to the outermost cell layers of their filial tissues (endosperm; embryo) that abut sites for nutrient release in coats (Fig. 15.32B). Reverse genetics demonstrate that amino acid and sucrose/ H^+ symporters play a crucial role in biomass gain by seeds. For example, knockdown of *OsSUT1* expression resulted in a shriveled grain phenotype in rice. Overexpression of a potato sucrose/ H^+ symporter (*StSUT1*) in *Pisum sativum* cotyledons enhanced rates of sucrose influx and biomass gain. Similarly, overexpression of *PsAAP1* in *P. sativum* seeds resulted in higher seed protein levels.

15.4.18 Phloem unloading also includes a flow of water

For growth sinks, imported phloem sap is the principal source of water for cell expansion, providing a direct link between phloem import and growth.

For storage sinks in which expansion growth has ceased, imported phloem water is recycled back to the mature plant body through the xylem following membrane exchange to the sink apoplast, possibly via aquaporins (Fig. 15.33). Such a system necessitates separation of nutrient and water flows at some point. Where ST saps are unloaded symplasmically, imported water could be exchanged to the sink apoplast along phloem unloading routes while imported nutrients are retained in the sink symplasm. Separation of water and nutrient flows are more critical in sinks in which an apoplastic step occurs in post-phloem unloading pathways (Figs. 15.31 and 15.32). Here, several strategies prevent imported nutrients released to sink apoplasts from being swept back to the parent plant body in water recycled to the xylem (Fig. 15.33).

15.5 Whole-plant organization of xylem transport

15.5.1 The cohesion-tension mechanism accounts for the ascent of sap

During transpiration, water evaporates from moistened cell walls lining the gas-filled spaces in leaves and then diffuses out of the leaf as vapor via open stomata. Surface tension in

micropores of cell walls places water under tension. For a capillary of diameter $0.01 \mu\text{m}$, such as those existing in leaf mesophyll cell walls, a tension of -15 MPa can occur. This is transmitted to water in TEs and down to root surfaces and soil solution. Thus, ascent of TE sap results from water being pulled along a continuous liquid pathway to leaf cell walls. This continuous unbroken file of water is aptly named the soil–plant–atmosphere continuum.

Air gaps in TEs cannot support large tensions necessary to counteract gravity and drive flow. Even the smallest diameter TEs ($10 \mu\text{m}$) can only maintain a height of 3 m by capillarity. Continuous water columns can only maintain a tension by virtue of cohesion through hydrogen bonding between water molecules. Centrifugation of water-filled capillaries and other measurements demonstrate that water can maintain tensions to -21 MPa , adequate to counteract gravity in tall trees.

Tensions within TEs and a continuous water column are crucial requirements of the cohesion–tension mechanism. Experimental observations have sometimes challenged these requirements but may suffer from disturbance of xylem tensions during measurement. The consensus is these tensions exist consistent with the cohesion–tension theorem, and controversy over the theorem relates more to the magnitude of the tensions rather than whether they exist, which is not in question. Recently an “artificial” tree was constructed using synthetic hydrogels to simulate microporous membranes in roots and leaves, connected by a microfluidic system with pore diameters between 11 and $73 \mu\text{m}$ and lengths up to 35 cm, similar to that of xylem vessels. Bulk flow through this system was demonstrated with tensions established in the “leaf” of up to -1.0 MPa (Fig. 15.34).

15.5.2 Cavitation is the Achilles heel of the cohesion–tension mechanism

TEs must remain filled with liquid water for sap ascent. Tension of continuous, water-filled TEs is in a metastable state that can rapidly switch to a different state if a gap is created consisting of water vapor in equilibrium with the remaining liquid water. This sudden reversal to vapor state is referred to as cavitation. Eventually air leaks into cavitated TEs, and pressure rises to atmospheric to cause an embolism. As TEs are progressively embolized, those that remain filled may be placed under increased tension because there are fewer available to supply water.

The initial sudden release of tension can be recorded as an acoustic event (AE) (Fig. 15.35), and the accumulative sum of AEs correlate with loss of hydraulic conductance. A sigmoidal curve generally describes cumulative AEs and loss of conductance with xylem tension. These xylem vulnerability curves can be used to define pressures at which 50% loss of hydraulic conductance (50% percentage loss of conductance, PLC) occurs as a measure of cavitation vulnerability. Species exhibit different values of xylem pressure at 50% PLC, reflecting water potential ranges encountered in the environment (Fig 15.35C) or different strategies of stomatal regulation (isohydric, where water potential at midday is maintained relatively constant

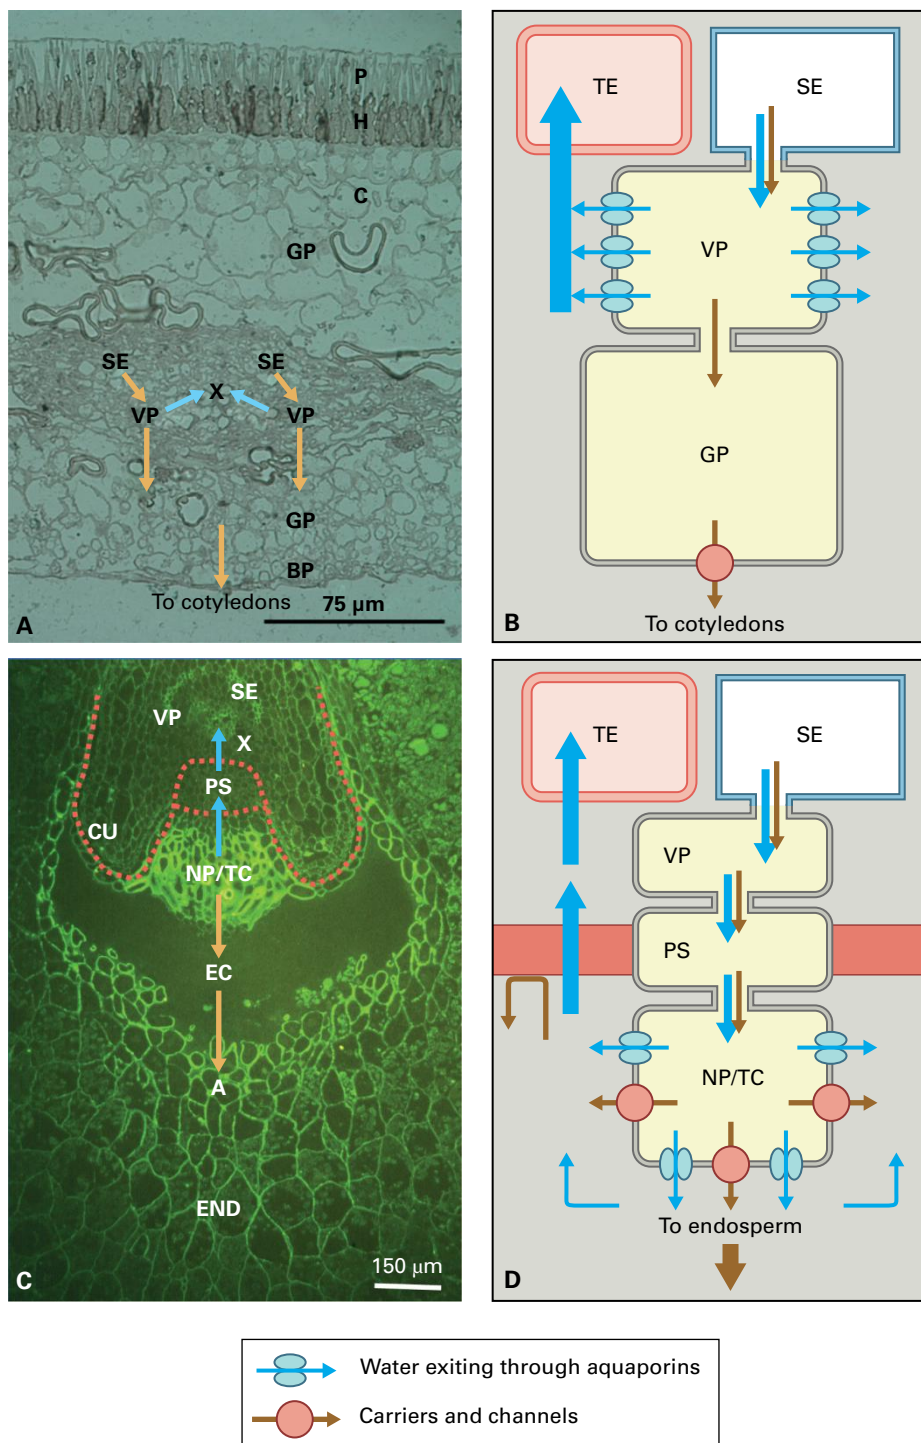

FIGURE 15.33 Strategies to separate phloem-imported water from nutrient movement to embryo/endosperm of developing seeds and return water to xylem for re-export. (A, B) Water (blue arrows) and nutrient (brown arrows) flows in coats of developing *P. vulgaris* seeds. (A) In situ localization of PvPIP2,3 (aquaporin) expression in vascular (VP) and ground (GP) parenchyma (radially inward of vascular bundle only) cells with strongest expression in VP as indicated by darkened cytoplasm (compare with GP above VP). BP, branch parenchyma; C, chlorenchyma; H, hypodermis; P, palisade layer; SE, sieve element; X, xylem elements. (B) Model of post-phloem nutrient and water flows. Symplasmic unloading from SE to VP by bulk flow (blue arrows alongside brown arrows). Water exits from VP through aquaporins and returns to xylem TEs down a water potential gradient for re-export. Nutrients diffuse to GP for release to seed apoplast through carriers and channels for onward movement to enclosed cotyledons (see Fig. 15.31B). (C, D). Water (blue arrows) and nutrient (brown arrows) flows in developing wheat grains. (C) Immunohistochemistry of sucrose transporters by treating section with a generic SUT antibody demonstrating these transporters are localized to sieve elements (SE), vascular parenchyma (VP), nucellar projection transfer cells (NP/TC) and aleurone (A). Dotted red line demarcates location of a water-permeable apoplastic barrier deposited in cell walls of the cuticular layer (CU) and pigment strand (PS). The apoplastic barrier separates crease vascular bundle (comprised of SE; VP, vascular parenchyma cells) from an apoplastic compartment containing NP/TC, the endosperm cavity (EC) and endosperm (END). The endosperm accumulates imported sucrose as starch (note large starch grains in END). (D) Model of post-phloem nutrient and water flows. Symplasmic unloading from SEs to VP by bulk flow that possibly extends through the PS to NP/TC. Here water and nutrients exit via aquaporins and nutrient transporters respectively. Water returns to xylem TEs down a water potential gradient for re-export to the parent plant through a water-permeable, but nutrient impermeable, apoplastic barrier deposited in walls of PS and CU cells (dark red). FIGURE 15.34 A synthetic tree demonstrating bulk flow and substantial tensions in “leaves” and “conduits”. (A) Synthetic tree comprising a leaf and root network (pHEMA hydrogel, colored in the diagram green and red respectively). Veins consist of 80 parallel channels of varying length arranged to form a circle (for both “leaf” and “root”) and are connected by a single “stem vessel” (internal diameter $\approx 10 \mu\text{m}$). (B) Bulk flow as a function of temperature applied to the “leaf”. As temperature is elevated there is greater transpiration from the “leaf” and greater bulk flow through the system. Shown against each point is the pressure difference in MPa across the “Stem” (ΔP_{load}) and negative pressure (P_{leaf}) that develops at the entrance to the leaf vein network.

with falling soil water content versus anisohydric, where water potential at midday is allowed to decline with falling soil water content). Emboli decrease TE hydraulic conductance and ultimately limit carbon gain because stomata close to prevent further cavitation and leaf desiccation.

15.5.3 Cavitation occurs by “air seeding”

Cavitation can be initiated either by pulling air into TEs through their walls or by vaporizing water within conduits. Evidence supports the first mechanism, termed “air seeding,” in which surface tension in the largest cell wall pores is overcome by tension within TEs to draw minute bubbles into the conduit. Air seeding can be simulated by increasing the air pressure in a collar around a piece of stem. As predicted by the air-seeding mechanism, externally applied pressure has the same effect on embolism formation as the equivalent xylem tension (Fig. 15.35A,C).

The most likely place for air entry is via pit membranes. Pore sizes in pit membranes are normally small enough to prevent air entry, but large tensions may distort pit membranes and cause damage to increase their pore size.

Bordered pits can act as valves that shut when there is a substantial pressure gradient across the pit (Fig 15.35D). In torus-margo pits, a central torus of lignified wall is pushed against the opening of the pit cavity (border), thereby sealing off the pit. This occurs when an embolized TE is adjacent to a functioning TE causing the torus to be appressed against the bordered pit of the functioning TE. This prevents air seeding of the functioning TE; however, under large tensions, the torus may be displaced across the opening and allow air to enter (Fig. 15.35D).

Freeze–thaw cycles also cause cavitation. Dissolved air can come out of solution during freezing and, when thawing occurs and tensions develop in TEs, air bubbles expand to form embolisms. Plants that grow in freezing environments must refill TEs or have new TEs produced by vascular cambia.

15.5.4 Embolized xylem can be repaired

TEs cavitate on a regular basis (Fig 15.35B) and must be refilled to allow transpiration to continue. Refilling appears to occur in some plants while transpiration proceeds, indicating that pressures in functioning TEs may be negative while refilling occurs. The mechanism is difficult to understand because physical principles dictate that the pressure must increase to force gas in bubbles back into solution. The gas must then diffuse from TEs driven by a gas concentration gradient. Pressures in gas bubbles will be above zero and higher positive pressures will increase the concentration gradient for diffusion. Models have demonstrated that gas bubbles can dissolve provided xylem pressures are more positive than about -0.1 MPa .

During the night, when transpiration slows or stops, significant positive pressure can develop in root xylem. This occurs by pumping ions into TEs to achieve lower water potential in TE sap than in surrounding soil. Water enters down the water potential gradient and increases TE pressures. Pressures of around 0.1 MPa can be measured for a detached distal segment of root connected to a pressure probe. These pressures are enough to force water up stems to heights of 10 m and could dissolve air in embolized TEs. This is an important mechanism for refilling TE in shrubs and herbs. It is not clear if trees use this mechanism.

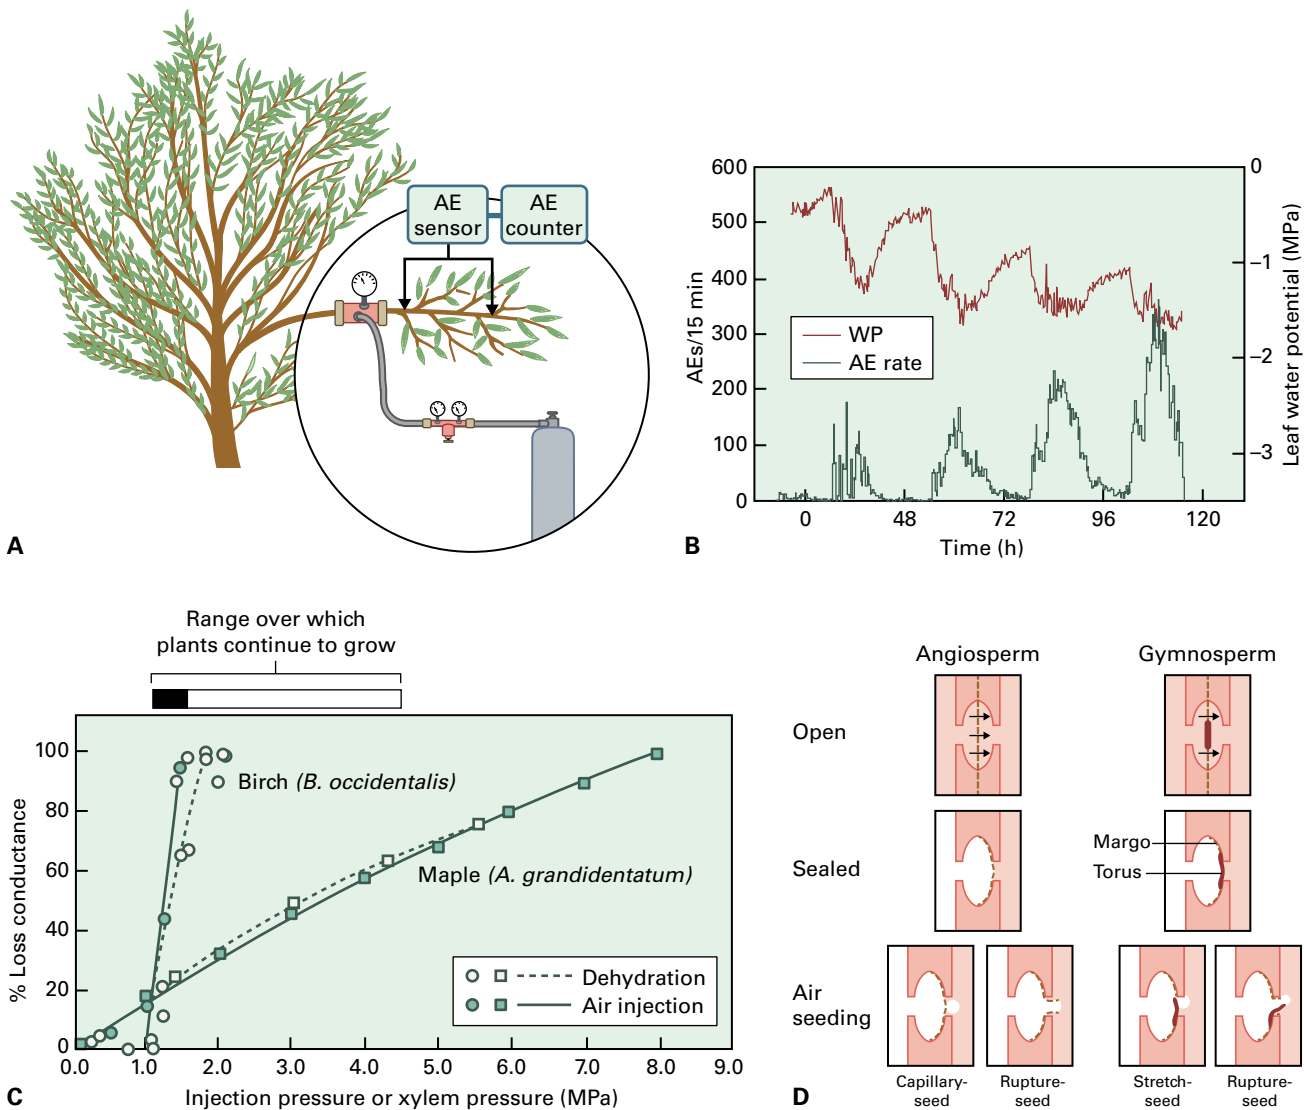

FIGURE 15.35 Cavitation occurs by air seeding and is likely to occur through pit membranes. (A) Induction of cavitation by air injection. Air under positive pressure applied in a sealed collar around the branch causes cavitation identical to xylem tensions. Acoustic emission (AE) sensors and counters monitor progress of cavitation. (B) AE sensors monitor increasing cavitation frequencies in the petiole of a leaf during daylight as a plant is progressively drought stressed. As leaf water potential (WP) became more negative acoustic signals increase in frequency. (C) Xylem vulnerability curves for birch (*Betula*) and maple (*Acer*). As branches dehydrate during drought and xylem tensions increase, cavitation causes a progressive loss of xylem function. The relationship between xylem tension and loss of xylem function differs between species, affecting conditions under which they can grow. This range is indicated by the solid bar for birch, and by the open bar for maple located above the graph. Xylem vulnerability curves developed by application of positive external pressures (see A) are similar to vulnerability curves caused by xylem tension. (D) Cavitation likely occurs through pit membranes. Angiosperms and gymnosperms differ in their pit architecture. Circular bordered pits are shown in transverse median section. Top: open configuration. Mid: sealed configuration where the embolized conduit is on the left. Bottom: Air seeding where a bubble escapes through damaged pit membrane (left) or via displacement of the torus from the pit opening (right).

For refilling to occur during transpiration, there needs to be a local increase in pressure in embolized TEs. Evidence indicates a requirement for metabolic energy and a supply of water from the phloem for refilling to occur. It is clear from computer tomography images of refilling xylem that xylem parenchyma adjacent to vessels have a role in refilling. Four hypotheses have been put forward to account for local refilling: cell membrane osmosis, pit membrane osmosis, tissue pressure, and membrane asymmetry. All hypotheses evoke mechanisms for building pressure in embolized TEs, and all

but the pit membrane osmosis mechanism envision an active role for xylem parenchyma cells in solute secretion and water movement into embolized TEs and a requirement that embolized TEs are hydraulically isolated from other conducting TEs under tension. Again properties of pits and pit membranes appear to be central, as these must be sites of hydraulic blockade so that pressure can be elevated in embolized TEs. Aquaporins have been implicated in the refilling process, since increased aquaporin gene expression in xylem-associated cells occurs when TEs are refilled after winter.

FIGURE 15.36 Stomatal closure pre-emptively prevents significant loss of leaf hydraulic conductance as leaf water potential declines. Stomatal closure occurs during initial phases of leaf xylem cavitation. Stomatal conductance (triangles thin line) is a surrogate measure of stomatal aperture. Leaf hydraulic conductance (circles bold line) includes leaf veins and pathways to sites of evaporation within leaves. Cavitation of veins results in loss of leaf hydraulic conductance. Data are from a tropical legume species.

15.5.5 Cavitation can act as a hydraulic fuse and amplify water stress impacts in leaves

Although cavitation decreases TE xylem conductivity, it is not necessarily always deleterious. This is because cavitation tends to occur in xylem pathway extremities (i.e., in leaves and small branches), reducing transpirational water loss and protecting against dehydration of critical pathways such as stems and major roots. To some extent, a greater tendency towards cavitation in smaller branches might be anticipated, because xylem pathway termini have the lowest water potentials and these are magnified by increases in TE resistances toward these sites. Hydraulic resistances of leaves can account for 30–80% of whole plant hydraulic resistance. TE cavitation in leaves can cause rapid leaf dehydration and stomata seem to be highly responsive as judged by a close association between leaf xylem vulnerability to cavitation and stomatal closure (Fig. 15.36).

Sensitivity of leaf water status to carrying capacity of petiolar xylem is demonstrated by the pea *ramosus2* (*rms2*) branching mutant where wilting occurs under high evaporative demand. This phenotype is due to reduced diameters of TEs in their petioles where the Hagen–Poiseuille law indicates a drastic reduction in hydraulic conductivity (Equation 15.B5 and Fig. 15.37A,B). Under high evaporative demand, decreased petiole conductivity requires a much lower leaf water potential to drive water flow, and this low leaf water potential reduces leaf turgor pressure, as evidenced by a lowered relative water content and wilting compared to wild-type plants (Fig. 15.37C).

15.5.6 Integration of conductivities and xylem efficiencies enhance water transport

Decreased TE susceptibility to cavitation is one of several factors allowing plants to maintain water balance. Others include stomatal response, leaf abscission, root–soil interactions, and patterns of seasonal growth. Strategies may differ in different environments and, even in the same environment, different strategies may achieve the same goal. An example of some of the trade-offs that may occur is evident in xylem vulnerability curves shown for maple (*Acer*) and birch (*Betula*) (Fig. 15.35C). Both species grow in moist environments, but maple also can grow in drier conditions. As xylem tension increases in birch, stomata must close promptly after cavitations begin if rapid loss of xylem function is to be avoided. This stomatal behavior has been observed, and birch xylem remains more than 90% functional in the field. In maple, stomata remain open to much lower water potentials without fully losing xylem function; in drier sites, 50% of maple xylem may be embolized.

Coordination of conductances between roots and shoots is also important to keep stem and leaf water potentials within acceptable ranges. If roots are unable to supply water demanded by shoots, stem water potentials decrease and could trigger excessive cavitation and wilting. Counterintuitively, this can occur after water logging in soil, which starves roots of oxygen. Oxygen starvation decreases cytosolic pH in root cells, and as a result, most plasma membrane aquaporins close. Sudden reductions in root hydraulic conductivity starve shoots of

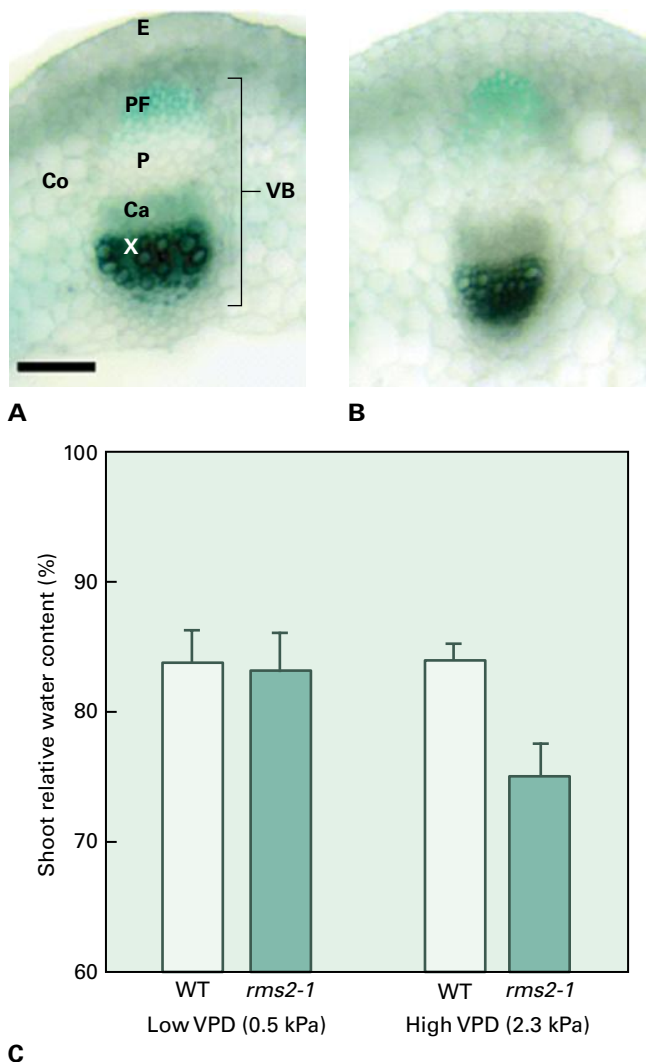

FIGURE 15.37 Petiole hydraulic conductance can restrict water flow to leaves and cause increased sensitivity to water stress. The *rms2-1* mutant of pea has increased branching but also shows transient wilting when plants are exposed to high vapor pressure deficits (VPD) that increase evaporation rates from leaves. (A,B) Petiole cross-sections from uppermost-expanded leaf stained to visualize xylem vessels (dark green) of (A) Wild type and (B) *rms2-1* mutant plants. Total xylem area and TE diameter is reduced in *rms2-1* petioles, resulting in a substantial decrease in hydraulic conductance. Bar = 100 μm . Ca, cambium; Co, cortex; E, epidermis; P, phloem; PF, phloem fibers; VB, vascular bundle; X, xylem. (C) Relative water content of shoot apices of WT and *rms2-1* plants under low and high vapor pressure deficits. A decrease in relative water content occurs when water loss exceeds water uptake and leaves wilt.

Source: Dodd et al. (2008). *Plant Cell Physiol.* 49:791–800.

sufficient water supply, causing plants to quickly wilt. Root-to-shoot signaling involving ABA transport in xylem can signal stomata to close under soil conditions not conducive to efficient water uptake by roots. Likewise, there appear to be shoot-to-root signals that match transpirational demand to the ability of roots to conduct water (Fig. 15.38). Clearly, this is a complex topic that cannot be pursued in detail here.

15.6 Whole-plant organization of phloem transport

15.6.1 The pressure-flow mechanism of phloem transport involves bulk flow between sources and sinks

In 1930, Ernst Münch published the first coherent concept of phloem transport in his outstanding book, *Die Stoffbewegungen in der Pflanze*. He advanced the pressure-flow hypothesis that phloem translocation occurs as a bulk flow driven by differences in hydrostatic pressure (P) between ST ends located in photoassimilate sources (P_{so}) and heterotrophic sinks (P_{st}) and Fig. 15.39).

Fierce opposition to the pressure-flow hypothesis arose when EM observations found deposits occluding sieve pores. These deposits were considered to impose sufficiently low hydraulic conductances to prevent bulk flow accounting for observed rates of phloem transport. Subsequent and more refined studies showed sieve pore deposits to be artifacts of tissue fixation, and opposition to the pressure-flow hypothesis crumbled.

Bulk flow (see Box 15.1) through STs has been demonstrated using a number of experimental approaches, including concurrence between propagation velocities of heat (solvent) and transport of radiolabeled photoassimilates (solute). Recently, real-time transit imaging of phloem-mobile fluorochromes and monitoring displacement of water molecules by nuclear magnetic resonance have provided conclusive evidence that phloem transport occurs through STs by bulk flow (Fig. 15.40).

Although the pressure flow hypothesis has become an established concept, a number of caveats remain. For example, STs are shorter than the plant axis and flow between consecutively arranged STs must occur through lateral sieve plates. To what extent their sieve pore geometries and accompanying deposits of proteins and ER impact hydraulic conductances (Equation 15.B5) is uncertain but broadly are considered not to hinder bulk flow (see Section 15.6.3).

15.6.2 Water flows and equilibrium states within and beyond the phloem are crucial to nutrient translocation

Water flows into collection phloem through aquaporins and along water potential gradients that are generated by active nutrient loading of SE/CC complexes (see Section 15.4.8). The resulting elevated hydrostatic pressure drives longitudinal flows of phloem sap through the STs (Fig. 15.39).

Water inflow into collection and transport phloem is not affected by considerable diurnal fluctuations in leaf/stem water potentials (Fig. 15.41), suggesting collection and transport phloem maintain a constant water potential difference with surrounding tissues to ensure this steady inflow. Consistent

FIGURE 15.38 Root capacity to import water from the soil as measured by root hydraulic conductance (L_o , y-axis) that is matched to shoot demand (transpiration, E , x-axis). This implies that signals are transmitted from shoot to root to coordinate water conductances. Root hydraulic conductance is normalized to root dry weight and measured using a flow meter attached to cut stumps of grapevine (*Vitis vinifera*) cultivars (listed to the right of graph) grown in pots. Immediately before measuring root conductances, transpiration rates of fully expanded leaves were recorded. Further measurements showed that root conductance was dependent on expression of aquaporins.

with this proposition is the observation that collection and transport phloem is capable of hydrostatic pressure homeostasis, which it achieves through osmoregulation of nutrient loading from the phloem apoplast, which interchangeably relies on K^+ or sucrose transporters).

The rates at which SE unloads water and nutrients must match those of bulk flow through the transport phloem. Since diffusion of water and each nutrient species occurs independently at rates driven by their concentration gradients and diffusion coefficients (see Box 15.1), it is problematic that rates of diffusive water and nutrient unloading from these STs could be organized to match the rates of bulk flow into STs of release phloem. In contrast, symplasmic unloading by bulk flow ensures rates of import into and unloading from STs are matched. In addition, unloading STs by bulk flow into the larger cell volumes (ca. 10-fold) of surrounding phloem parenchyma cells allows hydrostatic pressure heads in STs to be dissipated (in analogy to gas laws $P_1 V_1 = P_2 V_2$) (Fig. 15.28). Overall, these considerations point to bulk flow being the likely mechanism for symplasmic unloading of SEs.

15.6.3 Sites of overall regulation along the transport pathway predicted by the Münch flow concept can be deduced from the variables determining bulk flow

Potential sites of regulation of phloem transport can be deduced from the variables determining bulk flow (see Box 15.1 and Fig. 15.39). Such an analysis identifies structural (ST hydraulic conductances; ST numbers in path cross-section) and physiological (hydrostatic pressure; nutrient concentration) properties of STs that could regulate rates of nutrient transport. Phloem path cross-sectional areas have attracted considerable interest based on an apparent limit

to which nutrient fluxes could be supported (Fig. 15.39). However, for herbaceous plants, phloem path conductance ($n L_o$) does not exert a strong influence over nutrient translocation rates as illustrated by an experiment using *R. communis* (Fig. 15.42). The study also highlighted substantial regulation of phloem transport by sink hydrostatic back-pressures that, upon their dissipation by sink removal, caused considerable increases (10- to 20-fold) in phloem transport fluxes (Fig. 15.42A,B vs. C). Low plasmodesmal densities interconnecting SEs and phloem parenchyma cells of release phloem (Table 15.6) contribute to their correspondingly low hydraulic conductances. These in turn regulate symplasmic unloading, as reflected by large hydrostatic pressure differences located at these interfaces (Fig. 15.28). Thus, transport phloem can be thought of as a high-pressure manifold in which the hydrostatic pressure head is maintained by hydrostatic pressure-regulated loading of nutrients in collection and transport phloem. As a consequence, partitioning of nutrients between competing sinks is primarily controlled by hydraulic conductances of plasmodesmata linking SE/CC complexes with phloem parenchyma cells determining rates of phloem unloading (Fig. 15.43 and see Section 15.7.5).

Maintenance of a hydrostatic pressure difference between collection phloem and symplasmically connected sink cells focuses attention on phloem loading and unloading of major osmotic species to respectively raise and lower osmotic differentials between their cells and surrounding apoplasts (Fig. 15.39 and Equation 15.B7). In contrast, minor osmotic species have little influence on hydrostatic pressures and volume fluxes of water flowing through the transport pathway. Thus, for a given volume flux set by major osmotic species, phloem transport rates of minor osmotic species are solely determined by their concentration in ST sap arising from phloem loading and retrieval activities (Fig. 15.39). This is clearly illustrated by strong correlations found between concentrations of amino acids in ST saps and rates of amino N transport (Fig. 15.44).

FIGURE 15.40 Methods for assessing phloem as a translocation pathway and for monitoring bulk flow velocities. (A, B) Use of fluorescent phloem-mobile dyes in broad bean leaves. (A) Application of fluorochromes to a paradermal cut (2) made at the lower side of the main vein (MV) enables detection of fluorescence at an observation window (1) downstream of dye application by confocal laser scanning microscopy (Ob). (B) Strong fluorescence (green) in SEs of *Vicia faba* demonstrates these cells form the pathway for phloem transport. Longitudinal uniformity of fluorescence intensity is consistent with bulk flow and its retention across sieve plates (SP) shows that these structures or any deposits on them do not inhibit bulk flow. Fluorochromes (yellow) accumulate in CC vacuoles. (C, D) Nuclear magnetic resonance (NMR) records nuclear magnetic spin resonance of water molecules moving in phloem and xylem as illustrated for a cross-section of poplar hypocotyl. (C) A microscopic control cross-section. (D) Presented is a velocity flow (i.e., volume flux; see Equation 15.4B) map derived from water flowing downward through phloem (orange/yellow, $0.1\text{--}0.3\text{ mm s}^{-1}$) and upward through xylem (blue, $0.3\text{--}0.8\text{ mm s}^{-1}$). These measured velocities greatly exceed predicted velocities for diffusion over distances greater than several mm (see Equation 15.B3). The color scaling on the horizontal and vertical bars depict flow velocities. Source: (A, B) Knoblauch & van Bel (1998). *Plant Cell* 10:35–50. (C, D) Windt et al. (2006). *Plant Cell Environ.* 29:1715–1729.

FIGURE 15.39 Generation of pressure flow through sieve tubes. Driving force for bulk flow is determined by hydrostatic pressures (P) differences between source (P_{so}) and sink (P_{si}) ends of the transport pathway (i.e. ΔP_{so-si}). Since water approaches near equilibrium between SEs or sink cells and their surrounding apoplasts (apo), water potential of each cell is determined by the difference in P and osmotic pressures (π) as shown for SEs: $P_{se} - \pi_{se} = P_{apo} - \pi_{apo}$ (see Equation 15.B7) and hence $P_{se} = [(\pi_{se} - \pi_{apo}) + P_{apo}] = (\Delta\pi_{se-apo} + P_{apo})$. In source leaves, major osmotic species are loaded into STs to high concentrations so that π_{se} offsets transpiration-induced tensions in the leaf apoplast (P_{apo}) to drive water uptake and hence generate P_{so} . At sinks, exit of ST sap from STs occurs by bulk flow through plasmodesmata and, as a consequence, P_{si} is located in the post-SE unloading pathway (see Fig. 15.27). Since growth and storage sinks are hydraulically isolated from the remaining plant body, P_{si} is predominantly determined by $\pi_{si} - \pi_{apo}$ with P_{apo} exerting little influence. Thus phloem loading and unloading set the magnitude of $P_{so} - P_{si}$. Volume flow rate ($\text{m}^3\text{ s}^{-1}$) of ST sap (see Equation 15.B4) is modulated by pathway hydraulic conductance (L_o and see Equation 15.B5) summed over number (n) of conducting units in a path cross-section. Radii of sink plasmodesmal canals are major determinants of L_o . Bulk flow rate (R) of a nutrient species is then a function of volume flow rate and concentration (C) of the transported nutrient.

15.6.4 Sieve pore occlusion is a sophisticated surveillance system that prevents phloem sap loss from mechanically damaged SEs

Effective sieve-plate occlusion in response to wounding may have been a key factor in the evolutionary success of angiosperms. Occlusion prevents leakage of photoassimilates from

FIGURE 15.41 Phloem transport velocities (A, C) are unaffected by the marked diurnal changes in transport velocities through the xylem (B, D). The in situ velocity measurements were made using NMR of *Ricinus* stems (see Fig. 15.40C). The dark period is indicated by black horizontal bars.

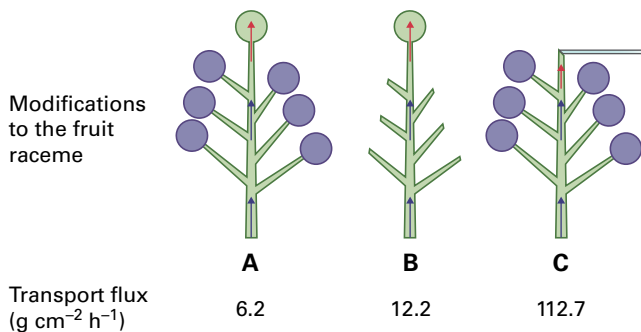

FIGURE 15.42 Demonstration of spare transport capacity of transport phloem using castor bean (*Ricinus communis*) plants; ST sap bleeders (see Section 15.4.4). Bulk flow rates of ST sap were expressed as transport fluxes through the transport phloem ST cross-sectional area (red arrows) at a site immediately below insertion of the most apical fruit (green circle) in the fruit cluster. Nutrient import by remaining fruits (purple circles) is depicted by purple arrows. In configurations A and B, transport fluxes were determined by dry weight increase of the most apical fruit across a set interval of days in which respiratory losses were accounted for (40–50% of imported carbon). In C, transport flux was determined as the dry weight of ST sap exuded from the cut stump immediately below the excised apical fruit and collected into a microcapillary across an interval of hours. Transport flux through transport phloem to the apical fruit in (A) of an intact fruit cluster and (B) in a cluster in which all other fruit development was prevented by excising flowers at anthesis. (C) Transport flux through transport phloem exuding through a cut stump with remaining fruit attached. Transport flux (R_p) = path conductivity (L_p) \times pressure difference (source-sink) ($P_{\text{source}} - P_{\text{sink}}$) \times nutrient concentration (C). Path conductivity (see Box 15.1) and nutrient concentrations are identical across the three treatments. If path conductivity were limiting bulk flow, then fruit removal should have proportionally increased flow to the remaining terminal fruit in B as spare phloem became available. Thus the observed doubled flux is less than an expected ca. sixfold increase if path conductivity was limiting flow. Rather sink hydrostatic back-pressure is operating through a plasmodesmal controlled release from

FIGURE 15.43 Symplasmic unloading of resources from SEs are constrained by a limited plasmodesmal connectivity (i.e., hydraulic conductivity) between SE/CCs and adjacent phloem parenchyma cells. As a consequence, large differences in hydrostatic pressure develop across SE/CC/phloem parenchyma cell interfaces far exceeding hydrostatic pressure differences between source and sink ends of the STs. Thus phloem functions as a high-pressure manifold distribution system in which hydrostatic pressure differentials between source and sink ends of STs are similar for different sink types. This highlights the role plasmodesmata interconnecting SE/CCs with phloem parenchyma cells play in regulating pressure differentials between STs and sink cells that in turn determine nutrient distribution patterns between sinks.

herbivore-severed SEs and is also a mechanical barrier against invasion by phytopathogens.

The plasmodesmal origin of sieve pores may shed some light on how occlusion evolved. Parenchyma cells react to abrupt turgor loss of neighboring cells—as happens with wounding—by plasmodesmal closure maintained by callose deposition at the PD orifices. Sieve pores have perfected this

FIGURE 15.42 (Continued) the fruit phloem terminus as demonstrated by fruit excision in C where plasmodesmal control is removed. Hydrostatic pressure at the exuding stump is zero thus drastically increasing $P_{\text{source}} - P_{\text{sink}}$ by a magnitude commensurate with the 18-fold increase in flux. This outcome demonstrates transport phloem has spare transport capacity.

FIGURE 15.44 Distinction between how major and minor osmotic species determine their rates of phloem transport. Carbon and amino N import rates into developing seeds of three Brassica genotypes plotted as a function of total amino acid concentrations in ST sap. Each point represents a data point for a genotype. Note strong concentration dependence of amino N import rate while that of carbon is independent. In these studies, amino N compounds contributed approximately 20% to osmotic content of the ST sap.

damage response strategy through an instantaneous influx of Ca^{2+} initiating callose deposition around sieve pores (Fig. 15.45A–D). In addition, sieve plates are often plugged by SE proteins, which are probably Ca^{2+} reactive. For instance, PP1 protein in cucurbit STs has Ca^{2+} -binding properties that may apply to many structural SE proteins, in particular to forisomes. These large protein bodies occur in *Fabaceae* SEs, where they disperse in response to Ca^{2+} supply and turgor shocks (Fig. 15.45E–G). Isolated forisomes show a reversible dispersion/contraction in the presence/absence of Ca^{2+} .

15.6.5 Macromolecular signals are transmitted through the phloem

Phloem functions as a long-distance transport conduit for macromolecular signals integrating homeostasis and development of spatially separated organs. The presence of proteins and RNA species in ST sap (see Section 15.4.4) has been linked to systemic signaling by grafting experiments (Fig. 15.46). Functional junctions formed between stock and scion of intergeneric grafts between family members (e.g., tomato on potato plants; Fig. 15.46D) are generated by plasmodesmal bridges developed between vascular cells (Fig. 15.46A–C). Studies on long-distance signaling require intergeneric grafts of individuals with (slightly) different genomes to detect a systemically transported gene product through the graft junction in the scion/rootstock.

Intergenic grafts have established that proteins, mRNAs and sRNA species (including siRNAs and miRNAs) engaged in transcriptional and posttranscriptional regulation are transported systemically and effect gene expression at sites remote from their point of origin (Fig. 15.46E–J). Hence, inter-organ responses can be coordinated through phloem-

FIGURE 15.45 Occlusion of sieve plates. (A) Surface view of a sieve plate of *V. faba*; callose collars (green) around sieve pores. (B) Transverse section of a normal sieve plate (white arrow) with thick callose deposits (stained by aniline blue) and a surface view of a lateral sieve plate (black arrowhead) in a longitudinal wall between two STs. (C) Aniline blue staining of callose collars around sieve pores (white arrows) and PPU (arrowheads). (D) Callose deposits (white arrows) and protein plugs (fading blue haze) in *V. faba* STs. (E) Electron micrograph of an intact SE (SP, sieve plate) of *V. faba* containing a forisome (f) and SE plastids (asterisks). (F, G) Confocal microscopic images of sieve plate (SP) occlusion by forisomes in *V. faba*. Fluorescence-labeled condensed forisome (between the arrowheads) in SE (F) disperses (G) after impalement by a microcapillary (not visible in G). SE, sieve element, CC companion cell. Source: (A–D) A. Furch, University of Giessen, Germany. (E) Ehlers et al. (2000). *Protoplasma* 214:80–92. (F, G) Knoblauch et al. (2001). *Plant Cell* 13:1221–1230.

translocated macromolecular signals. This is of paramount importance in orchestrating defense responses against fungal infection or herbivory. Furthermore, spatially separated developmental events are coordinated by macromolecular signals. For instance, floral initiation is under remote control of fully expanded leaves sensing day length changes, the signals (in this case, a CC-synthesised protein) for which are transmitted to shoot apices via the phloem (see Chapter 19).

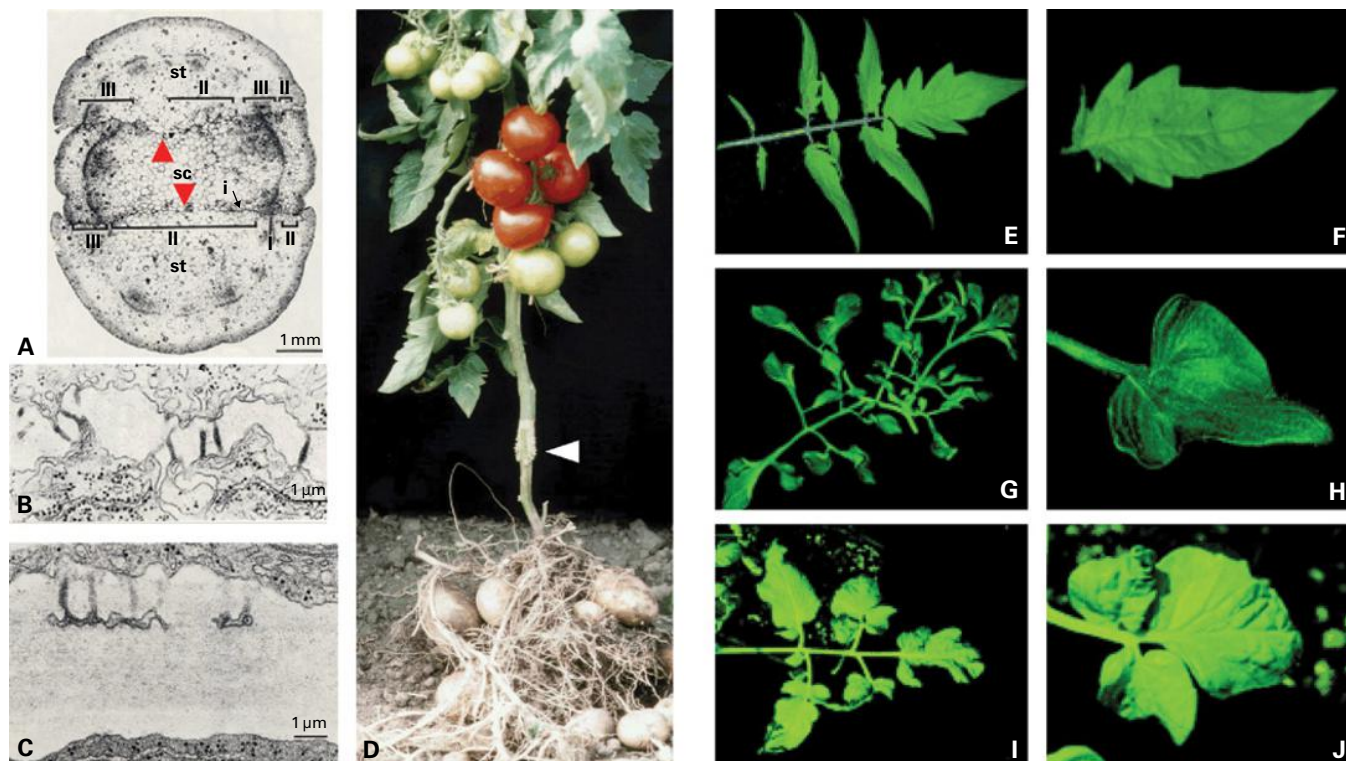

FIGURE 15.46 Graft unions and experimental use of graft constructs. (A) Transverse section of a graft interface of an *Impatiens walleriana* scion (shoot explant) and an *Impatiens oliveri* root stock. To obtain a functional graft, the scion (sc) must be placed onto the stock (st) so that their vascular areas align (I). In other areas (II aligned parenchymatous tissue; III mismatching tissues), cells are unable to interconnect via plasmodesmata; a prerequisite for functional coupling of scion and stock. Demarcation of scion and stock (i) is visible as a dark zone (red arrowheads). (B) Only in vascular areas (I; see A) are newly formed plasmodesmata able to coalesce. (C) In other zones, plasmodesmata fail to coalesce. (D) A heterograft of tomato (scion) and potato (stock) plants showing recovery of xylem and phloem functioning needed to produce tomato fruits and potato tubers. Graft union is marked with an arrowhead. (E–J) Grafting scions on stocks of tomato with differing genotypes shows that a mutation in the rootstock is phenotypically expressed in the scion. This demonstrates that mutant mRNA must be transported from root to shoot putatively in the phloem. (E) Leaf of Xanthophylllic (Xa, yellowish leaf) mutation, (F) Xa leaflet, (G) Mouse ear (Me) mutant leaf, (H) Me leaflet, (I) Xa heterografted scion with Me-like morphological traits such as altered leaf shape, increased leaf subdivision, trichomes in the middle region of developing leaves and a more intense green color, (J) Xa heterografted leaflets. Results indicate that genetic information for increased leaflet production and chlorophyll expression is translocated through the graft junction to the scion.

Recently, macromolecules also have been found in TE sap as part of a likely long-distance system that confers resistance against biotic and abiotic stresses.

Macromolecular messages are transcribed and translated in CCs (or phloem parenchyma cells), released into SEs, and carried by bulk flow to their sites of action. How macromolecular signals are released into SEs is a matter of debate. A prominent model (Fig. 15.47A) envisions that endogenous macromolecular complexes are formed in CCs and contain proteins with sites for plasmodesmal recognition, plasmodesmal docking, and for their unfolding. Actin filaments, in conjunction with ER, may function as tracks for macromolecular complex delivery to plasmodesmata, whether or not enclosed in membrane vesicles (Fig. 15.47B). Spirally arranged macromolecules on plasmodesmal ER-rods (Fig. 15.3C) may be actin filaments that enable transfer of macromolecular complexes through plasmodesmata (Fig. 15.47B). These trafficking mechanisms are presumably analogous to those operating for symplasmic trafficking between parenchyma cells (see

Section 15.1.2). In addition, less selective passage mechanisms exist. For instance, GFP (Fig. 15.22B) complexed with additional peptides up to molecular sizes of 65 kDa and expressed in CCs is released into SEs. It seems unlikely that such foreign proteins pass through PPU using specific trafficking mechanisms.

At least some SE proteins are retrieved by CCs and re-enter STs, thereby seeming to progress by “hopping” along the transport phloem. Re-entry of macromolecules into CCs may be crucial for long-distance signaling. For instance, signal amplification requires that macromolecules return into CCs along the pathway. Furthermore, macromolecular messages tagged by “zip codes” appear to find their way to specific recipient cell types, a phenomenon requiring selective entry and exit mechanisms.

Despite macromolecule abundance in ST sap, identities of macromolecules involved in long-distance signaling are largely unknown (Table 15.8), including those compounds involved in systemic acquired resistance (SAR). It is expected that a loose

FIGURE 15.47 Hypothetical models of macromolecular trafficking to, and through, plasmodesmata. (A) Upper cartoon: Only specific proteins (P) are picked up by chaperone (CH) and docking (DP) proteins to form macromolecular complexes (MC). This complex is recognized and processed by a protein structure at plasmodesmal orifices. After uncoupling of the docking protein, the P-CH complex is trafficked through plasmodesmata in an unfolded state and released at the other side, where the protein is released. Lower cartoon: In a similar way, innate RNA and viral RNA (NA) are trafficked through plasmodesmata. Viral movement proteins (see Fig. 15.48) possess similar functions to the chaperones in plasmodesmal trafficking of viral RNA. (B) Alternative models of intra- and intercellular transfer of macromolecules towards and through plasmodesmata. Left side: Myosin-bound macromolecular complexes are carried along actin filaments, most likely at interfaces between actin filaments and ER tubules, towards the recognition, docking and processing sites at the plasmodesmal orifices. Subsequent active trafficking of macromolecular complexes through plasmodesmata depends on interaction between myosin and actin. Right side: Golgi vesicles may be directed in a similar way towards the plasmodesmata and excreted by exocytosis in the vicinity of the plasmodesmal orifices.

maze of numerous intertwining reactions, spanning SEs, CCs, and phloem parenchyma cells, is responsible for SAR.

Plant viruses have hijacked nucleic acid replication machinery and mechanisms for trafficking macromolecules through plasmodesmata of host plants, and they rely on bulk flow through the phloem for long-distance transmission. Viral infections often spread from leaves by entering minor veins to be exported through STs (Fig. 15.48A). Viral multiplication and spread are characterized by efficient use of their small genomes. For example, the tobacco mosaic virus genome, which comprises only four open reading frames, encodes a 183-kD protein that enables breakdown of the host genome into macromolecular complexes and multiplies by subsequent rearrangement of nucleic acid units. A 126-kD protein is likely responsible for intracellular transfer of viral RNA and docking to plasmodesmata. Movement proteins carry viral complexes through plasmodesmal sleeves. Having arrived in CCs, capsid proteins are expressed. Similar to RNA–movement protein–capsid protein complexes are trafficked through PPU to minor vein SEs as demonstrated by cucumber mosaic virus. There, movement proteins are uncoupled and viral genomes are enveloped in capsid proteins (Fig. 15.48B).

Aphids transmit numerous viruses (see Box 15.3). Some of these viral groups (luteoviridae, geminiviridae) are unable to escape from SE/CCs and multiply solely in CCs. Confinement of these viral particles to SE/CC-complexes illustrates the dissimilar nature of phloem parenchyma/CC and SE/CC plasmodesmata.

15.6.6 Sieve tubes conduct electrical signals

Apart from chemical messages, STs also conduct electrical signals as electrical potential waves. Two types of electrical potential waves have been observed: one is designated an

FIGURE 15.48 Phloem transport events in viral spread. (A) Viral infection in a source leaf spreads by intercellular movement of viruses into the vasculature and is usually phloem transported. To enter phloem of a minor vein, a virus must travel through mesophyll cells (MC), bundle sheath cells (BSC) and possibly phloem parenchyma cells (PPC) before entering CC, and finally SE. It is unclear from which cell type, BSC or PPC, viruses move to enter CC and how this is achieved. (B) For mesophyll cell-to-SE viral transfer, movement proteins are involved. Movement proteins, mostly in cooperation with other viral proteins, are responsible for trafficking through plasmodesmata (see Fig. 15.47). In SE, viruses are often encapsidated (viral RNA encapsulated by coat protein monomers) during or after passage of a viral RNA/protein complex through PPU into SEs following uncoupling of movement proteins. X, xylem vessel; XP xylem parenchyma.

action potential, the other a wound or variation potential. Generally, action potentials are of shorter duration and move more quickly than variation potentials; amplitudes of variation potentials are commensurate with stimulus strength, while those of action potentials are not. Stimuli such as touch, light pulses, or abrupt temperature changes induce action potentials, whereas variation potentials arise from mechanical damage. Severe wounding by burning probably causes combined action and variation potentials.

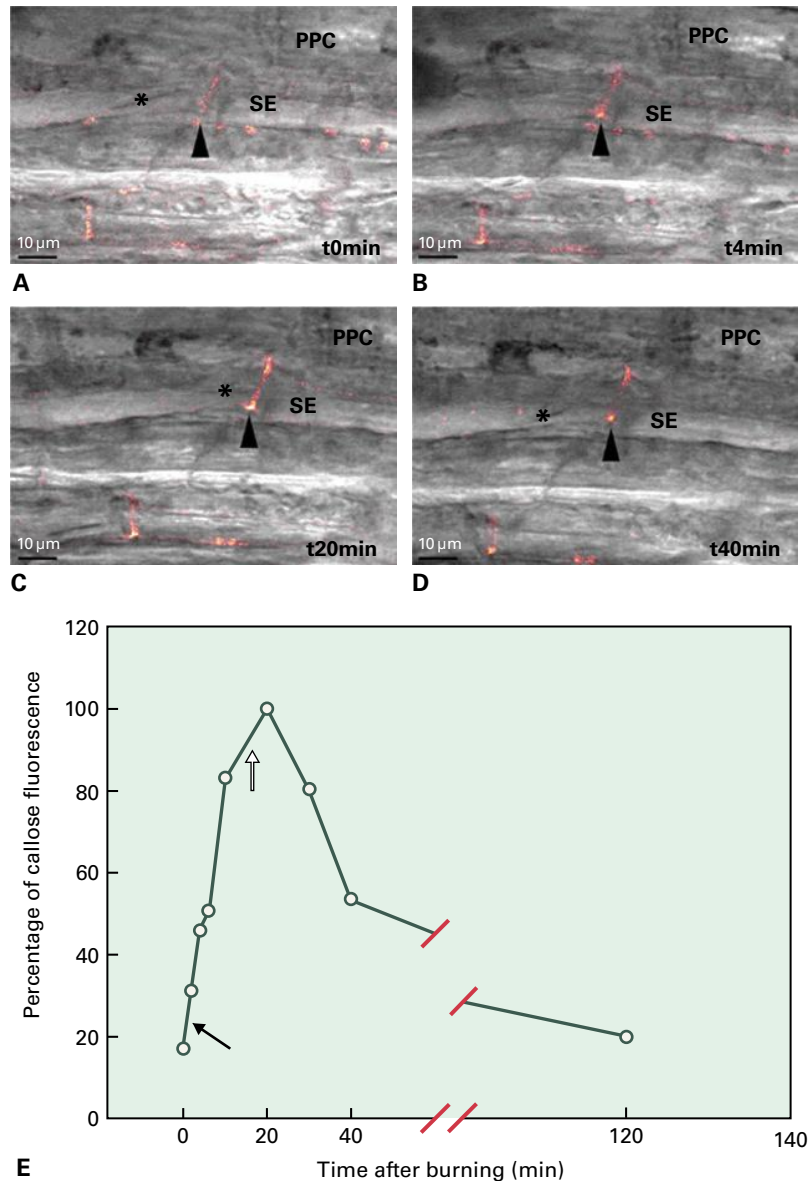

FIGURE 15.49 Induction of sieve-plate closure by a remote burning stimulus. (A–D) Real-time overlays of light microscope and multiphoton confocal laser scanning microscope images of forisome dispersion/contraction (asterisk), and callose deposition/degradation (demonstrated by aniline blue staining visible as red fluorescence) in SEs after burning of *V. faba* leaf tips (at a distance of 3 cm from the observation window). The forisome is dispersed in (B) and therefore not visible (PPC, phloem parenchyma cell). Relative fluorescence in images A–D was quantified at the sieve plate (arrowhead). (E) Time-correlated comparison of forisome dispersion (solid arrowhead)/contraction (open arrowhead) and callose deposition/degradation. Forisome re-contracted before callose deposition reached its maximum. Callose degradation to ground levels is completed after 2 hours. Source: (A–D) Furch et al. (2007). *J. Exp. Bot.* 58:2827–2838.

An initial Ca^{2+} influx followed by a massive Cl^- efflux and subsequent K^+ influx trigger propagation of electrical potential waves, mainly along STs, which impact remote organ functions. For instance, electrical potential waves stimulate expression of genes encoding enzymes that interfere with insect feeding and digestion. Electrical potential waves also influence photosynthesis and other physiological processes in distant leaves.

Remarkable is the remote electrical potential wave effect on sieve plate occlusion. In *V. faba* STs, the Ca^{2+} influx that

accompanies the passage of electrical potential waves leads to a sudden dispersion of forisomes (Fig. 15.49B). When forisomes have recontracted, callose is deposited around sieve pores and slowly degraded during the next few hours (Fig. 15.49C–E). Thus, severe wounding exerts remote control on ST closure by a two-step occlusion mechanism characterized by rapid plugging of sieve pores with proteins followed by callose deposition ensuring longer-term occlusion (Fig. 15.49E). If damage does not affect SE functioning, membrane-located pumps expel Ca^{2+} ions from SEs to restore sieve-plate conductivity.

15.7 Communication and regulation controlling phloem transport events

15.7.1 Source/sink limitations control solute flow in the phloem

Flux control analysis demonstrates that all phloem sectors contribute to regulating transport. The balance between resource supply and resource demand by heterotrophic sink organs modulates the degree of control imposed by any transport process located along the transport pathway. Source limitation, and hence control, is imposed under conditions where resource supply does not meet potential demand for resources by sinks. Conversely, sink limitation is imposed when potential resource supply exceeds sink demand. Source- or sink-limited flow is vulnerable to environmental conditions and alters during plant development. For example, transport to meristems tends to be source limited whereas flows to expanding and storage sinks are sink-limited.

Signals can exert coarse control by determining absolute quantities of transport structures (plasmodesmal numbers; plasma membrane areas; transporter densities) and/or fine control mediated through reversibly adjusting their capacities (plasmodesmal conductances; post-translational regulation of transporter kinetic properties).

15.7.2 Leaf photosynthesis and sugar metabolism/storage regulate photoassimilate export

Leaf photosynthesis provides feed-forward control of phloem transport under source-limiting conditions as demonstrated by top-down flux control analysis (see Section 15.7.1) of plants raised under low light levels. Here, some 80% of the control of photoassimilate transport from source to sink was deduced to be located in photosynthetic leaves. This state reflects photosynthetic rates determining concentrations of sugars available for phloem loading (Equation 15.B9) as well as possibly functioning as signals to regulate processes contributing to phloem loading, as outlined below.

Collectively, current photosynthesis, sucrose biosynthesis, and remobilization of stored leaf sugars determine the instantaneous sizes of the leaf sugar pool available for export. If photosynthetic rates fall below sink demand, depletion of leaf sugar pool sizes is ameliorated by balancing carbon flows into and from leaf storage pools. Carbon flows into the cytosolic sucrose pool of mesophyll cells are controlled by sugar-regulated expression of key photosynthetic enzymes (see Chapter 12), sucrose biosynthetic enzymes (see Chapter 13), and membrane transporters contributing to carbon exit from chloroplasts and vacuolar exchange (Fig. 15.50).

15.7.3 Nutrient flows through transport phloem are regulated by buffering supplies from adjacent storage pools

Radial resource exchange between transport phloem and the surrounding apoplast provides short-term buffering to longitudinal flow through the transport phloem when the balance between source supply and sink demand shifts. This buffering phenomenon is demonstrated by imposing a cold block to a stem. Downstream of the cold block, photoassimilate release is accelerated, while upstream retrieval of photoassimilates is enhanced to generate hydrostatic pressures favorable for driving phloem transport to and away from the cold block (Fig. 15.51). Apoplastic pools of sucrose are relatively small and have a half-life of minutes. If a downward shift in source/sink balance is sustained over hours, then buffering longitudinal flow increasingly depends upon remobilizing stem storage reserves (Fig. 15.25). Indeed, for some grain crops, remobilizing stem-stored carbohydrates contributes substantially to final grain yield, especially under drought conditions.

15.7.4 Sink demand for nutrients is communicated through signals that activate remote regulatory responses

Photoassimilate export from leaves of a source-limited system (see Section 15.7.1) does not respond rapidly if at all to an increase in sink demand. In contrast, alterations to demand in a sink-limited system (see Section 15.7.1) elicit substantial and rapid (minutes to hours) responses in rates of photoassimilate export (Fig. 15.52). These rapid responses indicate a close coupling between sink demand, and phloem loading can occur under sink limitation.

Alterations in sink demand of major osmotic species can be transmitted instantly to source leaves as changes in hydrostatic pressure of SE/CC complexes. Pressure regulation of H⁺-ATPase activity changes the *pmf* across plasma membranes of SE/CC complexes, providing a common mechanism for controlling apoplastic phloem loading by proton-coupled transport mechanisms.

Changes in steady-state balances between source supply and sink demand also can be sensed by upward and downward alterations in apoplastic sucrose contents in collection phloem. For example, transcript and protein levels of a sucrose/H⁺ symporter (*BvSUT1*) in CCs of excised sugar beet (*Beta vulgaris*) leaves were selectively and rapidly repressed in response to transpiration-delivered sucrose. Consistent with a regulatory system, these effects were reversed rapidly upon lowering apoplastic sucrose levels. How sucrose is sensed is not certain, but the signal transduction pathway includes a protein phosphorylation cascade (Fig. 15.53).

Changes in demand for minor osmotic species rely on altering their rates of phloem loading (Fig. 15.39 and associated text). Hence demand must be communicated from sink to source; likely candidates are hormone signals that undoubtedly interact with sugar-signaling pathways.

FIGURE 15.50 Biochemical and membrane transport processes contributing to the cytoplasmic sucrose pool available for phloem loading. Mesophyll cell with chloroplast and vacuole. Maltose (Mal) and glucose (Glc), products of starch hydrolysis in chloroplast stroma, along with C₃-generated triose-phosphate (TP), are exported across chloroplast envelopes by transporters. Within mesophyll cytosols these substrates are rapidly interconverted into sucrose. Sucrose and hexoses in excess of those required for phloem loading may be sequestered into mesophyll vacuoles respectively by sucrose/H⁺ antiporter energized by a tonoplast localized proton-pumping ATPase and by hexose carriers functioning by facilitated diffusion. Release from vacuolar storage is by sucrose symporters (e.g., SUT4) and hexose carriers. P_i, inorganic phosphate.

15.7.5 Plasmodesmal conductances exert a greater influence over transport rates compared to sink metabolism/compartmentation

A direct relationship between rates of cellular metabolism/compartmentation and phloem unloading infers that phloem unloading rates can be regulated by intercellular concentration or hydrostatic pressure gradients generated by metabolism/compartmentation. However, large concentration or

osmotic differences (0.7–1.3 MPa) (Fig. 15.28) between SEs and sink cells attenuate the influence that changes in sink cell nutrient concentration or osmotic pressure can exert on these differences. For example, the sucrose concentration expected in sink cell cytosol ranges from 10 to 100 mM, and a minimal SE sucrose concentration is 350 mM (Table 15.3). Thus, the concentration and osmotic differences that are available between SEs and sink cells for regulating phloem unloading range from 250 to 340 mM sucrose. Control exercised by metabolism/compartmentation in sink cells governing the concentration/osmotic gradient could at best alter unloading rates by 36% (i.e., 340/250). Experimental observations are consistent with this conclusion. For example, rates of phloem import into elongating roots are independent of differences in hydrostatic pressures as well as concentration of key osmotic compounds between phloem and ground tissue (Table 15.9). Applying diffusion and bulk flow equations to this finding (see Box 15.1), leads to the deduction that plasmodesmal conductance exercises major control over nutrient fluxes unloaded through symplasmic pathways (Fig. 15.43).

Plasmodesmal control will exert greatest impact on nutrient transport rates along symplasmic unloading pathways at points of their lowest conductance. In a range of sink types, these points are located at SE/phloem parenchyma cell boundaries, as reflected by estimates of plasmodesmal fluxes (Table 15.6) and the largest differences in sucrose concentration and hydrostatic pressure (Fig. 15.28). Hence, considerable control of phloem unloading is probably exercised by altering conductances of plasmodesmata connecting SE/CC complexes with surrounding phloem parenchyma cells. For instance, hormones are implicated in regulating plasmodesmal conductances to control symplasmic phloem unloading in stems (Fig. 15.54).

Overall, these observations suggest that sinks modulate conductance of strategically located plasmodesmata to regulate nutrient unloading rates to levels commensurate with their metabolic and growth demands.

15.7.6 Apoplastic unloading requires communication of sink demand across two adjoining plasma membranes at the apoplastic step

Apoplastic steps located in post-SE unloading pathways of developing seeds and fleshy fruits (Figs. 15.31 and 15.32) impose a requirement for communication of the demand by recipient sink tissues across two membranes: one responsible for nutrient release and the other for nutrient uptake. Feedback control, generated by nutrient demand, involves transmission of regulatory signal(s) from sites of metabolism/compartmentation within sink tissues to control nutrient transport processes. For major osmotic species, the following

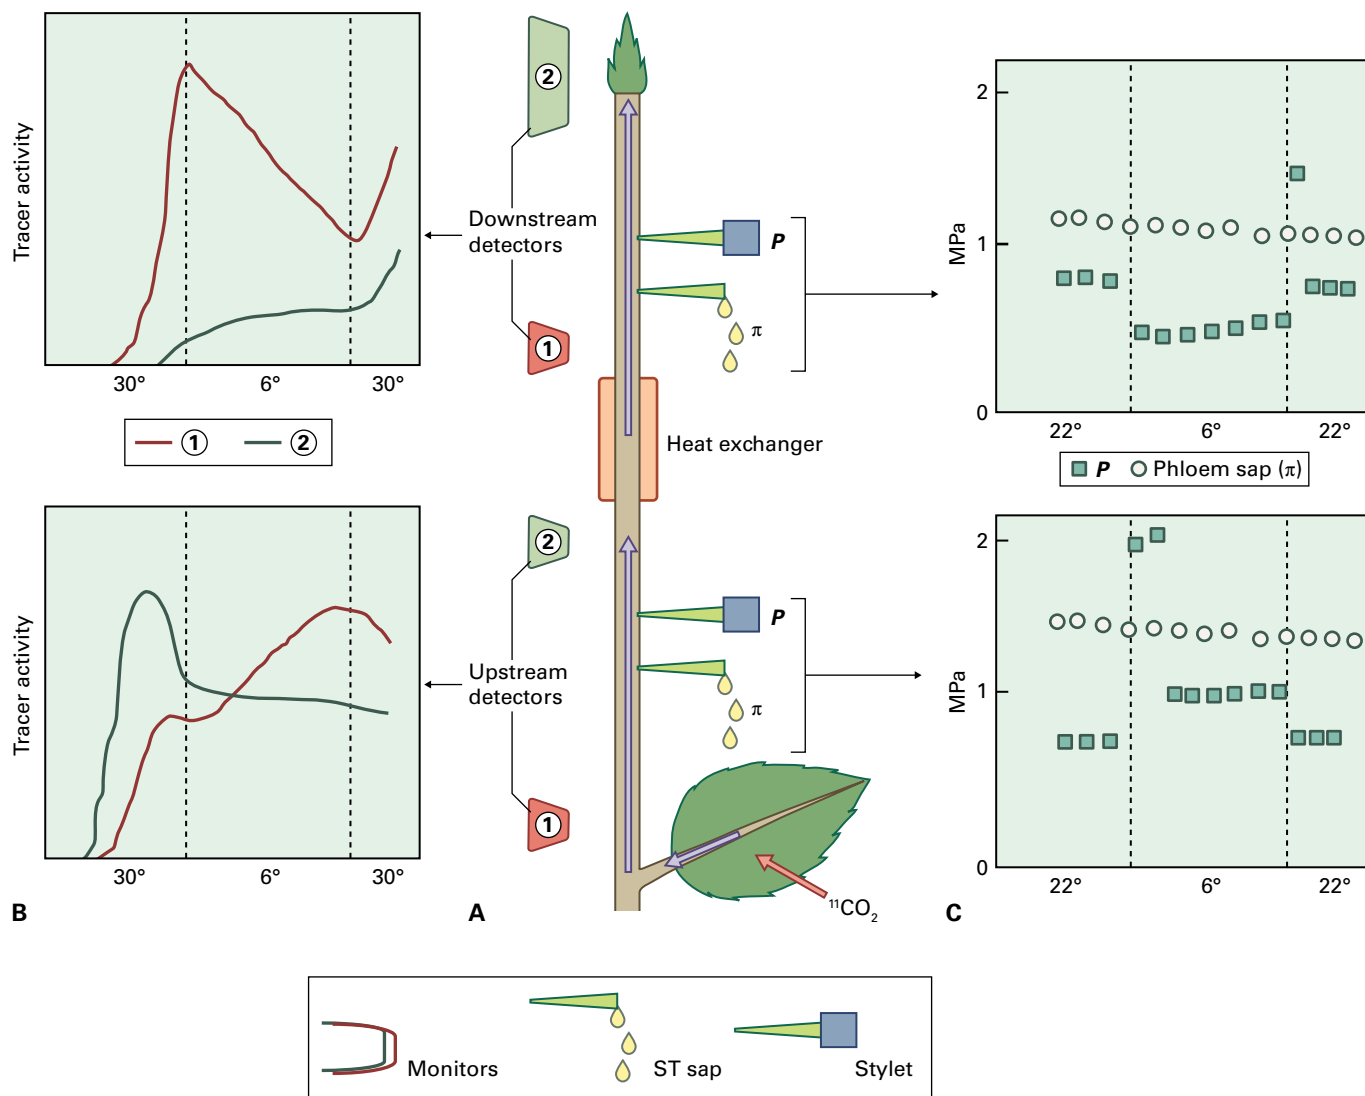

FIGURE 15.51 Rapid buffering of axial transport by radial water and solute exchange demonstrated using a cold block to interrupt axial transport. (A) Experimental set up. Continuous real-time measurement of photoassimilate transport using the strong gamma emitting carbon isotope C^{11} introduced by exposing a source leaf to $^{11}\text{CO}_2$. Transport of ^{11}C -photoassimilate (gray arrows) detected by monitors located at points up- or downstream of a stem portion enclosed within a heat exchanger. Cut aphid stylets, located up- and downstream of the heat exchanger, were used to collect ST sap for osmotic (π) determinations. SE hydrostatic pressure (P) was measured using a pressure transducer glued to each stylet. (B) Continuous recordings of ^{11}C -photoassimilate levels in a stem at selected sites along the axial pathway following exposure of a source leaf to $^{11}\text{CO}_2$. Transport was blocked by chilling a portion of a stem to 6°C . Axial transport continued both up- and downstream of the block. (C) Time-course measurements of P within SEs and ST sap π . P rapidly adjusted to altered stem temperature with an elevation upstream and a decline downstream of the temperature block. These adjustments account for photoassimilate flow being maintained either side of the temperature block. Since sap π was temperature independent, P changes must result from a coupled exchange of water and nutrients across SE/CCs with surrounding phloem apoplast. Net radial exchanges were in the opposite directions with net reloading upstream and net unloading downstream of the temperature block.

closed-loop control applies in developing legume seeds. Depletion of sucrose pools by increased rates of polymer formation in cotyledons ease substrate-regulated repression of *SUT1* expression and, as a result, increase sucrose uptake from the seed apoplast (Fig. 15.55C). Resulting decreases in apoplastic sap osmolality stimulate an efflux of nutrients from seed coats that is regulated by a turgor pressure–homeostat

mechanism (Fig. 15.55B). Under these conditions, the hydrostatic pressure of unloading cells acts as a key modulator to link demand for major osmotic nutrients by cotyledons to nutrient supply from seed coats. This, in turn, links demand to rates of phloem import (Fig. 15.55A), which are possibly augmented through regulating plasmodesmal conductance in some as yet to be determined mechanism (see Section 15.7.5).

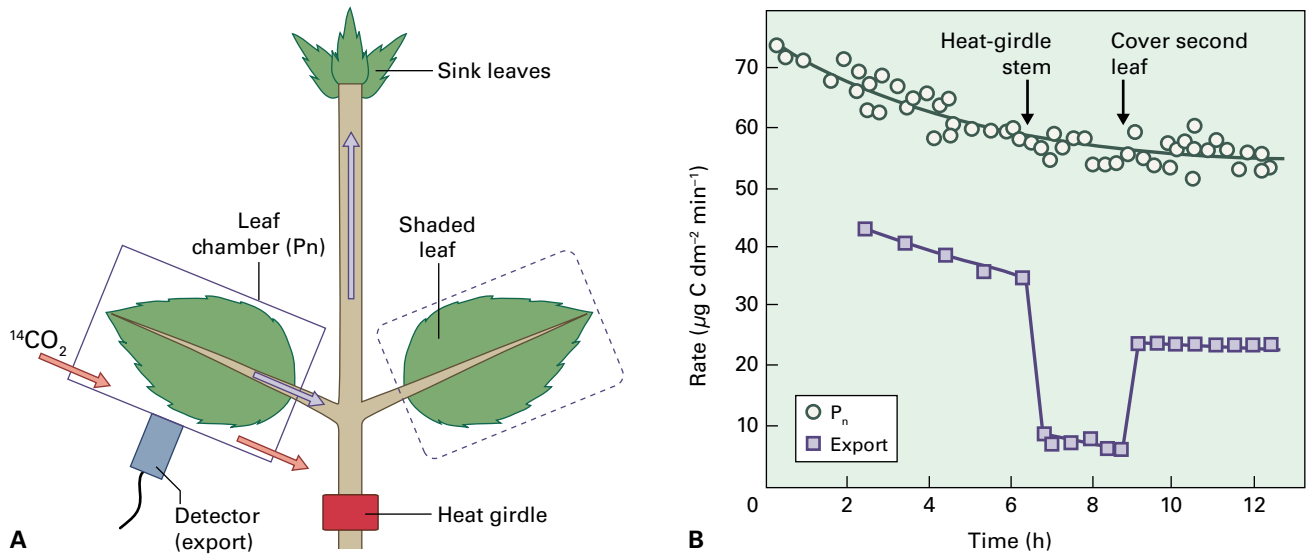

FIGURE 15.52 Rapid responses of photoassimilate export to changes in source supply or sink demand. (A) To concurrently monitor photosynthesis of, and export from, a source leaf, a source leaf is enclosed in a chamber and air containing constant specific activity $^{14}\text{CO}_2$ is passed through the chamber and ^{14}C export is monitored along with net photosynthetic rate (P_n determined by infrared gas analysis). Export rate is the difference between P_n and retention of carbon within the leaf (monitored by a GM detector). Also illustrated are the stem site of heat girdling to block phloem transport to roots and darkening of the remaining source leaf. (B) Real time measurements record impacts of altering source/sink ratios of a bean (*Phaseolus vulgaris*) plant on P_n and photoassimilate export. Source/sink ratios were altered by sequentially heat girdling the stem preventing flow to the root sink (increased source/sink ratio) and shading the remaining primary leaf (decreased source/sink ratio). Irrespective of the direction in which source/sink ratio was shifted there was an immediate response of export rate while leaf photosynthesis remained largely unaltered.

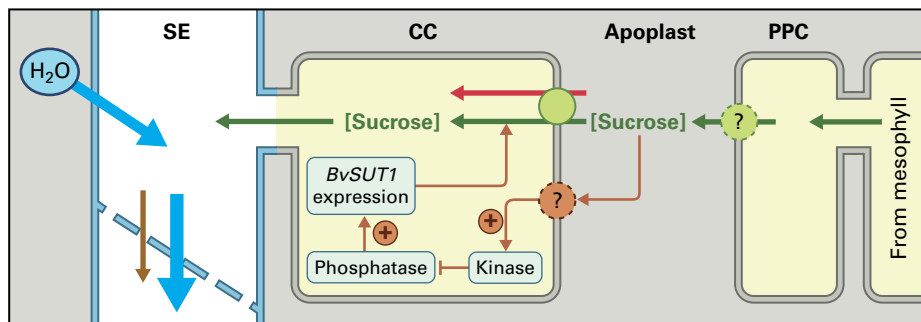

FIGURE 15.53 Sucrose repression of sucrose symporter activity in apoplastically loading leaves coordinates photosynthetic sucrose supply with sink sucrose demand. Dynamic changes in apoplastic sucrose concentrations balance sucrose demand with supply from the mesophyll. An unknown sucrose sensor unrelated to the hexokinase pathway is hypothesized to activate a protein kinase that in turn inhibits a phosphatase thus de-repressing expression of BvSUT1 transporter transcript.

TABLE 15.9 Relationship between instantaneous relative import rates of carbon-11 into, and cortical cell hydrostatic pressures (P) and intracellular nutrient concentrations at, specified intervals along the primary root axis of maize across which phloem P remains invariant at 1.4 MPa. Import of carbon-11 relative to total carbon-11 levels detected in the entire root.

Distance from root tip (mm)	Relative import of carbon-11	Cortical cell P (MPa)	Concentrations (mM) of:		
			Potassium	Sucrose	Hexose
0–5	0.18	0.66	95	12	90
5–10	0.09	0.66	51	1	150
10–15	0.02	0.61	ND	ND	ND

ND, no data.

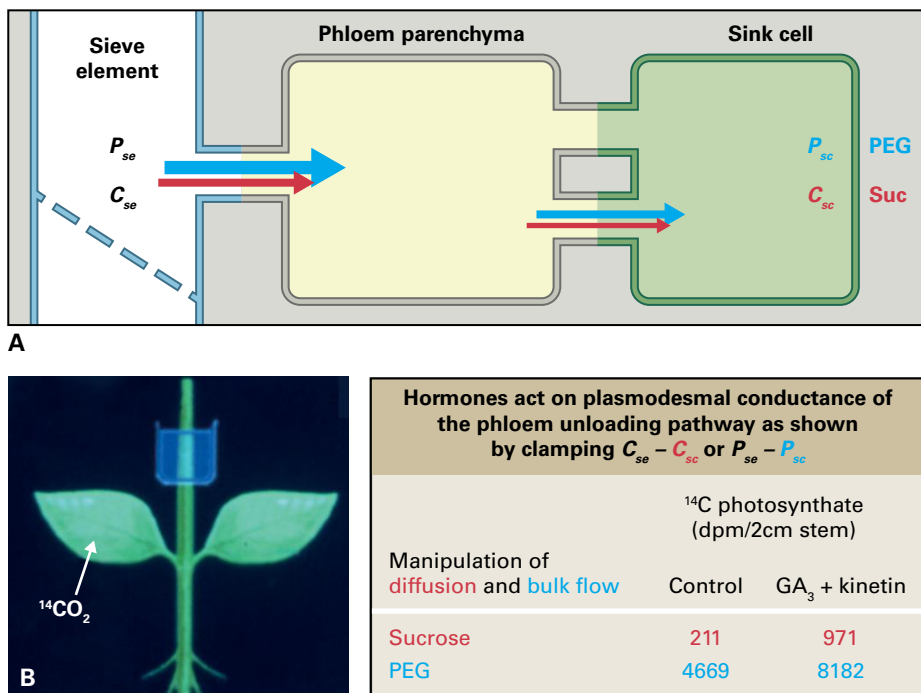

FIGURE 15.54 Plant hormones regulate conductance of symplasmic phloem unloading pathways. Experimental model of symplasmic phloem unloading in which sucrose concentration ($C_{se} - C_{sc}$) and hydrostatic pressure ($P_{se} - P_{sc}$) differences were clamped by exposing bean (*Phaseolus vulgaris*) stems to solutions containing $300 \text{ mosmol kg}^{-1}$ of sucrose or polyethylene glycol (PEG; 8 kDa). Arrows indicate movement of sucrose (red) and water (blue) through a symplasmic unloading pathway. For more details see Fig. 15.30. (B) Bath solutions containing sucrose or PEG solutions $\pm 10^{-5} \text{ M GA}_3$ + kinetin held in wells attached to stems. Following equilibration with bath solutions for several hours, a source leaf was exposed to a pulse of $^{14}\text{CO}_2$ (left hand panel). Levels (dpm, disintegrations per minute) of ^{14}C -photoassimilates (primarily transported as sucrose) accumulated in treated stem portions provide measures of phloem unloading. Stimulation of ^{14}C -photoassimilate accumulation by plant hormones, when $C_{se} - C_{sc}$ or $P_{se} - P_{sc}$ are clamped can only result from their action on pathway (plasmodesmal) conductance for diffusion (see Equation 15.B8) and bulk flow (see Equation B.5) respectively.

FIGURE 15.55 A mechanistic model describing how nutrient import to, and within, developing legume seeds is integrated. Phloem-imported nutrients are unloaded as a bulk flow (A; nutrients brown arrow, water blue arrow). Transporter-mediated efflux (brown arrow over yellow circle) from seed coat (sc) to apoplastic space (apo) is regulated by a turgor-homeostat (B). Changes in nutrient withdrawal from the seed apoplastic space by cotyledons causes an immediate osmotic change ($\pi_{sc} - \pi_{apo}$) in seed-coat turgor (P_{sc}). Any deviation in P_{sc} from a turgor set-point (P_{set}) produces a pressure error signal (broken blue line) that alters effluxer activity to match change in rates of nutrient uptake by cotyledons. Transporter-mediated uptake of nutrients from the seed apoplast by cotyledons (brown arrow over orange circle) is coupled to rates of conversion of nutrients into storage compounds (C). Here metabolically induced changes in intracellular nutrient pool sizes regulate activities of plasma membrane transporters by de-repressing transporter gene expression (broken line in C).

Summary

Long-distance transport of resources and signals in vascular plants follows two functionally distinct pathways, xylem and phloem, which closely parallel each other throughout the plant body. Volume flow in xylem is primarily driven by tensions resulting from transpirational water losses. Substances in xylem move to sites of transpiration, whereas movement in phloem is metabolically directed.

Xylem TEs and phloem SEs are structurally modified to form pathways of relatively high hydraulic conductivity. Such design features also accommodate other requirements, such as narrow TEs for strength and rapid sealing to prevent embolism spread. Similarly, proteins in SEs have the potential to impede bulk flow, but major control on transport appears to be exercised at the sink end of phloem pathways. Rapid sealing mechanisms prevent sap loss from damaged SEs.

Long-distance transport of resources and signals involves loading into, axial transport through, and unloading from vascular conduits. Loading and unloading depend upon short-distance transport processes that collectively determine overall fluxes of resources and signals. Plasma membrane (from and to the apoplast) and plasmodesmal (symplasmic) transport both play central roles in resource loading and unloading. Key to TE loading and unloading are efflux from and retrieval by xylem parenchyma cells, respectively. Xylem parenchyma cells also control the diversion of nutrients and toxic ions to different plant regions. These cells also are implicated in repair of embolized TEs after cavitation. Loading SE/CC complexes may be entirely symplasmic or include an apoplastic step at SE/CC/phloem parenchyma or bundle sheath cell interfaces. The concentrating step for symplasmic loading depends upon synthesis of large molecular weight sugar species (RFOs) in CCs that exceed plasmodesmal molecular exclusion limits preventing their back leakage to mesophyll cells. In contrast, apoplastic loaders depend

on activities of membrane symporters to load sucrose into SE/CC complexes. These symporters also function along the transport phloem to buffer onward sap transport in tandem with regulated plasmodesmal gating to control nutrient fluxes to and from SEs.

Macromolecular signals, synthesized in CCs, are transferred through PUs to SEs along with hormones and signals mediating systemic acquired resistance. Viruses have hijacked these transport mechanisms for systemic spread throughout their host plants. In most sinks, nutrients exit STs as a bulk flow of solution via plasmodesmata. This step has a low hydraulic conductance and is accompanied by a large hydrostatic pressure drop, making it effectively irreversible. Plasmodesmata in post-phloem unloading pathways have molecular exclusion limits of at least 30 kDa, presumably an important factor for accommodating high-solute fluxes. In certain circumstances, an apoplastic step is present and may contribute to a sink's capacity to accumulate osmotically active compounds to high concentrations.

Loading, axial transport, and unloading are highly regulated to deliver resources and signals at required levels. For phloem, transport rates are governed by loading of major osmotic species, principally sugars, to generate hydrostatic pressure. Pressure signals transmitted from sinks along phloem conduits function to regulate loading activities. Transport phloem has spare transport capacity but buffers transport fluxes against variation in source outputs. Control of resource partitioning is localized to recipient sink organs where plasmodesmal conductance appears to play an important role. For xylem, transport rates are more variable, being dependent on transpiration, but nutrient transport can be uncoupled from water transport through TE loading. Some nutrients are recycled from phloem to xylem, and K^+ recycling from phloem to xylem in roots is likely to be a component of signaling shoot K^+ status to regulate TE loading.

Nitrogen and Sulfur

Sharon R. Long, Michael Kahn,
Lance Seefeldt, Yi-Fang Tsay, and
Stanislav Kopriva

Introduction

The essential elements **nitrogen** and **sulfur** are acquired by plants primarily through interaction with solutions in the soil (Fig. 16.1). Uptake and use of nitrogen- and sulfur-containing ions occur through highly evolved morphological, physiological, and biochemical mechanisms. Nitrogen and sulfur are often present in soil in oxidized forms that must be reduced for the element to be used in metabolism. These conversions take place in highly reducing environments (characterized by low E° values) and link nitrogen and sulfur assimilation with pathways that generate reducing potential. Nitrate and sulfate reduction are compartmentalized and regulated to facilitate integration with other cellular metabolism. A combination of biochemical and molecular genetic approaches is further elucidating these pathways.

16.1 Overview of nitrogen in the biosphere and in plants

Nitrogen (N) is the fourth most abundant element in living organisms. While nitrogen constitutes less than 0.1% of the earth's crust, it makes up about 80% of the atmosphere, mostly as **dinitrogen** (N_2). Despite the disparity in content, the large mass of the earth's crust means the number of N atoms below ground is about 50 times greater than in the entire atmosphere. Most of this nitrogen is trapped in igneous rocks, and weathering of those rocks does not release much nitrogen to the living world.

The cycling of N between geochemical and biochemical states is quite complex (Fig. 16.2), given the many oxidation states the N atom can occupy in inorganic and organic compounds (Table 16.1). Most of the N taken up by organisms is recycled from a pool of nitrogenous compounds that have been used by other organisms. New inputs to this pool are generated during chemical reactions that accompany natural events (e.g., fire and lightning) or human activity (e.g., use of internal combustion engines and application of **chemical fertilizers**).

The main input to the nitrogen pool in natural ecosystems is from reduction of atmospheric and dissolved N_2 to **ammonia** (NH_3) through the biological process of **nitrogen fixation** (Table 16.2). Nitrogen fixation is carried out only by prokaryotes, including both eubacteria and archaea. The NH_3 produced by nitrogen fixation is usually assimilated into amino acids and thence to protein and other N-containing compounds. NH_3 released from organisms or added as fertilizer may be converted to **nitrite** (NO_2^-) and **nitrate** (NO_3^-) ions by nitrifying bacteria. In turn, NO_3^- enters metabolism through reduction to the **ammonium ion** (NH_4^+) and subsequent assimilation to amino acids by bacteria, fungi, and plants, or it can serve as an electron acceptor for denitrifying bacteria when oxygen is limiting. Losses from the nitrogen compound pool occur physically, when nitrogen (especially NO_3^-) is leached into inaccessible domains in the soil, and chemically, when **denitrification** or the anaerobic ammonium oxidation (**anammox**) reactions release N_2 (Fig. 16.2).

Plants can synthesize the suite of nitrogenous compounds common to all living organisms, as well as numerous molecules found only in plants (Fig. 16.3). The largest requirement for N is the synthesis of amino acids (see Chapter 8), the

FIGURE 16.1 Nitrogen and sulfur cycles in plants. Nitrogen and sulfur are both taken up by roots from the soil solution, and both undergo major changes in oxidation state as they are converted from inorganic to biochemically available forms. Nitrogen is converted from nitrate (NO_3^- ; oxidation +5) to ammonium (NH_4^+ ; -3) before being further converted to other compounds through the intermediate amino acid glutamine (Gln). Sulfur is converted from sulfate (SO_4^{2-} ; -6) to sulfite (SO_3^{2-} ; oxidation +3 and then to sulfide (S^{2-}) and sulfhydryl compounds (R-SH ; -2), such as the amino acid cysteine (Cys).

building blocks of proteins and precursors to many other compounds. Nitrogen is also an essential component of nucleic acids (see Chapter 6), cofactors, and other common metabolites, and is a major component of chlorophyll (see Chapter 12). The characteristic yellow color of nitrogen-starved plants (chlorosis) reflects their inability to synthesize adequate amounts of green chlorophyll under N-limited conditions (Fig. 16.4). Several plant hormones contain N or are derived from nitrogenous precursors (see Chapter 17). Plants synthesize diverse nitrogenous **secondary compounds**, most prominently the alkaloids (see Chapter 24). Although flavonoids and other plant phenolics do not contain N, they are derived from phenylalanine (see Chapter 24), which means their synthesis is linked to amino acid metabolism. The most important step in assimilating inorganic N into these organic metabolites is the condensation of ammonia and glutamate to form glutamine; this reaction is catalyzed by **glutamine synthetase**, an enzyme subject to extensive regulation in all plants (see Chapter 8).

FIGURE 16.2 The nitrogen cycle. Organic N compounds (top), which are constituents of all living organisms, are released into the environment by death and decay and are excreted as waste by some animals. Microorganisms deaminate organic nitrogen, utilizing the carbon as a food source and liberating ammonium (NH_4^+) in the process. Plants and microorganisms can take up nitrate (NO_3^-) (bottom) and reduce it to NH_4^+ for subsequent assimilation into organic N-containing compounds. Many biological processes that change the oxidation state of nitrogen are catalyzed exclusively by prokaryotes. These include nitrification (blue-green arrows; NH_4^+ or nitrite, NO_2^- , is oxidized and the energy released is used to fix inorganic carbon), denitrification (red; nitrogen serves as a terminal electron acceptor and is reduced during anaerobic respiration), annamox (purple; the anaerobic production of molecular nitrogen from NH_4^+ and NO_2^-), and nitrogen fixation (green; dinitrogen gas, N_2 , is reduced to NH_4^+).

TABLE 16.1 Inorganic nitrogen compounds.

Compound	Oxidation state of N	Name
N_2	0	Dinitrogen (nitrogen gas)
NH_3	-3	Ammonia
NH_4^+	-3	Ammonium ion
N_2O	+1	Nitrous oxide
NO	+2	Nitric oxide
NO_2^-	+3	Nitrite
NO_2	+4	Nitrogen dioxide
NO_3^-	+5	Nitrate

Plants may acquire nitrogen through NH_4^+ uptake and incorporation into organic compounds, NO_3^- uptake and reduction to NH_4^+ , or, in the case of plant hosts for nitrogen-fixing bacteria, acquisition of fixed N from bacterial **endosymbionts** (from the Greek: “living together within”).

TABLE 16.2 Rates of natural and anthropogenic nitrogen fixation.

Source	Amount of N fixed (Tg/year)*
Lightning	<10
Biological N-fixation in terrestrial systems†	90–140
Biological N-fixation in marine systems	30–300‡
N fertilizer chemical synthesis	100
Fossil fuel combustion	>20

*The standard unit of measure is the teragram, Tg (10^{12} g), equal to 10^6 metric tons.

†This estimate includes both natural ecosystems and agricultural nitrogen fixation.

‡Estimates differ because of variable data.

FIGURE 16.3 Selected organic nitrogenous compounds of biological importance. Though some, such as amino acids and nucleoside bases, are found in all living organisms, chlorophyll is found only in plants and other photosynthetic organisms. Alkaloids such as cocaine are often unique to plants, and hormones such as zeatin and IAA are found in plants and certain plant-interactive microbes.

Plants display diverse strategies in acquiring nitrogen, as is evident both in comparisons of different species with one another and in comparison of individuals of a given species that are grown in different environments (Fig. 16.5). For

FIGURE 16.4 Nitrogen deficiency phenotype in wheat plants. Compared to well-nourished plants (left), N deficiency (right) is associated with diminished growth and yellowing (chlorosis) of older leaves. Source: From CIMMYT gallery; International Maize and Wheat Improvement Center <http://www.flickr.com/photos/cimmyt/5083622155/>.

FIGURE 16.5 Schematic overview of N uptake from mineral nutrition (left) and by a nodulated legume with N-fixing symbionts (right). Plant roots can import nitrate (NO_3^-), ammonium (NH_4^+), and other nitrogenous compounds from the soil. For use in synthesis of amines, NO_3^- must be reduced to NO_2^- and then to NH_4^+ . Nitrate reduction in the cytosol and storage in the vacuoles can occur in either the roots or the leaves. Nodulated plants are able to take up nitrogen from the soil (not shown), and generate NH_4^+ also by reducing N_2 through the action of symbiotic bacteria. The NH_4^+ from nitrogen fixation is assimilated into amino acids and ultimately incorporated into amide amino acids (glutamine or asparagine) or ureides for export to the leaves (see Section 16.4.9 and Figs. 16.25 and 16.26).

Nitrogenous soil amendments have a long history

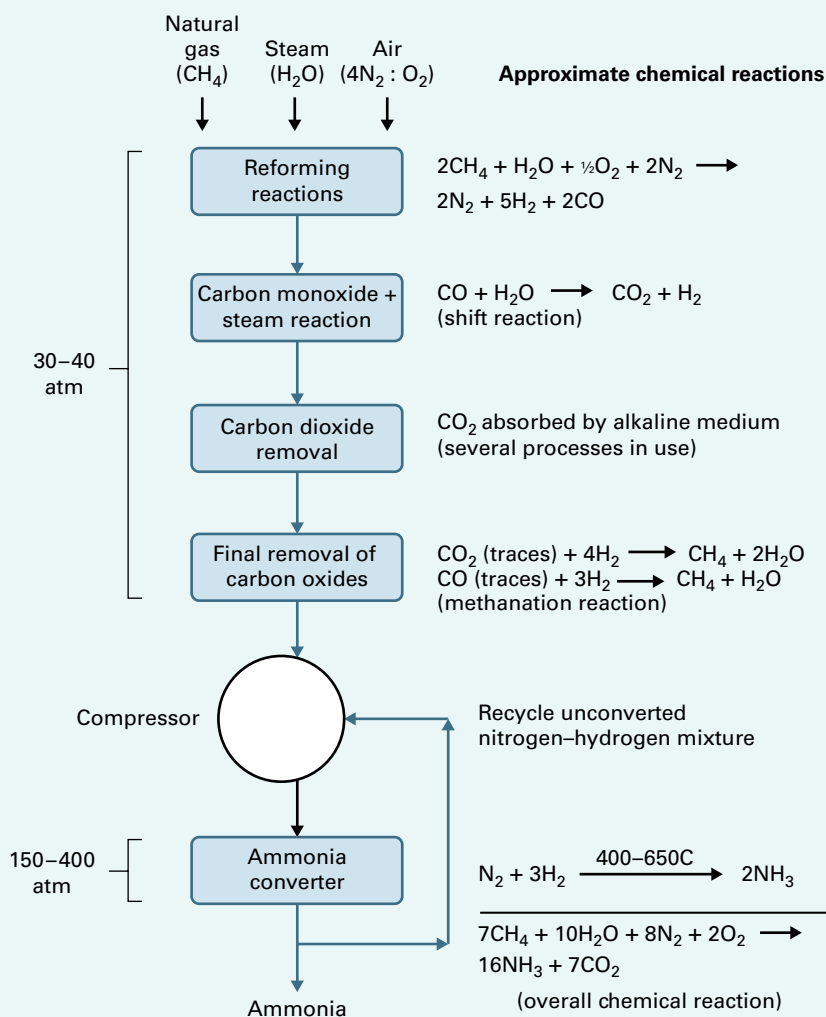

The use of soil amendments to enhance plant growth appears to have been widespread in many cultures, according to unwritten tradition and later written records. Farmers rotated crops and applied manure or simple minerals with little quantitative rigor until the 18th to 19th centuries, when chemical analysis of soils and study of plant growth requirements became more defined. By the early 19th century, nitrogen fertilizer was applied on a larger scale, both in the form of manures, including guano, and as mineral nitrates. However, the use of nitrogen supplies for fertilizer had to compete with the demand for these chemicals as components of explosives and gunpowder.

Production of ammonia (NH_3), initially a byproduct of the coking of coal, was transformed in 1913 by the work of Fritz Haber and Carl Bosch in Germany, who developed a complete practical synthesis of NH_3 from N_2 and H_2 in the presence of an iron catalyst at high temperature and pressure. The reaction of dinitrogen with hydrogen gas is actually exothermic (ΔH_f° for $\text{NH}_3(\text{g})$ is $-46.1 \text{ kJ mol}^{-1}$),

but the activation energy for the reaction is very high because of the triple bond in dinitrogen:

At room temperature the reaction is favored but very slow, and at very high temperature the equilibrium favors reactants, not products. K_{eq} is 6.0×10^5 at 298 K, $2.1 (\times 10^0)$ at 450 K, and 4.4×10^{-5} at 800 K. The industrial **Haber-Bosch** process that takes hydrogen from methane to make ammonia is a compromise, using pressures ranging from 150 to 400 atmospheres, temperatures ranging from 400°C to 650°C , and metal catalysts; ammonia is removed as it is formed (see figure). Agricultural practices based on inputs of NH_3 -based nitrogen fertilizers (see Table 16.2) require large amounts of fossil fuel (usually methane), which may become a serious limitation as energy costs rise. **Industrial nitrogen fixation** uses about 5% of world natural gas production to produce over $100 \times 10^{12} \text{ g N/yr}$ (see Table 16.2).

example, NO_3^- taken up by roots may be reduced and assimilated in the root ($\text{NO}_3^- \rightarrow \text{NH}_4^+ \rightarrow$ glutamine), or it may be transported to the shoot as NO_3^- and then assimilated. NO_3^- may also be stored in vacuoles in root or shoot cells. Plants able to establish symbioses control the formation and function of the required symbiotic structures in response to their nutritional environment. For example, legume plants grown in the presence of NO_3^- preferentially use this as a source of nitrogen for nutrition and do not form symbiotic nodules (see Section 16.4.2) or allow invasion of bacterial endosymbionts such as *Rhizobium*. Acquisition of nitrogen occurs in a context that is physiological, developmental, and environmental. A comprehensive investigation of nitrogen assimilation requires the study of genes and gene expression, of protein structure and activity, and of root development and physiology.

As photoautotrophs, plants are typically limited in their growth by the availability of nutrients other than carbon. They need relatively large amounts of nitrogen, and because usable nitrogen can be lost from the rhizosphere by leaching or microbial transformation, nitrogen availability frequently limits plant productivity. As a result, widespread application of nitrogenous **fertilizer** has been a key factor in improving agricultural yields during the 19th and 20th centuries (Box 16.1). As the human population grows and the demand for agricultural products increases, it becomes all the more important to understand the mechanisms of plant nitrogen acquisition.

16.2 Overview of biological nitrogen fixation

16.2.1 Some prokaryotes can reduce nitrogen gas to ammonia using the enzyme nitrogenase

N_2 constitutes about 80% of the earth's atmosphere, but the stability of its triple bond renders it inert and metabolically inaccessible to most organisms. Eukaryotes cannot use N_2 , but some microbes called **diazotrophs**, which include many different eubacteria as well as some methanogenic archaea, are able to catalyze the enzymatic reduction of this compound to ammonia (NH_3) using the enzyme nitrogenase (Reaction 16.1, see Section 16.3). Unlike the Haber–Bosch process (see Box 16.1), such biological nitrogen fixation occurs at ambient temperatures and atmospheric pressure.

Reaction 16.1: Nitrogenase

Diazotrophs are represented by free-living microbes as well as a few species of bacteria that are able to establish symbiotic associations with plants. Much of what we know about

the genetics and biochemistry of nitrogen fixation has been determined by studying free-living eubacteria such as *Clostridium*, *Klebsiella*, *Azotobacter*, and *Anabaena*, and results from these investigations have provided detailed information about factors that constrain all nitrogen-fixing systems. These free-living nitrogen-fixing microbes must obtain their energy from outside sources, for example, by oxidizing decaying or decomposing materials in the soil. By contrast, nitrogen fixed by bacteria in symbiosis is exchanged for carbon fixed by the plant, and nitrogen fixation is more efficient because the plant environment provides optimized physiological conditions. This support can overcome constraints that often limit nitrogen fixation by nonsymbiotic bacteria (see Section 16.4).

16.2.2 Nitrogen fixation is sensitive to oxygen

Nitrogen fixation is a unique biochemical reaction that consumes energy-rich compounds while requiring strong biological reductants (see Reaction 16.1). Because nitrogenase and some of the proteins that supply it with reductant are sensitive to oxygen, many nitrogen-fixing bacteria are anaerobes. Neither fermentation nor anaerobic respiration oxidizes reduced carbon compounds as efficiently as aerobic respiration, so anaerobic bacteria must process large quantities of substrate to generate the large amount of ATP required for N_2 fixation. In contrast, aerobes and microaerobes can take advantage of the increased ATP production from aerobic metabolism but must contend with the oxygen sensitivity of nitrogenase.

In some cases, free-living nitrogen-fixing organisms use mechanical, temporal, or biochemical barriers to keep oxygen away from the biological catalysts of nitrogen fixation. In other cases, the nitrogen fixation machinery is segregated spatially into specialized structures. For example, some **filamentous cyanobacteria** generate **heterocysts**, thick-walled cells that fix nitrogen but cannot complete all the reactions of oxygenic photosynthesis. Heterocysts produce the ATP needed for nitrogen fixation using cyclic photophosphorylation, a light-dependent process that does not create oxygen gas (see Chapter 12). Some nonfilamentous cyanobacteria segregate photosynthesis from nitrogen fixation temporally, performing oxygenic photosynthesis in the light, and nitrogen fixation in the dark.

16.3 Enzymology of nitrogen fixation

Nitrogenase is a complex, metal-containing enzyme. At least three distinct classes of nitrogenase are known that differ in their metal composition, but the best-studied nitrogenase is the **molybdenum** (Mo)-dependent enzyme (Fig. 16.6).

FIGURE 16.6 Structures of MoFe (Component I, nitrogenase; lower figure) and Fe (Component II, nitrogenase reductase; top of figure) proteins of nitrogenase, and electron flow through the two enzymes. The Fe protein is encoded by *nifH*, and it accepts electrons from a carrier, such as ferredoxin or flavodoxin. The identity of the carrier varies, depending on the biological system involved. The Fe protein, with net hydrolysis of ATP, transfers single electrons at very negative potential to P-clusters in the MoFe protein. The MoFe protein, an $\alpha_2\beta_2$ heterotetramer of subunits encoded by *nifD* and *nifK*, accepts electrons at the FeMo cofactor and binds H^+ ions and N_2 molecules in a stepwise cycle, ultimately leading to the production of H_2 and ammonia.

16.3.1 Nitrogenase is composed of two component proteins

Nitrogenase is a complex consisting of the **MoFe protein (dinitrogenase or component I)** a heterotetramer, and the **Fe protein (dinitrogenase reductase or component II)** a homodimer. The reduction of N_2 by nitrogenase involves a complicated interplay between these two components. The MoFe protein houses the active site metal cluster where N_2 binds, whereas the Fe protein delivers electrons to the MoFe protein component in a reaction coupled to the hydrolysis of MgATP. Enzymatic reduction of N_2 by nitrogenase also requires the reduction of two protons to form H_2 , so the reaction uses eight protons and eight electrons and hydrolyzes 16 MgATP to 16 MgADP and 16 P_i (see Reaction 16.1). Why nitrogenase evolves H_2 during N_2 reduction is not well understood.

Part of the complexity of the interactions between these two proteins is dictated by the fact that the Fe protein can only transfer one electron at a time to the MoFe protein. This transfer is coupled to the hydrolysis of two MgATP molecules to yield two MgADP and two P_i . After it has donated an electron to the MoFe protein, the oxidized Fe protein dissociates and another reduced Fe protein takes its place. Thus, the complete reduction of one N_2 molecule requires that Fe proteins associate and dissociate from the MoFe protein at least eight times in order to accumulate sufficient electrons to achieve N_2 and proton reduction and generate ammonia. The oxidized Fe proteins released from the MoFe protein are reactivated for the cycle by being reduced using a small electron carrier protein (i.e., ferredoxin or flavodoxin), with electrons coming from metabolism; the two MgADP are exchanged for two MgATP molecules.

Two similar nitrogenase classes (often called alternative nitrogenases) contain **vanadium (V)** or Fe in place of the Mo. Far less is known about how these enzymes reduce N_2 , but it is thought they follow the same basic reaction sequence outlined above for the Mo-dependent nitrogenase system. Related, but distinct genes code for the alternative nitrogenase classes. The metal content of the active sites are similar between the classes, with the key difference being the presence of a single Mo or V, or an additional Fe atom in the active site of the cofactor (see Section 16.3.2).

16.3.2 The MoFe protein binds N_2 at a unique metal cofactor

The MoFe protein houses the active site where N_2 binds and is reduced. The protein is a $(\alpha\beta)_2$ heterotetramer, with each $\alpha\beta$ dimer representing a functioning catalytic unit (Fig. 16.6). Each MoFe protein is, therefore, composed of two catalytic units, with each unit having a site for associating with an Fe protein.

Each $\alpha\beta$ dimeric unit of the MoFe protein contains two unique metal cluster assemblies, or cofactors. One cofactor, called the **FeMo cofactor** or FeMoco (fee-moh-koh), is composed of Mo, Fe, sulfur (S), carbide (C), and the organic acid **R-homocitrate** that are arranged in a complex metal cluster with an overall stoichiometry of $[1Mo-7Fe-9S-1C-1homocitrate]$ (Fig. 16.7). FeMoco can be viewed as a $[4Fe-3S]$ cube linked by three sulfides (S^{2-}) to a $[1Mo-3Fe-3S]$ cube. The organic acid R-homocitrate binds to the Mo on one end of the cofactor using two of its oxygen atoms. The cofactor is covalently bound to the protein through a cysteine (Cys) amino acid side chain ligand to a specific Fe on one end and through a histidine (His) side chain ligand to the Mo on the other end. A high-resolution X-ray structure of the MoFe protein shows an additional carbon atom (C) at the center of the FeMoco cage, an extraordinary configuration for a single carbon.

FeMoco is the site of N_2 binding and reduction, but exactly where N_2 binds to this metal cluster during the reaction is not yet established. Growing evidence suggests some substrates,

FIGURE 16.7 Molecular model of iron-molybdenum cofactor (FeMo cofactor). Carbon is shown in gray, iron in rust, sulfur in yellow, oxygen in red, nitrogen blue, and molybdenum in magenta. The atom at the center of FeMo-co is a carbide (C^{4-}) atom C. The Mo-type of nitrogenase is present in all symbiotic bacteria, including *Rhizobium* and *Bradyrhizobium*.

FIGURE 16.8 Structure of the P-clusters of the MoFe protein. Reduced and oxidized conformations are shown. Iron atoms are shown in rust, sulfur atoms in yellow.

including N_2 , bind to one or more of the Fe atoms in the central region. These studies have taken advantage of the fact that nitrogenase can reduce several nonphysiological substrates, small molecules that contain double or triple bonds. The classic alternative substrate for nitrogenase is the alkyne **acetylene** ($HC\equiv CH$), which is reduced to the alkene ethylene ($H_2C=CH_2$). Because ethylene is easily measured using gas chromatography, the reduction of acetylene by nitrogenase is commonly used as a test for nitrogenase activity, both in the field and with the purified enzyme.

Each $\alpha\beta$ dimer of the MoFe protein contains a second metal cluster called the **P-cluster** (see Figs. 16.6 and 16.8). This cluster contains Fe and S with a stoichiometry of $[8Fe-7S]$, arranged in an overall structure that can be viewed as a $[4Fe-4S]$ cube bridged by an S at one corner to a $[4Fe-3S]$ cube (Fig. 16.8). In addition to the usual binding of the

P-cluster to the protein through cysteine residues, the P-cluster is also linked to the protein in certain oxidation states through the O side chain of a serine and an amide from the protein backbone. The cluster rearranges as it is oxidized or reduced, but the function of this rearrangement remains unknown. The P-cluster likely accepts each electron donated by the Fe protein, and it transfers one or more electrons to the FeMo-cofactor to support substrate reduction. How many electrons accumulate on the P-cluster and the order of the electron flow through the P-cluster during the complete catalytic cycle remain to be firmly established.

16.3.3 The Fe protein is a reductase that also hydrolyzes MgATP

The Fe protein functions as a reductase, delivering electrons to the MoFe protein, and it is constructed from two identical protein subunits (γ_2). These two subunits are covalently linked to each other through a single $[4Fe-4S]$ cube cluster that is bound by two cysteine amino acids from each subunit (see Fig. 16.6). The $[4Fe-4S]$ cluster is located at one end of the Fe protein. Each protein subunit also contains a nucleotide-binding site, which is located on the end of the protein away from the $[4Fe-4S]$ cluster.

The binding of two MgATP molecules, one to each subunit, changes the overall structure of the Fe protein. Important consequences of this protein conformational change include changes to the properties of the $[4Fe-4S]$ cluster. The reduction midpoint potential of the $[4Fe-4S]$ cluster changes from -300 mV to -420 mV when MgATP binds. Since the nucleotide-binding site is located some distance away from the $[4Fe-4S]$ cluster, this change in potential must be accomplished through protein conformational changes. The more negative reduction potential of the $[4Fe-4S]$ cluster associated with ATP binding promotes electron transfer from the Fe protein to the MoFe protein. The MgATP-induced protein conformational change also increases the affinity for docking of the Fe protein to the MoFe protein. Thus, the MgATP-bound state of the Fe protein favors association with the MoFe protein and subsequent electron transfer.

This feature has been exploited to trap a stable Fe protein–MoFe protein complex by using a MgATP analog. The complex was examined by X-ray crystallography, revealing the location of Fe protein docking to the MoFe protein (see Fig. 16.6). This arrangement suggests an electron transfer chain that starts at the $[4Fe-4S]$ cluster of the Fe protein, goes to the P-cluster of the MoFe protein, and finishes at the MoFe-cofactor of the MoFe protein. The initial transfer of a single electron from the $[4Fe-4S]$ cluster of the Fe protein is activated by the hydrolysis of the two bound MgATP molecules. The reactions of the Fe protein and of the MoFe protein can be viewed as two joined cycles (Fig. 16.9), with the Fe protein cycle driving the stepwise progression of the MoFe protein cycle.

FIGURE 16.9 The Fe and MoFe enzyme cycles. E_n represents the redox state of the MoFe protein enzyme after it has accepted n electrons, and red arrows illustrate the transfer of a single electron and association of a proton. In the initial steps of the reaction, H_2 may evolve without productive binding of N_2 , essentially wasting the ATP and reductant invested in creating these intermediates. Dinitrogen (N_2) can bind to the enzyme by displacing H_2 from either the E_3 or E_4 forms; thus, formation of molecular hydrogen is an obligatory step in the enzymatic reduction of N_2 . Treatment of later complexes with acid releases ammonia, which suggests the N atoms in these complexes are associated with more than one H.

Multiple electrons must be accumulated within the MoFe protein, where they are distributed between the P-cluster, the FeMo cofactor, and partially reduced substrates. The MoFe protein must accumulate a minimum of eight electrons to complete the N_2 reduction catalytic cycle. The stepwise reduction of the MoFe protein is conveniently represented by designating the protein as being in an E_n state, where n is the number of electrons that have accumulated within the MoFe protein. In this nomenclature, E_0 represents the MoFe protein in its resting state, while each subsequent reduced state is designated as E_1 , E_2 through E_8 . Different substrates bind to different E states of the MoFe protein. For example, acetylene is proposed to bind to the E_2 state, while N_2 is proposed to bind to the E_3 and E_4 states.

For proton and acetylene reduction in the absence of N_2 , only the E_0 – E_2 states need to be accessed, as these reactions are only two-electron reductions. For the reduction of N_2 , all eight E states would be accessed. The intermediates that exist during the reduction of N_2 are not known, but it is assumed N_2 stays bound to FeMo-cofactor during the complete reaction, existing as partially reduced intermediates that stay bound to FeMo-cofactor until ammonia is released. Based on the reduction of N_2 with small metal compounds, it is reasonable to assume partially reduced intermediates bound to FeMo-cofactor occur at the levels of reduction of diazene ($HN=NH$) and hydrazine (H_2N-NH_2). The actual intermediates involved, the site of intermediate binding, and the distribution of electrons within the MoFe protein during catalysis must be established in future studies to gain a better understanding of the mechanism of this complex enzyme.

Reduced ferredoxin (or, in some organisms, flavodoxin) is thought to donate electrons to dinitrogenase reductase in

many free-living nitrogen-fixing bacteria. The enzyme pyruvate **ferredoxin (flavodoxin) oxidoreductase** can transfer electrons to oxidized ferredoxin (flavodoxin) from pyruvate. Some organisms, including rhizobial symbionts, may have alternative, electron transport-coupled methods of generating the low-potential electrons required to reduce these electron carrier proteins.

16.4 Symbiotic nitrogen fixation

In natural terrestrial ecosystems, 80–90% of the nitrogen available to plants originates from biological nitrogen fixation, and of that total, approximately 80% is produced in symbiotic associations. Symbiotically fixed nitrogen can increase plant growth and yield considerably, as seen in comparisons of plants grown on nitrogen-poor soils with or without effective symbiotic bacteria (Fig. 16.10). The benefits of nitrogen fixation, however, are not without cost: if all plant resources required to establish **nodules** (specialized structures where nitrogen fixation takes place; see Section 16.4.2), fix nitrogen, and transport the resulting ammonia throughout the plant are taken into account, obtaining nitrogen through symbiosis consumes 12–17 g of carbohydrate per gram of nitrogen fixed. Predictably, legumes have mechanisms to suppress nodule formation and function if nitrate or ammonia is available as an alternate source of nitrogen. Improved understanding of plant and bacterial genes used in symbiosis may allow plant breeders and microbiologists to provide better-functioning host bacteria for agricultural systems.

FIGURE 16.10 Legumes depend on effective rhizobia. At right, soybean provided with an effective rhizobial inoculum; at left, soybean grown with an ineffective native rhizobial resident in the soil.

Source: Vessey (2004) Crop Management doi:10.1094/CM-2004-0301-04-RV.

Quantitative isotope ratio measurements are used to assess the contribution of nitrogen fixation to total nitrogen in plants. Atmospheric nitrogen is essentially all $^{14}\text{N}_2$, and soil often contains greater amounts of the stable isotope ^{15}N . A plant that obtains fixed nitrogen from the atmospheric pool through nitrogen-fixing symbiosis will have less ^{15}N in its total nitrogen than if it obtains nitrogen only from soil sources. The best controls for this measurement are plants of the same species grown in the same soil but without symbiotic bacteria. **Rhizosphere** (root zone) and other associations of plants with some free-living nitrogen-fixing bacteria (e.g., *Azospirillum*, *Azoarcus*, and *Herbaspirillum*) increase yield in crops including sugar cane (*Saccharum* spp.) and sorghum (*Sorghum* spp.). The microbes enhance plant growth by producing plant hormones and other compounds, but the contribution of nitrogen fixation to this growth increase is not clear.

16.4.1 Diverse vascular plants establish nitrogen-fixing symbioses

Nitrogen-fixing symbioses are not restricted to vascular plants. Hosts for nitrogen-fixing bacteria include fungi (lichens) and animals ranging from marine corals to terrestrial termites. In the case of vascular plants, three major groups of prokaryotes establish morphologically developed N_2 -fixing symbioses.

The first group of symbioses exists between cyanobacteria, such as *Anabaena*, and diverse plants, including cycads, ferns, liverworts, hornworts, and one angiosperm genus, *Gunnera*. These hosts elaborate specialized structures to accommodate the cyanobacteria. For example, *Gunnera* is infected in glands at the base of leaf petioles, cycads produce specialized “coralloid” roots, and *Azolla*, a water fern that associates symbiotically with the cyanobacterium *Anabaena*, harbors the bacteria in a leaf cavity. The *Azolla*–*Anabaena*

pair is used as a cocrop with **rice** (*Oryza sativa*); it produces sufficient fixed nitrogen to allow continuous and sustainable rice cultivation.

A second type of symbiosis occurs between members of a Gram-positive **actinomycete** genus (*Frankia*) and a diverse group of dicots from over 20 genera in eight or more families within the **Rosid I lineage** of dicotyledonous plants (Fig. 16.11). The hosts include trees or woody shrubs such as alder (*Alnus*), myrtle (*Myrica*), *Casuarina*, and *Ceanothus*. These symbiotic associations play a significant role in the nitrogen economies of forests and other natural ecosystems. The *Frankia* symbionts group taxonomically as a few closely related clades, with no apparent transfer to distantly related actinomycetal species. The taxonomy of these *Frankia* groups correlates with that of the host plants.

Symbiotic *Frankia* and their hosts establish nodules, unique structures within the host roots in which nitrogen fixation occurs. *Frankia* penetrate the plant root with filamentous bacterial hyphae, either through root hairs or by means of intercellular penetration along contiguous cell walls. Within plant cells, the bacterial hyphae form branches, establishing a large bacterial surface area in intimate contact with plant cell membranes. The form of the invading bacteria differs between host plants, from simple or swollen branches to septate vesicles. The plant accommodates the invading bacteria by constructing a peripheral capsule rich in cell wall-like materials, and the body of the root nodule forms by new divisions of cortical and hypodermal cells. Plant hormone changes are associated with nodule formation and infection: auxin-dependent promoters, for example, show enhanced activity in infected host cells of actinorhizal nodules. The plant also differentiates by expressing nodule-specific genes encoding proteases, cell wall proteins, hemoglobin, cell division functions, and metabolic enzymes. At the molecular level, some genes required for legume symbiosis (see Section 16.4.3) have sequence and functional homologs in *Frankia* hosts (see Box 16.2).

FIGURE 16.11 Phylogenetic analysis of 99 *rbcl* genes (encoding the large subunit of Rubisco) from genera representing the subclass Rosidae and additional angiosperm taxa. Taxa that engage in nodular nitrogen-fixing symbioses are highlighted in yellow. (*Gunnera*, which hosts cyanobacterial endosymbionts, is marked in green.) Note that a single clade includes all the nodule-forming genera included in the tree. Subclades A, C, and D include actinorhizal symbiotic hosts; the legume family (*Fabaceae*) falls into subclade B.

A third group of symbioses involves rhizobia, which are Gram-negative bacteria that infect numerous **legumes** (*Fabaceae*) and one known nonlegume, *Parasponia* (*Ulmaceae*). These plants are also in the Rosid I lineage (Fig. 16.11, see Section 16.4.2). Rhizobial endosymbionts contribute nitrogen to commercially important seed legumes such as peanut (*Arachis hypogaea*), soybean (*Glycine max*), lentil (*Lens culinaris*), bean (*Phaseolus vulgaris*), pea (*Pisum sativum*), cowpea (*Vigna unguiculata*), and forage

crops, such as clover (*Trifolium* spp.) and alfalfa (*Medicago sativa*). Rhizobial symbioses are also important in plants used for land stabilization and reclamation, and in natural environments.

Taxonomic analyses group most of the rhizobial bacteria into distinct major clusters within the α -proteobacteria (including *Rhizobium*, *Sinorhizobium*, *Azorhizobium*, *Mesorhizobium*, and *Bradyrhizobium*), and β -proteobacteria (*Burkholderia* and *Cupravidius*). These genera do not form single clades within either the alpha or beta groups. Symbioses between groups of plant hosts and particular bacterial species, or biovars, display various levels of specificity (Table 16.3). Host specificity does not correlate strictly with bacterial phylogeny; disparate genera of bacteria may nodulate a single type of host plant. Host specificity does, however, correlate with the structures of bacterial signal molecules, the **Nod factors** (see Section 16.4.4), and with corresponding bacterial **nod genes**.

16.4.2 Legumes develop root nodules to house rhizobial symbionts

In the presence of compatible rhizobial species, legume hosts also form **root nodules** (Fig. 16.12), in which environments conducive to nitrogen fixation are established, especially the microaerobic conditions needed for bacteria to synthesize ATP and stabilize nitrogenase. Plant metabolism in the nodule generates organic acids, some of which are catabolized by the rhizobial symbionts to fix nitrogen. The bacteria release the resulting ammonia to the plant, which assimilates it into **amides** or **ureides**. These compounds are used to transfer fixed (reduced) nitrogen to the rest of the plant. Few rhizobia fix nitrogen outside the plant host. Bacterial nitrogen fixation is most useful to the plant when it has no other nitrogen sources; both nodule formation and function are subject to downregulation by host plants that are provided with nitrate or ammonia.

Root nodules are constructed by the plant in response to bacteria. Briefly, the rhizobia, attracted to molecules released by the host legume's roots (see Section 16.4.3), attach to the host's root hairs. The rhizobia produce chemicals called Nod factors (see Section 16.4.4) that cause the colonized root hairs to curl, trapping the rhizobia, which then penetrate the root hairs and typically form a tubular structure called an infection thread. Once the bacteria reach the root itself, they stimulate cortical cell division, leading to the formation of the nodule (see Sections 16.4.5–8). As the nodule develops, the rhizobia are released inside the plant cells that form the nodule, still surrounded by a plant-derived membrane. The bacteria within these plant membranes have weak cell walls and form large, irregularly shaped branching cells called bacteroids, at which point they depend entirely on the host legume for their energy needs (see Section 16.4.9).

The molecular signals and mechanisms underlying nodule formation have been studied by combining genetics with analysis of cell behavior, biochemical function, and gene expression.

BOX
16.2

Nodulation shares features of signaling pathways involved in other symbioses

Nod factors are structurally similar to chitin fragments, which are components and breakdown products of fungal cell walls that elicit plant defense reactions. It is intriguing that legumes detect a bacterial signal resembling a pathogenic elicitor, and that the plant inducers of bacterial *nod* genes are flavonoids, a chemical family employed in legumes as phytoalexin defense molecules in response to pathogens. The pattern of signaling in which an organism first evolves to tolerate a toxic molecule and then to respond to its presence is a classic paradigm of coevolution.

Recruitment of existing pathways for new uses is also suggested by the fact that some host genes required for rhizobial symbioses are also used for other plant symbioses. A *Casuarina* gene required for *Frankia* symbiosis is homologous to *SYMRK* and can complement a legume *SymRK*-deficient mutant. Some legume genes required for nitrogen fixing symbiosis—*SymRK*, ion channel, and *CCAMK*—are also required for

vesicular–arbuscular mycorrhizal infection of those same plants. Mycorrhizal cultures produce lipochitin oligosaccharide (LCO)-like chitin-oligomers that resemble Nod factors and can cause legume Ca^{2+} spiking. Ca^{2+} spiking can be triggered by unmodified chitin as well. It remains to be discovered whether the chemical modifications of mycorrhizal LCOs confer added information, such as host range and the ability to trigger unique functions to support mycorrhizal infection and differentiation.

Further evidence for the evolutionary relatedness of mycorrhizae and rhizobial symbioses comes from study of *Parasponia*, the only nonlegume nodulated by *Rhizobium*. In this plant, a single protein appears to act as receptor for both mycorrhizal and rhizobial signals. The ancient and widespread occurrence of **mycorrhizal symbioses** suggests the genes governing these associations may have been co-opted during coevolution to enable the more recent *Frankia* and *Rhizobium* symbioses.

TABLE 16.3 Examples of rhizobia-plant host range.

Bacterial species*	Frequently studied host plants†
<i>Sinorhizobium meliloti</i>	<i>Medicago</i> (alfalfa, barrel-medick)
<i>Rhizobium leguminosarum</i> bv <i>viciae</i> <i>R. leguminosarum</i> bv <i>trifolii</i>	<i>Vicia</i> (vetch) <i>Pisum</i> (pea) <i>Trifolium</i> (clover)
<i>Mesorhizobium loti</i>	<i>Lotus</i> (trefoil) <i>Lupinus</i> (lupine)
<i>Bradyrhizobium japonicum</i>	<i>Glycine</i> (soybean) <i>Macroptilium</i> <i>Vigna</i> (cowpea)

*Previous taxonomic schemes classified many of these genera as *Rhizobium*.

†Only the genus of the host plants is indicated. The list of host plants is not comprehensive, particularly for broad host-range bacteria. bv, biovar.

16.4.3 Plant flavonoids activate rhizobial transcription

Accurate mutual recognition in legume-rhizobia systems is accomplished by exchange of biochemical signals. Molecules released by the host plant induce bacterial gene expression

FIGURE 16.12 Photo of root nodules on pea (*Pisum sativum*). Source: Long, Stanford University, Palo Alto, CA; previously unpublished.

(Fig. 16.13), and this leads to production of bacterial signal molecules and proteins that modify plant metabolism and development.

Specific bacterial genes are involved in the sequential stages of symbiosis. The rhizobial genes responsible for early nodule formation are termed *nod* genes (see Section 16.4.4), and expression of these genes typically depends on a chemical signal from the plant (the inducer) and on a bacterial transcription

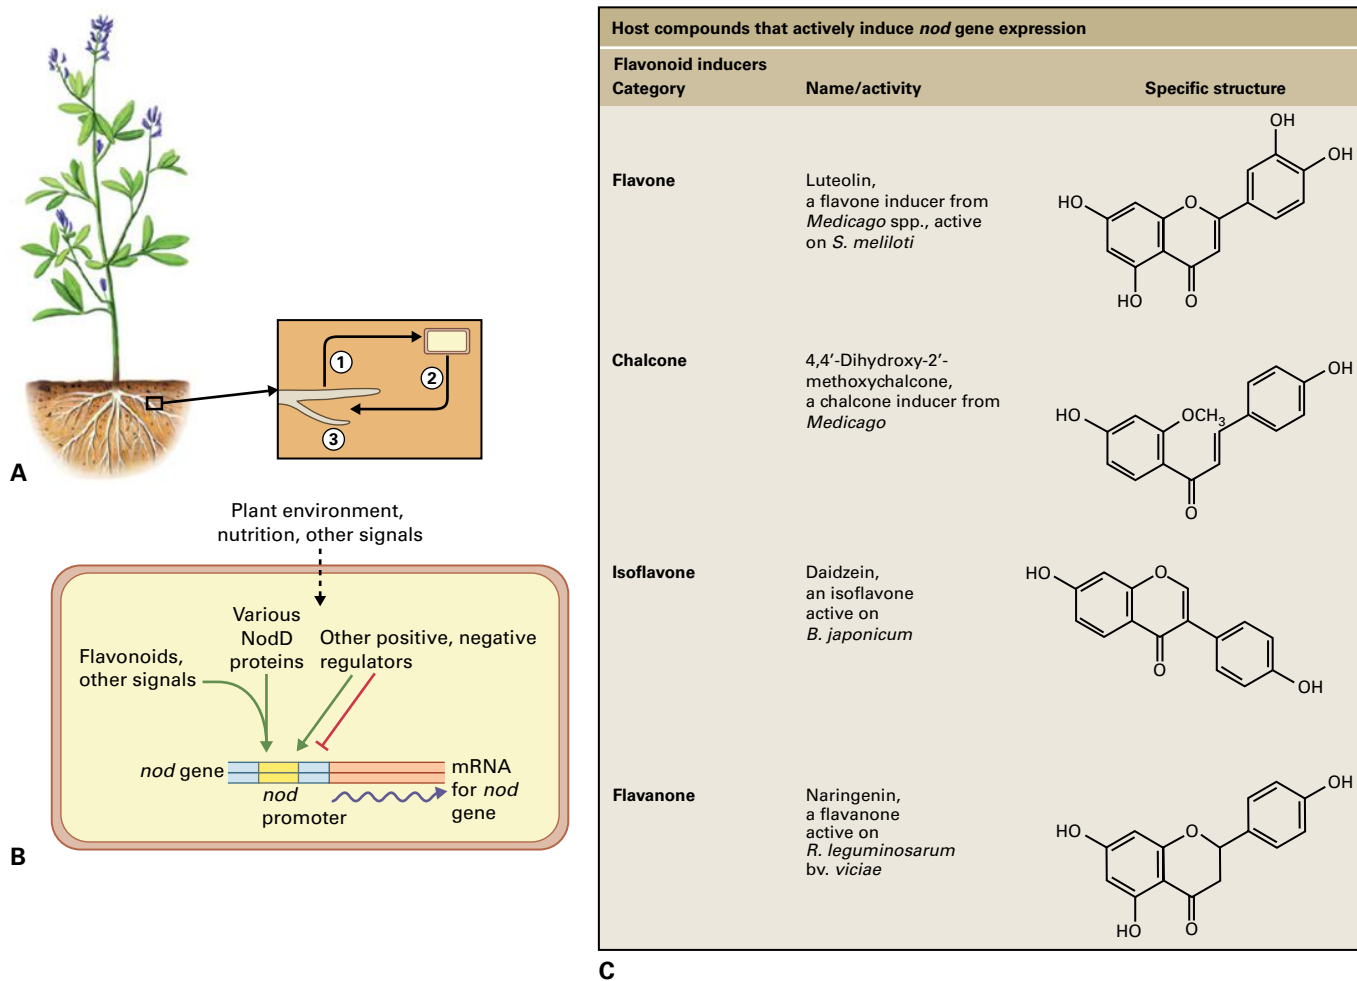

FIGURE 16.13 Signals in early nodule development. (A) Plant and bacteria exchange molecular signals. In many cases, step 1 is plant production of a root-derived flavonoid, and step 2 is recognition of the flavonoid and production of a bacterial Nod factor, which triggers responses in the plant (step 3). (B) In the bacterium, the transcriptional activator NodD interacts with a plant inducer and the transcriptional machinery of the bacterium to induce expression of bacterial *nod* genes. The circuits for *nod* gene activation may also respond to environmental cues and as yet unknown signals from the plant. (C) Flavonoids, the prominent inducers of rhizobial *nod* gene expression. The plant compounds that most actively induce expression of nodulation genes vary among different plant-symbiont systems. A bacterium's *nodD* genotype is a primary determinant of the preferred inducer structure.

activator, NodD (Fig. 16.13B). The plant signals that induce *nod* gene expression are commonly flavonoids (Fig. 16.13C; see also Chapter 24), and their diverse structures provide initial recognition for plant–bacteria communication.

Genetic and biochemical data indicate rhizobial **NodD proteins** interact directly with the signals generated by the plants. Plant pathways for inducer biosynthesis (see Chapter 24, Fig. 24.59) respond to bacterial signals; the **flavonoid** profile of **root exudates** changes in response to inoculation with rhizobia. The pattern of inducer and inhibitor production by the plant implies developmental and environmental regulation: for example, inducer release is most concentrated near the root tip, and flavonoid pathway enhancement in response to rhizobia is similarly localized. Additional negative and positive regulators of *nod* gene expression include bacterial proteins that respond to nutritional status and other environmental signals.

16.4.4 Bacteria synthesize molecular signals that control plant development

Symbiotic rhizobia also produce various molecular signals that trigger nodulation-related changes in the host plant, including **oligo-** and **polysaccharides** and proteins. Many rhizobial *nod* genes, for example, encode enzymes that direct the synthesis of Nod factors, bacterial products that act as nodule morphogens. Nod factors are **lipooligosaccharides**, fatty acid derivatized oligomers of chitin [β -1,4-linked **N-acetylglucosamine** (GlcNAc)] (Fig. 16.13D). The core Nod factor structure is a chitin backbone of three to five GlcNAc residues with an *N*-acyl substitution on the nonreducing end GlcNAc residue. This basic structure is constructed by three proteins common to all Nod factor-producing strains: NodA, NodB, and NodC. Other enzymes, which differ among bacterial species, decorate

D

FIGURE 16.13 (Continued) (D) Structures of Nod factors, the N-acylated chito-oligosaccharides produced by bacteria. Nod factors are synthesized by enzymes encoded in the bacterial nod genes (B) and exported from the bacteria to the plant (step 2 in A). Plants respond to Nod factors with changes in ion flux, calcium spiking, morphogenesis, and transcription (step 3 in A). Top: all known Nod factors have a linear backbone of β -1,4-linked N-acetylglucosamine. Modifications to the reducing and nonreducing ends differ according to bacterial strain or species. The Nod factor modifying groups determine which host plant(s) will display nodulation-like reactions to the factor. Bottom: the Nod factor synthesized by *Sinorhizobium meliloti* and active on *Medicago* species. The 6-O-sulfonoyl modification on the reducing end residue (right) and the modifications on the nonreducing end (6-O-acetyl and N-acyl) affect activity and host specificity of the molecule.

this core structure with various C-6 modifications on the reducing and nonreducing ends, N-methylation or O-carbamoylation of nonreducing end residues, and other O-substitutions on the inner GlcNAc residues. The pattern of these modifications determines which hosts the bacteria will nodulate, and it is assumed this recognition is mediated by the detailed structure of the Nod factor receptors in the host plant (see Section 16.46). Broad host-range rhizobia appear to produce multiple Nod factor structures. Enzymes made by *nod* genes may also form or modify other compounds that play a role in symbiosis, such as lipids and carbohydrates.

Additional types of specific extracellular polysaccharides are required to invade many host plants. For example, *S. meliloti* mutants with defects in the structure or processing of extracellular polysaccharides (EPSs) are unable to infect *Medicago*: infection thread growth after infection by these mutants is feeble and aborts early.

Prominent rhizobial extracellular carbohydrates include loosely associated EPSs (e.g., **succinoglycan**; Fig. 16.14A); **lipopolysaccharides** that extend from the lipid-A anchor in the bacterial outer membrane; K-antigens, unusual EPSs that contain keto-deoxyoctanoic acid; neutral cyclic beta-glucans; and cellulose. The roles played by various EPSs in symbiosis may differ from one host-rhizobial symbiotic pair to another.

Finally, in some broad host-range bacteria, **Type III/Type IV secretion systems** appear to play a major role in determining which plants can be nodulated (Fig. 16.14B). Such secretion complexes presumably deliver effector molecules to the extracellular environment or directly to the host cell. The processes of invasion and release, which require coordinated activity of the bacterial and plant cells, may also require specialized transfer of signals and material at the plant-bacterial interface.

FIGURE 16.14 Extracellular molecules are important for rhizobial infection of some plant hosts. (A) Some rhizobial species, here exemplified by *Sinorhizobium meliloti*, produce extracellular polysaccharides (EPS), which are required for host invasion. Left: schematic of Gram-negative bacterium with capsular and exopolysaccharides exterior to the outer membrane. Right: structure of the well-studied EPS-I (succinoglycan) of *S. meliloti*. The repeating unit of the EPS is an eight-sugar branched oligomer, consisting of a backbone of four residues [$\rightarrow 4$] β -Glc-($1\rightarrow 3$) β -Glc-($1\rightarrow 4$) β -Glc-($1\rightarrow 3$) β -Gal-($1\rightarrow$) and a four-residue side chain of mixed $\beta 1\rightarrow 3$ and $\beta 1\rightarrow 6$ Glc. The backbone and side chain are modified by acidic derivatization. The EPS contains hundreds of these eight-residue repeats, of which four are shown here. (B) In some broad host-range rhizobial strains such as *Sinorhizobium fredii* NGR234 and *Mesorhizobium loti*, Type III or IV secretion systems are required for symbiosis on some host plants. The secretion systems export proteins; in principle, these may be introduced into other bacterial cells, into plant cells, or into the medium.

16.4.5 Nodule development requires the interplay between molecular and developmental signals

In many cases, bacterial infection begins in the root hair initiation segment of the root. Cellular and molecular assays reveal multiple responses and altered root hair function following exposure to Nod factor (Table 16.4). These responses, which include altered ion fluxes and **Ca²⁺ spiking**, likely signal developmental changes in the root hair, such as its growth into the curled structure known as the “shepherd’s crook,” which traps one or more bacteria against the developing cell wall (Fig. 16.15A).

Over a period of hours to days, this wall deforms and extends into the root hair, leading to a tube-like structure known as the **infection thread**. As rhizobia grow and divide and the adjacent plasma membrane and infection thread wall expand, the bacteria push farther into the root (Fig. 16.15Bi). The bacteria interact with the underlying root tissues while remaining within a plant-derived membrane. Infection threads filled with dividing bacteria penetrate one or more root layers to meet dividing plant cells. The matrix (lumen) of infection threads contains a number of secreted bacterial and plant proteins and extracellular products, exemplified by a specific plant **arabinogalactan** protein in the **extensin** family. At least one molecular mechanism for the change in cell wall

TABLE 16.4 Root hair cellular responses to bacterial Nod factor.

Response	Timing
Membrane potential depolarization Ion currents Tip flux of Ca ²⁺ ion	Observed in root hairs within 1 minute of NF application
Ca ²⁺ spiking in and around root hair cell nucleus	Begins within ~10 minutes after NF exposure
Root hair growth perturbation: pause in growth, reinitiation of polar growth, curling	Occur over a period of hours
Reduction in rate of reactive oxygen production	Sustained for at least 1 hour; followed by ROS increase

activity is a plant pectin hydrolase. During this process, subepidermal and cortical plant cells display active reorganization of cytoskeleton, cytoplasm, and membrane systems that resemble predivision phragmoplasts. How infection threads exit a plant cell is not known, but it must involve fusion of the infection thread membrane with the cytoplasmic membrane and subsequent rhizobial penetration of cell wall spaces.

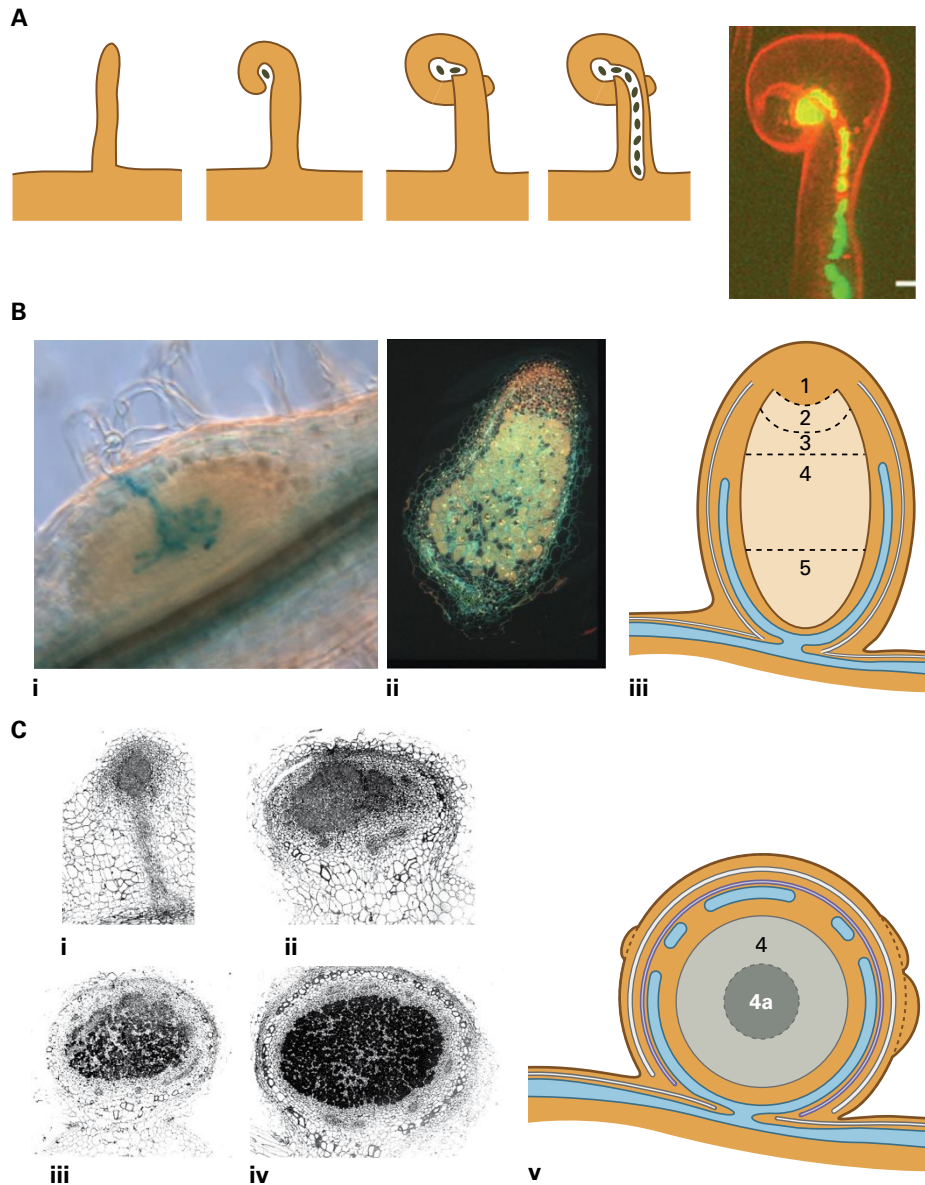

FIGURE 16.15 Formation of nitrogen-fixing nodules. (A) Diagrammatic representation of root hair invasion (left) and photograph of an infected root hair (right) from alfalfa (*Medicago sativa*). In the photograph, bacteria fluoresce green and yellow, and the plant cell fluoresces red. Root hair growth is perturbed so the hair deforms and curls as it elongates; bacteria trapped in the curl form an infection thread and proliferate as they invade. (B) Nodule morphogenesis for an indeterminate (cylindrical, meristematic) nodule, such as that generated by alfalfa (*Medicago*), pea (*Pisum*), and clover (*Trifolium*). The first cell divisions occur in the inner cortical layer of the root and continue as the infection thread penetrates (i); bacteria in the infection thread are stained blue from a LacZ marker. A nodule meristem forms and persists so that newly divided, uninfected plant cells are continuously formed at the distal (from the root) nodule tip. An elongated nodule, formed by activity of a persistent meristem, has zones of uninfected, infected, and senescent cells along a distal to proximal axis of the nodule. The nodule is stained with DAPI (labeling DNA and cell wall) and acridine orange (labeling RNA orange and DNA green) (ii). Numbers in diagram (iii) correspond to the following structures: 1, nodule meristem; 2, infection thread growth and cell penetration; 3, expanding infected cells; 4, mature bacteroid-containing tissue; 5, senescent bacteroid-containing tissue. (C) Nodule morphogenesis for a determinate (spherical) nodule, such as that produced by soybean (*Glycine*), trefoil (*Lotus*), and bean (*Phaseolus*). (i) Initial cell divisions are observed in the root outer cortex, followed by invasion of bacteria into plant cells; (ii–iv) many rounds of host and bacterial cell division give rise to zones of infected and uninfected cells in a spherical, stable nodule. Bars = 250 μm . (v) Schematic diagram of the zones of the fully formed determinate nodule: 4, mature bacteroid-containing tissue; 4(a), zone where senescence starts in determinate nodules. Mature determinate nodules lack meristematic tissues. Source: (A) Gage; (B) Long & Haney; © ASM press; (C) Long & Dudley Dudley © Springer citation Planta volume.

The nodule body forms through division of cortical cells that dedifferentiate and re-enter the cell cycle. Overall developmental features of root nodules may differ, but two well-studied forms are **determinate** (spherical) and **indeterminate** (cylindrical, meristematic) **nodules** (Fig. 16.15Bii, iii, and C).

Development and morphogenesis involve major plant hormone pathways as described below.

Alternative invasion mechanisms have been observed. For example, in crack invasion, Nod factor-producing bacteria take advantage of breaks in the epidermis, and cortical cells accessed

in this way are then invaded using a short infection thread. A variant on this is found in some *Bradyrhizobium* species that lack genes for Nod factor synthesis but can still promote infection and nodule development by a Nod factor-independent mechanism. These bacteria appear to penetrate roots through epidermal cracks and enter host cells by an endocytosis-like interaction with the intercellular wall and matrix. This type of entry may represent an ancestral mechanism for bacterial infection leading to symbiosis.

16.4.6 Molecular genetics and biochemical analyses have revealed plant genes and proteins required for nodulation

The molecular genetics of nodule development has been revealed by combining biochemical analyses, such as study of extracted protein or RNA species, with the use of plant or bacterial mutants. Plant mutants that form no nodules (Nod⁻ phenotype) or nonfixing nodules (Fix⁻ phenotype) are often characterized by analyzing molecular and cellular behaviors (Table 16.4) in responding roots, notably in the model systems *Lotus japonicus* and *Medicago truncatula*. Key insight has come from using such phenotypes to define the defects in plant mutants that fail to form nodules. For example, various Nod⁻ plant mutants can be distinguished by observing which early nodulation events they complete before the process fails. These combined data have led to identification of genes and gene products that contribute to symbiotic behavior across various developmental stages.

Proteins that interact with Nod factor have also been found in tissue culture, seeds, and roots through direct biochemical assay. Low- and high-affinity binding proteins have been described in roots and cell cultures from several legume species, and some purified lectins also bind Nod factor. Among other possible functions, these proteins may function directly in signaling or play a role in delivering, sequestering, or degrading Nod factor.

Multiple plant receptors are involved in Nod factor perception. Legume nodulation genes encoding receptor-like proteins have been identified in both *Lotus japonicus* and *Medicago truncatula*. In each species, distinct genes encode an inferred “entry” receptor and a “signaling” receptor. Mutations in either gene cause a severe nodulation defect: the plants do not form nodules, and they exhibit little or no response to bacteria or Nod factor.

Each of these two proteins is a membrane spanning receptor-like protein with an extracellular portion bearing several LysM domains (Fig. 16.16). Originally identified in bacterial and bacteriophage proteins, the **LysM motif** is an amino acid sequence of 44–65 residues that establishes a chitin-binding domain. It has been identified in plant proteins that bind chitin as part of a fungal detection program. Chitin constitutes the oligomeric backbone of Nod factor. The two LysM-bearing proteins are proposed to be the Nod factor receptors. Direct binding of the two LysM-type receptor proteins to Nod factor has not been demonstrated, but their membrane localization has been confirmed by cellular assays. Swapping extracellular LysM domains between the signaling receptors of two species can change their ability to partner

FIGURE 16.16 Required plant nodulation genes encode proteins with receptor-like features. The entry receptor (exemplified by *LjNFR1* and *MtLYK3*) has three extracytoplasmic LysM domains resembling protein elements that bind chitin and chitin-like molecules. The cytoplasmic domain of the entry receptor includes a kinase domain with several common kinase elements such as the P (phosphorylation) and A (activation) loops (shown by stars). The signaling receptor similarly has three extracytoplasmic LysM domains but lacks the kinase features found in the entry receptor. The signaling receptor (for example, *MtNFP* and *LjNFR5*) is required for any host response to NF. An entry receptor (for example, *MtLYK3* and *LjNFR1*) is required for infection. The symbiosis receptor kinase, *SymRK*, which is exemplified by *MtDMI2*, *LjSYMRK*, and inferred gene products in pea (*Pisum sativum*) and soybean (*Glycine max*), has three extracellular leucine-rich repeat domains in a large N-terminal segment. The cytoplasmic portion has a kinase domain that includes the conserved activation loop. Mutations in these residues eliminate *in vitro* autophosphorylation activity and generate a Nod⁻ phenotype *in vivo*.

with distinct rhizobial inocula, implying a direct role for the signaling receptor in species-specific Nod factor perception.

The entry receptor, exemplified by LjNFR1 and MtLYK3, includes a cytoplasmic domain showing the elements of a typical kinase (Fig. 16.16): a conserved glycine-rich P (phosphorylation) loop; a catalytic domain; an activation loop that, when phosphorylated, changes conformation to assist correct docking of the kinase and its substrate; and an Asp-Phe-Gly (DFG) triplet that is near the activation loop and plays a role in its phosphorylation. The entry receptor autophosphorylates with γ - ^{32}P -ATP and is postulated to transfer the phosphoryl group to a target signal transduction protein. The signaling receptor protein, however, lacks some sequence features that are usually present in active kinases; the C-terminal cytoplasmic domain has the catalytic domain characteristic of a kinase, but is missing the P-loop and activation loop, and it does not autophosphorylate. The signaling receptor may interact with other proteins to transmit a signal via kinase activity.

A candidate partner kinase for the signaling and entry receptors is the **symbiosis receptor kinase**, SymRK (Fig. 16.16). This receptor is required both for symbiosis with rhizobia and for establishing a symbiosis with broad host-range mycorrhizal fungi that enhances plant mineral uptake and drought resistance. The *SYM* gene predicts an extracellular domain with **leucine-rich repeats**, a membrane-spanning domain, and an intracellular kinase. The kinase domain is capable of autophosphorylation and can act as a kinase on target proteins *in vitro*.

The signaling and entry receptors affect some early root hair cell behavior (Table 16.4, Rows 1–3) even in the absence of SymRK, and it is inferred they influence ion channels and cytoskeletal elements. Biochemical and imaging analyses indicate the entry receptor protein interacts with E3-ubiquitin ligase and membrane-associated proteins, such as flotilins and remorins. It is presumed the receptors communicate with other signal transduction pathways in the root hair cell, perhaps by co-opting systems that are in place for other plant cell functions. Pharmacological studies indirectly point to phosphoinositide signaling; direct confirmation of secondary signaling mechanisms may come from definition of more host genes that transduce Nod factor receptor binding into subsequent cell activities.

Other plant proteins required for nodulation include **nuclear membrane** components, which are required downstream of the receptors. These include proteins that have sequence similarity to a K^+ ion transporter in the archaeal species *Methanobacterium thermoautotrophicum*. These channel proteins localize to the nuclear membrane (Fig. 16.17) and are required for subsequent Ca^{2+} spiking (see Section 16.4.7). Genetic studies imply that these proteins mediate flux of K^+ or similar monovalent cations and that the C-termini play a role in modulating channel function. It is possible that an ion flux mediated by these channels plays a role in the dynamic behavior of Ca^{2+} in the nucleus.

Other required genes encode homologs of conserved nucleoporin proteins included in the ring complex, which is located in the cytoplasmic and nuclear faces of yeast or

FIGURE 16.17 Elements of a nuclear pore are required for effective symbiosis signaling. Here, the cytoplasmic face of the membrane is at the top of the illustration, and the nuclear volume is at the bottom. Several required legume symbiosis genes are homologous to mammalian genes encoding components of the nuclear pore's ring complex. These proteins localize to the Nup107 complex (shown in blue), a part of the ring structure on both the cytoplasmic and nuclear sides of the membrane. Signaling also requires nuclear membrane proteins predicted to be ion channels (pink); it is not known whether these are on the inner or outer face of the nuclear membrane.

mammalian nuclear pores (Fig. 16.17). Nuclear pores are generally permeable to small molecules but play a more selective role in protein and mRNA transport. In animal cells, the ring complex is also implicated in phosphorylation events linked to the cell cycle, and it may play a role in spindle assembly and alignment in cell division. The localization of the symbiosis-related ion channel and nuclear pore proteins in the nuclear membrane implies a dynamic cytoplasm–nucleus interaction during Nod factor signaling.

16.4.7 Calcium spiking and a calcium-calmodulin-dependent protein kinase are elements of a central regulatory point in Nod factor signaling

Nod factor treatment causes root hairs to display “calcium spiking,” transient, periodic increases and decreases in Ca^{2+} ion levels (Fig. 16.18A). This behavior depends on the upstream receptors and nuclear membrane components described above. The spiking occurs in the nuclear and

A

B

C

FIGURE 16.18 (A) Calcium spiking in root hairs responding to *Rhizobium* nodulation factors. Nod factor may elicit this plant cell behavior by influencing calcium-specific pumps and channels. Cytoplasmic calcium was imaged using fluorescent calcium-sensitive dye and was quantified on the basis of the ratio of fluorescence observed at 340 and 380 nm. The single-wavelength image at right (340 nm) shows the nucleus (n), where calcium spiking is most prominent. (B) Within the plant nucleus, calcium-activated calcium- and calmodulin-dependent protein kinase (CCaMK) phosphorylates transcription factor NSP1. Activated NSP1 and a similar factor NSP2 are able to bind the promoters of genes for early nodulins, such as ENOD11, and for downstream regulators ERN and NIN. (C) CCaMK is a master regulatory switch for nodule development, and functional domains of wild-type CCaMK include: an N-terminal kinase domain, C-terminal EF-hand domains that bind Ca^{2+} directly, and a domain that binds Ca^{2+} -calmodulin (CaM). The wild-type protein (top) displays Ca^{2+} - and CaM-dependent *in vitro* activities: Ca^{2+} binding stimulates autophosphorylation, and CaM binding stimulates transfer of phosphate to a target protein. The activity of CCaMK is negatively autoregulated by a region adjoining the kinase domain. Plants carrying the wild-type CCaMK gene form nodules in the presence of homologous rhizobia. Deletions or certain point mutations in the autoregulatory domain in the *Lotus* and *Medicago* alleles of CCaMK result in proteins with constitutive activity. Plants carrying these deregulated forms of CCaMK form spontaneous nodules in the absence of bacteria.

FIGURE 16.19 Patterns of early nodulin (ENOD) gene expression in developing nodules vary according to each gene. For example, ENOD12 is expressed in the early infection zone of pea nodules (compare Figure 16.15C), as shown in this *in situ* hybridization. photographed in dark-field illumination. Silver grains from probe hybridization scatter light and, therefore, appear bright against the dark background.

Source: Scheres et al. (1990). *Cell* 60:281–294.

perinuclear regions within the root hair. Ca^{2+} spiking is a prominent signal transduction motif in some animal cell responses, such as T-lymphocyte responses to antigen and Sonic Hedgehog (Shh) signaling in vertebrate neuron development. Empirical studies and modeling analyses show that Ca^{2+} spiking behaviors must involve at least two components: (1) a channel that releases Ca^{2+} from a reservoir, and (2) an energy-dependent Ca^{2+} pump for reuptake of Ca^{2+} into the reservoir to restore the starting level of ion. The two components typically have a feedback system that sustains or attenuates the behavior. In animal systems, feedback mechanisms include secondary signals or Ca^{2+} - or other ion-induced effects. In the case of root hairs, the reservoir is believed to be the nuclear membrane lumen. Pharmacological evidence points to the involvement of phosphoinositide signaling and a Type IIA Ca^{2+} -pump.

Downstream of Ca^{2+} -spiking, a **calcium-calmodulin-activated protein kinase** (CCaMK) (Fig. 16.18B) is required for subsequent nodule development. This protein is structurally and functionally homologous to a previously characterized lily (*Lilium*) CCaMK. In response to Ca^{2+} ion, the symbiosis CCaMK autophosphorylates at a site in the N-terminal domain, thereby inhibiting activity of the C-terminal kinase domain. Deleting or mutating the autoinhibitory N-terminal domain of the symbiotic CCaMK protein creates a constitutively active protein that triggers spontaneous formation of root nodules in the absence of bacteria (Fig. 16.18C). CCaMK thus appears to be a central coordinating switch point for early steps in the signaling pathway. Symbiotic effectiveness of CCaMK requires a companion protein, CYCLOPS, which is likewise localized in the nucleus.

16.4.8 Nodulins are nodule-specific proteins synthesized by the plant

Nodules are distinct organs that express dozens to a few hundred nodule-specific, plant-synthesized proteins, or **nodulins**. Correspondingly, transcriptomic studies indicate that novel RNA sequences are expressed at various stages of nodule development. For the first 24 hours after inoculation, pure Nod factor and live bacterial cultures elicit equivalent transcriptional responses. After this point, a full plant response is seen only with live bacteria.

Plant genes expressed early, or in the absence of bacterial infection, are termed “early nodulins” (encoded by *ENOD* genes). In emerging nodules, some nodulins may be limited to a distinct cell type or nodule zone (Fig. 16.19). The functions of the *ENOD* gene products, and the significance of their expression patterns, are likely to be revealed through combined genetic and biochemical analysis. These can also serve as useful developmental markers for the successive stages of the plant response to bacteria, and as reporters for dissecting the effects of distinct microbial signals in early symbiosis.

Some *ENOD* genes are transcribed in root hairs as soon as 4 hours after adding bacteria or Nod factor. Induction requires the signaling pathway described above, plus proteins encoded by *NSP1* and *NSP2*, members of the plant-specific GRAS family of transcription activators. NSP1- and/or NSP1–NSP2 protein complexes bind to promoters of a well-studied early nodulin, ENOD11 (Fig. 16.20). More transcription factors, such as NIN and ERN, act later in symbiosis. Nodule gene expression is subject to additional control mechanisms: for example, microRNA (miRNA) controls a nodule meristem-associated transcript, MthAP.

The most prominent late nodulins are the leghemoglobins (Lb), which are required to establish an appropriate oxygen environment with high O_2 flux and low free O_2 tension (see Section 16.4.9). Other late nodulin proteins are involved in metabolizing carbon and nitrogen or in transporting compounds across the symbiosome membrane (see Sections 16.4.5–16.4.9). Some nodulins may mediate signal transduction or cellular response pathways required for the differentiation of plant and bacterial cells to accomplish nitrogen fixation. In some cases, selective gene expression is observed in uninfected host cells; functions for such genes include specialized metabolic steps and possible regulatory proteins. Bacteria likewise differentiate, most prominently by transcribing the genes for nitrogenase and for allied functions, including electron transport and metabolic pathways.

16.4.9 Plant hormones play a role in nodule development

Molecular and developmental studies imply roles for various plant hormones, including auxin, cytokinin, jasmonic acid, abscisic acid, and ethylene in the coordination of nodule

FIGURE 16.20 Transcription factors are required for expression of early nodulins and other regulators. (A) Electrophoretic mobility shift assay showing binding of the NSP1 protein to the promoter of *ENOD11*, a well-characterized early nodulin. Binding specificity is shown by competition with unlabeled promoter DNA fragments. (B) NSP1 binds to the promoters of genes *NIN* and *ERN1* which encode transcription factors required for downstream nodulation responses. (C) The *NIN* and *ERN1* genes are transcribed in wild-type nodules (left), but not in response to rhizobial inoculation in roots of *nsp1* or *nsp2* mutants. *dai*: days after inoculation. Source: Hirsch et al. (2009). *Plant Cell* 21:545–557.

morphogenesis. The effects of these hormones may overlap or compete, and the hormones may have distinct actions in different cell types (epidermal vs. cortical) and at different stages of nodule development (early signal transduction, nodule formation, and nodule growth and maturation).

Cytokinins are linked to nodule development through several lines of experimentation. Cytokinin content increases in roots exposed to compatible rhizobia, and the expression levels of cytokinin-responsive genes increase. Applying cytokinin-producing *E. coli* to the roots of some legumes causes the development of pseudonodules (bacteria-free organs that are similar to nodules in form and that express nodule-specific proteins). Nonfunctional mutant forms of the cytokinin receptor (*MtCre1* or *LjLHK1*, both homologous to *Arabidopsis AtCre1*) can severely limit nodule formation, indicating cytokinin responsiveness is required for nodule primordia formation. Furthermore, constitutive overexpression of *LjLHK* leads to spontaneous nodule-like growths in the absence of bacteria or Nod factor. Taken together, these data imply that cytokinins promote nodule morphogenesis. Genetic analyses suggest that cytokinins act

downstream of the Nod factor signaling pathway; it is also possible they act in parallel with other molecular controls of cell division.

The role of ethylene is complex, as indicated by plant mutant analyses, by inhibitor studies, and by the pattern of expression of ethylene biosynthesis genes in nodule tissues (Fig. 16.21). Ethylene diminishes plant sensitivity to Nod factor: responses such as calcium spiking and early nodulin transcription require higher Nod factor concentration as ethylene concentration goes up. Mutants unable to respond to ethylene (e.g., defects in the legume genes homologous to *AtEIN2*) form excessive numbers of nodules. On the other hand, ethylene may play a positive role in infection thread formation and some other responses.

Auxin transport is altered in plants undergoing nodulation, and auxin transport inhibitors (ATIs) can induce phenocopies of nodule development. By using the strength of auxin-dependent promoters to indicate auxin availability and activity, it is inferred that early nodule development, such as establishment of the primordium, is characterized by low auxin levels, but that later nodule growth is accompanied by increases in auxins. Specific members of auxin transporter gene families may play distinct roles in nodule development. The pathways for auxin, ethylene, and cytokinin interact with each other and with control mechanisms for other hormones including ABA, jasmonic acid, and salicylic acid.

FIGURE 16.21 Expression of a gene involved in ethylene biosynthesis, 1-aminocyclopropane-1-carboxylic acid (ACC) oxidase, in roots responding to rhizobia. In this cross-section of the pea root, hybridization of a probe for ACC oxidase transcripts is visualized as dark signal against the cleared root segment. The position of ACC oxidase expression correlates with the phloem elements of the root vasculature. Nodule primordia tend to form in the zones shown by arrowheads, representing the cortical cells just outside the xylem poles. This implies that nodule primordia are unlikely to form in zones adjacent to ethylene production. Source: Heidstra et al. (1997). *Development* 124:1781–1787.

16.4.10 Local and systemic molecules play a role in regulating nodule formation and differentiation

In addition to hormones, other intercellular signals play a major role in regulating nodulation and nodule number. In particular, regulation of nodule number occurs via signals exchanged between roots and shoots, and grafting studies show that the root and shoot genotypes both play a role. The ability to regulate nodule number is controlled by a number of genes. Among these, a homolog of *CLAVATA-1* acts in the shoot: plants with a mutation in this gene (*LjHar1*, *MtSUNN*, and soybean *NTS*) form abnormally high numbers of nodules. In turn, several nodule-active *CLV3*-like peptides (CLE category) act in roots to downregulate nodule formation. The ability of these peptides to decrease nodule number requires downstream *SUNN* (*NTS1*, *HAR1*). Thus, root CLE peptides—or a subsequent signal that they control—appear to interact with shoot receptor kinases to generate a second, shoot-produced signal that subsequently reduces formation of new nodules.

16.4.11 Rhizobia and their plant hosts interact to create a microaerobic nodule environment that enables nitrogen fixation

After the infection thread traverses one or more layers of host cells, or after the bacteria penetrate layers via intercellular spaces, the bacteria are released into infected cells. This endocytosis-like process generates cytoplasmic organelles called **symbiosomes** (Fig. 16.22), which contain the rhizobia within a plant-derived membrane. In the symbiosomes, rhizobia differentiate into nitrogen-fixing **bacteroids**, which in some plant hosts are morphologically distinct from the free-living bacterial forms (Fig. 16.22A,B). In some cases, bacteria duplicate their genomes without cellular division and appear to be terminally differentiated.

The symbiosome membrane is thought to mediate the flow of nutrients and energy between the plants and the bacteria (Fig. 16.22C). Some plant proteins are uniquely expressed in infected cells and are delivered to or across the symbiosome membrane. These proteins have distinct targeting peptides, which implies the symbiosome is a unique cell compartment. In some legumes, a specific plant signal peptidase is required for bacterial differentiation. This complex is localized to the endoplasmic reticulum and processes host precursor proteins, yielding mature forms that display differentiation-controlling effects on bacteria in culture, and when expressed transgenically in other host plants. A bacterial transporter, *BacA*, is also required for bacterial differentiation and nitrogen fixation and may participate in the process of plant–bacterial signal exchange.

The nodule provides a compartment where bacteria can fix nitrogen in amounts useful to the plant. Because the nitrogenase enzyme is oxygen sensitive, it is a physiological challenge to supply the enzyme with large amounts of ATP and low potential reductant simultaneously. Thus, a major feature of the nitrogen-fixing nodule is that it establishes a microaerobic environment that can stably support aerobic respiration and ATP synthesis, while also being compatible with the sensitivity of nitrogenase. The microaerobic conditions are generated by interaction between the two symbionts.

Three factors are important in maintaining low O_2 concentrations in nodules (Fig. 16.23). First, entry of O_2 into the nodule is controlled by a variable-permeability barrier in the nodule parenchyma. Experimentally induced increases or decreases in external O_2 concentration cause changes in the cellular O_2 content, but these changes are sensed and reversed by an unknown compensation mechanism that restores the O_2 concentration to its previous value.

Second, the O_2 -binding plant protein Lb plays an active role in regulating and delivering O_2 in the infected cells. Both apoprotein and heme are made by the plant cell. Legume leghemoglobin genes are similar to other genes that encode O_2 -binding proteins in widely diverse plant families, but their promoters are distinct. A high level of Lb expression is found only in nodules, where Lb is present at millimolar concentrations. Lb protein is a monomer with a single heme moiety, and despite its name, it is more analogous to myoglobin; it does not display the cooperative O_2 -binding behavior found in animal hemoglobins. The affinity of Lb for oxygen can be influenced by pH and organic acids, but whether Lb is regulated by small molecules within the nodule is not known. Leghemoglobin increases the flux of O_2 moving through the plant cytoplasm to the bacteroids while controlling the concentration of free O_2 . Although Lb-bound O_2 diffuses more slowly than O_2 , O_2 is far less soluble ($\approx 25 \mu\text{M}$) than the Lb: O_2 complex. As an O_2 -binding protein, Lb can also act as a buffer to moderate changes in O_2 concentration that result from fluctuations in the rate of respiration or the permeability of the diffusion barrier.

Finally, bacterial respiration is the major O_2 sink (Fig. 16.23). Whereas the free-living rhizobia typically have a cytochrome oxidase with a K_m for O_2 of around 50 nM, the bacteroid cytochrome oxidase has a much lower K_m for O_2 , about 8 nM (by contrast, K_m values for plant mitochondrial cytochrome oxidases are near 100 nM O_2). Highly expressed by bacteria within the nodule, this type of high-affinity cytochrome oxidase is required for nitrogen fixation. Because bacterial respiration is more effective than plant respiration at low O_2 concentrations, most nodule respiration is thought to occur in the bacteroids. However, plant mitochondria often have a more peripheral location in infected cells, which may give them better access to O_2 diffusing through the intercellular spaces.

Nodule physiology is vulnerable to oxygen-related compounds, such as peroxide, superoxide, and hydroxyl radicals, and although the oxygen concentration in nodules is low, the

FIGURE 16.22 Events that lead to nitrogen-fixing cells. (A) The infection thread releases bacteria into a target cell, which envelopes them in host plasma membrane. The bacteria then undergo limited cell division (indeterminate nodules) or extensive rounds of cell division accompanying host cell division (determinate nodules). (B) After release, bacteria differentiate to form morphologically distinct bacteroids. Different plant-bacterial combinations yield distinct bacteroid forms. (C) In the plant nucleus, a series of genes (late nodulins) are expressed only during later stages of nodule development, in response to bacterial differentiation. Some of these transcripts are specific to infected or uninfected cells. The plant-encoded products include the oxygen-binding protein leghemoglobin, specialized membrane proteins targeted to the symbiosome membrane, and enzymes that catalyze ammonia assimilation and synthesis of molecules used to carry N to the rest of the plant. Bacterial genes are also expressed during this period.

abundance of iron (Fe) proteins can lead to significant amounts of these reactive compounds. Plant cells and bacteroids each have active systems to detoxify these molecules; inhibiting these cellular defenses impairs nodule metabolism and nitrogen fixation.

The low O₂ concentration within the nodule is a key element in regulating bacteroid expression of nitrogenase. In some rhizobial species, the O₂-sensitive hemoprotein kinase FixL controls a regulatory cascade that activates transcription of nitrogen fixation genes (Fig. 16.24). Part of a

two-component regulatory system, FixL phosphorylates its partner FixJ, which once phosphorylated, activates transcription of other regulatory proteins. Two of these proteins, NifA and FixK, control expression of diverse *nif* and *fix* genes (*nif* genes are those that are required for nitrogen fixation for which similar genes exist in free-living diazotrophs; *fix* genes are those that are required for fixation in otherwise normal nodules). The bacteroids express nitrogenase (*nif*-HDK) and the associated proteins required for reduction of dinitrogen to ammonia only in the correct context of a

FIGURE 16.23 In nitrogen-fixing nodules, mechanisms that maintain ATP production in an appropriately low O_2 environment include a high-affinity cytochrome oxidase, the oxygen-binding protein leghemoglobin, and a variable-permeability barrier that controls gas exchange at the nodule periphery. The “empty” cells around the central region are thought to contain the permeability barrier that limits the flow of oxygen to the leghemoglobin-containing central region of infected host cells.

developed, microaerobic nodule. Specific ferredoxins and the high affinity cytochromes described above are examples of proteins encoded by the *fix* genes that are needed for fixation to occur in nodules. The plant can also contribute directly to the formation of an active nitrogenase by providing the bacteria with homocitrate, a component of its FeMoCo cofactor.

16.4.12 Host plants provide carbon to the bacteroids as dicarboxylic acids

Although photosynthate enters the nodule as sucrose, genetic and biochemical evidence show that bacteroids do not need to catabolize mono- or disaccharides to fix nitrogen effectively. Instead, sugars are converted to organic acids before the carbon is made available to the bacteria, probably by using pathways more often associated with fermentation than oxidation (Fig. 16.25).

Some evidence indicates phosphoenolpyruvate (PEP) is converted to oxaloacetate by PEP carboxylase, and NAD^+ is regenerated by reducing oxaloacetate to malate (see Chapters 13 and 14). Intact nodules rapidly incorporate $^{14}CO_2$ label into malate and aspartate, and tissue concentrations of PEP carboxylase and malate dehydrogenase are increased by the synthesis of nodule-specific isoforms of these enzymes. Transport activities further support an important role for organic acids in symbiotic carbon metabolism. The symbiosome membrane can transport dicarboxylic acids but not sugars, and most bacterial mutants with defects in dicarboxylic

FIGURE 16.24 In response to a low- O_2 environment, the FixL/FixJ signal cascade activates expression of bacterial genes required for nitrogen fixation. The FixL heme-containing protein is anchored in the bacterial plasma membrane. In the absence of O_2 , FixL is phosphorylated and in turn phosphorylates the soluble FixJ response regulator, which can bind to DNA and activate transcription of the genes needed for nitrogen fixation. Binding of oxygen to the FixL heme inhibits the protein's histidine kinase activity, repressing the expression of these genes under conditions where nitrogenase would be unstable. In addition to this O_2 -sensing system, bacterial differentiation is affected by plant nuclear-encoded peptides that are processed by the endoplasmic reticulum.

acid transport are ineffective. Amino acid transport may also be needed, because some symbiotic rhizobia, which do not require branched chain amino acids when growing as free-living bacteria, depend on plant-derived branched-chain amino acids in symbiosis.

In the nodule, dicarboxylic acids are used in both catabolic and anabolic processes. Some of these acids are fed to bacteroids, which oxidize them and transfer the electrons to O_2 by way of electron transfer chains that terminate at the high-affinity cytochrome oxidase. This respiration ultimately provides ATP for nitrogen fixation; however, the mechanism by which reductant destined for nitrogenase is generated and transferred to nitrogen fixation has not yet been defined. In another major role, dicarboxylic acids provide the carbon backbones for the nitrogen-containing transport compounds, such as asparagine and glutamine, which are exported from the nodule to carry nitrogen to other parts of the plant (Fig. 16.25).

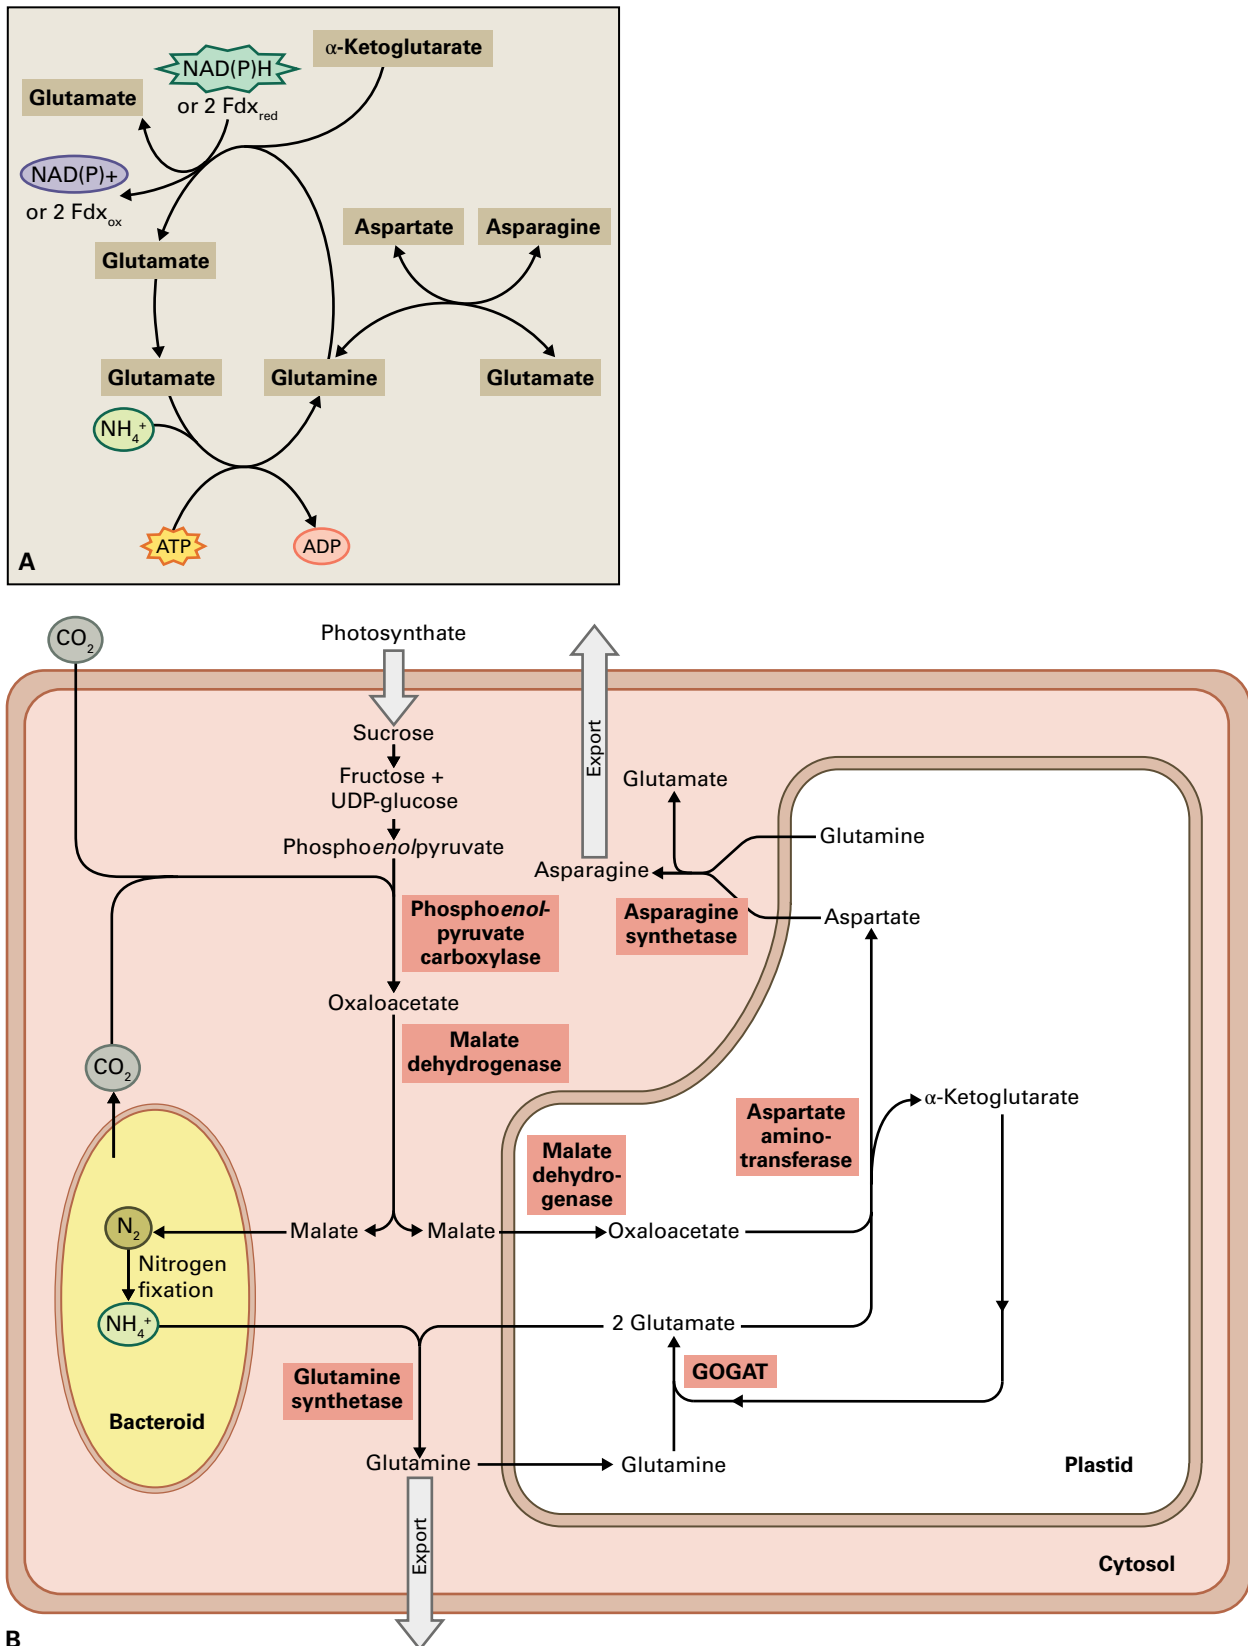

FIGURE 16.25 Primary nitrogen assimilation pathways in nodules of pea, alfalfa, and other species that export amides. (A) The GS-GOGAT cycle, in which ammonium (NH_4^+) is combined with glutamate to yield glutamine in an ATP-dependent reaction. Reaction of glutamine with α -ketoglutarate and a reductant yields two molecules of glutamate, one of which is used to regenerate the cycle, and the other to deliver amino groups to general metabolism. (B) Plant carbon metabolism produces dicarboxylic acids, which are used to generate the ATP and reductant needed for nitrogen fixation in the bacteroids. The reduced nitrogen released is assimilated in the plant cytoplasm and plastids to produce glutamine and asparagine, which are transported through the xylem to the rest of the plant.

16.4.13 Plant gene products assimilate ammonia and export nitrogen from the nodules

Unlike free-living bacteria, which assimilate the nitrogen they fix, bacteroids release nitrogen to the plant, primarily as ammonia (see Fig. 16.22C). Ammonia may traverse the symbiosome membrane by facilitated diffusion; in soybean (*Glycine max*), this transport is thought to be mediated by the NOD-26 aquaporin-related channel. Ammonia assimilation occurs in the plant cytosol and organelles. Plant glutamine synthetase (GS) and NADH-dependent glutamate synthase (NADH-GOGAT) are responsible for the initial assimilation of ammonia into organic compounds (Fig. 16.25A; see also Chapter 7). In some plants, a nodule-specific GS is expressed, whereas in others, synthesis of a vegetatively expressed GS is upregulated. GS can bind NOD-26, and this may increase the efficiency of ammonia assimilation.

After assimilation of ammonia into glutamine, its fate depends largely on the nitrogenous transport compounds used by the plant host. In one major class of legumes that includes alfalfa and pea, nodules export ammonia as **amides**, namely glutamine and asparagine (Fig. 16.25B), which are easily generated from citric cycle intermediates (see Chapter 14). Nodules contain active aspartate aminotransferases, which may be located in plastids at the periphery of infected cells. A nodule-induced asparagine synthetase produces asparagine from aspartate using glutamine as an amide donor (Fig. 16.25A). In trefoil (*Lotus*), an asparaginase that is usually active in roots is repressed during nodule development, and this repression may facilitate export of intact asparagine from the nodule. The amides can be metabolized in leaves by transamination and transamidation reactions similar to those used in their synthesis (see Chapter 7).

A second major group of legumes that includes soybean (*Glycine*) and cowpea (*Vigna*) also exports nitrogen from the nodules as the **ureides** allantoin and allantoic acid. The biosynthesis of these compounds involves multiple compartments, as purines are synthesized in the infected cells and then oxidized in neighboring uninfected cells (Fig. 16.26). In the leaves of nodulated plants, the allantoin is catabolized using allantoin amidohydrolyase to yield ammonia, rather than by hydrolysis of allantoin to generate urea with subsequent degradation of the urea using urease. The ammonia is then assimilated by GS and ferredoxin-dependent GOGAT.

16.5 Ammonia uptake and transport

For plants dependent on mineral nitrogen, ammonium (NH_4^+) and nitrate (NO_3^-) are the major sources. Though nitrate levels in soil are generally higher than ammonium levels, substantial levels of NH_4^+ ion may occur in acidic or anoxic soils, where rates of nitrification are low. For example,

ammonium is a major nitrogen source for rice plants grown in flooded paddy soil. Excess ammonium is toxic, however, and plants have evolved mechanisms to regulate its uptake and expel it actively in an energy-dependent process.

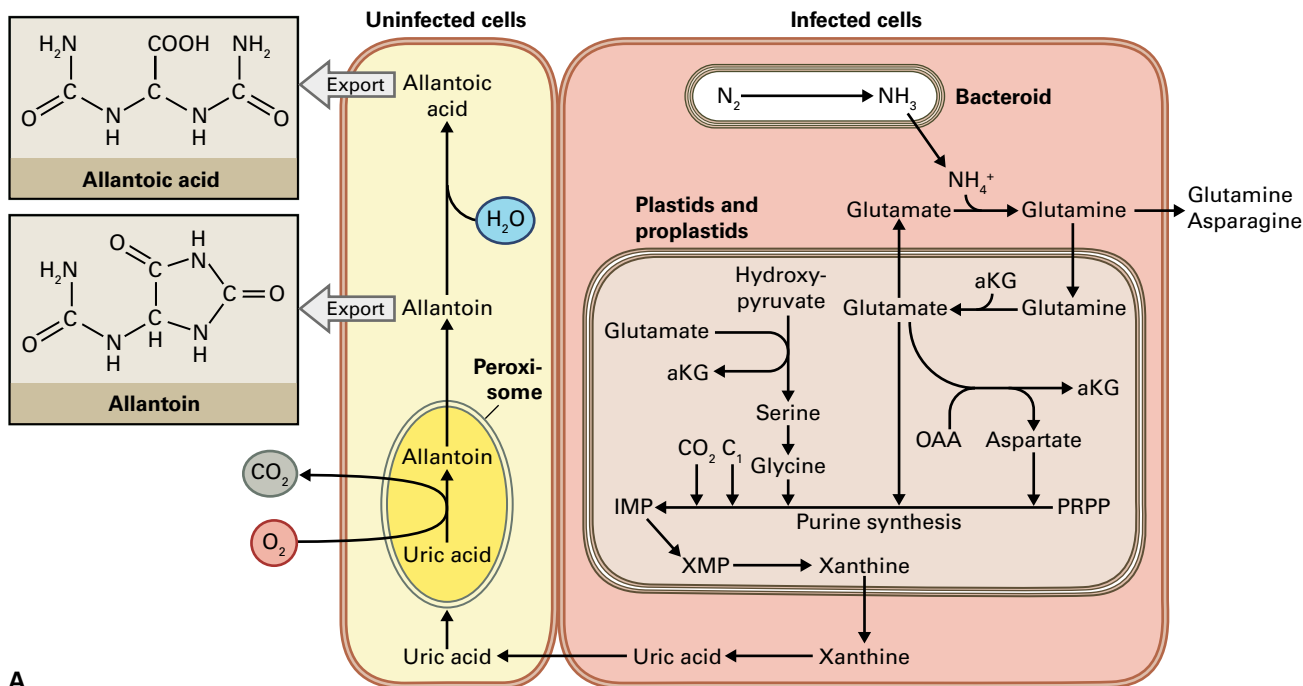

For **ammonium uptake** from the soil, plants use two separate transport systems: a nonsaturable, low-affinity system and a saturable, high-affinity system (Fig. 16.27A). The high-affinity ammonium uptake system involves transporters in the **AMT/Rh** family. *Arabidopsis* has six *AMT* genes: *AMT1;1-5* and *AMT2;1*. Four of these, *AMT1;1*, *AMT1;3*, *AMT1;5* (expressed in the rhizodermis), and *AMT1;2* (cortex and endodermis; Fig. 16.27B), account for ≈ 30 , ≈ 20 , ≈ 30 , and $\approx 10\%$, respectively, of the total high-affinity ammonium influx in *Arabidopsis* roots. Most organisms have *AMT/Rh* genes, but unlike the prokaryotic *AMT* transporter and human erythrocyte rhesus-associated glycoprotein Rh (both of which function as NH_3 channels), plant *AMT* transporters function as NH_4^+ uniporters. The proteins involved in the low-affinity system have not yet been identified, but potassium channels, nonselective cation channels, or aquaporins are potential candidates.

Plant *AMT* transporters are regulated at both the transcriptional and posttranslational levels. Transcript levels for *AMT1;1-3* and *1;5* are upregulated under nitrogen-deficient conditions, and *AMT1.1* and *AMT1.2* proteins are regulated by allosteric transactivation. Crystal structures of the *E. coli* and archaeal ammonium transporters reveal a trimer with a substrate-conducting channel in each monomer (Fig. 16.28). Homology models, suppressor screening, and phosphoproteomic studies suggest the cytosolic C-terminus of plant *AMT* transporters, which contains two conserved short α -helices, interacts with the cytosolic surface of a neighboring subunit. Phosphorylation of a threonine residue (460 in *AMT1.1* and 472 in *AMT1.2*) in the C-terminus of a single monomer leads to a conformational change that leads to the cooperative closure of all three pores in the trimer (Fig. 16.28). This provides a rapid shut-off mechanism that prevents toxic accumulation of ammonium.

Ammonium can accumulate in the vacuole, and the *Arabidopsis* **tonoplast intrinsic proteins** TIP2;1 and TIP2;3 transport NH_3 when expressed in yeast or oocytes. These tonoplast intrinsic aquaporins may be involved in loading NH_3 into the acidic vacuole, where it is then trapped as the NH_3 protonated form, NH_4^+ (Fig. 16.29). In sum, membrane potential is a driving force for the high-affinity ammonium uptake across plasma membranes mediated by *AMT* transporters, while vacuolar acidification could be the main factor for accumulating ammonium in the vacuole (Fig. 16.29).

16.6 Nitrate uptake and transport

Nitrate serves as both nutrient and signal, and it has pronounced effects on plant metabolism and growth. Nitrate is a major soil nitrogen source, and plants devote significant

A

Reaction	Enzyme	Location
Purine nucleotide synthesis		Proplastids of infected cells
Inosine monophosphate ^a (IMP)		
$\text{NAD}^+ \rightarrow \text{NADH}$	IMP dehydrogenase	Plastids of infected cells or cytosol
Xanthosine monophosphate		
Ribose, P_i	Nucleotidase or Nucleosidase	Proplastids of infected cells
Xanthine		
$\text{NAD}^+ \rightarrow \text{NADH}$	Xanthine dehydrogenase	Cytosol
Uric acid		
$\text{O}_2 \rightarrow \text{CO}_2$	Urate oxidase (= uricase)	Peroxisomes in uninfected host cells
Allantoin		
H_2O	Allantoinase	Endoplasmic reticulum in uninfected host cells
Allantoic acid		

^a An alternative possibility is conversion of inosine monophosphate to hypoxanthine, which is then oxidized to xanthine by xanthine dehydrogenase.

B

FIGURE 16.26 Complex cellular and subcellular compartmentation of ureide biosynthesis enzymes in plants such as soybean and cowpea. (A) In tropical legumes such as cowpea and soybean, nitrogenous compounds in addition to glutamine and asparagine are exported from infected cells. A substantial fraction of the fixed nitrogen is exported to adjacent uninfected cells as uric acid, a decomposition product of purines. In the uninfected cells, uric acid is degraded to allantoin and allantoic acid, which are then transported through the xylem to the rest of the plant. The uricase reaction which produces allantoin is especially interesting because it depends on oxygen, which is in limited supply. (B) The purine degradation pathway in nodules, showing the relevant enzymes and their locations.

carbon and energy reserves to its uptake and assimilation. Plants detect nitrate and integrate its assimilation with photosynthesis and overall carbon/nitrogen metabolism. This allows plants to control growth rates, root architecture, carbon/nitrogen ratios, reductant levels, and ionic and pH balances under diverse environmental conditions.

FIGURE 16.27 Ammonium uptake. (A) Uptake by the high-affinity system demonstrates Michaelis–Menten kinetics, and uptake by the low-affinity systems demonstrates nonsaturating kinetics. In *Arabidopsis*, four ammonium transporters (AMT1.1, AMT1.2, AMT1.3, and AMT1.5) are involved in high-affinity uptake. The proteins required for low-affinity uptake have not been identified. (B) Schematic illustration of spatial expression pattern of *Arabidopsis* ammonium transporters in roots.

Nitrate assimilation begins with its transport across the plasma membrane (Fig. 16.30). Usually, nitrate is taken up from the soil solution by root epidermal, cortical, and endodermal cells, though primary uptake can also occur in leaves. Uptake by leaves is important during foliar application of fertilizer, as well as for epiphytes. Once within the symplast, nitrate can be transported into the vacuole, where storage of high concentrations (>20 mM) is possible. Major storage organs for nitrate include the roots, stems, and leaf midribs, but nitrate can also be loaded into the xylem for long-distance transport to the shoot. Diverse physiological, genetic, and environmental factors determine how nitrate is allocated and stored.

Two types of **symporters** (NRT1 and NRT2) and one **antiporter** (CLC) are involved in nitrate transport in plants. NRT1 and NRT2 function in nitrate uptake and transport across both the plasma membrane and tonoplast, whereas CLC functions primarily in transport across the tonoplast.

16.6.1 Plants use both low- and high-affinity transport systems for nitrate uptake from the soil

Usable nitrate concentrations in the soil can vary by over four orders of magnitude, from micromolar to millimolar. To cope with this wide range of concentrations while avoiding both deficiency and toxicity, plants use two nitrate uptake systems: a high-affinity system with $K_m \approx 50$ μM and a low-affinity system with $K_m \approx 5$ mM (Fig. 16.31). Both are mediated by active H^+ -coupled mechanisms, using the H^+ gradient generated by the H^+ -ATPase as the driving force for nitrate import.

These two uptake systems involve two nitrate transporter families, NRT1 and NRT2. In *Arabidopsis*, two NRT1 transporters (AtNRT1.1 [CHL1] and AtNRT1.2), and four NRT2 transporters (AtNRT2.1, AtNRT2.2, AtNRT2.4 and AtNRT2.5) are assisted by one NAR2 protein (AtNAR2.1) for nitrate uptake. AtNRT2.1 and AtNRT2.2 are both nitrate-inducible, high-affinity nitrate transporters, whereas AtNRT1.2 is a

FIGURE 16.28 Schematic representation of the allosteric regulation of the ammonium transporter AMT. Ammonium transporters exist as homotrimers, and each monomer contains an independent pore for ammonium. The cytosolic C-terminus of a single monomer is proposed to interact with the neighboring monomer. Posttranslational phosphorylation of the C-terminus of a single monomer (indicated by red phosphate) is proposed to lead to a conformational change, resulting in cooperative closure of all three pores in the complex.

FIGURE 16.29 Ammonium uptake across the plasma membrane is mediated by ATMs, and membrane potential is the driving force. Ammonium transport across the tonoplast may be mediated by TIP2 aquaporins, and vacuolar acidification could be the main factor for accumulation of ammonium in vacuole.

constitutively expressed low-affinity transporter. AtNRT1.1 (CHL1) is a dual-affinity transporter involved in both high- and low-affinity uptake (Fig. 16.31).

AtNRT1.1 (CHL1) was the first member of the NRT1 family identified by genetic studies selecting for chlorate resistance. Chlorate is a chlorine analog of nitrate that becomes toxic when it is imported by nitrate uptake systems and reduced to chlorite by nitrate reductase (Fig. 16.32). One of the chlorate-resistant mutants, *chl1*, is defective in uptake. CHL1 contains 12 transmembrane domains, with the six N-terminal and six C-terminal transmembrane domains separated by a large hydrophilic loop (see Fig. 16.31). Functional studies of the protein expressed in *Xenopus* oocytes showed it is a H⁺-coupled nitrate transporter with a H⁺/NO₃⁻ ratio larger than one. The *Arabidopsis* genome includes 53 NRT1 (PTR) transporter genes; some of the proteins encoded by these genes (**NRT PTR family**) transport dipeptides, but not nitrate. Likewise, most NRT1 homologs isolated from cellular organisms are dipeptide transporters (e.g., DtpT from *E. coli*, PepT1 from human, and PTR2 from *Saccharomyces cerevisiae*). It is thought that nitrate transport activity evolved from an ancient dipeptide transporter.

The two modes of AtNRT1.1 activity are regulated by phosphorylation and dephosphorylation of the threonine 101 residue (Fig. 16.31). AtNRT1.1 is a high-affinity nitrate transporter when T101 is phosphorylated, whereas the dephosphorylated form of AtNRT1.1 is a low-affinity nitrate

transporter. The switch in phosphorylation is triggered by changes in external nitrate availability. This allows transporter function to adapt to available resource levels in the root environment.

NRT2 transporters are high-affinity H⁺-coupled nitrate transporters that also have 12 transmembrane domains (Fig. 16.31), but they share no significant sequence similarity with NRT1 transporters. The first member of the NRT2 family identified was *crnA* from *Aspergillus*, and subsequently several NRT2 genes were isolated from bacteria, yeast, mosses, algae, and plants. In algae and plants, an additional component, NAR2 (NRT3), is required for the high-affinity nitrate transport of NRT2. NAR2, which contains two transmembrane domains, plays a role in targeting AtNRT2.1 to the plasma membrane. *Arabidopsis* has seven NRT2 genes and two NAR2 (NRT3) genes; one of the NRT2 proteins, AtNRT2.7, is involved in vacuolar nitrate transport in seeds (see Fig. 16.30 and Section 16.6.2).

Consistent with their roles in uptake, expression of AtNRT1.1, 1.2, and 2.1 in *Arabidopsis* is restricted to the outer cell layers of the root, including the epidermis, cortex, and endodermis (Fig. 16.33). AtNRT2.1 is expressed mainly in the basal part (oldest portion) of the root, while AtNRT1.1 (CHL1) is expressed more in the young root. In addition, expression levels of the NRT1 and NRT2 genes are differentially regulated by nitrate, nitrogen starvation, and reduced forms of nitrogen. The relative contribution of these transporters in nitrate uptake depends on the age and nitrogen status of plants.

16.6.2 Transporters responsible for vacuolar storage and xylem loading have also been identified

Once inside the cell, a major part of free nitrate is stored in vacuoles, where concentrations can reach 20–70 mM. When plants are shifted to nitrate-depleted or nitrate-sufficient media, vacuolar nitrate concentrations may vary considerably, even while cytosolic nitrate concentration is kept constant. The homeostasis of cytosolic nitrate is determined by the balance between uptake, efflux, nitrate reductase activity, and vacuole storage and remobilization (see Fig. 16.30).

Arabidopsis AtCLCa is a 2NO₃⁻/1H⁺ antiporter involved in **nitrate homeostasis**. Located in the tonoplast and predominantly expressed in leaf laminae, it is responsible for nitrate accumulation in the vacuole (see Fig. 16.30) and belongs to the **large chloride channel (CLC) family**. Some members of the CLC family are H⁺-gated anion channels (e.g., mammalian CLC-0 and CLC-1), while others are Cl⁻/H⁺ antiporters (e.g., mammalian lysosomal CLC7 and *E. coli* ClCec-1). Unlike these CLCs, however, AtCLCa has much higher permeability for nitrate than chloride. *Arabidopsis* has seven CLC genes.

Different plant tissues may employ distinct transporters, as illustrated by nitrate relations in developing *Arabidopsis* seeds. One of the tonoplast-localized transporters, AtNRT2.7 (see Fig. 16.30), is expressed mainly during the later stages of

FIGURE 16.30 Nitrate assimilation by plant cells involves transport of nitrate across the plasma membrane and then reduction to ammonia in a two-step process. Nitrate can be stored in and remobilized from the vacuole. A H^+ -ATPase maintains the electrochemical gradient that drives cellular uptake of nitrate. The values shown for electrical potentials and intracellular nitrate concentrations are typical, but can vary significantly.

seed development. Lower seed nitrate content in an *nrt2.7* mutant suggests AtRNT2.7 mediates nitrate loading into the vacuole during seed maturation. By contrast, the plasma membrane-localized transporter AtNRT1.6 is expressed in the funiculus at the early stages of embryo development. Increased seed abortion rate and embryo abnormality in an *atrnt1.6* mutant indicate nitrate is important for early embryo development.

Root-to-shoot nitrate transport is mediated by the xylem. For **xylem loading**, nitrate must be transported out of the parenchymal cells that are close to the xylem. According to electrochemical gradients, nitrate should undergo passive transport out of a plant cell, likely through a channel. However, two NRT1 transporters (NAXT1 and AtNRT1.5) mediate **nitrate export**, and AtNRT1.5 expressed in pericycle cells next to root xylem is responsible for nitrate xylem loading (see Fig. 16.30 and 16.33). Root-to-shoot nitrate transport is not completely eliminated in *atrnt1.5* mutants, suggesting additional genes or mechanisms are involved in xylem loading.

16.7 Nitrate reduction

Nitrate itself is not incorporated into organic compounds, but is first reduced to ammonium in a two-step process (see Fig. 16.30). Nitrate is first reduced to nitrite by **nitrate reductase** (NR, Reaction 16.2), then nitrite is reduced to ammonium by **nitrite reductase** (NIR, Reaction 16.3) in a reaction involving reduced **ferredoxin** (Fdx_{red}). During this eight-electron transfer, the oxidation state of nitrogen drops from +5 to -3. The subsequent reactions that assimilate ammonium into amino acids also consume organic carbon (see Chapter 7). Plants reduce nitrate and nitrite in both root and shoot tissues.

Reaction 16.2: Nitrate reductase

Reaction 16.3: Nitrite reductase

FIGURE 16.31 Kinetics of nitrate uptake. Nitrate uptake displays two saturated phases, with K_m in the micromolar range for the high-affinity system and in the mM range for the low-affinity system. In Arabidopsis, CHL1 (AtNRT1.1; shown in blue) is a dual-affinity nitrate transporter involved in both high- and low-affinity uptake, with the two action modes switched by phosphorylation/dephosphorylation of T101. AtNRT2.1 and AtNRT2.2 (shown in red) associated with AtNAR2.1 (shown in yellow) are involved in high-affinity uptake, while AtNRT1.2 (shown in green) participates in low-affinity uptake.

In the reduction of nitrate to nitrite (Reaction 16.2), NADH or NADPH serves as the reductant and a proton is consumed in the reaction. This reaction is catalyzed by NR, a complex metalloenzyme that forms homodimers (Fig. 16.34) and homotetramers. NR has binding sites for NAD(P)H and for nitrate, and three cofactors—FAD, heme-Fe, and the molybdenum cofactor (MoCo, Fig. 16.35)—provide the redox centers that facilitate the chain of electron transfer reactions. In the native enzyme, the midpoint potentials (E'°) for FAD, heme-Fe, and MoCo are -272 , -160 , and -10 mV, respectively. Each NR subunit is almost 1,000 amino acids long and contains all three cofactors. Most forms of plant NR

use NADH, but some are bispecific and can use either NADPH or NADH.

16.7.1 NR subunits contain three distinct regions, each associated with a specific electron transport cofactor

Within the NR holoenzyme, each cofactor is a redox center associated with a distinct functional and structural region of the protein. Partial proteolysis of the enzyme produces

FIGURE 16.32 Nitrate uptake mutants can be selected by treating plants with chlorate. Wild-type plants take up chlorate and reduce it to the toxic product chlorite, resulting in chlorosis. Nitrate uptake mutants are unable to import chlorate and so remain green. Source: Crawford, University of California–San Diego, La Jolla, CA, previously unpublished.

discrete fragments that display partial enzymatic activity. One fragment binds FAD and can use NADH to reduce ferricyanide, an artificial electron acceptor. A second fragment contains MoCo and heme-Fe and can reduce nitrate in the presence of methyl viologen, an artificial electron donor. The partial activities associated with NR fragments are consistent with the structural evidence for discrete functional regions.

The spatial arrangement of functional regions, inferred from cDNA sequences, are as follows: the **MoCo domain** is near the N-terminus, the **heme-Fe domain** is in the middle, and the **FAD domain** is at the C-terminus (see Fig. 16.34). The three functional regions are connected by two hinges, one of which contains a regulatory site that is phosphorylated and binds 14-3-3 proteins, which modulate NR activity (see Section 16.7.4 and Chapters 3 and 18). Figure 16.34B shows a model for the structural and functional relationship of the domains.

Each functional region of NR is an independent unit that belongs to a distinct protein family. The FAD-binding region (260–265 amino acids) is similar to the **ferredoxin-NADP⁺ reductase (FNR)** family of flavin oxidoreductases, which includes FNR, cytochrome P450 reductase, nitric oxide synthase, and cytochrome *b*₅ reductase. The crystal structure of the FAD region reveals two domains, each forming a lobe separated by a cleft (see Fig. 16.34B): the N-terminal lobe binds FAD, and the C-terminal lobe binds the substrate NAD(P)H. In the C-terminal lobe, a cysteine provides a thiol group that interacts with the NAD(P)H and is thought to position the NAD(P)H to facilitate electron transfer to FAD. Although this cysteine is invariant in the FNR family of flavoproteins, it is not required by NR; a serine substitution for the cysteine renders NR less active but still able to bind NADH and reduce FAD.

The central heme domain of 75–80 residues is similar to that of the **cytochrome *b*₅ family** of heme proteins. These

FIGURE 16.33 Schematic presentation of spatial expression pattern of Arabidopsis nitrate transporters in different zones of root tissue. Bottom: cross-section of root near the tip, in which the epidermal cells have not begun to form a hair extension. Center: cross-section of a root with emerging root hair. Top: more mature part of the root in which a root hair is fully formed. CHL1 (*AtNRT1.1*), *AtNRT1.2*, *AtNRT2.1*, and *AtNRT2.2* are involved in uptake, and *AtNRT1.5* is involved in xylem loading.

proteins share certain properties: they can oxidize cytochrome *c* and have a characteristic cytochrome *b*-type fold that binds the heme moiety noncovalently. Proteins in the cytochrome *b*₅ family may be soluble or membrane bound, and they often associate with flavoproteins. The axial ligands of the NR heme-Fe are thought to be histidines provided by the NR protein.

The large N-terminal domain containing the MoCo (360–370 amino acids) belongs to a special class of MoCo-binding proteins. Of the enzymes that contain a MoCo, including **xanthine oxidase**, **biotin sulfoxide reductase**, **dimethyl sulfoxide (DMSO) reductase**, and **sulfite oxidase** (Section 16.14.5), only sulfite oxidase has significant sequence similarity to NR. Like NR, sulfite oxidase has an attached cytochrome *b*₅ heme domain, although this heme domain is N-terminal to the MoCo-binding region in sulfite oxidase

FIGURE 16.34 (A) Domain structure of nitrate reductase. An NR monomer has three major domains that bind molybdenum cofactor (MoCo), heme, and FAD respectively. The FAD-binding region receives electrons from NAD(P)H, and the heme domain shuttles electrons to the MoCo-binding region, which transfers electrons to nitrate. Hinge 1 and 2 (hI and hII) which separate the functional domains. (B) Crystal structure of the FAD-binding domain of NR. The C-terminal fragment of NR, showing the N-terminal lobe of the fragment (green), a linker domain (blue), and the C-terminal lobe (red). The N-terminal lobe is bound to FAD, whereas the C-terminal lobe binds NAD(P)H.

FIGURE 16.35 Molybdenum cofactor (MoCo) of NR. (A) Chemical structure. (B) Space-filling model.

and C-terminal to the MoCo region in NR. These alternative arrangements of functional protein units imply domains have been shuffled in different configurations to form new enzymes during the course of evolution. Compared to sulfite oxidase, the substrate funnel of the NR MoCo domain narrows to an elongated slot wide enough for the planar nitrate molecule, but not for the bulkier sulfate molecule. This may explain why nitrate inhibits sulfite oxidase, but sulfate does not inhibit NR.

16.7.2 Nitrate is reduced in the cytosol of root and shoot cells

NR and nitrate reduction occur in the cytosol of cells throughout the vegetative organs of the plant. In most species, NR is found in both shoots and roots, and its distribution depends on environmental conditions. However, some species [e.g., cranberry (*Vaccinium macrocarpon*), white clover (*Trifolium repens*), and young chicory (*Cichorium intybus*)] localize almost all their NR in roots, whereas others (e.g., cocklebur (*Xanthium* spp.)) express NR almost exclusively in leaves.

Within a specific organ, NR shows cell type-specific localization. At low external nitrate concentrations, NR is found primarily in epidermal cells and cortical cells close to the root surface. At higher external nitrate concentrations, activity is also detected in cells of the cortex and vascular system. In maize (*Zea mays*), a C_4 plant, NR is located in the mesophyll, but not in **bundle sheath cells**—a finding consistent with the far greater capacity of mesophyll chloroplasts to generate reductant by way of noncyclic photosynthetic electron transfer (see Chapter 12).

16.7.3 NR gene transcription is regulated by diverse signals

Green tissues have much more NiR activity than NR activity, and this ensures that nitrite does not accumulate to toxic levels. Thus, NR is thought to catalyze the rate-limiting step in the conversion of nitrate to ammonium. Plants use several mechanisms to adjust the concentration and activity of NR in response to such diverse signals as nitrate abundance, nitrogen metabolites (especially glutamine), CO_2 , carbon metabolites (especially sucrose), cytokinins, and light.

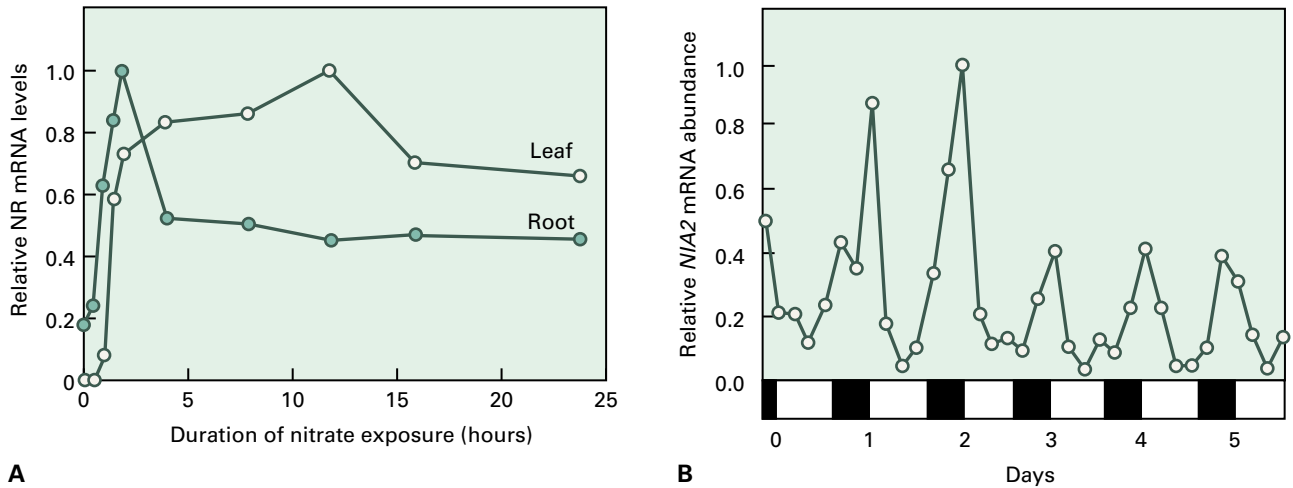

FIGURE 16.36 Regulation of NR gene expression. (A) Transcription of NR mRNA levels in roots and leaves is influenced by the availability of nitrate. Seven day old barley seedlings grown in the absence of nitrate were treated with 15 mM nitrate at time zero. RNA was extracted from roots and leaves at the indicated times, and relative NR mRNA levels were determined. (B) In plants grown in the presence of nitrate, NR mRNA levels demonstrate a diurnal cycle. RNA was extracted from leaves of tomato plants at the indicated times, and relative NR mRNA levels were determined.

TABLE 16.5 Signals that influence the transcription and activity of NR.

Signal	Effect on NR	
	Transcription	Enzyme Activity
Glutamine	↓	
Nitrogen starvation	↓	
Circadian rhythm	Modulates, depending on time of day	
Nitrate	↑	
Cytokinin	↑	
Sucrose	↑	
Light	↑	↑
Darkness	↓	↓
High [CO ₂]		↑
Low [CO ₂]		↓
Oxygen		↑
Anoxia		↓

Expression of the NR gene is substrate inducible in many plants (Fig. 16.36A and see Section 16.9), and in leaves, NR induction also requires functional, genetically intact chloroplasts. This coordinated regulation of a cytosolic enzyme by plastid signals probably prevents nitrite production in

cases where a chloroplast defect renders NiR activity is deficient.

In addition to the primary signal, nitrate, NR mRNA quantities respond to other signals that link nitrate reduction to photosynthesis, carbon metabolism, and diurnal cycles. For maximal induction of NR mRNA, plants require light or a source of reduced carbon. Genetic and physiological data imply **phytochrome** (see Chapter 18) mediates this light-induced enhancement of NR mRNA concentrations. Light regulation is most dramatic in etiolated seedlings, but also occurs in green tissues. Once the NR gene is induced, NR mRNA quantities cycle in a diurnal rhythm driven by circadian clocks (Fig. 16.36B). A downstream metabolite may act as a signaling molecule that controls NR activity. Several lines of evidence suggest that glutamine can repress expression of NR genes (Table 16.5). During diurnal cycling, glutamine concentrations increase as NR transcript concentrations decrease in wild-type plants; further, in NR mutant plants, glutamine concentrations are always high and NR mRNA concentrations low.

In summary, key regulatory mechanisms control NR gene expression so that nitrate reduction is coordinated with the demand of the shoots for nitrogen, the availability of nitrate and light (reduced carbon), and proper chloroplast function.

16.7.4 Phosphorylation-dependent binding of 14-3-3 proteins post-translationally modulates NR activity in response to endogenous and environmental signals

Post-translational mechanisms control NR protein concentration and activity in response to certain physiological conditions. For example, NR protein levels decrease when plants are

FIGURE 16.37 Proposed model for regulation of nitrate reductase activity by phosphorylation/dephosphorylation and reversible binding of 14-3-3 protein. NR is phosphorylated by protein kinases on a serine residue in hinge 1. Phosphorylated NR is still active but is bound by 14-3-3 dimers, which inactivate NR. NR in 14-3-3 complexes is more rapidly degraded than free NR and not a substrate for phosphatases. If NR is released from 14-3-3 proteins, the regulatory phosphate can be removed by protein phosphatase PP2A.

deprived of nitrogen or light for several days, even while amounts of NR mRNA remain high. A more rapid and reversible inhibition of NR activity occurs when plants are held in darkness or exposed to low concentrations of CO_2 . Under these conditions, NR inhibition occurs within minutes, resulting from the phosphorylation of a conserved serine in the hinge 1 region (see Fig. 16.34) by calcium-dependent protein kinases, followed by Mg^{2+} - or Ca^{2+} -dependent binding of **14-3-3 proteins** (Fig. 16.37). A type 2A protein phosphatase (PP2A) reactivates NR by dephosphorylating the hinge 1 serine, which prevents 14-3-3 proteins from binding. The reactions that inhibit and reactivate NR are modulated by Ca^{2+} , 5'-AMP, and P_i , which may act as secondary messengers. The kinase/14-3-3 inhibition mechanism allows rapid and reversible inhibition of NR activity when conditions do not favor nitrate assimilation.

The regulation of both NR transcription and enzyme activity allows plants to fine-tune the amount of nitrate reduction. Light (or its photosynthetic product, sucrose) induces NR transcription, particularly in etiolated plants. Probably serving as a feed back regulatory loop, light also increases the concentration of glutamine, which suppresses NR transcription (see Chapter 8). Once induced, however, NR transcription in photosynthetic tissues demonstrates a cyclic pattern, so that maximal transcript values are achieved just before the appearance of light (see Fig. 16.36B). NR protein in photosynthetic tissues is reversibly inhibited by conditions that prevent photosynthetic carbon reduction, such as darkness or CO_2 deprivation. Upregulation of NR transcription has the potential to enhance nitrite production. Thus when NiR activity is low, as in darkness, NR activity must also be down-regulated to prevent accumulation of toxic concentrations of nitrite. A list of signals influencing NR transcription and activity is provided in Table 16.5.

16.8 Nitrite reduction

After nitrate reduction, the next step in nitrate assimilation is the reduction of nitrite to ammonia, which is catalyzed by **NiR** (Reaction 16.3). Six electrons are transferred in this step, and the source of electrons is reduced ferredoxin (Fdx_{red}), produced in chloroplasts by noncyclic (linear) photosynthetic electron transfer. Nitrite reduction also uses Fdx_{red} in the plastids of nonphotosynthetic tissues such as the root. In such colorless plastids, NADPH from the oxidative pentose phosphate pathway (Chapter 13) reduces ferredoxin in a reaction catalyzed by **ferredoxin-NADP⁺ reductase** (Reaction 16.4). Significantly, the ferredoxin in nonphotosynthetic plastids is more electropositive (by ca. 70 mV) than its chloroplast counterpart, thereby facilitating its reduction by NADPH.

Reaction 16.4: Ferredoxin-NADP⁺ reductase

NiR is a nuclear-encoded protein with an N-terminal transit peptide that is cleaved from the mature enzyme as it is translocated into the plastid. The enzyme, a monomer of 60–70 kDa, has two functional domains and cofactors that shuttle electrons from Fdx_{red} to nitrite (Fig. 16.38A). The N-terminal half of the enzyme is thought to bind ferredoxin. The C-terminal half, which shares sequence homology with bacterial NADPH-sulfite reductases, contains the binding site for nitrite, as well as two redox centers, a 4Fe–4S center, and a **siroheme** (Fig. 16.38B). These two prosthetic groups are in close proximity, bridged by a sulfur ligand. Four cysteines located in two clusters provide both the bridging ligand and sulfur ligands for the 4Fe–4S cluster. Mutations that place bulky side chains next

FIGURE 16.38 (A) Structure of nitrite reductase from higher plants. The N-terminal region oxidizes ferredoxin. The C-terminal region, which binds an Fe_4S_4 center and a siroheme group, reduces nitrite to ammonium. (B) Structure of siroheme prosthetic group.

to two of these cysteine residues result in diminished NiR activity and can change the spectra of the siroheme in NiR protein, supporting a role for these cysteines in cofactor binding.

NiR is regulated transcriptionally, usually in coordination with NR. Because nitrite is toxic, cells must contain sufficient NiR to reduce all the nitrite produced by NR. Thus, plants maintain an excess of NiR activity whenever NR is present by inducing NiR gene expression in response to light and nitrate. If NiR concentrations are diminished, either by mutation or antisense expression, plants accumulate nitrite and are chlorotic. The regulatory mechanisms that control NR activity are thought to assist in preventing nitrite accumulation.

16.9 Nitrate signaling

In addition to being a nutrient, nitrate acts as a signal molecule that regulates its own uptake and assimilation. Nitrate induces transcription of nitrate transporters, NR, and NiR as well as the production of the reducing equivalents needed for nitrate assimilation. This rapid transcriptional regulation, termed primary nitrate response, can be triggered within 10 minutes by addition of as little as 100 nM nitrate and does not require de novo protein synthesis. Nitrite, the product of nitrate reduction, also acts as a potent signal to upregulate expression of the genes needed for nitrate uptake and assimilation; however, organic nitrogen compounds like glutamate (see Table 16.5) repress these genes as a mechanism of negative feedback regulation.

In roots, the levels of nitrate-induced expression of primary nitrate response genes in roots display two saturable phases involving the dual-affinity nitrate transporter NRT1.1 (CHL1; see Section 16.6.1), which also acts as a nitrate sensor.

Using dual-affinity binding and a phosphorylation switch regulated by protein kinase CIPK23, NRT1.1 (CHL1) senses changes in nitrate concentration and induces a different level of transcriptional responses (Fig. 16.39).

In addition to mediating transcriptional responses in plants, nitrate also regulates seed dormancy, leaf expansion, and root architecture. Nitrate stored in the seed or applied exogenously relieves seed dormancy, and ABA and AtNRT1.1 (CHL1) are involved in this signaling pathway. **Root architecture** is also regulated by nitrate in a complicated way; for example, localized application of nitrate can stimulate primary and lateral root growth, while high nitrate concentrations cause a systemic inhibition of root development. Such regulation could allow plants to seek sufficient nitrogen sources and optimize their nitrogen uptake. ABA, auxin, nitrate transporters NRT2.1 and NRT1.1 (CHL1), transcription factor ANR1, and miRNA167 and its target ARF8 participate differently in the regulatory and signaling pathways mediating root adaptation to nitrate supply.

16.10 Interaction between nitrate assimilation and carbon metabolism

To coordinate the production of the carbon skeletons needed for amino acid synthesis, nitrate also upregulates genes involved in carbon metabolism. Plants exposed to nitrate redirect carbon from starch synthesis to the production of amino acids and organic acids, such as malate, by controlling

FIGURE 16.39 Schematic representation of signaling pathways for nitrate-regulated transcriptional responses in Arabidopsis. Low external nitrate stimulates phosphorylation of the nitrate transporter CHL1, which induces a low level of primary nitrate response gene expression; high external nitrate represses CHL1 phosphorylation and leads to high levels of gene expression. Under low-nitrate conditions, CIPK23 phosphorylates CHL1, and CIPK8 is involved in high-nitrate responses. NLP7 and the lateral organ boundary domains (LBDs) are transcription factors regulating nitrate-related genes.

the synthesis and activity of key enzymes. For example, **PEP carboxylase** (which catalyzes the synthesis of oxaloacetate, a citric cycle intermediate readily converted to α -ketoglutarate) is upregulated by high nitrate. In contrast, **ADP glucose pyrophosphorylase**, which is required for starch biosynthesis, is downregulated in response to treatment with high concentrations of nitrate. These regulatory events are expressed most dramatically in NR^- mutants, which cannot reduce, but instead accumulate nitrate. Thus, nitrate acts as a signal that directs plants to redirect carbon flow into compounds that support nitrogen assimilation into amino acids.

On the other hand, expression of genes involved in nitrate uptake and assimilation is induced by light and sugars. Repression of these genes in the dark can be prevented by providing high concentrations of reduced carbon, such as sucrose. However, unlike other sugar responses in which hexokinase functions as a sugar sensor independently of its metabolic activity, glucose 6-phosphate is the sugar signal, and the catalytic activity of hexokinase is required for the induction of nitrate uptake transporters NRT1.1 and NRT2.1 by sucrose. Coordinated regulation between nitrate metabolism and carbon metabolism ensures efficient utilization of these two nutrients to allow maximum plant growth.

16.11 Overview of sulfur in the biosphere and plants

Sulfur is an essential macronutrient for all living organisms, and it occurs in nature in various oxidation states as part of inorganic and organic compounds. All these oxidation states

can support growth of various bacteria and archaea. The major inorganic form of sulfur is **sulfate** (SO_4^{2-}), which is found in many minerals (e.g., gypsum) and at a high concentration in the oceans (ca. 26 mM or 2.8 g L⁻¹). Natural organic sulfur compounds include gases such as hydrogen sulfide and dimethylsulfide, which are emitted to the atmosphere both by geochemical processes and by action of the biosphere.

Sulfur deficiency in plants is associated with reduced yield and quality of crops and increased susceptibility to disease. While sulfur inputs from the atmosphere or soil are typically adequate, recent decreases in atmospheric sulfur availability have resulted in sulfur deficiency in many growing regions. Sulfur deficiency triggers multiple changes in plant metabolism, and these molecular responses to sulfur starvation have been extensively studied by a variety of genetic and genomics technologies. As a result, plant sulfur physiology has become an excellent model for plant systems biology.

Sulfate enters a plant primarily through the roots by way of an active uptake mechanism (Fig. 16.40). Although roots can assimilate sulfate, most sulfate is translocated to the shoot. In photosynthetic cells, sulfate can be transported either into the vacuoles for storage, or into the chloroplasts for assimilation. There are two major assimilation pathways: one in which sulfate is reduced to **sulfide** and incorporated into cysteine, and another in which sulfate is activated to **3'-phosphoadenosine 5'-phosphosulfate (PAPS)** and added to organic molecules. Sulfate can be linked to an oxygen atom to form a sulfate ester, to a nitrogen atom to form a sulfamate, or to a carbon atom to form a sulfonic acid; further metabolism of thiols produces thioethers, methylsulfonium compounds, and sulfoxides (Table 16.6 and Figure 16.40).

FIGURE 16.40 Overview of sulfur uptake, reduction, and transport in plants. Like nitrate, sulfate uptake across the plasma membrane is energized by an electrochemical gradient that is maintained by a proton-pumping ATPase. Part of the sulfate is stored in vacuoles. Reduction of sulfate takes place in the plastids of root and leaf cells. Cysteine synthesis occurs in the cytosol, plastids, and mitochondria, while glutathione can be synthesized in the cytosol and plastids. The assimilation of sulfate into sulfated compounds takes place in the cytosol

16.12 Sulfur chemistry and function

16.12.1 Cysteine, the sulfur donor in methionine synthesis, is essential for protein synthesis

Cysteine and methionine are the two sulfur-containing amino acids used in protein synthesis. In plants, cysteine is the primary product of sulfate assimilation and a starting point for synthesis of methionine in a reaction series known

as transsulfuration (Fig. 16.41, see Chapter 7). Cysteine is particularly important for the structural and catalytic functions of proteins. The thiol groups of two cysteine residues can be oxidized to form a covalent disulfide bond, which is the most important linkage for establishing tertiary and, in some cases, quaternary protein structures. These disulfide bonds can be also reversed by reduction, a property crucial for controlling activity of proteins. The redox state of the cysteines that can form disulfide bonds (reduced or oxidized) is ultimately controlled by cellular processes and reactions that generate biological reducing agents (e.g., noncyclic electron transfer and the oxidative pentose phosphate pathway). The activities of some chloroplast enzymes functioning

TABLE 16.6 Structures and examples of sulfur-containing compounds formed by plants.

Compound	Generic structure	Examples
Thiols (mercaptans)	RSH	L-Cysteine, coenzyme A
Sulfides or thioethers	RSR ₁	Hydrogen sulfide (H ₂ S), L-methionine
Sulfoxides	RSOR ₁	Allicin
Methylsulfonium compounds	(CH ₃) ₂ S ⁺ R	S-Adenosyl-L-methionine, S-methylmethionine, DMSP, dimethylsulfonic hydroxybutyrate
Sulfate esters	$\begin{array}{c} \text{O} \\ \parallel \\ \text{R}-\text{O}-\text{S}-\text{O}^- \\ \parallel \\ \text{O} \end{array}$	Phenol sulfates, polysaccharide sulfates
Sulfamates	$\begin{array}{c} \text{O} \\ \parallel \\ \text{R}=\text{N}-\text{O}-\text{S}-\text{O}^- \\ \parallel \\ \text{O} \end{array}$	Aryl sulfamates, mustard oil glycosides
Sulfonic acids	$\begin{array}{c} \text{O} \\ \parallel \\ \text{R}-\text{O}-\text{S}-\text{O}^- \\ \parallel \\ \text{O} \end{array}$	Glucose-6-sulfonate, cysteic acid, taurine, sulfoquinovosyl diacylglycerol

DMSP, dimethyl sulfoniopropionate.

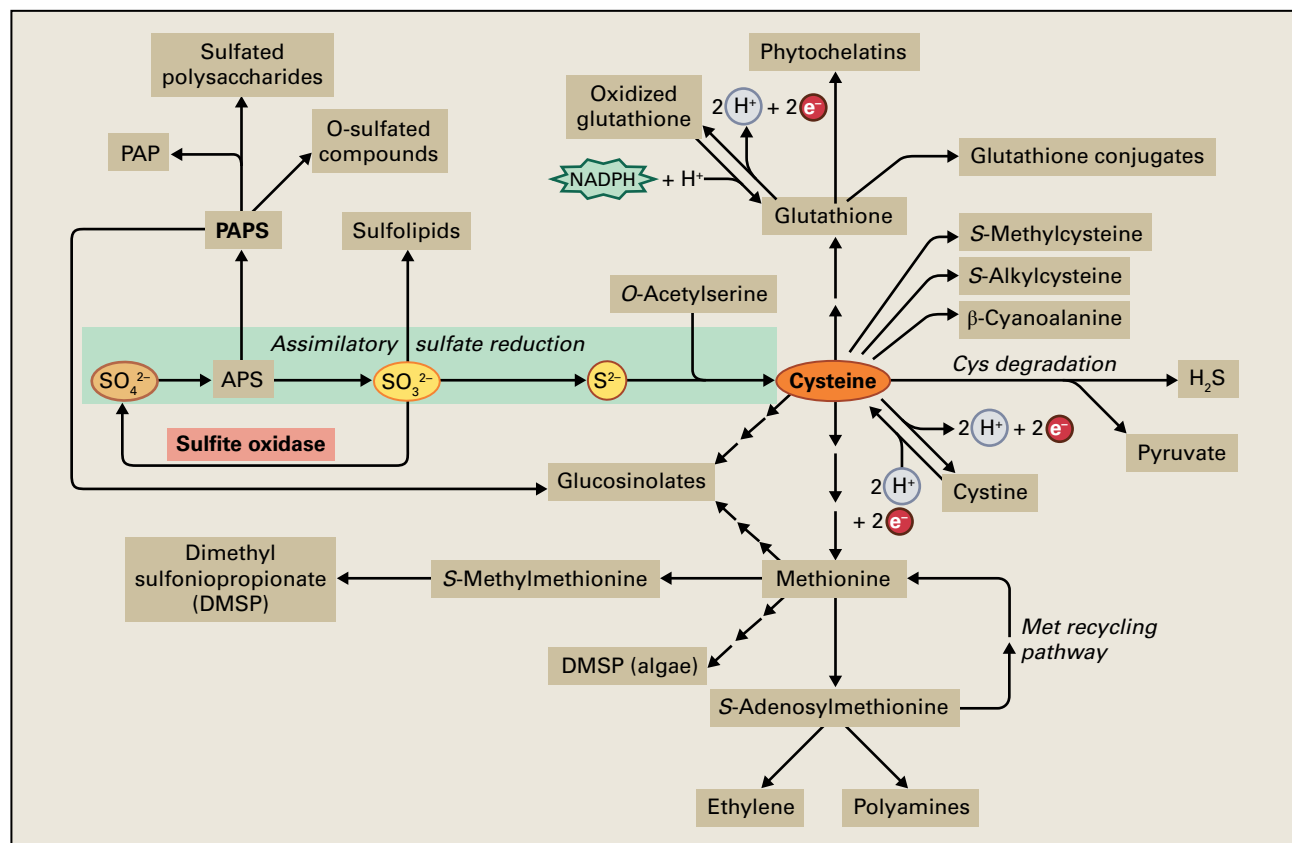

FIGURE 16.41 Sulfur assimilation in plants. Sulfate is incorporated into a wide range of compounds. Most sulfate is first reduced to sulfide and subsequently incorporated into cysteine, which functions as a sulfur donor in many reactions. Some sulfur is incorporated in the oxidized form to sulfated compounds in an early branch in the pathway. Some metabolites, like glucosinolates, contain both reduced and oxidized sulfur. The sulfo- group in sulfolipids is derived from sulfite. APS, adenosine 5'-phosphosulfate; PAPS, 3'-phosphoadenosine-5'-phosphosulfate; PAP, adenosine 3',5'-biphosphate.

FIGURE 16.42 Structures of representative sulfur-containing compounds: group-transfer cofactors, signaling molecules, and phytoalexins.

in carbon metabolism are regulated by reversible disulfide bond formation, which is mediated by proteins (e.g., **thioredoxin**, **glutaredoxin**) and the nonprotein tripeptide, glutathione (see Section 16.15).

16.12.2 Many plant products, including coenzymes, lipids, and secondary metabolites, contain sulfur

Plants contain a wide variety of sulfur compounds, some with important functions in primary and natural product (secondary) metabolism, and others for which no function has been established. Several group-transfer coenzymes and vitamins, including coenzyme A, S-adenosyl-L-methionine (SAM), thiamine, biotin, lipoic acid, and S-methylmethionine contain functionally important sulfur moieties (Fig. 16.42). Chloroplast membranes contain a **sulfolipid**, **sulfoquinovosyldiacylglycerol** (see Chapter 10). Some signaling molecules contain sulfur as a key component, including the sulfated lipooligosaccharides that function as Nod factors (see Fig. 16.13D), and turgorin (Fig. 16.42), a sulfated derivative of **gallic acid** responsible for thigmotactic movement in leaves of the sensitive plant (*Mimosa pudica*). Several **peptide hormones**, such as **phytosulfokines**, require sulfation of their tyrosine residues for biological function.

Sulfur-containing compounds play a particularly important role in plant stress defense. The major component of various defense systems is glutathione (described in detail in Section 16.15). In addition, many sulfur-containing **phytoalexins**, such as **camalexin** (Fig. 16.42), are produced by members of the Brassicaceae in response to pathogen attack. Thioredoxin is also emerging as a defense protein with certain pathogens. Some plants deposit elemental sulfur in their stems as a potent fungicide, but perhaps the best known sulfur-containing defense compounds are the **alliins** in onion and garlic and **glucosinolates** in Brassicaceae, which are also responsible for the flavor and smell of the corresponding vegetables and provide health benefits (see Chapter 24).

16.12.3 Sufficient sulfur in agricultural soils is important for the yield and quality of crops

Animals, including humans, require dietary sources of methionine because they are unable to reduce sulfur. The value of crop plants, therefore, is influenced by their methionine and cysteine content, and so sulfur availability and sulfur content have a significant impact on plant productivity and utilization. Seed proteins of some crop plants, particularly legumes, have low **methionine content**; as a result, food

FIGURE 16.43 Aerial photograph of two *Brassica napus* fields, one fertilized with sulfate (foreground), the other not (background). *B. napus*, an oilseed variety, must be fertilized with sulfur to maximize yield. The difference in abundance of blooms between the sulfur-fertilized and the unfertilized fields is evident.

FIGURE 16.44 Loaves of bread baked from (left to right) low-, high-, and excess-sulfur wheat. Limitations in sulfur availability cause a shift in the expression profile of seed storage proteins in wheat. In grain from wheat plants grown under S-limiting conditions, proteins with fewer cysteines predominate. The low-cysteine proteins are unable to form abundant disulfide bonds and adversely affect the baking quality of wheat flour.

Source: Byers et al. (1987). Aspects Appl. Biol. 15:337–344.

derived from legumes must be supplemented with foods rich in this amino acid. Improving the nutritional index by altering the amino acid composition of seed storage proteins is a goal for many biotechnological projects.

Sulfur was long considered a nonlimiting nutrient for agriculture, but recent curbs on emission of sulfurous air pollutants, such as sulfur dioxide, have resulted in lower sulfur soil content. Many agricultural areas, especially in northern Europe, must be fertilized with sulfate to maintain crop yields and quality (Fig. 16.43). Sulfur deficiency adversely affects the yield of oilseed *Brassica* species and the baking quality of wheat flour (Fig. 16.44). Sulfur deficiency is also a cause of increased **acrylamide** contents in many bakery products. Acrylamide is formed during baking by a reaction between reducing sugars and asparagine. Sulfur-deficient plants accumulate large quantities of free amino acids, thereby increasing the potential for acrylamide formation. In addition, sulfur deficiency is associated with increased susceptibility of crops to attack by insects and fungi, consistent with the prominence

of some sulfur-containing compounds and proteins in plant defense against pathogens.

16.12.4 Plants play a major role in the global biogeochemical sulfur cycle

The interconversion of oxidized and reduced sulfur species on Earth is known as the biogeochemical sulfur cycle (Fig. 16.45). Although the burning of fossil fuels is the greatest contributor to atmospheric sulfur content, a large amount of atmospheric sulfur is derived from marine algae, many of which produce **dimethylsulfoniopropionate (DMSP)**, a tertiary sulfur analog of the quaternary nitrogen compounds known as **betaines** (Fig. 16.46A). DMSP has many functions, including roles as osmoprotectant, cryoprotectant, and repellent against planktonic herbivores. When released from algae, DMSP is degraded to **dimethyl sulfide (DMS)**, which is volatilized into the atmosphere and subsequently oxidized to DMSO, sulfite, and sulfate (Fig. 16.46B). Atmospheric sulfate acts as a nucleus for formation of water droplets and is associated with the formation of clouds. The link between oceanic algae and cloud formation has been proposed as a climate-regulating mechanism.

16.13 Sulfate uptake and transport

Sulfate transport into root cells, like that of nitrate, is driven by active proton cotransport (see Fig. 16.40). Because plant roots contain multiple transporters with differing affinities for sulfate, the rate of sulfate uptake into roots is multiphasic over a range of sulfate concentrations (Fig. 16.47). Sulfate uptake is generally inhibited by **selenate**, **molybdate**, and

FIGURE 16.45 The biogeochemical sulfur cycle. Plants and microorganisms reduce sulfate to sulfide for assimilation into cysteine. Some anaerobic bacteria use sulfate as a terminal electron acceptor much as aerobic organisms use oxygen. This process, known as dissimilation, generates H_2S . Oxidation of reduced sulfur to sulfate completes the cycle. Oxidation occurs through aerobic catabolism of sulfur compounds, which is carried out by animals, microorganisms, and plants or by bacteria that use reduced sulfur compounds as electron donors for chemosynthetic or photosynthetic reactions. Reduced sulfur is also oxidized geochemically when oxygen is present.

A

B

FIGURE 16.46 The phytoplankton-climate connection. (A) Phytoplankton produce DMSP, which is broken down by bacteria to DMS and acrylate. (B) DMS volatilizes and is oxidized to DMSO and sulfate, which nucleates water droplets, leading to cloud formation. Sulfate is returned to the sea dissolved in rain. Because cloud cover reduces the growth of phytoplankton and is accompanied by atmospheric cooling, phytoplankton may serve as a homeostatic climate regulation mechanism. The extent to which phytoplankton regulate climate is still debated.

FIGURE 16.47 Uptake of sulfate by barley roots. The graph shows the multiphasic rate of sulfate uptake by barley roots incubated with a range of sulfate concentrations. DW, dry weight.

chromate anions, which compete with sulfate for binding to the transporters. Plants possess gene families encoding 12–16 sulfate transporters that fall into four groups. Individual transporters have different kinetic properties and distinct expression patterns and regulation, indicating specialized functions of the groups as well as of individual members within the groups.

Sulfate-uptake systems can be classified as either sulfate permeases or facilitated transport systems. Plant **sulfate permeases** are similar to fungal and mammalian $\text{H}^+/\text{SO}_4^{2-}$ cotransporters. They consist of a single polypeptide chain with the 12 transmembrane domains characteristic of cation/solute transporters. These plant transporters can functionally complement a mutant strain of yeast lacking sulfate permease. A second mechanism, ATP-dependent transport, is exemplified by a system in cyanobacteria that includes a

multiprotein complex of three cytoplasmic membrane components (CysA, CysT, and CysW) and a sulfate-binding protein (SbpA) in the periplasmic space (SulT family transporter). This is the predominant type of sulfate transporter in bacteria, and it mediates sulfate transport into plastids in *Chlamydomonas*.

Despite progress in characterization of plant sulfate transport, the transporter responsible for the major flux of sulfate across the tonoplast into the vacuole remains to be identified.

16.14 The reductive sulfate assimilation pathway

The reduction of sulfate to sulfide is an energy-intensive process that consumes 732 kJ mol^{-1} . In contrast, nitrate and carbon assimilation require less energy (347 and 478 kJ mol^{-1} respectively). In plant tissues, the energy for **sulfate assimilation** is largely met by the ATP and reductant derived from photosynthesis. In nonphotosynthetic tissues, the reducing power for sulfate assimilation is probably generated by the oxidative pentose phosphate pathway, and the energy (ATP) for sulfate assimilation by respiration.

Sulfate assimilation is divided into three steps: activation of inorganic sulfate, reduction to sulfide, and incorporation of sulfide into cysteine. Plastids are the only compartment that contains the entire pathway for cysteine biosynthesis from inorganic sulfate. The activation step can take place in

the cytosol as well as plastids, and cysteine synthesis occurs in all compartments capable of protein synthesis (i.e., cytosol, plastids, and mitochondria).

16.14.1 Sulfate activation is catalyzed by ATP sulfurylase

Sulfate is chemically inert, and to enter the assimilatory pathway, it must be activated by the enzyme ATP sulfurylase (EC 2.7.7.4), as depicted in Figure 16.48 and Reaction 16.5. The resulting compound, **adenosine 5'-phosphosulfate (APS)**; sometimes referred to as 5'-adenylylsulfate), contains a phosphoric acid-sulfuric acid anhydride bond that enables the sulfonyl moiety to undergo modification in subsequent metabolic reactions.

Reaction 16.5: ATP sulfurylase

APS is a central branch-point intermediate that feeds two pathways: sulfate reduction and sulfation. The free energy of APS formation (ΔG°) is estimated to be $+41.8 \text{ kJ mol}^{-1}$, which favors ATP formation. Therefore, at equilibrium, APS can accumulate only to approximately 10^{-7} M . The forward reaction is driven by efficient removal of APS and PP_i , and at least two plant enzymes, **APS kinase** and **APS reductase**, metabolize APS while inorganic pyrophosphatase hydrolyzes PP_i (see Chapter 13).

FIGURE 16.48 Reaction catalyzed by ATP sulfurylase.

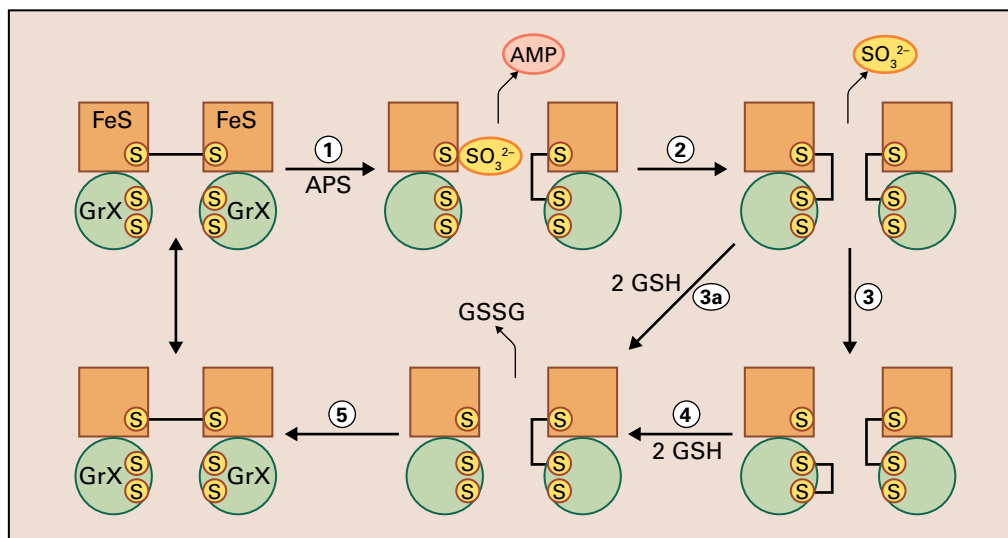

FIGURE 16.49 Possible reaction mechanism of APS reductase (APR). The N-terminal, iron-sulfur cluster (Fe-S) containing the APR domain is represented as a square, and the C-terminal glutaredoxine-like domain (Grx) is shown as a circle. In its resting state, APR is a dimer held together by a disulfide bridge between the N-terminal Fe-S-containing domains, formed by Cys-248. The active center in the Grx domain is reduced. When APR reacts with APS (1), a stable intermediate with sulfite bound to Cys-248 is formed, and AMP is released. A thiolate of the Grx domain reacts with the sulfocysteine, releasing sulfite; a disulfide bond between the Grx domain and Cys-248 forms (2). The second Cys in the Grx domain can then attack the disulfide bond, transferring it to the Grx active site (3), or glutathione (GSH) can reduce the Grx-Cys248 bond directly (3a); the preferred reaction is not known. The Grx active site/Grx-Cys248 bond is then reduced by GSH, releasing GSSG (4). The disulfide bond between Cys-248 is re-established through an intra molecular reaction (5).

Plant ATP sulfurylase is a homotetramer of 52–54 kDa polypeptides, and its substrates bind in an ordered and synergistic manner, with MgATP binding before sulfate. This enzyme activity is present predominantly in plastids (85–90% of total activity), with the remainder in the cytosol. In *Arabidopsis*, chloroplast ATP sulfurylase activity decreases during plant growth, while cytosolic activity increases. Plant ATP sulfurylase is encoded by small multigene families in all plant species analyzed to date. In many species, distinct plastidic and cytosolic isoforms can be identified, whereas in *Arabidopsis*, the four genes that encode ATP sulfurylase all contain a plastid-targeting peptide.

The contribution of ATP sulfurylase to the regulation of sulfate assimilation in plants is unclear. In some plants, steady-state ATP sulfurylase mRNA and enzyme activity both increase in response to sulfate starvation and are repressed by feeding of reduced sulfur compounds, such as cysteine and glutathione. Thus, in these species ATP sulfurylase gene expression is regulated by the demand for pathway end products. In other plants, including *Arabidopsis*, ATP sulfurylase is not regulated to such a great extent, and the control of the pathway resides elsewhere. Even in this latter case, disruption of ATP sulfurylase results in accumulation of sulfate. ATP sulfurylase transcripts are targeted and cleaved by microRNA (see Section 16.17.1). Overexpression of ATP sulfurylase in Indian mustard (*Brassica juncea*) results in greater accumulation of various metals and increased tolerance to selenate. These plants thus have a potential use for **phytoremediation** of soils contaminated with selenium.

16.14.2 APS reductase reduces activated sulfate to sulfite

APS is reduced to sulfite (SO_3^{2-}) by APS reductase (EC 1.8.4.9), with glutathione as the physiological electron donor (Reaction 16.6).

Reaction 16.6: APS reductase

APS reductase is localized in the plastids of plants and algae, with the notable exception of the sulfate reducing center found in the mitochondria of *Euglena gracilis*. The plant enzyme occurs as a dimer of 45-kDa subunits, each of which contains a reductase and a glutaredoxin-like domain. The N-terminal reductase domain possesses an atypical diamagnetic and asymmetric $[\text{Fe}_4\text{S}_4]$ iron-sulfur cluster, while the C-terminal domain interacts with the electron donor, glutathione, and is so equivalent to the thioredoxin cofactor needed for PAPS reduction in bacteria and fungi. Accordingly, the reduction of APS to sulfite can be divided into three distinct steps (Fig. 16.49).

Plants contain multiple APS reductase genes (*Arabidopsis* possesses three isoforms), and the enzyme is regulated by multiple environmental conditions, generally according to the demand for reduced sulfur. Transcript levels and enzyme activity increase under conditions of sulfur starvation and are

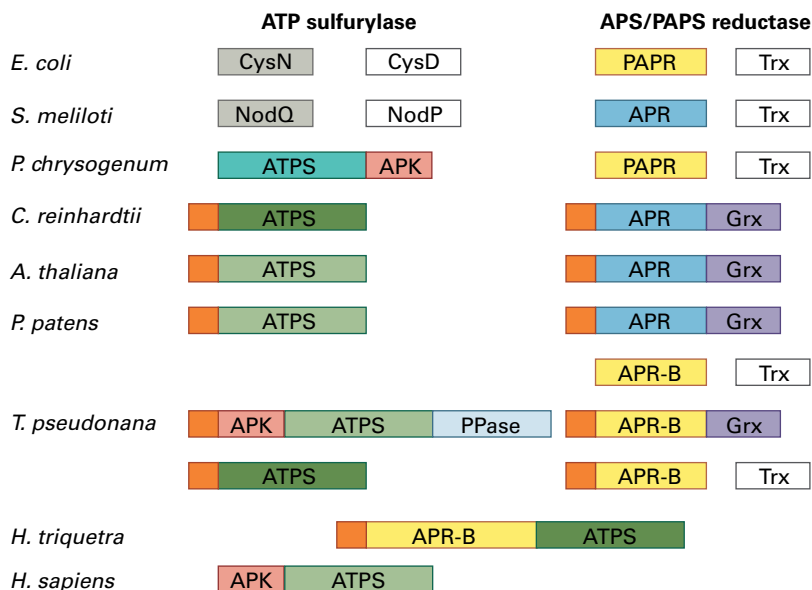

FIGURE 16.50 Forms and fusions of ATP sulfurylase and APS or PAPS reductase found in various organisms. Depicted are enzymes from *Escherichia coli*, *Sinorhizobium meliloti*, *Penicillium chrysogenum*, *Chlamydomonas reinhardtii*, *Arabidopsis thaliana*, *Physcomitrella patens*, *Thalassiosira pseudonana*, *Heterocapsa triquetra*, and *Homo sapiens*. Note the different origin of ATP sulfurylase in plants and green algae and similarity of the plant and animal genes. Isoforms of ATPS are shown in varied shades of green. $[\text{Fe}_4\text{S}_4]$ cluster binding domains are depicted in blue, the cofactor-independent PAPS reductase/APR-B is yellow, the glutaredoxin domains (Grx), sometimes referred to as Trx/Grx domains, are purple, while free thioredoxin necessary for the enzyme reaction is white. Orange rectangles represent N-terminal plastid-targeting peptides.

repressed when plants are treated with reduced forms of sulfite. In *Arabidopsis*, flux control analysis revealed APS reductase controls 90% of the reduction of internal sulfate into thiols and proteins. Control is shared with the sulfate uptake system. Disruption of the *Arabidopsis* APR2 isoform of APS reductase reduces flux through the pathway and increases accumulation of sulfate. In addition, overexpression of APS reductase in plants increases the amounts of compounds containing reduced forms of sulfur and may result in cellular damage when the activity is too high.

16.14.3 Sulfite reduction is catalyzed by ferredoxin-dependent sulfite reductase

Plant **sulfite reductase** (EC 1.8.7.1) adds six electrons to free sulfite, forming sulfide (S^{2-} , Reaction 16.7). Reduced ferredoxin is the source of electrons.

Reaction 16.7: Sulfite reductase

Plant sulfite reductase is a monomeric 65-kDa hemoprotein found in plastids. Like NiR (see Section 16.8 and Reaction 16.4), sulfite reductase contains one siroheme (see Fig. 16.38) and one $[\text{Fe}_4\text{S}_4]$ iron-sulfur cluster. The amino acid sequence of the plant enzyme is also homologous to NiR, indicating sulfite and nitrite reductases emerged as a result of a gene

duplication event. In fact, purified sulfite reductase from spinach (*Spinacia oleracea*) can reduce nitrite, although its affinity for nitrite is two orders of magnitude lower than for sulfite, its physiological substrate.

Unlike ATP sulfurylase and APS reductase, the enzyme activity and transcript levels of sulfite reductase are not affected appreciably by sulfur nutrition. Sulfite is a toxic anion that would damage cells if accumulated, so presumably sulfite reductase activity is maintained in excess. Significantly lower levels of sulfite reductase lead to a substantial reduction of plant growth.

16.14.4 Enzymes of sulfate assimilation exist in different forms in various organisms

Although the individual reactions of sulfate assimilation are common among plants, fungi, and prokaryotes, the enzymes catalyzing these reactions are often diverse (Fig. 16.50). For example, a new isoform of APS reductase isoform, APR-B, found in the moss *Physcomitrella patens* and other basal plants, is more similar to bacterial PAPS reductases because it does not require the $[\text{Fe}_4\text{S}_4]$ cofactor and does not possess the glutaredoxin-like domain (Fig. 16.50). In this case, Trx serves as the reductant, as in bacteria. In addition, the APS reductase of many prokaryotes is similar to the N-terminal domain of plant APR instead of **PAPS reductase**. Further diversity within eukaryotes has been revealed within

FIGURE 16.51 Model of interaction between plant sulfite oxidase (SO) and catalase. During each catalytic cycle, plant SO oxidizes one molecule of sulfite and generates one molecule of H_2O_2 . At low sulfite concentrations, all H_2O_2 formed is immediately degraded by peroxisomal catalase. At high sulfite concentrations, however, catalase is inhibited by sulfite, and the H_2O_2 molecule generated by plant SO nonenzymatically oxidizes a second molecule of sulfite. The oxygen introduced by the sulfate produced from H_2O is identified with an asterisk.

genome sequences. The genomes of eukaryotic microalgae originating from secondary or tertiary endosymbiotic events, such as diatoms and haptophytes, are especially valuable sources of new variants and gene fusions (Fig. 16.50). Interestingly, the sequenced genomes of eukaryotic microalgae possess only APR-B-like genes. The APR-B class of APS reductase seems to be the predominant form among the marine phytoplankton, where it might represent adaptation to iron-limited environments. These new genes may potentially be used to improve efficiency of sulfur metabolism of crop plants.

16.14.5 Sulfite oxidase protects plants against surplus of SO_2

Sulfite-oxidizing enzymes have been known in animals and microorganisms for years, but their presence in plants has been revealed only in the last decade. Sulfite oxidase (EC 1.8.3.1) belongs to a family of molybdoenzymes possessing a **dioxomolybdopterin cofactor**. The protein occurs as a dimer of 45-kDa subunits, is localized in peroxisomes, and exhibits constitutive expression in a variety of tissues. The enzyme catalyzes the oxidation of sulfite to sulfate, with molecular oxygen as an electron acceptor (Reaction 16.8). Hydrogen peroxide (H_2O_2), the other reaction product, can either be metabolized by catalase or can nonenzymatically oxidize another sulfite molecule (Fig. 16.51).

Reaction 16.8: Sulfite oxidase

The role of **sulfite oxidase** in plants is not clear, as the enzyme actually catalyzes a reaction that acts against the direction of sulfate assimilation. A futile cycle between sulfate reduction to sulfite and reverse oxidation by sulfite oxidase is prevented by compartmentalization of the two processes in **plastids** and **peroxisomes**, respectively. Plants deficient in sulfite oxidase are more sensitive to treatment with bisulfite or to fumigation with SO_2 , while overexpression of the gene leads to increased protection. Thus, the function of sulfite oxidase in plants is most probably protection against excess sulfite.

16.15 Cysteine synthesis

16.15.1 The combined activities of serine acetyltransferase and O-acetylserine (thiol) lyase convert serine to cysteine

The final step in the **reductive sulfate assimilation** pathway is the synthesis of cysteine by condensation of **O-acetylserine (OAS)** and **sulfide**. OAS is formed from serine and acetyl-CoA in a reaction (Reaction 16.9 and Fig. 16.52) that is catalyzed by serine acetyltransferase (EC 2.3.1.30) and is

FIGURE 16.52 Reactions responsible for assimilation of reduced sulfur into cysteine.

specific to cysteine biosynthesis. OAS and the sulfide ion then react to form cysteine (Reaction 16.10 and Fig. 16.52) in a reaction catalyzed by **OAS(thiol)lyase** (EC 2.5.1.47), a pyridoxal phosphate-containing enzyme.

Reaction 16.9: Serine acetyltransferase

Reaction 16.10: O-acetylserine (thiol)lyase

Serine acetyltransferase and OAS (thiol)lyase are localized in the cytosol, plastids, and mitochondria, and accordingly, both enzymes are encoded by small multigene families.

All plant species analyzed to date possess at least three **serine acetyltransferase** (*SERAT*) genes. The *Arabidopsis* *SERAT* isoforms differ significantly in their kinetic properties, and they also display different sensitivity to feedback inhibition by cysteine. Plant species differ in the localization of cysteine-sensitive serine acetyltransferases: in *Arabidopsis* the cytosolic *SERAT*1;1 and 3;2 are inhibited by cysteine, and in pea (*Pisum sativum*) it is the plastidic isoform. Analysis of *Arabidopsis* plants with multiple *SERAT* genes disrupted by T-DNA insertions revealed that each isoform can support plant growth, even when the total enzyme activity is less than 1% that of wild-type plants. The enzyme activity is nonetheless indispensable for plants, as disruption of all *SERAT* genes leads to embryo lethality. Significant reduction of the mitochondrial isoform may cause growth retardation depending on conditions. Altogether, it seems that mitochondria are the major site of *SERAT* activity and of OAS synthesis.

OAS (thiol)lyase belongs to the family of β -substituted alanine synthases (BSAS) in the superfamily of pyridoxal phosphate-dependent enzymes. BSAS enzymes are encoded by nine genes in *Arabidopsis* and eight in rice (*Oryza sativa*), and evolutionarily basal plants possess at least four genes. In addition to cysteine synthase activity, BSAS isoforms catalyze the synthesis of β -cyanoalanine from cysteine and HCN and S-sulfocysteine from OAS and thiosulfate. As with the *SERAT* gene family, there is some functional redundancy among the individual BSAS isoforms, but some isoforms have specialized functions. Disruption of individual BSAS genes does not yield any obvious phenotypic changes under normal growth conditions, with the exception of the mitochondrial *AtBSAS2;2*, which results in a slightly lower biomass accumulation. The total enzyme activity was, however, strongly reduced in plants lacking the cytosolic or plastidic forms of OAS (thiol)lyase, BSAS1;1 or BSAS2;1, respectively. **β -Cyanoalanine synthase** activity may be the primary activity of mitochondrial BSAS3;1, which thus functions in detoxification of cyanide. It appears the major site of cysteine synthesis is the cytosol, and this process utilizes OAS primarily synthesized in mitochondria and sulfide produced in the plastids.

In contrast to the enzymes involved in activating and reducing sulfate, *SERAT* and BSAS genes are highly similar to those from microorganisms and do not show great diversity. All OAS (thiol)lyase and serine acetyltransferase mRNAs are expressed in both leaves and roots, and in general, the steady state levels of these mRNAs are not responsive to sulfate starvation. Attempts to increase cysteine synthesis and, consequently, various cysteine metabolites by overexpression of serine acetyltransferase and OAS (thiol)lyase have yielded mixed results. Overexpression of OAS (thiol)lyase in plastids

FIGURE 16.53 Regulation of cysteine synthesis by OAS and thiol compounds. Active forms of enzymes are green, inactive states are presented in red. Squares represent OAS (thiol)lyase dimers, which are present in excess over the serine acetyltransferase (SERAT) hexamers indicated as circles. During sulfur sufficient conditions, sulfide promotes formation of the complex, thereby stimulating OAS production. OAS is used by free OAS (thiol)lyase to synthesize cysteine. Sulfate uptake and assimilation genes are repressed by compounds containing reduced sulfur. In sulfur-deficient conditions, OAS accumulates because of an insufficient production of sulfide. The complex is destabilized by OAS, inactivating serine acetyltransferase. OAS accumulation induces expression of genes involved in sulfate uptake and assimilation. Sulfide inhibits expression of these genes.

or the cytosol of different plant species has only a small effect on cysteine and glutathione content, but these plants are often more tolerant to various stress conditions that cause increased demand for reduced sulfur. Overexpression of serine acetyltransferase does lead to increased cysteine and glutathione levels, and the extent of the increase depends on the subcellular compartment and cysteine sensitivity of the expressed isoform. The two enzymes together form an enzyme complex named cysteine synthase.

16.15.2 The cysteine synthase multienzyme complex displays a novel regulatory mechanism in control of sulfate assimilation

The cysteine synthase complex of serine acetyltransferase and OAS (thiol)lyase does not facilitate substrate channeling in the enzymatic reaction. Instead, the protein–protein interaction plays a regulatory role. The active complex is composed of a hexamer (dimer of trimers) of serine acetyltransferase and two dimers of OAS (thiol)lyase. The protein–protein interaction in the complex greatly increases the catalytic activity of serine acetyltransferases, but OAS

(thiol)lyase is inactive in the complex (Fig. 16.53). The two proteins are not expressed to the same levels in plants; OAS (thiol)lyase is much more abundant. The ratio among the enzymes varies widely in the different compartments, with about 300-fold surplus of OAS (thiol)lyase in plastids and threefold surplus in mitochondria. Therefore, in vivo only a small fraction of the total OAS(thiol)lyase actually associates with serine acetyltransferases, leaving sufficient free enzyme for cysteine synthesis.

The binding properties of the two proteins are strongly affected by concentrations of OAS and sulfide: OAS dissociates the complex, whereas sulfide promotes complex formation (Fig. 16.53). The concentration of OAS causing 50% dissociation of the complex (58 μM) is well within the range of physiological OAS concentration; therefore, relatively small fluctuations of OAS levels may have large effects on the rates of OAS and cysteine synthesis. This regulatory mechanism complements the transcriptional regulation of sulfate transporters and APS reductase during sulfur deficiency, which may include OAS as a signal, thereby allowing fine-tuning of pathway control. Experiments with *Arabidopsis* mutants reveal that complex formation in chloroplasts is indirectly linked to noncyclic electron transport through a **cytochrome *b₆***—a protein foldase whose activity is enhanced by reduced thioredoxin (see Chapter 12).

16.16 Synthesis and function of glutathione and its derivatives

As a major end product of the reductive sulfate assimilation pathway, the tripeptide glutathione is the major nonprotein thiol in plants. It is present in millimolar concentrations that far exceed the low micromolar concentrations of cysteine. Glutathione and its derivatives are involved in storage and long-distance transport of reduced sulfur, in signal transduction pathways, in scavenging hydrogen peroxide and other reactive oxygen species (see Chapter 22), in detoxifying xenobiotics (e.g., herbicides; see Chapter 3), in activating and conjugating phenylpropanoids and hormones, and in serving as substrate for phytochelatin synthesis. Glutathione also plays a major role in maintaining redox balance of the cell.

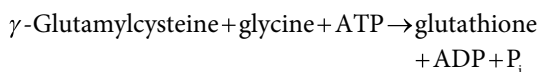

16.16.1 Glutathione is synthesized enzymatically in two ATP-dependent steps

Two enzymes make up the **glutathione** biosynthetic pathway (Fig. 16.54). First, γ -glutamylcysteine synthetase (EC 6.3.2.2) catalyzes the formation of a peptide bond between the γ -carboxyl group of glutamate and the α -amino group of cysteine (Reaction 16.11). Next, glutathione synthetase (EC 6.3.2.3) catalyzes the formation of a peptide bond between the cysteinyl carboxyl group of γ -glutamylcysteine and the α -amino group of glycine (Reaction 16.12). ATP is hydrolyzed in each reaction.

Reaction 16.11: γ -Glutamylcysteine synthetase

Reaction 16.12: Glutathione synthetase

Some plants produce tripeptides related to glutathione. Species in the order Fabales synthesize **homoglutathione** (in which β -alanine replaces glycine), and species in the Poaceae (grass family) generate **hydroxymethylglutathione** (in which serine replaces glycine). A third class (in which glutamate replaces glycine) is found in maize (*Zea mays*). However, all these plant species also form glutathione. In the legumes, homoglutathione is synthesized by a specific homoglutathione synthetase (EC 6.3.2.23) that evolved from a recent duplication of a glutathione synthetase gene. The two thiols are essential for formation and function of nodules. Specific functions of glutathione homologs have not been established.

Glutathione is present in all plant cell compartments, but it is synthesized only in plastids and the cytosol. The

γ -glutamylcysteine synthetase was originally found in both compartments; however, the enzyme was subsequently shown to be exclusively targeted to the plastids, at least in the Brassicaceae. In *Arabidopsis*, for example, both the plastidic and cytosolic forms of glutathione synthetase are encoded by a single gene that produces two transcripts, one with and one without the plastid-targeting peptide, by using alternative transcript initiation sites. Complete disruption of the γ -glutamylcysteine synthetase gene is embryonic lethal; seeds of plants lacking glutathione synthetase do germinate, but do not survive beyond a seedling stage even if glutathione is supplied externally. This phenotype can be complemented by targeting the enzyme solely to the cytosol. Thus, glutathione synthesis and distribution in *Arabidopsis* rely on multiple transport steps. Not only must glutathione be transported into mitochondria and plastids, to ensure its synthesis in the cytosol, the intermediate γ -glutamylcysteine must be exported from the plastids; this exchange across plastid membranes is facilitated by orthologs of the *Plasmodium* chloroquine-resistance transporter.

The γ -glutamylcysteine synthetase enzyme shows great diversity among different organisms. Although it can complement a γ -glutamylcysteine synthetase mutant of *E. coli*, the plant enzyme shares little sequence similarity with proteins from *E. coli*, fungi, or mammals. Plant γ -glutamylcysteine synthetase is feedback-inhibited by glutathione and regulated by changes in cellular redox homeostasis. The crystal structure of the protein from *Brassica juncea* shows two cysteine pairs that form disulfide bonds (Fig. 16.55). One of these disulfides is conserved among all plant γ -glutamylcysteine synthetases and is responsible for redox regulation. This feedback inhibition mechanism may be important for preventing accumulation of high (nonphysiological) concentrations of glutathione if the supply of precursor amino acids becomes too large. Details of the mechanism for reduction of the oxidized enzyme under physiological conditions are not known.

Manipulation of glutathione synthetase has only a limited effect on glutathione levels, but γ -glutamylcysteine synthetase is an important determinant of glutathione concentration in the cell. Transgenic plants overexpressing the bacterial gene for this enzyme show increased GSH levels that often correlate with higher resistance to abiotic stress. The rate of glutathione synthesis also appears to depend on the availability of cysteine and glycine (a product of photorespiration; see Chapter 14). *Arabidopsis* γ -glutamylcysteine synthetase mutants all contain significantly lower glutathione levels and typically exhibit compromised tolerance to various stresses. The *cad2* mutant, for example, is sensitive to the heavy metal cadmium, *pad2* is sensitive to pathogens, and *rax1* is impaired in chloroplast-nucleus signaling and constitutively expresses stress-inducible genes. One mutant with very low glutathione levels, *rml1*, lacks a root meristem and is unable to develop primary roots. Glutathione-controlled redox homeostasis is also important for auxin transport and signaling in root tips.

FIGURE 16.54 Reactions responsible for glutathione (A) biosynthesis and (B) redox homeostasis.

16.16.2 Glutathione is the precursor of phytochelatins

Phytochelatins are small cysteine-rich oligopeptides with the general structure $(\gamma\text{-Glu-Cys})_n\text{Gly}$ ($n=2\text{--}11$). They bind heavy metals and are found in plants, fungi, and other

organisms upon exposure to metals, such as cadmium (Cd^{2+}), or high concentrations of micronutrients, such as copper (Cu^{2+}).

Phytochelatin is synthesized enzymatically from glutathione by the enzyme phytochelatin synthase (EC 2.3.2.15). In this transpeptidation reaction, which requires the presence of metal ions, γ -Glu-Cys dipeptides from

FIGURE 16.55 Redox regulation of γ -glutamylcysteine synthetase from *Brassica juncea* (BjGCL) is implemented via two intramolecular disulfide bonds. (A) Stereo view of oxidized BjGCL (gray surface) indicating the relative position of a β -hairpin motif (in red). The disulfide bond CC1 (in yellow) may function as a loaded spring that fixes the hairpin over the substrate-binding sites. The inhibitor buthionine sulfoximine bound in the active site is shown in bond representation (in yellow) along with ADP (in black), whose position has been inferred from the *E. coli* structure (PDB ID: 1VA6). The side chain of rax1-1 R220 is shown as a space-filling model. (B) Surface view of the dimer found in crystals grown under nonreducing conditions. Redox regulation of BjGCL occurs via dimer-to-monomer transition. At the level of the dimer interface, the surface has been removed to show the contributing helical elements (in blue). The disulfide bond CC2 in both molecules is highlighted in yellow, and a molecule of ADP is shown in the nucleotide-binding site. (C) Enlarged view of the dimer interface in the same orientation as seen in B and D, following a 90° rotation. Seven salt bridges (in magenta) with bonding distances smaller than 3.1 Å and three conserved aromatic residues at the surface of each molecule contribute to interface stabilization.

glutathione are transferred onto an elongating phytochelatin oligopeptide (or another molecule of glutathione) (Fig. 16.56 and Reaction 16.13).

Reaction 16.13: Phytochelatin synthase

Plant phytochelatin synthase is composed of a conserved N-terminal and variable C-terminal domain. Cyanobacteria possess a truncated protein lacking the variable domain. Phytochelatin synthase belongs to a superfamily of Cys proteases, such as papain. In accordance with the papain reaction mechanism, phytochelatin synthase also transfers a γ -Glu-Cys unit from glutathione (bound to metal) onto a catalytic cysteine residue before it transfers this onto the N-terminus of glutathione or phytochelatin. Phytochelatin synthase also degrades glutathione conjugates.

Phytochelatins serve as a mechanism for detoxification of heavy metals by vacuolar sequestration, an example of one

type of biomineralization (Fig. 16.57). As such, phytochelatins are important for plant tolerance to heavy metals, in particular Cd and arsenic (As). Mutations or complete lack of phytochelatin synthase result in cadmium sensitivity in *Arabidopsis cad1* (*Cd-sensitive*) mutants or in the Bryophytes, respectively. Overexpression of phytochelatin synthase or of γ -glutamylcysteine synthetase leading to increased glutathione content generally increases tolerance to Cd and As. Such increased potential to synthesize phytochelatins leads to greater metal accumulation in plant tissues, and such plants may be good candidates for use in phytoremediation.

16.16.3 Glutathione plays an important role in detoxification of xenobiotics

Plants can detoxify or inactivate many substances, including endogenously produced toxins and hormones and **xenobiotic** chemicals such as herbicides, by forming conjugates

FIGURE 16.56 Phytochelatin synthase catalyzes the transpeptidation reaction of glutathiones to produce $(\gamma\text{-Glu-Cys})_n\text{Gly}$ ($n = 2\text{-}11$). Initially, the glycine moiety of one glutathione is removed and a new peptide bond is formed with the residual cysteine and the amino group of the glutamate on a second molecule of glutathione. This reaction is repeated to form the phytochelatin oligomers.

B

FIGURE 16.57 Two molecules $[(\gamma\text{-Glu-Cys})_2\text{Gly}]$ coordinated with a cadmium ion. (A) By binding toxic heavy metal ions, phytochelatins remove them from the cellular machinery. It is thought the thiol groups of phytochelatins serve as the ligand for heavy metal ions. (B) A model for the mechanism of CdS mineralization and sequestration in plant cells mediated by phytochelatins. Both phytochelatins and low-molecular-weight (LMW) phytochelatin-Cd complexes formed in the cytosol enter the vacuole by way of an ABC transporter (1). Cd ions enter the vacuole by way of an antiporter in exchange for protons (2). HMW, high molecular weight. The electrochemical gradient across the tonoplast is maintained by a proton-pumping ATPase (3). The end product is a CdS crystallite.

with glutathione. This reaction is catalyzed by glutathione S-transferase, which links the reactive thiol group of cysteine to the xenobiotic (Fig. 16.58; see also Fig. 3.14 in Chapter 3). The conjugates are then transported into vacuoles by an ABC-type glutathione translocator. Within the vacuole, detoxification is completed as glutathione conjugates are hydrolyzed to cysteine conjugates.

Plant glutathione transferases (EC 2.5.1.18) are encoded by a large and diverse gene family, such as the 48-member family in *Arabidopsis*. The enzymes are usually localized in the cytosol, where they catalyze the detoxification of xenobiotics and reduction of the organic hydroperoxides formed during oxidative stress. In addition, glutathione transferases facilitate transport of natural products into the vacuole and

FIGURE 16.58 Detoxification of a herbicide (e.g., Metolachlor) by conjugation to glutathione. The conjugate is then transported into the vacuole.

FIGURE 16.59 In situ localization of glutathione. The tissue was infiltrated with 100 μM monochlorobimane, which after conjugation to glutathione produces a fluorescent product, and in (B) and (C) additionally with 50 μM propidium iodide, staining cell walls in red, and 5 mM sodium azide to prevent transport of the conjugate into the vacuoles. (C) Poplar (*Populus*) leaf upper epidermis showing glutathione labeling in cytosolic strands and nucleus.

Source: Combined from (A) Fig. 6A from *J. Microsc.* (2000). 198(3):162–173. (B) Fig. 2D from *Proc. Natl. Acad. Sci. USA* (2000). 97(20):11108–11113. (C) Fig. 1A from *Plant Cell Environ.* (2003). 26(6):965–975.

are involved in various stress-signaling pathways. While individual isoforms bind specific substrates, the general structure of the proteins is conserved.

This mechanism for **herbicide** detoxification has been applied successfully to agriculture by identifying the substances that stimulate expression of glutathione *S*-transferase and the vacuolar transporter, or that result in an increased rate of glutathione synthesis. These substances, termed **safeners**, are used to increase the resistance of crop plants to herbicide.

The conjugation of glutathione to xenobiotics has also been exploited for in vivo glutathione imaging. Since

conjugation requires catalysis by a glutathione transferase, the measurement is specific for the cytosolic glutathione pool. This enables quantitative measurement of cytosolic glutathione in a noninvasive, cell-specific manner using confocal laser scanning microscopy (Fig. 16.59). Using this method, the cytosolic glutathione concentration in cells of root epidermis was estimated to be 3 mM, but marked differences in glutathione concentration are evident between different cell types in plant organs (Fig. 16.59). Glutathione redox potential can also be visualized using modified, redox-sensitive fluorescent proteins targeted to individual cell compartments.

FIGURE 16.60 Sulfate assimilation into sulfated metabolites. Sulfate is activated by adenylation to adenosine 5'-phosphosulfate (APS) in an ATP-dependent reaction catalyzed by ATP sulfurylase (ATPS). APS is further phosphorylated by APS kinase (APK) to 3'-phosphoadenosine 5'-phosphosulfate (PAPS). PAPS is the sulfate donor for sulfation of hydroxylated precursor (X-OH) by sulfotransferase (SOT) to form sulfated metabolite and adenosine 3',5'-biphosphate (PAP).

16.17 Sulfated compounds

Most of the sulfate that enters plant cells is metabolized by the sulfate reduction pathway, but some is converted to PAPS and incorporated in various sulfated compounds. Many of the known sulfated plant metabolites play roles in defense against biotic and abiotic stress. The glucosinolates are the best-characterized group of such sulfated secondary compounds (see Chapter 24), and another large group of sulfated compounds are sulfated flavonoids, which are important in medicine. Present in more than 250 species, where they are involved in detoxifying reactive oxygen species and regulating plant growth, sulfated flavonoids also possess an anticoagulant activity and inhibit platelet aggregation and may be used for prevention of thrombosis. Several other sulfated compounds participate directly in plant defense against pathogens, such as sulfated derivatives of jasmonic acid and sulphated β -1,3-glucan and fucan oligosaccharides, the latter inducing salicylic acid defense signaling. In addition, sulfated compounds are involved in seismonastic movements of *Mimosa*, and small sulfated peptides, such as phytosulfokines and PS1, are important regulators of plant growth.

16.17.1 APS kinase is the enzyme at the interface between primary and secondary metabolism

To be incorporated into sulfated compounds, sulfate is activated in two steps. As mentioned in Section 16.14.1, sulfate is first activated by ATP sulfurylase, which adenylates the sulfate to generate the intermediate APS (see Reaction 16.5). In the second step, APS is further phosphorylated by APS kinase to PAPS, the activated form of sulfate for all sulfation reactions (Reaction 16.14, Fig. 16.60).

Reaction 16.14: APS kinase

PAPS is synthesized in the plastids and cytosol, the two compartments where APS is also produced. Plant APS kinases show strong sequence conservation with their homologs from bacteria, fungi, and animals and are encoded by a small gene family. *Arabidopsis*, for example, possesses one cytosolic and three plastidic isoforms, but the plastidial and cytosolic PAPS pools are interchangeable and connected by specific envelope-localized PAPS transporters.

Consistent with the function of sulfated compounds in plant stress response, APS kinase transcript levels are regulated by oxidative stress and by compounds involved in stress signaling. Disruption of two plastidic APS kinase isoforms, APK1 and APK2, reduces levels of glucosinolates and other sulfated compounds. The reduced synthesis of these secondary metabolites results in redirection of sulfur flux into primary assimilation, and the plants accumulate glutathione. In addition, similar to other enzymes of the pathway, APS kinase is redox regulated.

16.17.2 Sulfotransferases catalyze the transfer of sulfo-group to various metabolites

Transfer of the functional sulfo-group to hydroxylated substrates, that is, sulfation, is catalyzed by sulfotransferases in a reaction that requires PAPS as the sulfate donor and a compound with an available hydroxyl group as an acceptor. Advanced eukaryotes encode multiple sulfotransferase isoforms that accommodate the structural diversity of the biological acceptors of the sulfate group. The sulfotransferase family in *Arabidopsis* includes 18 members, but substrate specificities and biological functions are known for fewer than half of these. Sulfotransferases SOT16, SOT17, and SOT18 catalyze the final step of glucosinolate biosynthesis, sulfation of desulfoglucosinolates. Accordingly, these have broad substrate specificity (see Chapter 24). By contrast, *Arabidopsis* SOT15 specifically catalyzes sulfation of 11- and 12-hydroxyjasmonate. Consistent with the potential role of sulfated compounds in plant defense, mRNA levels of several

sulfotransferase isoforms increase upon treatment with jasmonate or salicylic acid and upon interaction with bacterial pathogens and elicitors. Several additional sulfotransferases have been isolated, cloned, and characterized from other species, including flavonol sulfotransferases from *Flaveria chloraefolia* and *F. bidentis*, and a sulfotransferase from *Mimosa putida* that catalyzes synthesis of turgorin. No sulfotransferases were found in the moss *Physcomitrella patens* or green alga *Chlamydomonas reinhardtii*, implying a late evolutionary origin for these enzymes.

16.18 Regulation of sulfate assimilation and interaction with nitrogen and carbon metabolism

16.18.1 Glutathione plays an important role in demand-driven regulation of sulfate assimilation

Sulfate assimilation is regulated according to the physiological need for reduced sulfur. Demand for sulfur increases when its supply becomes limited (sulfate starvation). It also increases during stress because of the involvement of glutathione and other sulfur-containing compounds in stress response. Glutathione levels can be depleted experimentally by inhibition of γ -glutamylcysteine synthetase with buthionine sulfoximine. Conversely, demand is reduced for plants that are supplied with reduced sulfur, which can be achieved by fumigation with sulfur dioxide or hydrogen sulfide, or by treatments with thiols. According to the demand-driven model of regulation of sulfate assimilation, sulfate uptake and the flux through the pathway increase when demand is high and decrease when the demand is low (Fig. 16.61). Because the activities of APS reductase and sulfate transporters are regulated by changes in demand for reduced sulfur, they possess the highest control over the flux. These treatments and environmental conditions each affect glutathione level, and it is likely the plant senses and responds to fluctuations in glutathione.

Sulfate assimilation pathway components show parallel regulation at the levels of enzyme activity, protein accumulation, and mRNA levels, pointing to a straightforward transcriptional regulation of the pathway. A sulfur-starvation response *cis* element, SURE, and a transcription factor, SLIM1, are involved in regulating expression of genes involved in sulfate assimilation. SLIM1 belongs to the ethylene-insensitive-like family of transcription factors and plays a central role in plant response to sulfur starvation. SLIM1-deficient plants are unable to induce sulfate transporters during low sulfur availability, resulting in significant growth defects

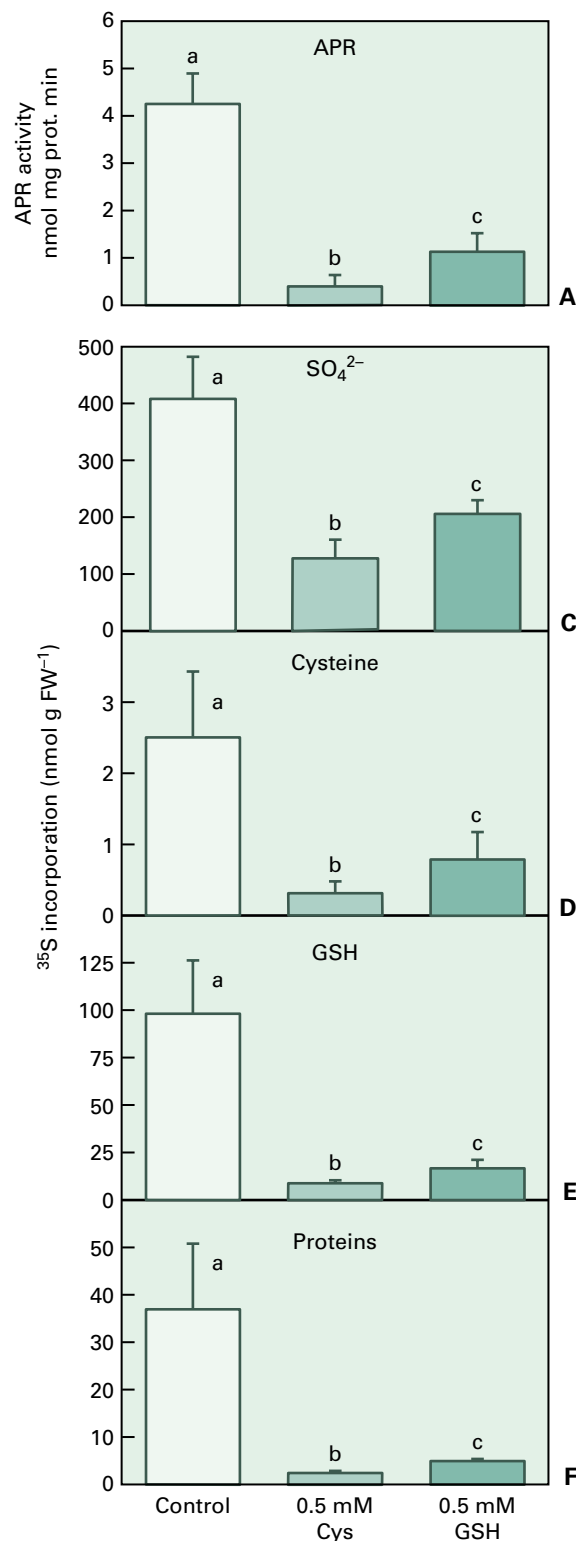

FIGURE 16.61 Feedback regulation of flux through sulfate assimilation. *Arabidopsis thaliana* root cultures were supplemented with 0.5 mM cysteine or 0.5 mM glutathione (GSH) for 20 hours. Radioactive [³⁵S] sulfate was then added, and the cultures were further incubated for 4 hours. APS reductase activity (APR) and incorporation of radioactivity from [³⁵S] sulfate into sulfate (a measure of sulfate uptake), cysteine, glutathione, and proteins were measured. Controls were cultivated without additions.

FIGURE 16.62 *SLIM1* is a central regulator of plant sulfur deficiency response. Arabidopsis plants were grown at 1,500 μ M sulfate (green bars) or 15 μ M sulfate (white bars). Transcript levels of two genes induced by sulfate deficiency (At4g08620 and At2g4460) and one gene repressed (At5g43780) by S deficiency were measured in two independent RNA preparations from wild-type plants, and two alleles of *slim1* mutants by quantitative real-time PCR. (A) *SULTR1;1* is a high-affinity sulfate transporter; (B) *Thioglucosidase*; (C) *APS4* is a form of ATP sulfurylase. Data were normalized using ubiquitin as an internal standard.

under such conditions (Fig. 16.62). Other regulatory mechanisms are involved in fine-tuning the plant response to environmental cues, including post-translational inhibition of APS reductase and γ -glutamylcysteine synthetase by glutathione, feedback inhibition of serine acetyltransferase by cysteine, and modulation of OAS (thiol)lyase and serine acetyltransferase binding by OAS and sulfide. The response of mRNA levels to changes in sulfur demand may be uncoupled from the changes in corresponding enzyme activity: such post-transcriptional regulation has been described for sulfate transporters and APS reductase.

One such post-transcriptional mechanism uses the microRNA miR395, which is induced by sulfur starvation. It accumulates to high levels in roots and shoots of sulfur-starved plants in a *SLIM1*-dependent manner, and it targets three isoforms of ATP sulfurylase and the low-affinity *SULTR2;1* sulfate transporter. This microRNA enables efficient transport of sulfate to the shoots under sulfur-deficient conditions by restricting *SULTR2;1* expression to xylem parenchyma cells of the roots and limiting sulfate assimilation in the roots. Accordingly, ectopic expression of miR395 results in sulfate accumulation in the leaves.

16.18.2 Sulfur starvation response is a frequent model for systems biology

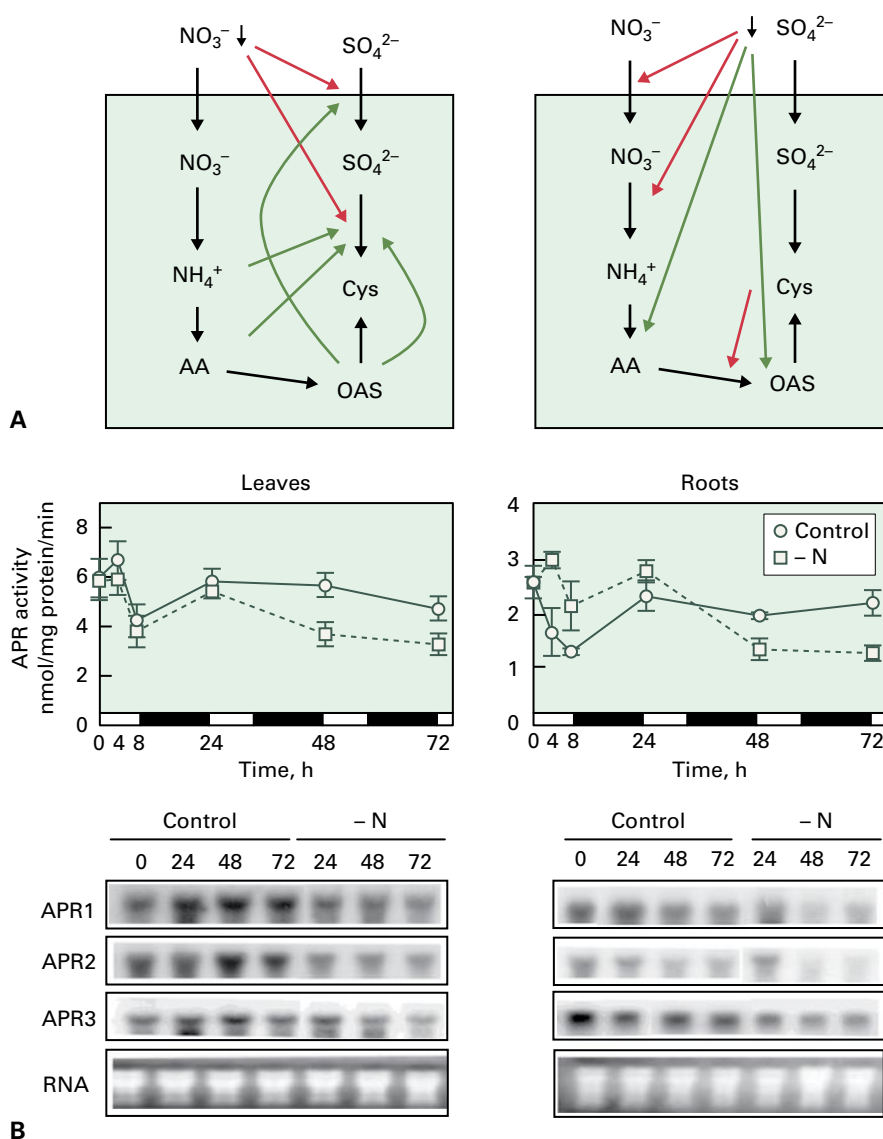

Sulfur deficiency broadly affects general plant metabolism, as shown by transcript and metabolite profiling of plants grown under normal and sulfur-depleted conditions. Numerous

sulfate assimilation genes show increased expression, while genes involved in glucosinolate biosynthesis are strongly reduced. Corresponding metabolite analyses show glucosinolates are degraded during sulfur-deficient conditions, and they serve as an alternative sulfur source. Network analysis of combined transcript and metabolite data revealed novel regulators and several new genes involved in glucosinolate synthesis. Sulfur deficiency leads to accumulation of free amino acids, particularly of OAS, and to increased mRNA levels of sulfate transporters, APS reductase, and many other genes that respond to sulfate starvation. At least some of these genes are directly induced by OAS. Sulfur deficiency also affects expression of genes involved in jasmonate and auxin biosynthesis and those in major metabolic pathways, such as the Calvin–Benson cycle, glycolysis, and lipid synthesis.

Components of the sulfur starvation signal transduction pathway have been identified in the green alga *Chlamydomonas reinhardtii*. Mutations in **sulfur acclimation** (*sac*) genes result in a lack of response to sulfur limitation: *sac1* mutants lack both general and specific responses to sulfur starvation, including the effects on photosynthesis, whereas *sac2* and *sac3* mutants are deficient only in sulfate uptake and assimilation. The *Sac1* gene encodes a protein homologous to ion channels, one inferred to be a sulfate sensor, *Sac3* encodes an Snf1-like kinase (its disruption leads to derepression of **arylsulfatase** expression), and *Sac2* is involved in post-transcriptional regulation of APS reductase, but has not been identified. Another Snf1-like kinase epistatic to *Sac3* is indispensable for eliciting the sulfur starvation response in the alga. It is not known whether land plants employ similar regulatory mechanisms and components.

16.18.3 Sulfate assimilation is closely linked with carbon and nitrogen metabolism

Synthesis of cysteine connects the three major pathways of primary metabolism—carbon fixation, nitrate assimilation, and sulfate assimilation. Accordingly, the pathways are well coordinated. Sulfate uptake and APS reductase activity decrease during nitrogen and carbon starvation (e.g., in low CO_2 atmosphere). Sulfate starvation leads to reduction of nitrate uptake and nitrate reductase activity, chlorophyll degradation, and reduced photosynthesis (Figs 16.63 and 16.64). APS reductase, in parallel with nitrate reductase, displays a diurnal rhythm in activity and transcript levels, and it is induced by light and carbohydrates (Fig. 16.64). Flux through the sulfate reduction pathway is far greater in the light than in the dark and is increased by addition of reduced nitrogen

sources and carbohydrates. Recently, the transcription factor LONG HYPOCOTYL5 (HY5) was identified as important for light induction of APS reductase and its regulation by OAS and nitrogen availability.

Phytohormones also affect sulfate assimilation. The genes of sulfate assimilation and glucosinolate synthesis are coordinately upregulated by jasmonic acid. APS reductase, the key enzyme in the pathway, is upregulated by other phytohormones involved in stress signaling, namely salicylate and ethylene. Interestingly, abscisic acid promotes synthesis of cysteine and glutathione but has a negative effect on APS reductase. Cytokinins, which are strongly connected with nitrogen and phosphate nutrition, regulate sulfate assimilation as well. The upregulation of sulfate transporters by sulfur starvation is partially dependent on cytokinin signaling. The regulation of sulfate assimilation is thus complex, involving and coordinating many signals and effectors.

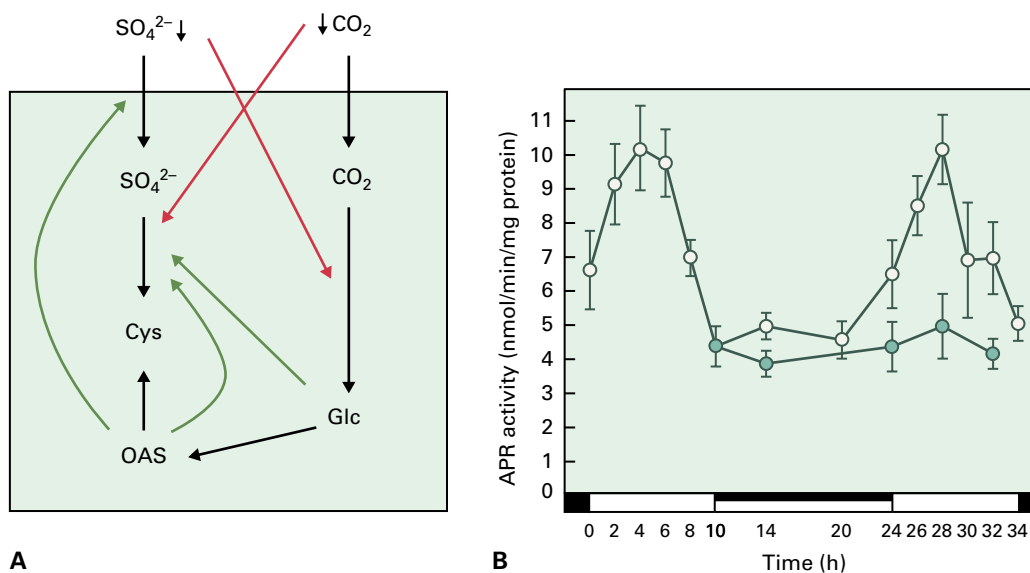

FIGURE 16.64 Regulatory interaction of sulfate and carbon assimilation. (A) Green arrows represent upregulation, red arrows denote repression by CO_2 or sulfate deficiency. (B) Diurnal rhythm of APR activity at normal day/night rhythm (full symbols) and constant light (open symbols).

Summary

Plants are major players in the geochemical cycles of both sulfur and nitrogen. The inorganic forms of these elements are incorporated into carbon-bonded molecules using reducing power derived from photosynthesis. The reduction and assimilation reactions are integrated into general plant metabolism: For example, they are regulated by light and carbon availability, plant growth, hormones, and other factors. Nitrogen and sulfur are required for protein synthesis, and each is essential for making multiple types of other small and macromolecules. Nitrogen or sulfur assimilation functions are sometimes compartmentalized within plant cells or located in specific tissues or organs.

The biochemically useable state of nitrogen is ammonia (NH_3). Biochemically useful nitrogen can also be derived from the reduction of nitrate (NO_3^-) or by bacterial nitrogen (N_2) fixation. The key catalyst of nitrogen fixation, nitrogenase, has two functional component proteins. Dinitrogenase is the enzyme that actually reduces molecular N_2 . It contains unusual metal clusters including one type that generally includes Fe, S, and either Mo or V. Dinitrogenase reductase uses ATP to lower the potential of reductants obtained from metabolism to a level where electrons can reduce the dinitrogenase clusters.

Some plants, including agriculturally and ecologically important legumes, can enter into symbiosis with nitrogen-fixing bacteria to acquire bacterially produced

ammonium in exchange for plant carbon from photosynthesis. The cellular and developmental functions underlying legume symbiosis include signal exchange and specific gene expression to accomplish metabolic exchange. The nitrogen-fixing forms of the bacteria, termed bacteroids, are surrounded by a plant-derived membrane that controls the exchange of nutrients between the bacteroid and the plant cytoplasm.

A mature nodule is organized to support the energy-intensive nitrogen fixation reaction by delivering oxygen and carbon sources to the bacteroids at low concentrations of free O_2 in order to protect nitrogenase, a notoriously oxygen-sensitive enzyme. Ammonium released by bacteroids is first assimilated in the plant by glutamine synthetase and other enzymes, sometimes employing nodule-specific isozymes. Assimilated nitrogen leaves the nodule as either amides or ureides, depending on the host species, which leads to distinct patterns of gene expression, compartmentation, and regulation of these final steps in different hosts.

Plant use of environmental ammonium and nitrate begins with high- and low-affinity transporters that are subject to various levels of regulation. High-affinity ammonium transporters in the AMT/Rh family appear to act as uniporters and are regulated at the transcriptional level and by posttranslational phosphorylation. Nitrate transporters include the symporters NRT1 and NRT2, which function at both the plasma membrane and

tonoplast, along with the tonoplast antiporter CLC protein. To adapt to environmental nitrate availability, which can vary over four orders of magnitude, the NRT1/2 transporters participate in both high- and low-affinity transport using active proton-coupled mechanisms. The various forms are subject to tissue-specific and environmentally regulated expression and to posttranslational modification. Nitrate loading into cellular vacuoles may employ distinct transporters.

To be assimilated, nitrate is reduced to nitrite and subsequently to ammonia, overall an eight-electron transfer. To avoid build up of toxic nitrite, NR activity is highly regulated and NiR is not limiting. NR gene expression is regulated by diverse signals, including nitrate levels, light, carbon availability, and hormones. The NR polypeptide includes three domains, each binding a specific cofactor and associated with separable partial activities: an N-terminal molybdenum cofactor (MoCo)-binding domain, a central heme-binding domain similar to cytochrome b_5 family, and a C-terminal FAD-binding region that also binds the substrate NAD(P)H. The three functional regions are joined by hinge segments that participate in posttranslational regulation of activity, such as phosphorylation-dependent 14-3-3 protein binding. NR is localized in the cytoplasm and in some cases shows cell type-specific localization.

Ferredoxin (Fdx) provides the reducing power for plastid-localized NiR to catalyze conversion of nitrite to ammonia, a six-electron transfer. Fdx_{red} is produced in the chloroplasts of green tissues by noncyclic electron transport; in nonphotosynthetic cells a more electropositive Fdx is reduced via ferredoxin-NADP⁺ reductase, using NADPH from the oxidative pentose phosphate pathway.

Sulfur is required in all organisms for synthesis of proteins and cofactors. Sulfur is used in plants for additional unique structures and functions, such as the sulfoquinovosyl-diacylglycerol lipids in chloroplast

membranes. As the primary producers of organic sulfur compounds, plants play a key role in the global sulfur cycle by coupling photosynthesis to the reduction of sulfate, assimilating sulfur into cysteine and metabolizing this amino acid to form methionine, glutathione, and other compounds; this, in turn, is the source of reduced sulfur for animals.

The sulfate ion is taken up into plants via active proton cotransporters in root cells. Permeases and facilitated transport systems accomplish sulfate transport between organs, cells, and subcellular compartments. Multigene families encode these transporters, which display different kinetics and expression patterns to accomplish sulfate distribution across the plant.

For assimilation, sulfate is first activated by reaction with ATP to form adenosine 5'-phosphosulfate (APS), a reaction catalyzed by ATP sulfurylase. The S atom in APS can be reduced first to sulfite by APS reductase and then to sulfide by sulfite reductase. Reduction of sulfate is highly energy-intensive. It can be carried out in plastids of many cell types, but a preponderance of sulfate reduction occurs in green tissues, and it is more active in the light than the dark. Cysteine is synthesized by condensation of sulfide with *O*-acetylserine; enzymes for production of *O*-acetylserine and cysteine are encoded by multigene families and are localized in all compartments that carry out protein synthesis. Cysteine is the donor of reduced sulfur for synthesis of other sulfur-containing metabolites, such as methionine and glutathione.

Alternatively, APS is further activated by APS kinase to form PAPS (phospho-adenosyl phosphosulfate), which is the molecular source for sulfate used in sulfated polysaccharides, glucosinolates, and other metabolites. Sulfate uptake and assimilation are regulated by demand, and at multiple levels from transcription to activity. This regulation integrates factors including growth, light, and sulfur availability, and these functions are an appealing target for systems analysis.

Biosynthesis of Hormones

Gerard Bishop, Hitoshi Sakakibara,
Mitsunori Seo, and Shinjiro Yamaguchi

Introduction

Plant hormones are signal molecules, present in trace quantities. Changes in hormone concentration and tissue sensitivity mediate a range of developmental processes in plants, many of which involve interactions with environmental factors. This chapter is concerned with the biosynthetic, catabolic, and conjugation pathways that together control plant hormone homeostasis. Attention will be focused on the so-called “classic,” first five plant hormones discovered—gibberellins, abscisic acid, cytokinins (CKs), indole-3-acetic acid and ethylene—and more recently investigated compounds that have regulatory roles in plant development, such as brassinosteroids, polyamines, jasmonic acid, salicylic acid, and strigolactones (Fig. 17.1). Each of these hormones has its own particular properties, so the pathways regulating their production and degradation are diverse and have been elucidated by synergistic use of many disciplines, including chemistry, biochemistry, plant physiology, genetics, and more recently molecular genetics. Mutant plants that are unable to catalyze an enzymatic reaction leading to the formation or degradation of a bioactive hormone have been powerful tools in plant hormone research. Such mutants have been invaluable in hormone analysis studies and in phenotypic rescue experiments using intermediates in the biosynthetic pathway. They also provide the essential material for cloning of genes that encode biosynthetic enzymes. In addition, inhibitors of plant hormone biosynthesis have been used to dissect reactions for which relevant mutants have not been identified. More recently, transgenic technology has provided insights into pathways by altering the expression of

genes involved in biosynthesis or catabolism of hormones. In summary, each hormone biosynthetic pathway has been elucidated using similar techniques with biases towards certain methodologies according to the nature of the biosynthetic pathway and the availability of mutants.

17.1 Gibberellins

Gibberellins (GAs) were first isolated from the fungus *Gibberella fujikuroi* in 1926 by the Japanese scientist Eiichi Kurosawa, who was investigating the causative agent of *bakanae*, the “foolish seedling” disease of *Oryza sativa*, which was frequently responsible for major reductions in grain yield. Diseased *O. sativa* seedlings exhibited excessive shoot elongation and yellowish-green leaves (Fig. 17.2). Those that survived to maturity were taller than their healthy counterparts and seeds were either absent or poorly developed. Kurosawa demonstrated that diseased *O. sativa* plants were infected with a fungal pathogen, *G. fujikuroi*, which secreted a factor that increased the rate of shoot elongation. He also noted that the active factor promoted the growth of *Zea mays*, *Sesamum indicum*, *Pennisetum glaucum*, and *Avena sativa* seedlings. In the 1930s, the fungal growth-inducing factor was crystallized and named gibberellin. At about the same time, scientists in the West were actively investigating hormonal regulation of plant growth by auxin (see Section 17.4). They either failed to appreciate the significance of the Japanese work on GAs or were unaware of its existence, despite the availability of English translations. Not until the early 1950s did GA research become

FIGURE 17.1 Structures of representatives from the 10 types of plant hormones discussed in this chapter.

international in scope when groups from the US and UK initiated their own studies with *G. fujikuroi*. The British isolated gibberellic acid and the Americans gibberellin X. The compounds proved to be identical, and the structure of gibberellic acid, now known as GA₃, was elucidated in 1956. Shortly thereafter, GAs were shown to be endogenous components of plants, and it became apparent that they were not merely an interesting group of fungal metabolites but endogenous regulators of many aspects of higher plant growth and development.

17.1.1 Among more than 100 GAs identified from plants, only a few act as bioactive hormones

The GAs are a group of tetracyclic diterpenes. At the time of writing, 136 different GAs had been characterized. To avoid confusion, the nomenclature GA₁ to GA₁₃₆ has been adopted,

and the numbers GA₁₃₆ to GA_n will be allocated sequentially as further GAs are characterized. Among more than 100 GAs identified from plants, only a few function as bioactive hormones. Many nonbioactive GAs present in plants are biosynthetic precursors of bioactive forms or are inactivated metabolites. The most commonly found bioactive GAs in plants are GA₁ and GA₄, both of which have a hydroxyl group on C-3β, a carboxyl group on C-6, and a γ-lactone between C-4 and C-10 (Fig. 17.3). The recent identification of a soluble GA receptor, GIBBERELLIN INSENSITIVE DWARF 1 (GID1), from *O. sativa* and its homologs in *Arabidopsis* and *Hordeum vulgare* has demonstrated that these structural requirements for bioactive GAs are reflected in their affinity for the GID1 receptor. GA₁ has been identified frequently in a variety of plant species, suggesting that it acts as a widespread bioactive hormone. However, GA₄ also exists in most species and is considered to be the major bioactive GA in *Arabidopsis* and some Cucurbitaceae. GA₃ and GA₇, 1,2-double bond analogs of GA₁ and GA₄, respectively, are also active per se in plants (Fig. 17.3).

FIGURE 17.3 Structures of bioactive GAs in plants.

17.1.2 Bioactive GAs affect many aspects of plant growth and development

GAs are best known for their influence on stem elongation (Fig. 17.4) and leaf growth (Fig. 17.5), but they also affect other developmental processes in a wide range of plants. In some species, GAs stimulate fruit growth without fertilization of ovules (parthenocarpy). In flowering plants that require one or more long days to flower or that require a cold treatment, GA application often can substitute for the environmental signal. GAs can stimulate seed germination in many plant species. *Arabidopsis* and *Solanum lycopersicum* mutants that are severely

defective in GA synthesis are nongerminating, and their germination can be induced by GA treatment. GA-induced de novo synthesis of α -amylase and other enzymes in the aleurone layer of cereal grains has been used extensively in studies of GA action. Because of this effect, GA_3 is used widely in the malting industry to speed up and regularize malt production. In general, vegetative tissues contain low nanogram or sub-nanogram quantities of GAs per gram fresh weight, whereas GAs occasionally accumulate at much higher levels in some reproductive organs such as anthers and developing seeds.

17.1.3 GA biosynthesis starts in the plastid

The initial steps in biosynthesis of GAs involve formation of isopentenyl diphosphate and its conversion to geranylgeranyl diphosphate (GGDP), a common precursor for various terpenoids, such as carotenoids and phytol (Fig. 17.6). Plants have two distinct pathways for biosynthesis of isopentenyl diphosphate: the mevalonate pathway in the cytosol, and the methylerythritol phosphate (MEP) pathway in plastids (see Chapter 24). Metabolism studies using isotope-labeled precursors in *Arabidopsis* seedlings showed that the MEP pathway in plastids provides the majority of isopentenyl diphosphate to GAs, whereas only a minor contribution is from the cytosolic mevalonate pathway.

Three different classes of enzymes are required for GA biosynthesis from GGDP in plants: terpene synthases (cyclases), Cytochrome P450 monooxygenases, and 2-oxoglutarate-dependent dioxygenases (see Sections 17.1.4–17.1.6).

FIGURE 17.5 Promotion of Tanginbozu dwarf *O. sativa* (d35) leaf sheath elongation 3 days after treatment with GA_3 : (left) control; (center) 100 μg of GA_3 per seedling; (right) 1 ng of GA_3 per seedling.

FIGURE 17.7 Early stages of plant GA biosynthesis. CPS, ent-copalyl diphosphate synthase; KS, ent-kaurene synthase; KO, ent-kaurene oxidase; KAO, ent-kaurenoic acid oxidase. Colored carbon atoms on GA₁₂ are oxidized for the synthesis of GA₁ (see also Fig. 17.9).

17.1.4 In plants, the synthesis of ent-kaurene from geranylgeranyl diphosphate is catalyzed by two distinct enzymes

Synthesis of ent-kaurene from GGDP is catalyzed by two distinct terpene synthases, ent-copalyl diphosphate synthase (CPS) and ent-kaurene synthase (KS) (Fig. 17.7). CPS catalyzes conversion of GGDP to a partially cyclized product, ent-copalyl diphosphate. This reaction does not involve the removal of the diphosphate group and is initiated by addition of a proton to the terminal olefin bond of the substrate. KS catalyzes formation of ent-kaurene, a tetracyclic hydrocarbon, from ent-copalyl diphosphate. This cyclization reaction is initiated by elimination of the diphosphate group. A gene encoding CPS was first identified as the causal gene of the *Arabidopsis* *ga1-3* mutant, an extreme dwarf resulting from GA deficiency. A cDNA clone encoding KS was initially isolated based on partial amino acid sequences of a purified enzyme from immature pumpkin seeds, a rich source of GA biosynthesis enzymes. Evidence suggests that both CPS and KS have an amino-terminal plastid-targeting signal, and that ent-kaurene synthesis occurs in plastids.

17.1.5 Cytochrome P450 monooxygenases convert ent-kaurene to GA₁₂

ent-Kaurene is oxidized to GA₁₂ by NADPH-dependent, membrane-bound CYP450 monooxygenases: ent-kaurene oxidase (KO, CYP701A) and ent-kaurenoic acid oxidase (KAO, CYP88A) (Fig. 17.7). KO catalyzes the three-step

oxidation on C-19 to synthesize ent-kaurenoic acid. KAO also is a multifunctional enzyme that catalyzes the three-step conversion of ent-kaurenoic acid to GA₁₂, including the conversion of ent-7 α -hydroxy-kaurenoic acid to GA₁₂, which involves contraction of the B-ring from a C₆ to a C₅ structure. The nitrogen-containing heterocyclic compounds paclobutrazol, uniconazole, tetcyclasis, and ancymidol retard plant growth by inhibiting KO (see Fig. 17.8) However, these compounds are not specific inhibitors of GA biosynthesis because they also affect other CYP450 enzymes, including those involved in the biosynthesis of brassinosteroids and the catabolism of abscisic acid (see Section 17.6.4). Several GA-deficient dwarf mutants, including *lh* (*P. sativum*), *d35* (*dx*) (*O. sativa*), and *ga3* (*Arabidopsis*), have defective KO activity. A gene encoding KAO was first identified as a causative gene of the *H. vulgare* *grd5* mutant, a GA-responsive dwarf. Experiments using enzymes fused to green fluorescent protein (GFP) suggest that KO is present in the outer membrane of the plastid, whereas KAO is located in the endoplasmic reticulum.

17.1.6 Conversion of GA₁₂ to bioactive GAs involves two pathways: one in which C-13 is hydroxylated early, and one in which C-13 is not hydroxylated

The multistep conversion of GA₁₂ to bioactive GAs proceeds via one of two pathways, one where C-13 is hydroxylated producing GA₂₀ and GA₁, the other where hydroxylation at C-13 does not occur producing GA₉ and GA₄ (Fig. 17.9). Although a soluble, 2-oxoglutarate-dependent 13-hydroxylation activity

FIGURE 17.8 Structures of uniconazole, paclobutrazol, and brassinazole. Uniconazole and paclobutrazol are triazoles that inhibit KO (see Fig. 17.7). However, uniconazole is not specific and also suppresses BR biosynthesis. The structurally related compound, brassinazole, is a strong BR inhibitor, blocking at least one CYP450 mediated step in the BR biosynthesis pathway (see Fig. 17.58). Its effect on GA biosynthesis is undetermined.

has been detected in cell-free extracts from *Spinacia oleracea* leaves, the 13-hydroxylase activity identified in *Cucurbita* spp. endosperm, developing *H. vulgare*, and *P. sativum* embryos are all monooxygenases.

In either pathway, GA 20-oxidase and GA 3-oxidase, both soluble 2-oxoglutarate-dependent dioxygenases, are responsible for the production of bioactive GAs (Fig. 17.9). GA 20-oxidase catalyzes the sequential oxidation of C-20, including the loss of C-20 as CO_2 and the formation of γ -lactone. The subsequent introduction of a 3β -hydroxyl group by GA 3-oxidase converts inactive precursors (GA_{20} and GA_9) to bioactive forms (GA_1 and GA_4). Some GA 3-oxidases have minor catalytic activity to synthesize GA_3 from GA_{20} via GA_5 , a 1,2-double bond analog of GA_{20} (Fig. 17.9). The subcellular localization of GA 20-oxidase and GA 3-oxidase has not been demonstrated experimentally, but they are considered to be cytosolic enzymes because they lack obvious targeting sequences.

In both *Arabidopsis* and *O. sativa*, enzymes catalyzing early steps of GA biosynthesis are encoded by one or two genes, and mutants defective in these enzymes typically exhibit severe dwarfism. In comparison, GA 20-oxidase and GA 3-oxidase

are each encoded by multigene families, and mutants defective in a GA 20-oxidase or GA 3-oxidase isoform display a moderately dwarfed phenotype. In *P. sativum*, a major GA 3-oxidase that controls internode elongation is encoded by the *Le* gene, originally described by Gregor Mendel in his breeding experiments with tall and dwarf peas.

17.1.7 Bioactive GAs are rendered inactive via multiple metabolic routes in plants

GAs are inactivated in several different ways in plants. The best-characterized inactivation reaction is oxidation on C-2, catalyzed by GA 2-oxidase, a 2-oxoglutarate-dependent dioxygenase (Fig. 17.10). Initially identified GA 2-oxidases utilized bioactive GAs (GA_1 and GA_4) and their immediate precursors (GA_{20} and GA_9) as substrates. Later, a new type of GA 2-oxidase was discovered, which accepts only earlier intermediates, GA_{12} and GA_{53} . Thus, many GAs in the biosynthesis pathway are targets of GA 2-oxidation. Genes encoding GA 2-oxidases were first identified through functional screening of a cDNA expression library.

A study on a tall mutant of *O. sativa*, *elongated uppermost internode (eui)*, led to the discovery of a new GA inactivation mechanism. The *eui* mutant accumulates large amounts of bioactive GAs in internodes. The *Eui* gene encodes a CYP450 monooxygenase, CYP714D1, which inactivates GAs by epoxidation of the 16,17-double bond of various GAs, including GA_4 , GA_9 , and GA_{12} (Fig. 17.10). The 16,17-epoxides are hydrolyzed to give 16,17-dihydrodiols either in vivo or during purification. The occurrence of GA 16,17-dihydrodiols in many plant species suggests that 16,17-epoxidation may be a widespread GA inactivation mechanism. More recent work has shown that *Arabidopsis* GAMT1 and GAMT2 catalyze methylation of the C-6 carboxyl group of GAs using S-adenosyl-L-methionine (SAM) as a methyl donor (Fig. 17.10). As seen for GA 2-oxidase and EUI, both GAMT1 and GAMT2 use a variety of GAs as substrates, and produce the corresponding methyl esters. Whether methylation of GAs is a common inactivation reaction in other plants has yet to be investigated.

GAs can be converted into conjugates in plants. Conjugation of GAs to glucose takes place either through a hydroxyl group of GA to give a GA-O-glucosyl ether or through the 6-carboxyl group to give a GA-glucosyl ester. Genes encoding enzymes that catalyze the formation of GA conjugates have not been identified.

17.1.8 There are remarkable differences in GA biosynthesis pathways and enzymes between plants and fungi

Recent identification of fungal genes encoding GA biosynthesis enzymes from *G. fujikuroi* and a species of *Phaeosphaeria* uncovered substantial differences in GA biosynthesis genes and

FIGURE 17.9 Conversion of GA_{12} to bioactive GAs in plants. 20ox, GA 20-oxidase; 3ox, GA 3-oxidase; 13ox, GA 13-oxidase.

FIGURE 17.10 GA_4 inactivation pathways. Inactivation by GA 2-oxidase introduces a 2 β -hydroxyl group. In some cases, further metabolism occurs to form GA-catabolites, in which C-2 is oxidized to a ketone and the lactone is opened with the formation of a double bond. 16 α ,17-epoxy GAs produced by CYP714D1 (EUI) are hydrolyzed to give 16,17-dihydrodiols either in plants or during purification. GAMT catalyzes methylation of the C-6 carboxyl group. GAs are also converted into various glucose conjugates in plants (not shown).

enzymes between plants and fungi. In plants, two separate terpenene synthases, CPS and KS, are involved in the synthesis of *ent*-kaurene from GGDP (see Fig. 17.7), whereas these two steps are catalyzed by a single bifunctional enzyme in *G. fujik-*

uroi and *Phaeosphaeria*. *G. fujikuroi* has a CYP450 monooxygenase (CYP68A) that plays a similar role to that of KAO in plants, but this enzyme also catalyzes 3 β -hydroxylation to produce GA_{14} , 3 β -hydroxylated GA_{12} . GA_{14} is converted to GA_4 by

another CYP450 monooxygenase (CYP68B) that exhibits GA 20-oxidase activity. Thus, unlike in plants, 3 β -hydroxylation and 20-oxidation are catalyzed by CYP450 monooxygenases in *G. fujikuroi*. Notably, GA biosynthesis genes are clustered on a single chromosome in fungi, whereas they are randomly located on chromosomes in plants. These significant differences in genes and enzymes suggest that plant and fungi evolved their GA biosynthesis pathways independently.

17.1.9 Some enzymes that participate in GA biosynthesis are feedback-regulated

The concentration of bioactive GAs in plants is under homeostatic control via feedback regulation. A link between GA biosynthesis and action was first suggested by the presence of abnormally high concentrations of GAs in certain GA-insensitive dwarf mutants, such as *Rht3* (*Triticum* spp.), *D8* (*Z. mays*), and *gai* (*Arabidopsis*). Transcript analysis in a number of plant species showed that the effect of GA concentration is targeted to late biosynthesis enzymes, GA 20-oxidase and GA 3-oxidase, and the GA inactivating enzyme, GA 2-oxidase: Expression of genes encoding GA 20-oxidase and GA 3-oxidase is highly elevated in GA-depleted plants, whereas they are down-regulated after GA application (Fig. 17.11). Such changes in transcript levels usually occur within 1-3 hours of GA application, before a growth response is discernible. By contrast, expression of genes encoding GA 2-oxidase are downregulated in GA-deficient plants, but upregulated upon GA treatment (Fig. 17.11). Thus, GA homeostasis in plants is likely to be maintained at least in part through coordinated regulation of biosynthesis and inactivation genes.

FIGURE 17.11 Feedback regulation of GA biosynthesis and inactivation pathways. T-bars and black arrow depict negative and positive regulation, respectively. Gray arrows indicate metabolic conversions. 20ox, GA 20-oxidase; 3ox, GA 3-oxidase; 2ox, GA 2-oxidase.

17.1.10 GA mediates light-induced germination of lettuce seeds

Evidence suggests that in some cases, bioactive GAs function as key mediators between perception of environmental signals and the resulting growth responses. Seed germination can be controlled by light in plants such as *Lactuca sativa* and *Arabidopsis* where the effect of light is primarily mediated by phytochrome.

A clear link between GA metabolism and phytochrome has been established in the case of red light (RL)-induced germination of photodormant Grand Rapids *L. sativa* seed. In a typical phytochrome-mediated response, RL induces germination and this effect is reversed by a subsequent treatment with far red light (FRL) (see Chapter 18). Following a pulse of RL, germination is preceded by elevated GA 3-oxidase expression and an increase in the GA₁ content (Fig. 17.12). When RL treatment is followed by a pulse of FRL germination is not induced, the GA₁ pool size does not increase, and GA 3-oxidase transcription remains unaltered (Fig. 17.12). Germination in darkness occurs only after treatment with GA.

The amounts of the GA₁ precursors GA₁₉ and GA₂₀ are not affected by RL and FRL treatments (Fig. 17.12). Whether RL and FRL control the turnover rates for these compounds is unclear. Of the two GA 20-oxidase genes cloned from *L. sativa* one is light regulated, its expression repressed by RL and enhanced by FRL, whereas the other is light-independent. Under all light regimes, however, *L. sativa* seeds contain far more GA₂₀ than GA₁, so GA 20-oxidase activity and the rate of GA₂₀ synthesis do not limit the amount of substrate available for GA₁ production (Fig. 17.12). These results together indicate that RL-inducible GA 3-oxidase gene expression and the increase in GA₁ concentration plays a critical role in regulating seed germination in *L. sativa*.

17.1.11 Mutations in the GA pathway led to major advances in agriculture

In the 1960s, the introduction of semi-dwarf cultivars of cereal crops, including *O. sativa* and *Triticum* spp., in combination with increased fertilizer use, led to a dramatic increase in food production worldwide. The impact of these advances in agriculture was termed the “green revolution”. The major semi-dwarfing gene of *O. sativa*, *sd-1*, originally derived from the Chinese cultivar Dee-Geo-Woo-Gen, produced *O. sativa* cultivars with short, thick culms and improved lodging resistance without affecting grain quality. Since the 1960s, *sd-1* has been the predominant semi-dwarfing gene introduced into *O. sativa* cultivars and shown to encode a defective GA 20-oxidase. Because GA 20-oxidases are encoded by small gene families, members of which have redundant functions, the loss-of-function GA 20-oxidase mutants are only mildly GA-deficient (Fig. 17.13). Interestingly, in *Triticum* spp., a semi-dwarfing gene that contributed to the green revolution was defective in GA signaling. These instances highlight the important role of GAs in regulating developmental processes that are critical in agriculture.

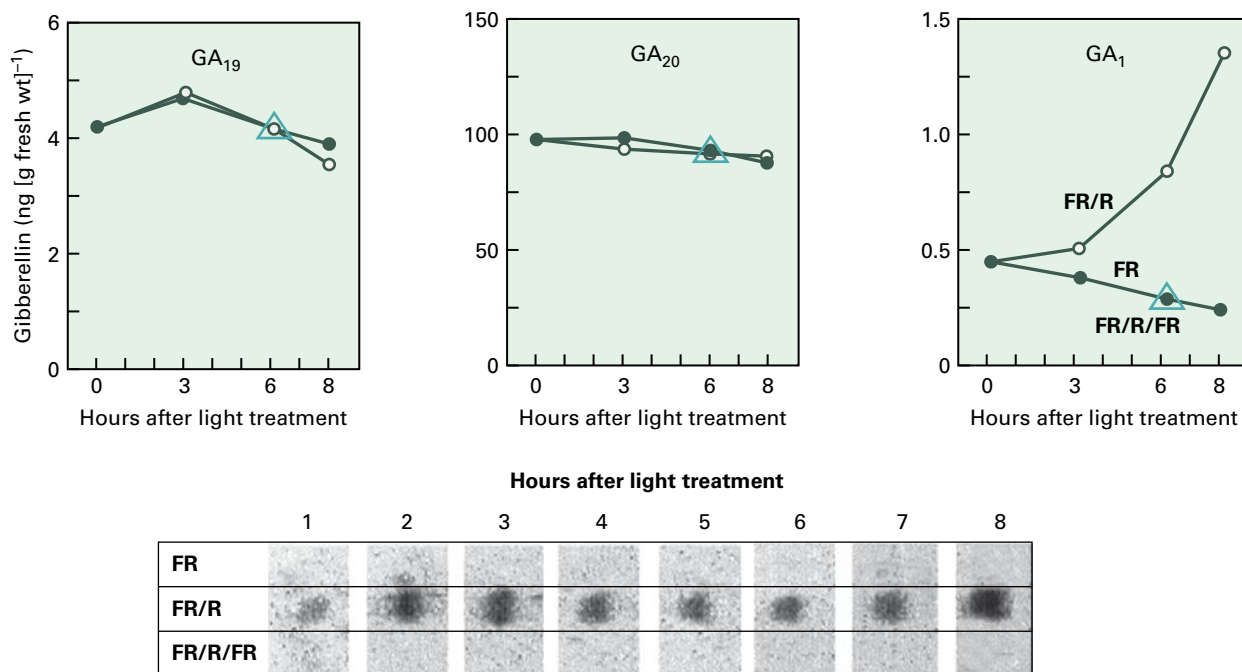

FIGURE 17.12 Regulation of GA in Grand Rapids *L. sativa* by red (R) and far-red (FR) light. (Upper panels) Effects of R and FR light on GA levels. Note that phytochrome-mediated, R light induced seed germination is associated with increased GA_1 content. 17.2 Abscisic acid

Growth-inhibiting compounds were isolated from plants in the early 1950s. Acidic compounds separated by paper chromatography were tested for their ability to promote growth in oat coleoptile, but instead these experiments

detected compounds that inhibited coleoptile elongation, referred to as the β -inhibitor complex. Subsequent investigations correlated high β -inhibitor levels with suppression of *Solanum tuberosum* tuber sprouting, abortion of *Lupinus arboreus* pods, and bud dormancy in deciduous trees, such as *Acer pseudoplatanus* and *Betula pubescens*. In the early 1960s, US scientists isolated an abscission-accelerating compound called “abscisin II” from young *Gossypium hirsutum* fruits and simultaneously researchers in the UK isolated a dormancy-inducing factor called “dormin.” The structure of abscisin II, later called **abscisic acid** (ABA), was determined in 1965 and dormin was subsequently shown to be ABA.

ABA has a single chiral center at C-1'. Only the (S)-enantiomer occurs in nature (Fig. 17.14). In contrast, synthetic ABA is a racemic mixture although stereospecific synthesis of both (S)-ABA and (R)-ABA have been reported. The 2-*cis* double bond of both enantiomers is isomerized by light to the 2-*trans* isomers, (S)-2-*trans*-ABA and (R)-2-*trans*-ABA (Fig. 17.14). For convenience, the term ABA hereafter will refer to the naturally occurring (S)-enantiomer.

17.2.1 Contrary to its name, ABA does not induce abscission

As its name indicates, ABA was originally thought to induce abscission, however, abscission is regulated by ethylene rather than ABA. Moreover, increased internal concentrations of ABA are unlikely to impose dormancy of *S. tuberosum* tubers or

FIGURE 17.14 Structures of ABA enantiomers. (S)-ABA is naturally occurring form.

resting buds of deciduous trees. Studies with ABA-deficient mutants of *Z. mays* have provided no support for conjecture that asymmetric distribution of ABA is involved in the negative geotropic response of roots. Accumulation of ABA during seed development, however, has been associated with maturation of the seed, development of desiccation tolerance, and suppression of vivipary (Fig. 17.15). Certain types of seed dormancy are linked to high concentrations of ABA, and rapid increases in ABA lead to water stress-induced closure of stomata (Fig. 17.16).

17.2.2 Many fungi, including fungal pathogens of the genera *Cercospora* and *Botrytis*, synthesize ABA from farnesyl diphosphate

Although ABA is a relatively simple C_{15} compound, its biosynthetic pathway proved difficult to define—in part, because of poor incorporation of label from putative precursors, even in water-stressed leaves that were synthesizing ABA rapidly. By the early 1970s, two pathways leading to ABA had been proposed. The “direct C_{15} ” route envisaged ABA production from the C_{15} precursor farnesyl diphosphate, while the “indirect C_{40} ” route postulated oxidative cleavage of a putative C_{40} intermediate, such as violaxanthin, to yield a C_{15} intermediate of ABA (Fig. 17.17; also see Fig. 17.6).

Although the first pathway was initially favored, evidence for its operation was scant. Suggestions that ABA might originate from a xanthophyll were based on reports that exposure to light or lipoxygenase could convert violaxanthin to xanthoxin, a C_{15} compound similar in structure to ABA. Xanthoxin is present in plant tissues in trace quantities, and metabolism of [^{14}C]xanthoxin to ABA was demonstrated in tomato and bean (*Phaseolus* sp.) plants. Nevertheless, conclusive evidence that endogenous ABA originated from xanthoxin was lacking, and it remained to be established whether xanthoxin was formed in vivo from a C_{40} precursor or more directly from farnesyl diphosphate (Fig. 17.17).

In 1977, investigators discovered that the plant pathogen *Cercospora rosicola* produced large amounts of ABA, well in

FIGURE 17.15 Precocious germination (vivipary) of immature *Z. mays* seeds homozygous for vp1. The color-less vp1 kernels lack anthocyanins in the aleurone layer, and germinate before maturity because of ABA insensitivity. The seed is viable if transplanted directly from immature ears.

Source: S. McCormick, University of California, Berkeley; previously unpublished.

excess of the levels found in plants. In a simple synthetic liquid medium, *C. rosicola* cultures grown for 20 days accumulate up to 30 mg of ABA per liter. Unlike plants, the fungus incorporated labeled acetate, farnesol, and other intermediates into ABA and 1'-deoxyABA. When fed to *C. rosicola*, [^{14}C] 1'-deoxyABA was metabolized to ABA, indicating that 1'-hydroxylation is the final step in the fungal ABA biosynthesis pathway. Figure 17.18 illustrates possible biosynthesis pathways for ABA in fungi. Note that the pathway may be slightly different among species and genera. Nonetheless, it is evident that a direct C_{15} ABA biosynthesis pathway operates in fungi.

17.2.3 Gas chromatography–mass spectrometry showed that plants synthesize ABA from a C_{40} precursor

Experiments with mutants and with inhibitors of carotene synthesis were keys to understanding ABA biosynthesis. Carotenoid-deficient *Z. mays* mutants, for instance, had reduced ABA content and ABA content was depleted in wild-type *H. vulgare* and *Z. mays* after treatment with fluridone,

FIGURE 17.16 ABA-induced stomatal closure. Epidermal strips of *Commelina communis* L. incubated in buffer (10 mM Pipes, pH 6.8) containing 50 mM KCl and supplied with CO₂-free air. The stomata are open after two to three hours (A). When transferred to the same solution plus 10 μM ABA, the pores close within 10 to 30 minutes (B).

FIGURE 17.17 Summary of two possible ABA biosynthetic routes. In the direct C₁₅ pathway, farnesyl diphosphate is modified to yield ABA. Alternatively, in the indirect C₄₀ pathway, a carotenoid, 9-cis-violaxanthin, is cleaved to form a C₁₅ ABA precursor, xanthoxin.

which inhibits β-carotene synthesis by blocking the conversion of phytoene to phytofluene (see Fig. 17.19). Firm evidence that C₄₀ xanthophylls are intermediates in ABA biosynthesis was obtained in 1984. Water-stressed *P. vulgaris* and *Xanthium* leaves were incubated in ¹⁸O₂, reasoning that if 1'-deoxy-ABA were the immediate precursor of ABA in plants, as it is in *C. rosicola*, one ¹⁸O atom would be associated

with the hydroxyl group incorporated into ABA ring at the 1'-position (Fig. 17.20A). Gas chromatography (GC) was used to separate the ¹⁸O₂-labeled metabolites, which were then characterized by mass spectrometry (MS). (See Chapter 2, Box 2.2, for a discussion of analytical techniques that utilize MS.) GC-MS revealed that no ¹⁸O was incorporated into the ABA ring. Instead, one labeled atom appeared in the

FIGURE 17.18 Possible fungal C_{15} ABA biosynthesis pathways.

side chain carboxyl group, demonstrating that 1'-deoxy-ABA was not the immediate ABA precursor in water-stressed leaves. These results indicated that ABA was synthesized from a pre-formed precursor with oxygen atoms at the 1' and 4' positions.

This was consistent with a C₄₀ pathway to ABA, with ¹⁸O₂ cleaving violaxanthin to form xanthoxin labeled at the 1-CHO group, followed by oxidation of the labeled xanthoxin to yield ABA with one ¹⁸O atom in the carboxyl group (Fig. 17.20B).

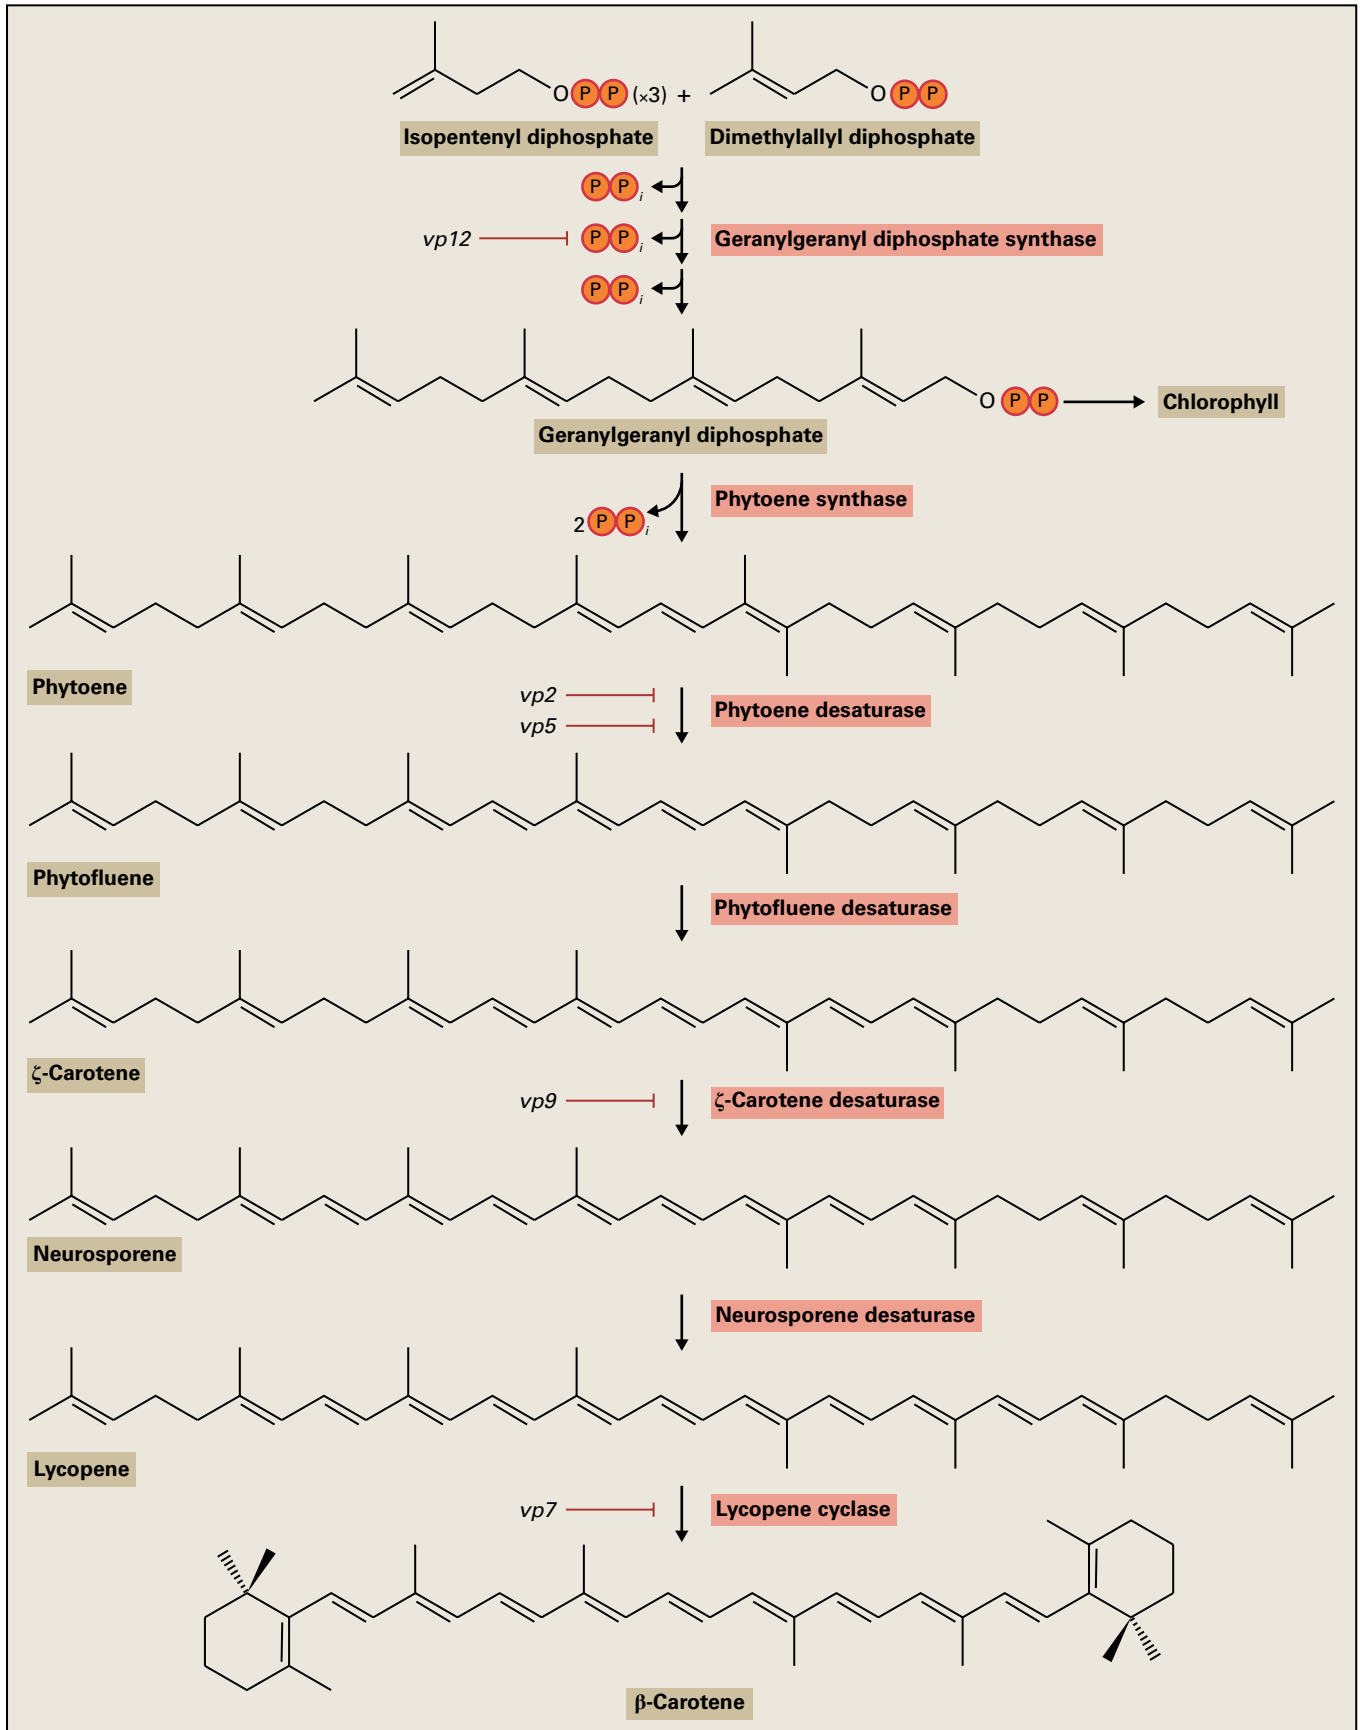

FIGURE 17.19 Early stages in the indirect C_{40} ABA biosynthesis pathway: production of geranylgeranyl diphosphate (GGDP) and synthesis of β -carotene. Enzymes deficient in *Z. mays* vp mutants are indicated. The chemical inhibitors fluridone and norflorazon block conversion of phytoene to phytofluene (not shown).

FIGURE 17.20 Isotopic labeling experiments confirmed the existence of an indirect C_{40} plant ABA biosynthetic pathway. GC-MS revealed that ABA synthesized by plant tissues in the presence of $^{18}\text{O}_2$ was not labeled at the 1'-hydroxyl group, as would be expected if ABA were generated directly from 1'-deoxy-ABA (A). However, the appearance of label in the ABA carboxyl group was consistent with oxidative cleavage of all-trans-violaxanthin and subsequent conversion of xanthoxin to ABA (B).

17.2.4 ABA synthesis is regulated by a cleavage reaction that generates the first C_{15} intermediate

Many ABA-deficient viviparous (*vp*) mutants of *Z. mays* are blocked at various points in the terpenoid and carotenoid biosynthesis pathways (see Fig. 17.19). GGDP synthase, a key enzyme in the terpenoid pathway, catalyzes the three successive condensations with isopentenyl diphosphate that convert dimethylallyl diphosphate to the C_{20} compound GGDP. As a consequence of GGDP deficiency, seedlings of the *vp12* mutant have low chlorophyll content and reduced capacity for synthesis of carotenoids and ABA. Like the chemical inhibitor fluridone, the *vp2* and *vp5* mutations block the conversion of phytoene to phytofluene. Available evidence implies that the *vp9* mutant cannot synthesize neurosporene from ζ -carotene; the *vp7* lesion restricts the conversion of lycopene to β -carotene.

Following the conversion of β -carotene to zeaxanthin, two epoxidation reactions catalyzed by zeaxanthin epoxidase convert zeaxanthin to all-trans-violaxanthin via antheraxanthin (Fig. 17.21). Both epoxidation steps are blocked in the ABA-deficient *aba1* mutant of *Arabidopsis* and the *aba2*

mutant of *Nicotiana plumbaginifolia*. The *ABA2* gene encodes a chloroplast-imported 72.5-kDa protein that shares sequence similarities with bacterial oxidases. *ABA2* catalyzes the two-step conversion of zeaxanthin to all-trans-violaxanthin in vitro. *ABA1* was shown to be orthologous to *ABA2*.

All-trans-violaxanthin is converted to 9'-cis-neoxanthin or 9-cis-violaxanthin. In *Arabidopsis* ABA-deficient *aba4* mutants, endogenous levels of 9'-cis-neoxanthin and all-trans-neoxanthin are reduced, whereas those of all-trans-violaxanthin and 9-cis-violaxanthin are increased. *ABA4* encodes a protein with a predicted chloroplast-targeting peptide. Mature *ABA4* protein has a predicted molecular mass of 17.0 kDa and four transmembrane domains. *ABA4* is thought to function as a neoxanthin synthase or as part of components required for neoxanthin synthesis. To date, no mutant defective in isomerization of all-trans-violaxanthin or all-trans-neoxanthin has been isolated.

The first committed step in the ABA biosynthesis pathway, oxidative cleavage of 9'-cis-neoxanthin and/or 9-cis-violaxanthin, yields the first C_{15} intermediate, xanthoxin. Studies with *vp14*, an ABA-deficient viviparous *Z. mays* mutant generated by transposon tagging, have successfully cloned the gene encoding 9-cis-epoxycarotenoid dioxygenase that catalyzes this conversion. The derived amino acid sequence of VP14 is

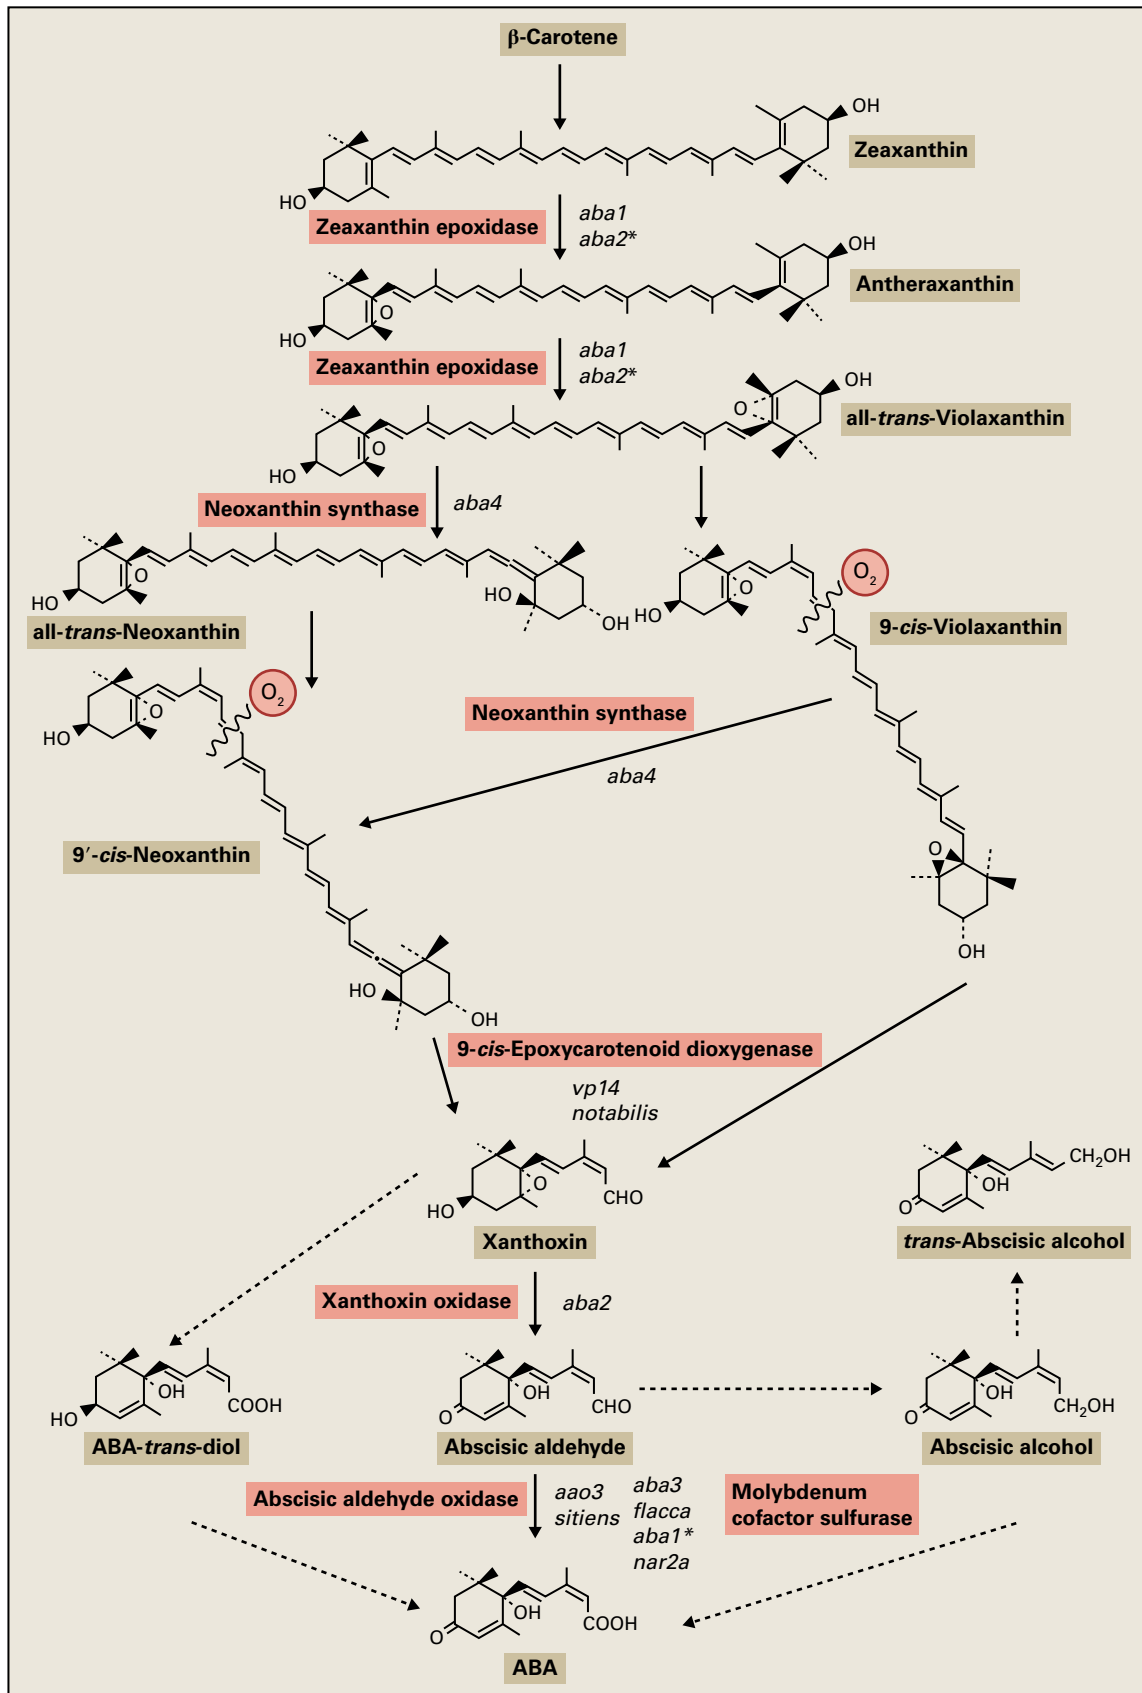

FIGURE 17.21 Later stages in the indirect C_{40} ABA biosynthesis pathway: β -carotene to ABA. Biosynthetic steps blocked in the following mutants are indicated. Arabidopsis mutants: *aa03*, *aba1*, *aba2*, *aba3*, *aba4*; *H. vulgare*: *nar2a*; *S. lycopersicum* mutants: *flacca*, *notabilis*, *sitiens*; *N. plumbaginifolia* mutants: *aba1**, *aba2**; *Z. mays* mutant: *vp14*

similar to sequences of bacterial lignostilbene dioxygenases, which catalyze a reaction resembling the oxidative cleavage of 9'-*cis*-neoxanthin. Recombinant VP14 protein catalyzes the *in vitro* conversion of both 9'-*cis*-violaxanthin and 9'-*cis*-neoxanthin to xanthoxin, while the corresponding *trans* isomers are not cleaved. Production of xanthoxin from 9'-*cis*-epoxycarotenoids is also blocked in the wilted *S. lycopersicum* mutant *notabilis*. 9'-*cis*-epoxycarotenoid dioxygenase is encoded by a multigene family. In *Arabidopsis*, a 9'-*cis*-epoxycarotenoid dioxygenase encoded by *AtNCED3* gene is responsible for ABA production upon water stress, while *AtNCED6* and *AtNCED9* gene products are involved in ABA production in seeds. This conversion appears to be a rate-limiting step in ABA biosynthesis; ABA accumulation in response to water stress correlates well with 9'-*cis*-epoxycarotenoid dioxygenase mRNA and protein levels, and overexpression of this gene resulted in ABA overproduction. Characterization of this control point is likely to provide intriguing insights into regulation of seed dormancy, drought resistance, and cold hardening.

The penultimate step of the ABA biosynthesis pathway converts xanthoxin to abscisic aldehyde. This reaction involves oxidation of the 4'-hydroxyl group to a ketone, desaturation of the 2'-3' double bond and opening of the 1'-2' epoxide ring. No intermediates have been detected. Chemical oxidation of the 4'-hydroxyl group facilitates quantitative conversion of xanthoxin to abscisic aldehyde, suggesting that the reaction *in vivo* may result from a single enzymatic step and subsequent rearrangements. The *Arabidopsis aba2* mutant was shown to have a defect in this reaction. The *ABA2* gene encodes a protein, xanthoxin oxidase, that belongs to a family of short-chain dehydrogenase/reductases. Recombinant *ABA2* protein catalyzes the conversion of xanthoxin to abscisic aldehyde in the presence of NAD. Oxidation of the 1-CHO group of abscisic aldehyde, catalyzed by abscisic aldehyde oxidase, leads to formation of ABA (Fig. 17.21). There are many mutants defective in conversion of abscisic aldehyde to ABA, including *sitiens* and *flacca* in *S. lycopersicum*, *nar2a* in *H. vulgare*, *aba3* and *aao3* in *Arabidopsis*, and *aba1* in *N. plumbaginifolia*. *flacca*, *aba3* and *aba1* mutants lack the activities of xanthine dehydrogenase in addition to that of aldehyde oxidase.

FLACCA and *ABA3* encode Mo cofactor sulfuryase, which catalyzes the final step of Mo cofactor synthesis required for aldehyde oxidase and xanthine dehydrogenase activities (Fig. 17.21). The *nar2a* mutant has a defect in nitrate reductase activity in addition to aldehyde oxidase and xanthine dehydrogenase activities, indicating that the corresponding gene encodes an enzyme responsible for an earlier step of Mo cofactor synthesis. The *Z. mays* viviparous mutants *vp10/vp13* and *vp15* are also impaired in earlier steps of Mo cofactor synthesis. On the other hand, the *sitiens* and *aao3* mutants are impaired specifically in abscisic aldehyde oxidase activity. The *AAO3* gene encodes abscisic aldehyde oxidase that functions as a dimer of the 147-kDa protein containing non-heme iron, FAD, and Mo as prosthetic group. The activity to produce ABA from xanthoxin via abscisic aldehyde is not increased following the onset of water stress, albeit the

expression of *AAO3* and *ABA3* is induced in this condition. These two final conversions do not appear to limit the rate of ABA biosynthesis, as foliar levels of xanthoxin and abscisic aldehyde are invariably very low compared to ABA.

The *S. lycopersicum flacca* and *sitiens* mutants and *aba3* in *Arabidopsis* convert abscisic aldehyde to abscisic alcohol and accumulate *trans*-abscisic alcohol. A shunt pathway from abscisic alcohol to ABA, representing a minor source of ABA in most plants, allows these mutants to synthesize low amounts of ABA. Wild-type *S. lycopersicum* and the *flacca* and *sitiens* mutants all contain ABA-1',4'-*trans*-diol and convert [²H]ABA-1',4'-*trans*-diol to ABA (Fig. 17.21). However, the origins of the diol have not been established, and its relationship to ABA *in vivo* remains to be clarified.

17.2.5 ABA is metabolized to several compounds, including phaseic acid, dihydrophaseic acid, and glucose conjugates

ABA metabolism is summarized in Figure 17.22. The main route involves hydroxylation of the 8' carbon, spontaneous rearrangement of the resulting 8'-hydroxy-ABA to form phaseic acid (PA), and reduction to dihydrophaseic acid and *epi*-dihydrophaseic acid. Dihydrophaseic acid undergoes conjugation at the 4'-position to form dihydrophaseic acid-4'-*O*- β -glucoside. Because of its rapid conversion to PA, 8'-hydroxy-ABA has rarely been isolated, but its formation has been inferred by the presence of the conjugate 8'-*O*-(3-hydroxy-3-methylglutaryl)-8'-hydroxyABA. The alternative routes in ABA metabolism involve conversion to 7'- and 9'-hydroxy-ABA, as well as conjugation to form ABA- β -glucosyl ester and ABA-1'-*O*-glucoside. *P. sativum* seedlings convert ABA to ABA-1',4'-*trans*-diol; in *S. lycopersicum*, however, the diol is an ABA precursor rather than a catabolite.

ABA 8'-hydroxylase is a membrane bound CYP450 monooxygenase classified as *CYP707A*. Single or multiple mutants defective in these genes contain elevated endogenous ABA levels, and exhibit enhanced stress resistance and increased seed dormancy. Conversely, constitutive expression of a *CYP707A* gene results in reduced ABA content, demonstrating that 8'-hydroxylation is the predominant pathway for ABA catabolism.

Numerous bioassays have indicated that the biological activity of ABA is dependent on the presence of a free 1-carboxyl group, a 2-*cis*,4-*trans*-pentadienoic side chain, a 4'-keto group, and a 2'-3' double bond. Except for 8'-*O*-(3-hydroxy-3-methylglutaryl)-8'-hydroxyABA, ABA metabolites and conjugates formed from ABA do not possess all of these features and are probably deactivation products (Fig. 17.22). In theory, ABA β -glucosyl ester and ABA-1'-*O*- β -glucoside could act as storage products that can be hydrolyzed to release free ABA. Genes encoding enzymes that catalyze β -glucosidation of ABA and hydrolysis of ABA β -glucosyl ester *in vitro* have been isolated but their physiological importance remains to be determined.

FIGURE 17.22 ABA metabolism pathways. The major route proceeds by way of 8'-hydroxy ABA, which is rapidly converted to phaseic acid; this in turn, is reduced to epi-dihydrophaseic acid and dihydrophaseic acid. Dihydrophaseic acid undergoes conjugation to yield dihydrophaseic acid -4'-O-glucoside. ABA can also be conjugated, forming ABA β-glucosyl ester and ABA-1'-O-β-glucoside.

17.3 Cytokinins

The discovery of CKs has its roots in the 1930s quest for chemical factors that would allow the culturing of plant tissues in synthetic media. In the 1950s, a substance that strongly stimulated cell proliferation in *Nicotiana tabacum* tissue culture was first purified and crystallized from autoclaved herring sperm DNA extracts. This growth-stimulating compound N^6 -furfuryl aminopurine was named kinetin (Fig. 17.23). Kinetin has not been found in living plants and is believed to be an artificial by-product of DNA breakdown. Kinetin, in combination with auxin, was found to promote the initiation and maintenance of cell division in cultured *N. tabacum* parenchyma. A naturally occurring kinetin-like substance was first isolated from immature *Z. mays* endosperm in the early 1960s and named zeatin (*trans*-zeatin, tZ; Fig. 17.23). Usage of the term “cytokinins” for kinetin-like compounds was defined

FIGURE 17.23 CK structures. The first CK identified was the synthetic compound Kinetin. The first plant CK isolated was *trans*-Zeatin.

as a “generic name for substances which promote cell division and exert other growth regulatory functions in the same manner as kinetin.” Endogenous plant CKs have been isolated, all of which are adenines that have a substituted N^6 terminus on either an isoprene-derived side chain (greater abundance), or an aromatic derivative side chain (less abundant).

FIGURE 17.24 *Arabidopsis* callus production is induced by auxin (IBA) and CK (tZ). Callus subcultured on auxin medium produces only roots (left); but on medium containing a high ratio of CK to auxin produces shoots (right).

Source: T. Kakimoto, Osaka University, Japan; previously unpublished.

FIGURE 17.25 Structures of naturally occurring CKs. In general, isoprenoid CKs are in greater abundance than aromatic CKs. Aromatic CKs have been described in only some plant species. Benzyladenine is found in *P. patens*.

Although CKs were first identified as activators of cell proliferation, it is now known that they are involved in a wide variety of plant growth and development processes, usually in close cooperation with one or more of the other plant growth

regulators. For instance, a high CK to auxin ratio promotes shoot differentiation from callus in culture, whereas auxin alone initiates root formation (Fig. 17.24), and intermediate ratios promote largely undifferentiated callus. CKs are also

involved in the regulation of apical dominance, retardation of leaf senescence, and competence of reproductive organs.

17.3.1 Structural variations occur in the side chains of CKs

Isoprenoid CKs have an isoprene-derived side chain and the common active forms include isopentenyladenine (iP; N^6 -(Δ^2 -isopentenyl)adenine), *trans*-zeatin (tZ), *cis*-zeatin (cZ), and dihydrozeatin (DZ) (Fig. 17.25). There are differences in their activity, abundance, and stability in vivo, but as yet there is no widely accepted view of the physiological relevance of these variants. In general, iP and tZ are active, and their derivatives are abundant, but they are susceptible to degradation by CK oxidase (CKX). cZ is thought to be less active and relatively more stable than tZ and iP because of its low affinity for CKX. cZ and its conjugates are more abundant than tZ- and iP-type CKs in *Z. mays*, *O. sativa*, chickpea (*Cicer arietinum*) and a moss (*Physcomitrella patens*). DZ appears to be biologically stable because of its resistance to CKX and is generally found in small quantities except for some legumes.

The aromatic CKs, which have aromatic derivative side chains, have been described in only a few plant species, including poplar (*Populus × robusta*), white lily (*Zantedeschia aethiopica*), *Arabidopsis*, and *P. patens*. Aromatic CKs are found as *ortho*-topolin and *meta*-topolin, as hydroxylated benzyladenines, and *ortho*-methoxytopolin, and *meta*-methoxytopolin (Fig. 17.25). It is not clear whether the aromatic forms are common in plants.

17.3.2 CKs are present as conjugates

CKs are present in plants as nucleoside, nucleotide, and glycosidic conjugates (Fig. 17.26), implying that there is a metabolic network for their interconversion. Glucosylation of CK occurs at the $N3$, $N7$, or $N9$ -positions of the purine moiety to form *N*-glucosides (Fig. 17.26). In tZ, DZ, and cZ, glycosylation can occur at the hydroxyl group of the side chain to form *O*-glucosides or *O*-xylosides, with *O*-glucosylation being more common than *O*-xylosylation, found only in *Phaseolus* sp. Conjugation generally greatly reduces biological activity but increases stability. Conjugates are a storage form of CK, and as such are generally in greater abundance than their more biologically active cognate CK.

Amino acid conjugates of CK have also been isolated from some organisms. Lupinic acid, which was first found in lupine seedling, is an alanine conjugate of tZ at the $N9$ position of the adenine moiety (Fig. 17.27) and is more stable but less active. In the slime mold *Dictyostelium discoideum*, discadenine (Fig. 17.27) has been found to be an inhibitor of spore germination. Lupinic acid has been found in several plant species, such as *Z. mays* and *P. sativum*, but discadenine appears to be restricted to *Dictyostelium*.

17.3.3 The initial step of isoprenoid CK biosynthesis is catalyzed by adenosine phosphate-isopentenyltransferase

The major isoprenoid CK biosynthesis step in plants is conjugation of adenine nucleotide and the prenyl-moiety of dimethylallyl diphosphate (DMAPP), catalyzed by adenosine phosphate-isopentenyltransferase (IPT) (Fig. 17.28). This reaction requires a divalent metal ion, such as Mg^{2+} . Plant IPTs predominantly use ATP or ADP rather than AMP as a prenyl-acceptor. In plants, *IPT* is encoded by a small multi-gene family, members of which are differentially expressed according to tissue. Expression patterns of *IPT* in *Arabidopsis* indicate that the initial step of CK biosynthesis occurs in various parts of plant body, such as phloem of roots and shoots, immature seeds and lateral root primordia. *IPT* mutants of *Arabidopsis* show severely decreased levels of iP and tZ-type CKs, suggesting that IPTs are responsible for the bulk of iP and tZ-cytokinin synthesis. The biosynthetic pathway of aromatic CKs is poorly characterized and the enzymes are yet to be cloned.

17.3.4 *trans*-Hydroxylation in tZ biosynthesis is catalyzed by a CYP450 monooxygenase

In *Arabidopsis* the *trans*-hydroxylation of the prenyl side chain in tZ biosynthesis is catalyzed by CYP450 monooxygenases CYP735A1 and CYP735A2 (Fig. 17.28). CYP735A predominantly hydroxylates iPRMP or iPRDP, rather than iPRTP, and does not hydroxylate iP or iPR. Expression of *CYP735A1* and *CYP735A2* is upregulated by CK itself and downregulated by auxin or ABA, indicating that the two hormones cooperatively and negatively regulate tZ formation by repressing *CYP735A*.

17.3.5 There are two pathways for formation of active CKs

To become biologically active, iP and tZ nucleotides are converted to a nucleobase. There are two pathways for active CK formation: a two-step pathway and a direct pathway (Fig. 17.28). In the two-step pathway, dephosphorylation from a CK nucleotide to a nucleoside is catalyzed by 5'-ribonucleotide phosphohydrolase (5'-nucleotidase), and the deribosylation step is catalyzed by adenosine nucleosidase. These enzymes have been characterized in several plant species from partially purified preparations, but corresponding genes have not been identified. In both steps, the enzymes are not specific to CK nucleotides and nucleosides, but they have a higher affinity for adenine nucleotide and adenosine than for the corresponding N^6 -substituted compounds. Thus,

FIGURE 17.26 Conjugates of tZ. Only representative structures are shown. Conjugation of iZ, cZ, and DZ occurs in the same manner, but iP conjugates do not include O-glycosides because they lack a hydroxyl group at the end of the side chain. P represents a phosphate group.

FIGURE 17.27 Structures of amino acid CK conjugates. Discadenine is only found in slime molds.

the two-step pathway is thought to be a part of the purine metabolic pathway.

17.3.6 LONELY GUY catalyzes the direct activation pathway

The direct pathway mediates release of a CK nucleobase from the corresponding nucleotide in a one-step reaction, which is catalyzed by CK riboside 5'-monophosphate phosphoribohydrolase (Fig. 17.28). This enzyme is defective in the *O. sativa* lonely guy (*log*) mutant that has abnormal shoot apical

FIGURE 17.28 Plant CK de novo biosynthesis pathway. Plant IPTs preferably utilize ATP or ADP as isoprenoid acceptors to form iPRTP and iPRDP, respectively. CYP735A preferentially utilizes iPRMP and iPRDP as substrate. Synthetic route indicated by gray arrows are not well characterized at the genetic level. For enzymes involved in the two-step pathway, see Fig. 17.33. P, phosphate group. Me (II), a divalent metal ion.

meristems. LOG only metabolizes CK nucleotides (5'-monophosphate) and not AMP, indicating that it is a specific enzyme for CK metabolism. Similar to IPT, LOG is encoded by a small multigene family with members exhibiting distinct patterns of expression. At present, it is not clear whether there is a functional difference between the two-step pathway and the direct pathway.

17.3.7 *Agrobacterium* IPT has distinct substrate specificity

Some plant pathogenic bacteria utilize CKs to influence plant growth. *Agrobacterium tumefaciens* infects eudicots as well as some monocots and induces the formation of crown galls (Fig. 17.29) by integrating the T-DNA (Transfer-DNA) region of the Ti-plasmid into the plant nuclear genome. Ti-plasmids commonly contain an IPT (*Tmr*) within the T-DNA and nopaline-forming Ti-plasmids contain another IPT gene (*Tzs*) in a region that is not transferred to the host plant. *Tmr* and *Tzs* are structurally related to higher plant IPTs, but differ in their substrate specificity. *Tmr* and *Tzs* can utilize

FIGURE 17.29 Three-month-old crown gall tumor on a *Rosa* spp. stem inoculated with wild-type *Agrobacterium tumefaciens*.

FIGURE 17.30 CK biosynthesis pathway catalyzed by *Agrobacterium IPT*. *Agrobacterium IPT*s, *Tmr* and *Tzs*, exclusively utilize AMP as an isoprenoid acceptor and can utilize HMBDP or DMAPP as the donor. In *Agrobacterium*-infected cells, *Tmr* preferentially utilizes HMBDP and produces tZRMP in plastids. P represents a phosphate group. Me (II), divalent metal ion.

DMAPP and 1-hydroxy-2-methyl-2-(*E*)-butenyl 4-diphosphate (HMBDP) as prenyl-donor substrates to produce iP nucleotide and tZ nucleotide, respectively, and exclusively use AMP as the prenyl acceptor (Fig. 17.30). HMBDP is a metabolic intermediate in the methylerythritol phosphate (MEP) pathway, which occurs in plastids and in many prokaryotes (see Chapter 24). *Agrobacterium IPT*s can synthesize tZ nucleotide directly in the absence of host plant CYP735A when HMBDP is the substrate.

17.3.8 *Agrobacterium IPT* creates a bypass of direct tZ-type CK synthesis in host plastids

In *Agrobacterium*-infected plant cells, *Tmr* and *Tms*, encoded on the T-DNA, overproduce CK and auxin, respectively, resulting in hypertrophic and hyperplastic cell growth. Although *Tmr* utilizes DMAPP and HMBDP *in vitro*, crown galls and *Tmr*-overexpressing transgenic plants almost exclusively contain tZ-type CKs. Recent studies have demonstrated that *Tmr* is targeted to and functions in plastids of infected host plant cells, although it does not contain a typical transit peptide for plastid import. In plastid stroma, *Tmr* allows the cell to synthesize CK from HMBDP without CYP735A-mediated hydroxylation. This bypass enables *A. tumefaciens* to produce large amounts of tZ in order to induce gall formation.

After infection of olive (*Olea europaea*), oleander (*Nerium sp.*), and privet (*Ligustrum sp.*), *Pseudomonas savastanoi* produces large amounts of CKs and auxin, most of which are tZ and tZR, leading to the formation of unorganized galls. Plasmids of *Ps. savastanoi* have the *Ptz* gene, which encodes an IPT, and *Tms*. Although these genes have substantial homology to the corresponding genes in *A. tumefaciens*, *Pseudomonas* tumors involve no transfer of genetic material. So, it is not clear whether *Ptz* utilizes HMBDP produced in the plastids of infected host plant cells or not.

17.3.9 Structural studies reveal the molecular mechanism of the initial step in CK biosynthesis

The crystal structure of *Tzs* indicated that the initial step of CK biosynthesis, a carbon–nitrogen-based prenylation, proceeds via the SN₂-reaction mechanism (Fig. 17.31). *Tzs* has a solvent-accessible channel that serves as the reaction center. In the reaction, the carboxylate group of an aspartate residue (Asp33 in *Tzs*) serves as a general base to deprotonate the N⁶-amino group of AMP. The resulting nucleophile attacks the carbon (C¹) of DMAPP. Collapse of the penta-covalent transition state yields iP riboside 5'-monophosphate and diphosphate as products. Threonine and arginine residues (Thr10 and Arg138 in *Tzs*) stabilize the penta-covalent transition state.

FIGURE 17.31 Structure of an *Agrobacterium* IPT, Tzs (upper), and proposed reaction mechanism of prenyl transfer (lower). Arg-138 in the absence of divalent metal ion [Me(II)] is shown in orange, and in the absence of prenyl-donor substrate in gray. Dashed line indicates hydrogen-bonding network among substrates and amino acid residues. Highlighted amino acid residues are important for reaction process.

17.3.10 CKs are also produced through degradation of tRNA

In addition to prenylation of adenine nucleotide by IPT, plants can produce CK through degradation of tRNA. Organisms such as mammals and bacteria, in addition to plants, contain prenylated adenine in a subset of tRNA species. Degradation of tRNA thus can release CKs. Several CK species derived from tRNA-degradation have been reported, such as iP riboside

(iPR), *cis*-zeatin riboside (cZR), tZR and their 2-methylthio derivatives (Fig. 17.32). The first step of modification is catalyzed by tRNA-isopentenyltransferase (tRNA-IPT) with DMAPP as a prenyl-donor, and further modifications produce the other CKs. *Arabidopsis* and *O. sativa* have two tRNA-IPT genes, one of which is similar to eukaryotic genes and the other is like its prokaryotic counterparts. In *Arabidopsis*, a tRNA-IPT double mutant lacks tRNAs with isopentenyl or *cis*-hydroxylated side chains, but also cZ-type CKs, strongly suggesting that cZ-type CKs arise from tRNA degradation in *Arabidopsis*. It is

FIGURE 17.32 CK production by tRNA degradation. tRNA-IPT conjugates DMAPP to adenine in a subset of tRNA species. Further modification and degradation results in the release of CKs. Structures of CKs derived from tRNAs are shown.

still unclear whether all cZ-type CKs are derived from tRNA degradation in cZ-abundant plant species, such as *O. sativa*.

17.3.11 The initial step of CK biosynthesis occurs in multiple subcellular compartments using DMAPP from different origins

DMAPP is produced through the MEP and mevalonate (MVA) pathways (see Chapter 24). In general, the MEP pathway is found in bacteria and plastids, and the MVA pathway in the cytosol of eukaryotes. IPTs are localized in multiple subcellular compartments. In *Arabidopsis*, IPT1, IPT3, IPT5, and IPT8 are located in plastids, and the relative expression levels of IPT3 and IPT5 are higher than the other IPTs. A selective labeling experiment in *Arabidopsis* seedlings demonstrated that side chains of iP and tZ-type CKs originate predominantly from the MEP pathway. On the other hand, IPT4 and IPT7 localize in

cytosol and mitochondria, respectively. Application of lovastatin, an inhibitor of the MVA pathway, leads to a decrease in tZ-type CK accumulation in tobacco BY-2 cell cultures, suggesting that the MVA pathway can be the predominant origin of tZ-type CKs at other developmental stages and under different conditions. A majority of cZ-type CK side chains have also been shown to come from the MVA pathway.

17.3.12 tZ can be converted to DZ and cZ

The double bond of the tZ side chain can be enzymatically reduced to DZ by a zeatin reductase and this enzyme has been isolated from immature embryos of *Phaseolus vulgaris*. Zeatin reductase, which requires NADPH as a cofactor, uses tZ as substrate, but not cZ, tZR, iP, or tZ-O-glucoside.

In addition to degradation of tRNA, cZ-type CKs can be formed by isomerization of tZ, a reaction that is catalyzed by zeatin *cis-trans* isomerase. The isomerase was partially

purified from immature seeds of *P. vulgaris*, and catalyzes isomerization of zeatins in both directions in favor of *cZ* to *tZ*. Since the *Arabidopsis tRNA-IPT* double mutant lacks *cZ*-type CKs, *trans* to *cis* isomerization is a minor factor in *cZ* production in *Arabidopsis*. At present, the physiological significance of CK reduction and isomerization is not well understood. The genes responsible for side chain-modifying reactions have not been identified.

17.3.13 Interconversion of CK nucleobase, nucleoside and nucleotide are partially shared with the purine salvage pathway

Exogenously applied CK nucleobase and nucleoside are rapidly metabolized to the corresponding nucleotide, and then further converted to other forms, suggesting that nucleotide formation plays a key role in metabolizing exogenous CKs. It is currently accepted that some of the enzymes in the purine salvage pathway catalyze the interconversion of CK nucleobase, nucleoside and nucleotide (Fig. 17.33).

Adenine phosphoribosyltransferase (APT) should catalyze the conversion from CK nucleobase to the corresponding nucleotide, as well as adenine. A reduction in metabolic conversion of exogenously applied CK nucleobase in an *APT Arabidopsis* mutant supports this idea. Adenosine kinases phosphorylate CK nucleosides in vitro. Adenosine phosphorylase can also convert CK nucleobase to its corresponding nucleoside. As is the case with 5'-nucleotidase and nucleosidase, these enzymes have a higher affinity for adenine and adenosine than for the *N*⁶-substituted compounds, indicating that these conversions are side reactions of the purine salvage pathway.

These pathways, via the purine nucleoside phosphorylase/adenosine kinase pathway and the APT pathway, could play a

role in regulating CK activity in vivo. However, the extent of any physiological contribution to endogenous CK metabolism has not yet been well defined.

17.3.14 Degradation by CKX plays a key role in regulating cytokinin activity

In addition to biosynthesis and activation, deactivation is an important step in controlling active CK levels. CKX mediates irreversible CK degradation by cleaving the side chain of an unsaturated isoprenoid side chain (Fig. 17.34). Among the naturally occurring CKs, *iP*, *iPR*, *tZ*, *tZR*, *cZ*, *cZR*, *N*-glucosides, and *N*-alanyl conjugates can be in vitro substrates, but generally CKX has a higher affinity for *iP*, *tZ*, and their nucleosides than others. Aromatic CKs are resistant to CKX. CKX is a flavoprotein, a member of an FAD-dependent oxidoreductase superfamily, and reacts more efficiently as a dehydrogenase with an electron donor other than oxygen.

Like *IPT* and *LOG*, *CKX* is encoded by a small multigene family. Among the *Arabidopsis CKXs*, there are significant differences in gene expression patterns, subcellular localization, and substrate specificity, perhaps because of functional differentiation among the CKX enzymes. Overexpression of *CKX* decreases CK content and retards shoot development due to a large reduction in cell proliferation rates within the shoot meristem (Fig. 17.35). Conversely, overexpression enhances root growth and the size of root meristems. Thus, CKs play opposite roles in regulating shoot and root meristem development. On the other hand, reduction of *CKX2* expression by natural variation increases CK levels in *O. sativa* (Fig. 17.36), indicating that control of CK activity in shoot apical meristems at the degradation step is important for agricultural productivity.

FIGURE 17.33 Possible interconversion of CK nucleobases, nucleosides, and nucleotides. *LOG* is a specific enzyme for CK metabolism, but others are not.

FIGURE 17.34 CKX removes the side chain from CK molecules. CKX catalyzes the oxidation of the secondary amine group on the side-chain of the adenine ring. The resulting imine product is nonenzymatically hydrolyzed, producing adenine and an aldehyde.

FIGURE 17.35 Opposite phenotypes resulting from reduction of CKs in *N. tabacum* shoot and root. RM, root meristem; P, leaf primordia. Bar represents 100 μ m.

17.3.15 Local CK metabolism plays an important role for regulating apical dominance

The mutual regulation of auxin and CKs plays a central role in the control of axillary bud outgrowth and dormancy (Fig. 17.37). This regulatory system consists of the auxin-dependent expression of CKX and PIN, which is a component of auxin polar transport, and repression of IPT by auxin. In an intact plant,

basipetal transport of auxin from shoot apices represses IPT and maintains CKX and PIN expression in the stem, resulting in a reduction of steady-state CK levels and maintenance of auxin transport. After meristem decapitation, defects in auxin polar transport in the stem induces IPTs and represses CKX, resulting in the accumulation of CKs in the nodal stem. The de novo CKs promote development of axillary buds into new shoot apices. After new shoot apices are established, basipetally transported auxin represses IPT and upregulates CKX to reduce CK activity to pre-decapitation levels.

17.3.16 Glucosylation of the side chain hydroxyl group is catalyzed by zeatin O-glucosyltransferase

O-glucosylation of zeatins (i.e., tZ, cZ and DZ) is catalyzed by zeatin O-glucosyltransferase with UDP-glucose as the donor substrate. The zeatin O-glucosyltransferase identified in *P. lunatus* and *Arabidopsis* preferentially uses tZ over cZ, DZ, or tZR. On the other hand, *Z. mays* zeatin O-glucosyltransferases predominantly utilize cZ over tZ. Although the role of O-glucosides in metabolic homeostasis is not fully understood,

FIGURE 17.36 *O. sativa* CKX gene mutation increases grain number. Panicles of Koshihikari (left) and Habataki (right). Natural variations within the Habataki CKX2 gene reduce expression levels in shoot meristems, resulting in increased grain numbers.

these glucosylated compounds can be reactivated by β -glucosidase to release active CKs. A possible CK β -glucosidase gene, *Zm-p60.1*, was isolated from *Z. mays*, although its physiological relevance remains unresolved.

17.3.17 N-Glucosylation of the purine moiety is catalyzed by N-glucosyltransferase

Glucosylation of CKs occurs at the 3, 7, and 9 positions of the purine moiety, and modification at the 7 and 9 positions results in inactivation. In *Arabidopsis*, CK N-glucosyltransferase, UGT76C1 and UGT76C2, conjugates glucose to CK nucleobases at the N7- or N9-position of the adenine moiety, but N3-glucosides are rarely found in planta and the biochemical nature of glucosyltransferases acting at the N3-position is not known. Since *Zm-p60.1* does not hydrolyze N7- and N9-glucosides, the N-glucosides are thought to be irreversibly inactivated forms.

17.4 Auxins

During the 19th century, Theophilus Ciesielski studied the geotropic responses of plants, and Charles Darwin and his son Francis investigated phototropism as well as geotropism. These investigations laid the groundwork for Fritz Went, who in 1926 obtained from oat coleoptiles a diffusible growth-promoting factor subsequently named “auxin.” The primary auxin present in most plants was eventually identified as **indole-3-acetic acid (IAA)** (Fig. 17.38). Indole-3-butyric acid (IBA), 4-chloroindole-3-acetic acid, and phenylacetic acid, which are also known as auxins, naturally

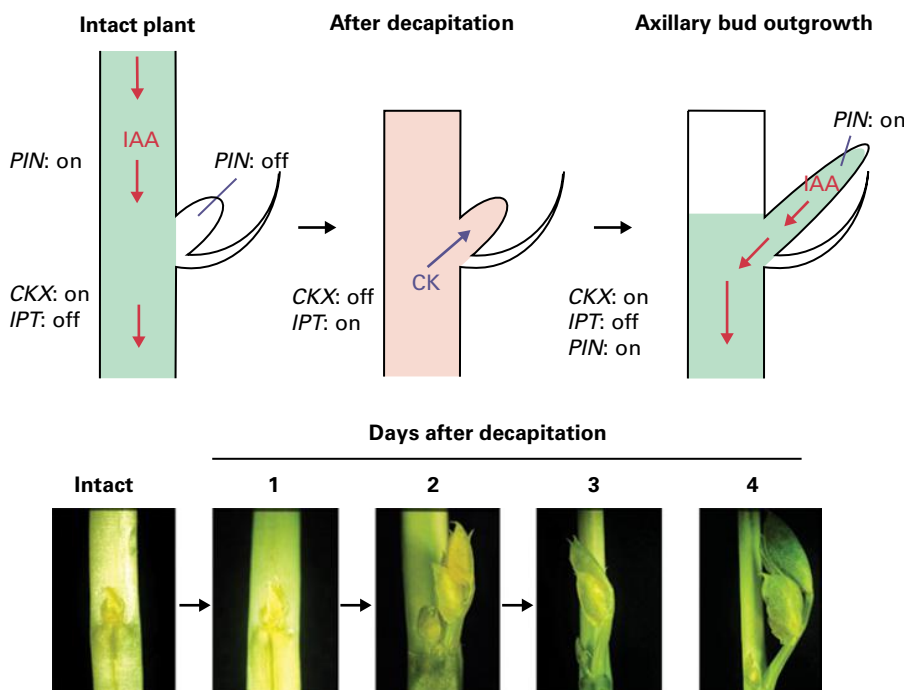

FIGURE 17.37 A model of the interactions between auxin and CKs in controlling apical dominance. In an intact plant, auxin derived from the shoot apex maintains PIN1 and CKX expression and represses IPT expression. Since CK level is kept lower, axillary bud outgrowth does not occur. After decapitation (1 day after decapitation in photo), the auxin level in the stem decreases, resulting in the release of repression of IPT expression and down-regulation of CKX and PIN1 expression. The de novo synthesized CK in the stem is transported into dormant axillary buds and initiates their outgrowth. After axillary bud outgrowth (2 day and after in photo), de novo synthesized IAA from the new shoot apex again represses IPT expression and induces CKX and PIN1.

FIGURE 17.38 Structures of auxins. IAA is the most widely distributed plant auxin. IBA, 4-chloroindole-3-acetic acid, and phenylacetic acid also naturally occur, but are less prevalent. 2,4-D and NAA are synthetic auxins.

occur in plants but are less prevalent than IAA. Auxins are involved in regulation in a wide variety of physiological processes, including apical dominance, tropisms, phyllotaxis, shoot elongation, induction of cambial cell division, and root initiation. Synthetic auxins such as 2,4-dichlorophenoxyacetic acid (2,4-D) and naphthalene-1-acetic acid (NAA) (Fig. 17.38) are used extensively in horticulture to induce rooting and to promote the set and development of fruit. At high concentrations the synthetic auxins are effective herbicides against broad-leaved plants.

The auxin activity in plants is primarily regulated by control of IAA content via several processes: de novo biosynthesis, and inactivation by various conjugation and catabolic pathways. There are two de novo IAA biosynthesis pathways, one of which is dependent on the amino acid precursor L-tryptophan and the other is L-Trp-independent, although the L-Trp-dependent pathway is likely to be dominant. Hydrolysis of IAA conjugates also releases active auxin. IAA content in individual tissues can also be influenced by basipetal polar transport that results in the downward movement of IAA from apical meristems and young leaves towards the root system.

17.4.1 Multiple routes are employed in the L-Trp-dependent auxin biosynthesis

In plants, multiple routes have been identified in L-Trp-dependent IAA biosynthesis: their first products are indole-3-pyruvic acid and tryptamine (Fig. 17.39). Indole-3-pyruvic acid is formed by Trp aminotransferase, followed by conversion to IAA by YUCCA, a flavin-containing monooxygenase. Tryptamine is produced by decarboxylation of L-Trp, catalyzed by Trp decarboxylase

(Fig. 17.39). Tryptamine is then converted to indole-3-acetaldehyde, and then to IAA.

Indole-3-ethanol and its conjugates are produced in a side shunt from indole-3-acetaldehyde. These compounds may have a storage role, given that they can be rapidly reconverted to indole-3-acetaldehyde and used as a substrate for IAA biosynthesis.

IBA has been found in a number of plants. It has auxin activity and is used to induce root formation on cuttings. IAA is converted to IBA in *Z. mays* and *Arabidopsis* (Fig. 17.39). In vitro studies with *Z. mays* have demonstrated that IBA synthase uses acetyl-CoA and ATP as cofactors, and exogenous IBA is conjugated rapidly by plants. Conversion of IBA to IAA has also been reported. Whether IBA is an auxin per se, or its biological activity results from conversion to IAA, is not clear.

17.4.2 YUCCAs play a key role in auxin biosynthesis and plant development

Although plants have multiple routes for the L-Trp-dependent pathway, several lines of evidence from studies on gain-of-function and loss-of-function mutants demonstrates a key role for YUCCAs in auxin biosynthesis. *Arabidopsis yuc-1D*, a gain-of-function mutant of YUCCA, contains increased concentrations of free IAA and shows characteristic phenotypes found in auxin overproduction mutants. Transgenic rice (*O. sativa*) and *Petunia*, overexpressing YUCCA homologs, also display an auxin overproducing phenotype with increasing IAA concentrations. YUCCA is encoded by a small multigene family, members of which are differentially expressed according to tissue. The expression of YUCCAs is temporally and

FIGURE 17.39 *L-Trp*-dependent auxin biosynthesis pathway. Blue arrows indicate metabolic pathway shared with glucosinolate biosynthesis.

spatially restricted and they are expressed in shoot and inflorescence apices, cotyledon tips in mature embryos, stamens, pollen, and stipules. Double and quadruple mutants of *YUCCA* exhibit various auxin-deficient phenotypes. *Arabidopsis yuc1yuc4* double mutants make less vascular

tissue, fail to produce normal flowers and are sterile, and *yuc1yuc4yuc10yuc11* quadruple mutants produce seedlings lacking a hypocotyl and a root meristem. Thus, de novo IAA biosynthesis mediated by *YUCCA* has a crucial role in the formation of floral organs and vascular tissues.

17.4.3 IAA biosynthesis pathway is shared with glucosinolate biosynthesis pathway in a few plant families

Some plant families, such as Brassicaceae and Caricaceae, contain glucosinolates, a class of sulfur-containing secondary metabolites derived from glucose and amino acids. In the biosynthesis of indole glucosinolates, L-Trp is successively converted to indole-3-acetaldoxime by CYP79B2 or CYP79B3, to 1-*aci*-nitro-2-indolyl-ethane by CYP83B1 (SUR2), and to indole-3-methylglucosinolate (Fig. 17.39). SUR1 is involved in the conversion of 1-*aci*-nitro-2-indolyl-ethane to indole-3-methylglucosinolate. In these plant families, the IAA biosynthesis pathway is shared with the glucosinolate synthesis pathway. Indole-3-acetaldoxime is converted to IAA via indole-3-acetonitrile or indole-3-acetamide. CYP71A13 catalyzes conversion of indole-3-acetaldoxime to indole-3-acetonitrile, and nitrilase catalyzes conversion from indole-3-acetonitrile to indole-3-acetamide or IAA. Recent work in *Arabidopsis* establishes conversion of indole-3-acetaldoxime to IAA via indole-3-acetamide but the catalytic enzymes have not been characterized. The physiological relevance of this pathway in IAA biosynthesis is evidenced by increased concentrations of IAA in *Arabidopsis* seedlings of CYP79B2 overexpression lines and decreased concentrations of IAA in *cyp79B2cyp79B3* double mutants. In either *sur1* or *sur2* *Arabidopsis* mutants, auxin is overaccumulated probably because indole-3-acetaldoxime could not be used for glucosinolate biosynthesis but is channeled into IAA biosynthesis.

17.4.4 TAA1s also play a role in auxin biosynthesis and plant development and are required for shade avoidance

Identification of genes for Trp aminotransferase (TAA1) in *Arabidopsis* revealed that auxin biosynthesis via indole-3-pyruvic acid is involved in shade avoidance responses and in ethylene–auxin interactions. The *TAA1* allele is a causal gene

of *shade avoidance* mutants, which are unable to elongate in simulated shade. *TAA1* was also identified as a causal gene of *weak ethylene insensitive* mutants, which show root-specific decrease in sensitivity to ethylene. *TAA1* encodes a small family of aminotransferases with strong similarity to C-S lyase. Multiple mutants of this family of genes show severe auxin-related phenotypes, such as defects in root gravitropism, vasculature organization, and shoot and flower development. Since any defects in shade-induced hypocotyl elongation are not seen in multiple YUCCA mutants (*yuc3yuc5yuc7yuc8yuc9*), YUCCAs may not be required for shade avoidance.

17.4.5 Tryptophan-independent IAA biosynthesis was demonstrated, but the biological importance remains unclear

Evidence for IAA biosynthesis independent of L-Trp has been obtained with the orange pericarp (*orp*) mutant of *Z. mays*, a Trp auxotroph (Fig. 17.40). The *orp* phenotype results from mutations in two genes that encode the β -subunit of Trp synthase, which catalyzes the condensation of L-Ser and indole (Fig. 17.41; see also Chapter 7). Seeds of the *orp* mutant contain increased concentrations of two L-Trp precursors, anthranilate and indole (Fig. 17.41). Seeds germinate and form shoots normally, but seedlings die at the four- to five-leaf stage unless supplemented with L-Trp. Despite their diminished capacity for L-Trp synthesis, *orp* mutants are rich in IAA. Although *orp* seedlings contain roughly one-seventh the L-Trp present in wild-type *Z. mays*, IAA contents are increased 50-fold. Furthermore, labeling with $^2\text{H}_2\text{O}$ has indicated that isotopic enrichment of the *orp* IAA pool was much greater than in the L-Trp pool. [^{15}N]L-Trp does not label the IAA pool significantly in either wild-type or *orp* seedlings, but [^{15}N]anthranilate is incorporated into IAA to a similar extent in both tissues. These findings suggested the existence of L-Trp-independent IAA biosynthesis in *Z. mays*. The IAA precursor is probably an indolic intermediate of Trp biosynthesis, downstream from anthranilate and upstream from L-Trp. The conversion of indole-3-glycerol phosphate to

FIGURE 17.40 *Z. mays* ear segregating kernels for the two-gene recessive trait orange pericarp (*orp*); the orange kernels are homozygous for both mutant genes.

Source: J. Cohen, University of Minnesota, MN, and A.D. Wright, University of Missouri, Columbia; previously unpublished.

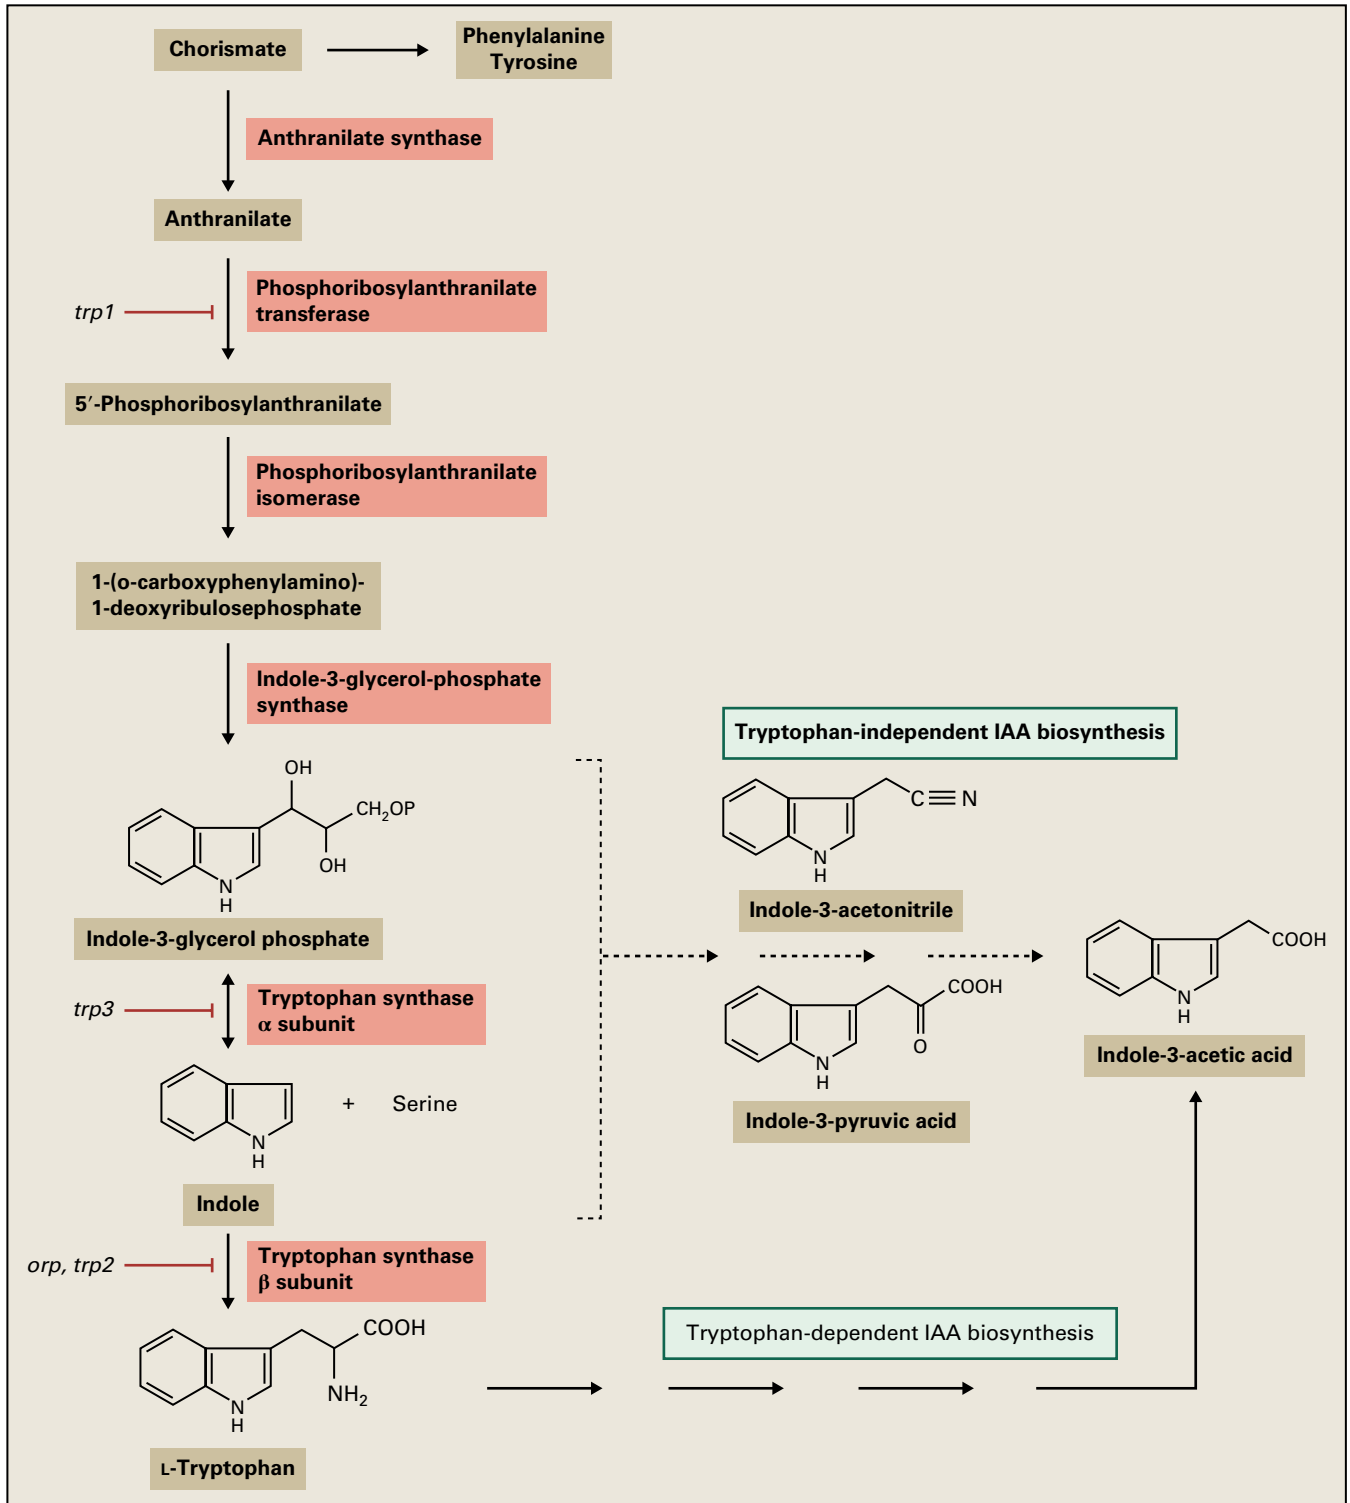

FIGURE 17.41 Biosynthesis of *L*-Trp and *L*-Trp dependent and independent IAA biosynthesis. The enzymes affected in *Z. mays* *orp* and *Arabidopsis* *trp1*, *trp2*, and *trp3* mutants are indicated.

indole is reversible, and the available data suggest that either of these compounds could be the branch point for IAA biosynthesis (Fig. 17.41).

Although the experimental data in *Z. mays* *orp* appear robust, and there are several reports suggesting a dominant

role of Trp-independent pathway for IAA synthesis, subsequent studies indicate that *L*-Trp-dependent IAA synthesis is the predominant route for auxin biosynthesis, and that the independent pathway plays only a minor role. ^{13}C -labeled precursor feeding experiments in a *Z. mays* kernel culture

FIGURE 17.42 Nondecarboxylative catabolism and conjugation of IAA in *S. lycopersicum* pericarp discs. *N*-(1-β-Glucoxyloxindole-3-acetyl)-L-aspartic acid and *N*-[1-(4-O-β-glucosyl-β-glucosyl)oxindole-3-acetyl]-L-aspartic acid are permanently deactivated IAA conjugates formed in both green and red *S. lycopersicum* fruits, whereas the 1-O-(indole-3-acetyl)-β-glucose formed by red pericarp tissues can be converted back to IAA.

showed that [3,3'-¹³C]tryptophan was efficiently incorporated into IAA with retention of the 3,3' bond, excluding the possibility that absorbed Trp is degraded to indole which then serves as an IAA precursor. Furthermore, in an evaluation of the metabolic origin of the IAA carbon skeleton by feeding [U-¹³C₆]glucose the possibility that IAA was synthesized by way of indole-3-glycerol phosphate was also excluded.

Although occurrence of a Trp-independent pathway was also suggested with *Arabidopsis trp1*, *trp2*, and *trp3* mutants all conditional Trp auxotrophs, experiments with *trp3* and labeled precursors ([²H]₅-L-Trp and [¹⁵N] anthranilate) suggested a minor role of the independent pathway, if any, in the biosynthesis.

17.4.6 Several pathways for IAA conjugation and catabolism have been elucidated

IAA catabolism results in loss of auxin activity and irreversibly decreases the size of the IAA pool. Catabolism can proceed by decarboxylative or nondecarboxylative pathways, and in either case can involve oxidation of the indole ring. As with CKs, catabolism of IAA sometimes involves conjugation reactions. While some conjugated IAA species appear to be permanently inactive, others can be cleaved to yield active free hormone (see Section 17.4.8).

Peroxidase-catalyzed decarboxylation of IAA has been studied in vitro with a variety of plant materials. The action of peroxidase (frequently referred to as IAA oxidase) results in the production of either decarboxylated oxindoles or decarboxylated indoles. For many years, the decarboxylative catabolism was thought to represent the major IAA degradation pathway in plant tissues. However, evidence obtained with *Z. mays*, tomato and pea indicates that peroxidases have only a minor role in the regulation of endogenous IAA pools. IAA-amino acid conjugates that were once perceived as storage products have been identified as intermediates in nondecarboxylative catabolic pathways that deactivate IAA irreversibly.

The principal IAA deactivation pathway in green *S. lycopersicum* fruits converts IAA to *N*-(indole-3-acetyl)-L-aspartic acid (IAA-Asp). The indole ring of IAA-Asp is oxidized to form *N*-(oxindole-3-acetyl)-L-aspartic acid (OxIAA-Asp), which is subjected to successive glycosylations at the indole nitrogen (Fig. 17.42). An IAA to OxIAA-Asp deactivation pathway also operates in *Dalbergia*, but instead of *N*-glycosylation, the indole ring of OxIAA-Asp is hydroxylated at C-3 or C-4. A parallel pathway in *Dalbergia* forms similar products that are conjugated to Glu rather than Asp. Additional nondecarboxylative IAA degradation pathways that involve conjugation reactions have been identified in *Vicia faba* and *Z. mays* seedlings (Fig. 17.43).

17.4.7 IAA ester conjugates serve as storage products in *Z. mays* seeds

The conjugation reactions discussed above, including aspartylation or glutamylation of the 1' carboxyl, *N*-glycosylation of the indole ring, and glycosylation of either the 3 or 7 hydroxyl groups, appear to permanently deactivate IAA. However, *O*-glycosylation of the 1' carboxyl is typically reversible, so IAA-ester conjugates may function as storage products (see Fig. 17.42).

In *Z. mays*, IAA-ester conjugates are formed primarily in the liquid endosperm of developing seeds. IAA is first converted to 1-*O*-(indole-3-acetyl)-β-glucose (1-*O*-IAA-glucose) in a reaction catalyzed by IAA glucosyltransferase (Fig. 17.44). Isomers of 1-*O*-IAA-glucose can be formed by nonenzymatic reactions. Two of these isomers, 4-*O*-IAA-glucose and 6-*O*-IAA-glucose, can be cleaved by 6-*O*-IAA-glucose-hydrolase to release active IAA. A second enzyme that liberates active hormone, 1-*O*-IAA-glucose hydrolase, also can transfer IAA from 1-*O*-IAA-glucose to glycerol. However, the major pathway from 1-*O*-IAA-glucose involves its conversion to 2-*O*-(indole-3-acetyl)-*myo*-inositol, which is further conjugated to 2-*O*-(indole-3-acetyl)-*myo*-inositol arabinoside and 2-*O*-(indole-3-acetyl)-*myo*-inositol galactoside (Fig. 17.44). During the first days of germination, the *Z. mays* embryo derives most of its IAA from these three conjugates. However, the supply of hydrolyzable IAA conjugates declines as the seedling grows, and the young plant rapidly develops the capacity to synthesize IAA.

In *Z. mays* and *Arabidopsis*, genes for IAA glucosyltransferase, *iaglu*, and *UGT84B1*, respectively, have been identified. In vitro studies show that *UGT84B1* reacts with IAA as well as indole-3-butyric, indole-3-propionic, and cinnamic acids. Surprisingly, the closest *Arabidopsis* homolog of *iaglu*, *UGT75D1*, showed no activity toward IAA.

17.4.8 Amino acid conjugation of IAA is catalyzed by enzymes of the GH3 family and together with IAA-amido hydrolases are involved in IAA homeostasis

Studies in *Arabidopsis* identified a subset of GH3 family proteins as IAA-amido synthetase, which catalyzes amino acid conjugation of IAA in the presence of ATP and Mg²⁺. GH3.2 to GH3.6 and GH3.17 conjugate various L-amino acids, such as L-Ala L-Asp, L-Glu, L-Met, and L-Tyr to IAA in vitro, and can utilize indole-3-pyruvic acid, indole-3-butyric acid, phenyl acetic acid, and naphthalene-1-acetic acid as substrates. Most of the IAA-amido synthetase genes are responsive to auxin treatment, suggesting that plants use feedback regulation to control the amounts of active auxin. Genes for IAA-amido hydrolases were identified in *Arabidopsis* and are encoded by a small multigene family. The

FIGURE 17.43 Noncarboxylative catabolism and conjugation of IAA in seedlings of *Z. mays* and *Vicia faba*.

IAA-amido synthetases and hydrolases play a complementary role in the maintenance of IAA homeostasis (Fig. 17.45).

17.4.9 Some bacterial pathogens encode novel IAA synthesis and conjugation pathways

As described in Section 17.3.7, some bacterial enzymes catalyze the production of plant hormones. The enhanced synthesis of IAA in *A. tumefaciens*-induced galls and tumors (see Fig. 17.29) results from expression of two bacterial genes

that are transferred to the plant when the T-DNA integrates into the host genome. These genes are associated with a unique two-step Trp-dependent pathway to IAA. The *iaaM* gene encodes Trp monooxygenase, which converts L-Trp to indole-3-acetamide. The product of the *iaaH* gene, indole-3-acetamide hydrolase, catalyzes the conversion of indole-3-acetamide to IAA. Cognate genes with similar functions occur in the plant pathogen *Ps. savastanoi*. A third *Ps. savastanoi* gene, *iaaL*, encodes IAA-Lys synthase. When expressed in the cells of the plant host, IAA-Lys synthase conjugates IAA and L-Lys to form ϵ -N-(indole-3-acetyl)-L-Lys, which is metabolized further to α -N-acetyl- ϵ -N-(indole-3-acetyl)-L-Lys (Fig. 17.46).

FIGURE 17.44 Biosynthesis and hydrolysis of IAA ester conjugates in *Z. mays*.

17.4.10 Transgenic plants expressing IAA biosynthesis genes have been used to study the effects of excess amounts of endogenous IAA

Transgenic plants expressing the *A. tumefaciens* IAA biosynthesis genes have been produced in several laboratories. Weak coexpression of the *iaaH* and *iaaM* genes in

transgenic tobacco (*N. tabacum* cv. Petit Havana SR1) results in a marginal increase in endogenous IAA. Depending on the tissue, there is a two- to threefold increase in the amount of IAA conjugates—primarily IAA-Asp and IAA-Glu, with smaller amounts of 1-O-IAA-glucose. Transgenic plants exhibited no obvious changes in vegetative phenotype, but their flowers were heterostylous and pollen production was impaired, resulting in infertility. Thus, when IAA production is enhanced, conjugation

FIGURE 17.45 Metabolic homeostasis regulating IAA concentration by IAA-amido synthetases and hydrolases. Dotted arrow shows transcriptional activation for several IAA-amido synthetase genes.

appears to play a key role in regulating the size of the endogenous IAA pool and maintaining an almost normal phenotype. However, strong *iaaH/iaaM* expression driven by the CaMV 35S promoter increased the concentration of free and conjugated IAA in stems by 10- and 20-fold, respectively, whereas foliar IAA and IAA conjugates increased three- to fivefold. This increased IAA content was accompanied by major phenotypic effects, including pronounced apical dominance, dwarfism, excess adventitious root formation, increased phloem and xylem formation, excess lignification, leaf epinasty, and abnormal flower production (Fig. 17.47). Similar phenotypes have been observed in several transformed plants that overproduce IAA, including *Petunia* and *Arabidopsis*.

High concentrations of IAA are typically accompanied by an increased rate of ethylene biosynthesis, and it was not initially possible to determine whether the phenotypic effects

of IAA overproduction were a direct result of IAA or a consequence of increased ethylene levels. To investigate these possibilities, investigators crossed IAA-overproducing transgenic *N. tabacum* cv. Samsun plants with plants expressing a bacterial ACC deaminase that catalyzes the breakdown of the ethylene precursor ACC and thereby reduces ethylene concentration (see Section 17.5.2). With cv. Samsun (Fig. 17.48) the phenotypic effects of IAA-overproduction are not as severe as with the Petit Havana SR1 transformant (see Fig. 17.47), although inhibition of stem growth, leaf epinasty, and reduced apical dominance are still evident. The phenotype of the Samsun double-transformants, in which IAA overproduction is not accompanied by increased ethylene biosynthesis, shows that apical dominance and leaf epinasty are controlled primarily by IAA, whereas reduced stem elongation is an indirect consequence of high ethylene concentrations (Fig. 17.48).

FIGURE 17.46 IAA biosynthesis and conjugation pathways in *A. tumefaciens* and *Pseudomonas savastanoi*. *IaaL* does not occur in *A. tumefaciens*.

17.4.11 GAs increase IAA pools, whereas CKs may down-regulate IAA synthesis and turnover

Application of GA_3 to Little Marvel dwarf pea seedlings enhances shoot growth with a concomitant eightfold increase in IAA content of elongating tissues. Conversely, the size of the endogenous IAA pool is reduced in the Alaska pea seedlings dwarfed by treatment with uniconazole, a GA biosynthesis inhibitor (see Section 17.1.5). The effects of uniconazole on both internode growth and IAA content are counteracted by GA_3 treatment.

FIGURE 17.47 Eight-week-old tobacco plants, *N. tabacum* cv. *Petit Havana SR1*: wild-type plant (left); IAA-overproducing plant expressing *A. tumefaciens* *iaaH* and *iaaM* genes under the control of the CaMV 35S promoter (right). Little is known about the mechanism by which GA_3 increases endogenous IAA concentrations in peas. One proposal postulates that D-Trp is converted to IAA more effectively than its L-isomer and acts as an intermediate between L-Trp and indole-3-pyruvic acid in the IAA biosynthesis pathway; moreover, GA_3 treatment supposedly enhances the activity of the racemase that regulates the conversion of L- to D-Trp, thereby increasing the rate of IAA biosynthesis.

In contrast to GA_3 , CK reduce the size of endogenous IAA pools. Transgenic tobacco plants that express the *A. tumefaciens ipt* gene overproduce CKs. Compared with wild-type plants, these transgenics contain significantly lower concentrations of free IAA and in most cases IAA conjugates. Rates of IAA biosynthesis also are reduced, as determined by $^2\text{H}_2\text{O}$ incorporation studies, and exogenous $^{13}\text{C}_6$ IAA is degraded more slowly in the *ipt*-transformed plants. Thus, elevated amounts of CKs, primarily tZ, tZR, and tZRMP, not only reduce the size of the endogenous IAA and IAA conjugate pools but also appear to lower the rate of IAA turnover.

Just as CK overexpression antagonizes IAA synthesis, IAA overexpression appears to downregulate CK production. IAA-overproducing tobacco plants that express *iaaH* and *iaaM* (see Fig. 17.47) contain lower concentrations of endogenous tZ and related CKs than wild-type plants. Since IAA represses expression of *IPT* and *CYP735A* (see Sections 17.3.4 and 17.3.15), an action point of auxin for downregulating CK production is the early step of CK biosynthesis.

17.5 Ethylene

In 1886, while a graduate student in St. Petersburg, Dimitry Nikolayevich Neljubow noticed that etiolated pea seedlings grew horizontally in laboratory air, and vertically in air from outside the laboratory. After an extensive study to exclude

cultural practices, light, and temperature as causative agents, he showed that **ethylene**, in the gas used for lighting, induced this abnormal growth. Many of ethylene's physiological effects on plant growth and development, including its impact on seed germination, root and shoot growth, flower development, senescence and abscission of flowers and leaves, and the ripening of fruit, were discovered prior to 1940. Subsequent work has since shown that ethylene also participates in the modulation of plant responses to a range of biotic and abiotic stresses.

When investigators in the 1930s proposed that ethylene was both an endogenous plant growth regulator and a fruit-ripening hormone, their hypothesis was met with skepticism by their contemporaries, many of whom considered ethylene to be an unimportant product of the paramount plant hormone, auxin. This prejudice hampered research on ethylene while attention focused on auxin, GAs, and CKs.

Initial ethylene quantification was cumbersome and insensitive, and some relied on bioassays based on leaf epinasty or the growth of etiolated *P. sativum* and *Vigna radiata* seedlings (Figs. 17.49A,B). Gas chromatography and the development of the flame ionization detector increased ethylene detection by a factor of 10^6 . This major development led to rapid advances in ethylene research and ethylene was quickly established as an endogenous plant growth regulator.

17.5.1 Ethylene is synthesized from S-adenosyl-L-methionine via the intermediate 1-aminocyclopropane-1-carboxylic acid (ACC)

Synthesis of ethylene from its immediate precursor 1-aminocyclopropane-1-carboxylic acid (ACC) is catalyzed by ACC oxidase (ACO). ACC is produced from SAM in a

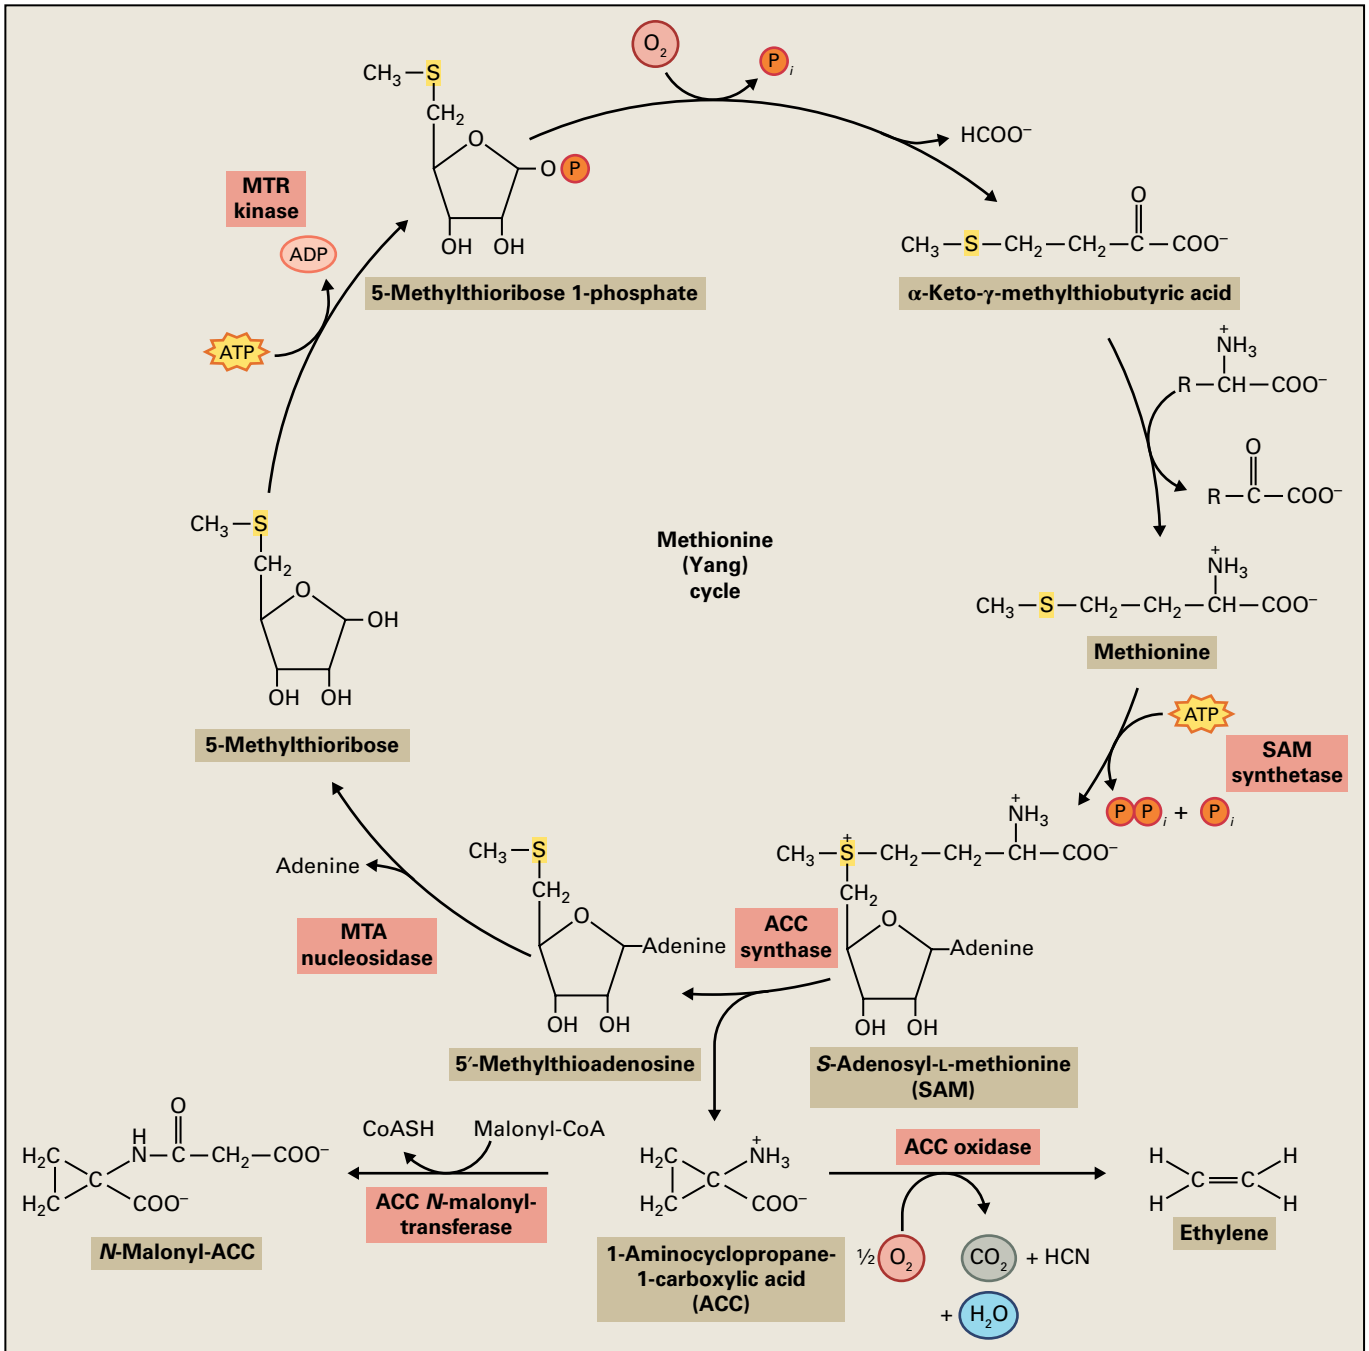

FIGURE 17.50 The Met cycle and ethylene biosynthesis. Ethylene is synthesized from Met by way of SAM and ACC. The enzymes that catalyze these three steps are SAM synthase, ACC synthase (ACS), and ACC oxidase (ACO). 5'-Methylthioadenine, a product of the ACO reaction, is salvaged for the resynthesis of Met through the methionine cycle (see Chapter 7). If the methylthio-group from SAM were not recycled, Met availability and ethylene biosynthesis would probably be restricted by sulfur availability. By converting ACC to N-malonyl-ACC instead of to ethylene, plants can deplete the ACC pool and thereby reduce the rate of ethylene production.

reaction catalyzed by ACC synthase (ACS). These reactions are part of the methionine cycle or Yang cycle named after S. F. Yang, who carried out the early work in elucidating the pathway (Fig. 17.50). In addition to its role in ethylene biosynthesis, SAM is involved in the biosynthesis of polyamines (PA) (see Section 17.7) and a wide range of methylation reactions.

ACS, which cleaves SAM to form the ethylene precursor ACC and 5'-methylthioadenosine (Fig. 17.50), was first characterized in a semi-purified preparation from *S. lycopersicum* pericarp. The enzyme has subsequently been isolated from a number of plant tissues following induction by factors that include exogenous IAA, wounding, lithium chloride stress, and climacteric fruit ripening. ACSs have been cloned from

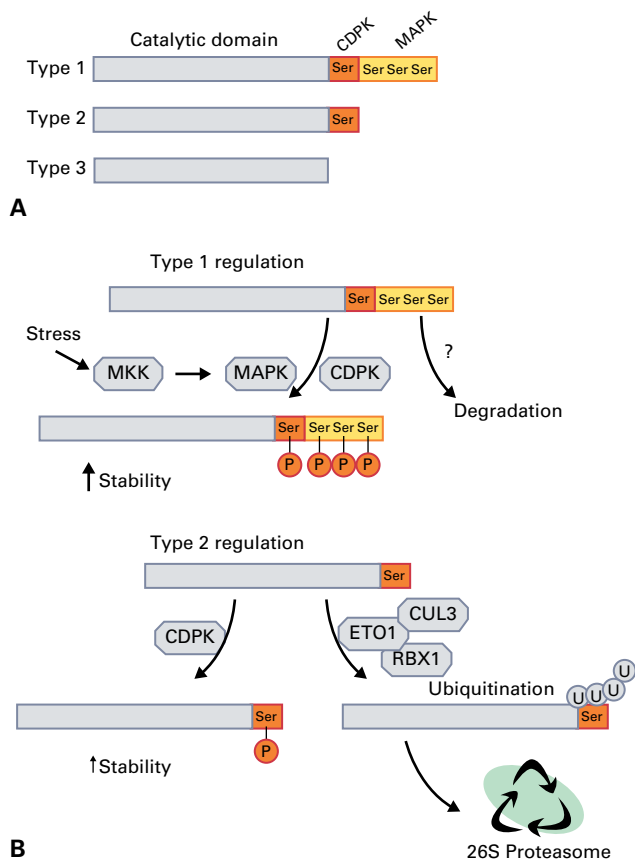

FIGURE 17.51 ACS types and mechanisms of protein regulation. (A) ACS proteins fall into three major classes according to their C-terminal sequences. Type 1 have three conserved Ser residues (yellow) that can be phosphorylated by a MAPK and a single conserved Ser (red) that can be phosphorylated by a CDPK. Type 2 are slightly truncated and have a Ser that can be phosphorylated by a CDPK. Type 3 lack any conserved C-terminal Ser residues. (B) Type 1 regulation: CDPK and MAPK phosphorylation of C-terminal region increases ACS stability. The MAP kinase (MKK), induces MAPK activity when stimulated by stress e.g. wounding or pathogen attack. Unphosphorylated protein is removed by a yet to be defined mechanism. Type 2 regulation: CDPK phosphorylation of C-terminal Ser increases ACS stability by preventing binding of the ETO protein. Unphosphorylated ACS undergoes ETO binding and this facilitates the formation of a RING E ligase complex that includes a Cullin3 (CUL3) protein and a RING Box 1 protein (RBX1). The E3 ligase adds ubiquitin (U) moieties to the ACS protein thereby targeting it for degradation by the 26S proteasome.

numerous species and the highly conserved sequences include a lysine (Lys) residue that reacts with SAM and pyridoxyl 5'-phosphate at the active site. Plants typically contain several isoforms of ACS that are differentially expressed in response to wounding, ripening, and various stresses. In *Arabidopsis* three major groups of ACSs have been classified according to C-terminal sequences that play a role in protein turnover (Fig. 17.51). Type 1 enzymes have three conserved C-terminal serine (Ser) residues that can be phosphorylated by a mitogen-activated protein kinase (MAPK) and a single conserved Ser as a substrate for calcium-dependent protein kinases (CDPKs). Type 2 enzymes only have the CDPK site

and the C-terminus is shorter. Type 3 enzymes lack both types of phosphorylation sites.

17.5.2 ACSs are major regulators of ethylene biosynthesis

ACSs catalyze the rate-limiting step in ethylene biosynthesis and their levels are controlled by transcription and protein stability. Increased ethylene production, associated with germination, ripening, flooding, and chilling, is invariably accompanied by increased ACC production due to induction or activation of ACS. The enzyme requires pyridoxal phosphate for activity and is sensitive to inhibitors of pyridoxal phosphate, especially aminoethoxy-vinyl glycine and amino-oxy acetic acid. These inhibitors allow investigators to distinguish between the effects of ACS and ACO. The naturally occurring isomer of SAM, (-)-S-adenosyl-L-methionine, is the preferred substrate for ACS, while (+)-SAM is an effective inhibitor. However, incubating the enzyme with high concentrations of (-)-SAM can irreversibly modify and inhibit ACS. This "suicide inactivation" involves covalent linkage of a fragment of the SAM molecule to the active site of the enzyme. This substrate-dependent inactivation may be a contributory factor in the rapid turnover of ACS in plant tissues.

Transcriptional control

Ethylene biosynthesis rates are influenced by other plant hormones and by ethylene itself. Auxins promote ethylene synthesis by enhancing the rate of ACC production. Transcript analysis showed that auxin application results in increased levels of certain ACS mRNAs, indicating transcriptional control, and the respective ACS genes have been shown to have cis-acting auxin-response elements. Transcriptional control of ACS levels is also observed during *S. lycopersicum* fruit development and ripening. Unripe developing fruits have auto-inhibitory ethylene production and certain ACS genes are transcribed. During ripening ethylene can promote (autocatalyze) its production and different ACS genes are transcribed.

Control via protein turnover

Early observations indicated that ACS stability in *S. lycopersicum* fruits varied between ripe and unripe fruits. More recent experiments have shown that ACS turnover plays an important role in regulating ethylene production and that the C-terminal regions of the ACS protein act in regulating this turnover. The stability of ACS proteins is influenced by their phosphorylation status at C-terminal regions with the phosphorylated forms being more stable. Type 1 ACS proteins are phosphorylated by a MAPK in response to stress, for example, pathogen and wounding, and by a CDPK. Phosphorylation increases protein stability whereas unphosphorylated proteins are degraded by an undefined mechanism. Type 2 ACS proteins are phosphorylated by a CDPK and this prevents binding of the ETO (Ethylene overproducing)

gene product that is part of an E3 ligase required for ubiquitination of proteins. ETO1 binds ACS and also CUL3 (Cullin3 another part of E3-ligase) that can catalyze the addition of ubiquitin to ACS. The E-ligase complex associated with ACS degradation is the RING ligase that is composed of an E2 conjugating enzyme, a cullin, RBX1 (Ring Box 1), and an adaptor protein(s) (Fig. 17.51). Once ACS is ubiquitinated it is targeted for proteolysis by the 26S proteasome. See Chapter 18 for more details on ubiquitination and proteasome degradation.

17.5.3 ACC oxidase resisted biochemical characterization and was cloned using molecular techniques

The conversion of ACC to ethylene is catalyzed by ACO, previously referred to as “ethylene-forming enzyme” (see Fig. 17.50). The ACO reaction can be summarized in Reaction 17.1:

ACO is activated by one of its products, carbon dioxide. The cyanide generated by the reaction is detoxified by conversion to β -cyanoalanine, which is further metabolized to Asn or γ -glutamyl- β -cyanoalanine.

ACO, which is extremely unstable, proved difficult to purify by conventional techniques. A cDNA clone (pTOM13) of the enzyme was identified using a differential screen of cDNAs in tomato fruit. pTOM13 antisense tomato plants have reduced ethylene production (Fig. 17.52) and confirmation

that pTOM13 encodes an ACO was shown in yeast expressing pTOM13. Recombinant yeast were able to convert ACC to ethylene and the recombinant 35-kDa protein met all criteria for authentic ACO activity, including inhibition by Co^{2+} .

All plant tissues appear to contain ACO, as measured by the rate of ethylene evolution in the presence of a saturating concentration of ACC. Under stress conditions, in response to ethylene, and at selected stages of development (e.g., fruit ripening), ACO activity increases markedly. Both senescence and ripening-induced increases in ACO activity are a result of increased transcription.

17.5.4 When supply of available SAM is low, ethylene and polyamine biosynthetic pathways may compete for this shared substrate

Biosynthesis of both ACC (see Fig. 17.50) and PAs (see Fig. 17.63) involves the incorporation of the aminopropyl group from SAM. Under certain conditions, competition for SAM may restrict rates of ethylene or PA production. Inhibition of ACC synthesis by aminoxyacetic acid results in increased PA production. Conversely, inhibition of PA biosynthesis leads to increased concentrations of ACC and ethylene. This implies that one SAM-dependent pathway is stimulated when the other is blocked. When competition for the available SAM is circumvented by low demand for PAs, or when ACC levels are increased by upregulation of 5'-methylthioribose-recycling enzymes (see Fig. 17.50), ethylene and PA production will not directly interact. Whether ACC/PA interactions represent a

FIGURE 17.52 Effect of antisense ACO genes on ripening and spoilage of *S. lycopersicum* cultivar Ailsa Craig fruit picked three weeks after onset of ripening and stored at room temperature for three weeks. (Left) Fruits from the descendants of the original TOM13-antisense plants, which generate about 5% of the normal amount of ethylene. They ripen fully but do not overripen and deteriorate. (Right) Fruits from wild-type plants grown and stored under identical conditions. They produce normal amounts of ethylene and consequently exhibit severe signs of over-ripening.

Source: D. Grierson, University of Nottingham, UK; previously unpublished.

widespread means for controlling ethylene production remains an open question.

17.5.5 Most hormones must be catabolized, but volatile ethylene can be released as a gas

Prior to 1975, ethylene metabolism by plants was considered to be an artifact, caused by bacterial contamination. However, there is now evidence from plants grown in sterile conditions that [^{14}C]ethylene is oxidized to [^{14}C]CO₂ or converted to [^{14}C]ethylene oxide and [^{14}C]ethylene glycol. Ethylene metabolism exhibits a very high K_M indicative of a chemical reaction rather than a physiological process. In peas, the concentration of ethylene yielding a half-maximal rate of ethylene metabolism is $\approx 1,000$ times the concentration required for half-maximal response in the pea growth test illustrated in Figure 17.49A. It is likely that ethylene metabolism is largely a consequence of artificially elevated ethylene levels. The major route by which plant tissues lose ethylene is probably diffusion to the surrounding atmosphere.

17.5.6 Repression of ethylene biosynthesis can delay over-ripening in fruit, and represents an important field of biotechnological research

There is a great deal of interest in downregulating ethylene biosynthesis, since elevated levels can trigger ripening and subsequent over-ripening of climacteric fruits such as bananas, apples and tomatoes. Two different biotechnological strategies have been employed to generate transgenic tomato fruit that resist over-ripening. One, the overexpression of a *Pseudomonas* gene encoding ACC deaminase, reduces ethylene levels in fruits by catalyzing the conversion of ACC to α -ketobutyric acid and NH₃. The second approach to limiting ethylene biosynthesis involves use of antisense gene constructs against either ACO or ACS. Analysis of transgenic fruit produced by these procedures has demonstrated a direct correlation between the level of ethylene inhibition and rate of ripening.

The phenotype of transgenic tomato fruit expressing antisense ACO has been studied in most detail. In these fruit, ethylene production is inhibited by about 95% during ripening. ACO antisense fruit grow normally and begin to change color, losing chlorophyll and accumulating lycopene, at the same stage of development as nontransformed fruit. However, transgenic fruit exhibit reduced reddening and an increased resistance to over-ripening and shriveling when stored at room temperature for prolonged periods (Fig. 17.52). Transgenic fruit do not soften as readily and can be left on the

plant longer to ripen more fully. Biotechnological manipulation of ethylene production for improved crop yield and less spoilage is possible in other climacteric fruits, such as melons, pears (*Pyrus* sp.), kiwi (*Actinidia deliciosa*) fruit, apples (*Malus* sp.), nectarines (*Prunus* sp.), avocados (*Persea americana*), and a range of tropical fruit that are rarely seen outside their country of origin because they over-ripen and spoil readily. The same technology can also be used to delay the senescence of flowers and enhance the longevity of cut blossoms.

17.6 Brassinosteroids

In the early 1960s, researchers hypothesized that the rapid germination and growth of pollen grains was associated with the presence of a growth promoter. A crude extract of pollen from *Brassica napus* (rape) induced rapid elongation of *P. vulgaris* (pinto bean) internodes distinct from GA-mediated stem elongation. This early work led to the isolation and identification of brassinolide (BL) the first steroidal plant growth regulator (Fig. 17.53). A second plant steroid, castasterone (CS; Fig. 17.53) was isolated from insect galls of chestnut (*Castanea*). Since these reports, a number of related steroidal compounds have been isolated from a variety of plant sources, and collectively called **brassinosteroids** (BRs)

FIGURE 17.53 Structures of brassinolide and castasterone.

FIGURE 17.54 Etiolated *O. sativa* seedlings used to obtain excised leaf lamina (left) and the effects of increasing concentrations of BL on the rice lamina inclination bioassay (right). BL and other BRs induce a dose-dependent swelling of the adaxial cells of the joint between the leaf's blade and sheath. This bioassay is very sensitive and is used in studies on BR structure–activity relationships as well as for screening fractionated plant extracts for BR activity.

Source: T. Yokota, Teikyo University Utsunomiya, Japan; previously unpublished.

that exhibit significant biological activity in the *O. sativa* lamina inclination assay (Fig. 17.54).

BRs occur in algae, ferns, gymnosperms and angiosperms but have not been detected in microorganisms. More than 40 BRs have been identified and, structurally, they are C_{27} -, C_{28} -, and C_{29} -steroids with different functional groups on the A- and B-rings and side chain (Fig. 17.55). Brassinolide, a C_{28} -BR, has the highest biological activity of the BRs and is distributed widely in the plant kingdom, along with biosynthetically related compounds. The biosynthesis of BL from campesterol has been studied most extensively using normal and transformed cells of *Catharanthus roseus* (Madagascar periwinkle).

17.6.1 BRs affect a range of morphological characteristics

Application of BRs induces a broad spectrum of responses, including increased stem elongation, pollen tube growth, unrolling of grass leaves, bending of grass leaves at the sheath/blade joints, proton pump activation, reorientation of cellulose microfibrils, xylogenesis, and enhanced ethylene production. The existence of dwarf mutants of *Arabidopsis*, *P. sativum*, *O. sativa* and *S. lycopersicum* defective in BR biosynthesis or signaling indicates that BRs promote the growth or elongation of plant cells. *Arabidopsis* mutants grown in light have dark green leaves with reduced cell size, reduced apical dominance and diminished male fertility (Fig. 17.56). Curiously, when grown in dark, these

mutants do not etiolate and share some characteristics with light grown plants. When BL is applied to BR biosynthesis mutants these phenotypic abnormalities are reversed.

17.6.2 The plant sterol campesterol is a precursor of brassinolide

All plant sterols are synthesized from cycloartenol (Fig. 17.57), which is derived from squalene by way of 2,3-epoxysqualene; cholesterol biosynthesis in animals, in contrast, proceeds from lanosterol. A characteristic feature of plant sterols is alkylation at C-24 with C1 or C2 substituents. Cholesterol, however, a widely distributed minor sterol in plants, is not alkylated at C-24 (Fig. 17.57). Common sterols found in plants include sitosterol (C_{29}), stigmasterol (C_{29}), campesterol (C_{28}), 24-epicampesterol (or 22-dihydrobrassicasterol) (C_{28}), and cholesterol (C_{26}). One of the rarer sterols includes 24-methylene-25-methylcholesterol, and sterol biosynthesis intermediates such as 24-methylenecholesterol (C_{28}) and isofucosterol (C_{29}) are also present in some species (Fig. 17.57). Except for stigmasterol, all these compounds are thought to be BR precursors, with the parent sterol and the BR derivative sharing the same C-24 and C-25 substituents.

Sitosterol is the most abundant sterol and comprises 50–80% of the total sterol content of many plants, but it appears not to be a preferred precursor for BR biosynthesis. In many plants, BL and biosynthetically related compounds are the major BRs, indicating that campesterol is utilized preferentially for biosynthesis. Analysis of mutants defective

FIGURE 17.55 Functional groups in the A ring, B ring, and side chain of natural BRs. BL is the most biologically active BR.

FIGURE 17.56 Sixteen-day-old *Arabidopsis* seedlings: wild-type (left), BL-deficient *det2* mutant (center), BL-deficient *dim* mutant (right). Source: T. Yokota, Teikyo University, Utsunomiya, Japan; previously unpublished.

in sterol biosynthesis indicates that synthesis of sitosterol and campesterol utilize the same enzymes.

17.6.3 The synthesis of BL from campesterol

The biosynthetic pathways leading to production of BL was initially established in cultured cells of *C. roseus* through feeding labeled substrates and following their metabolism. Phenotypic rescue experiments and analysis of endogenous BR levels of mutants defective in BR synthesis provided novel tools to further characterize the pathway. The presence of many C-6-deoxy intermediates led to the generation of the early and late C-6 oxidation pathways. Subsequently BL synthesis has been proposed to occur via a “metabolic grid” in which the order of oxidation at certain C atoms is arbitrary. Analysis of recombinant

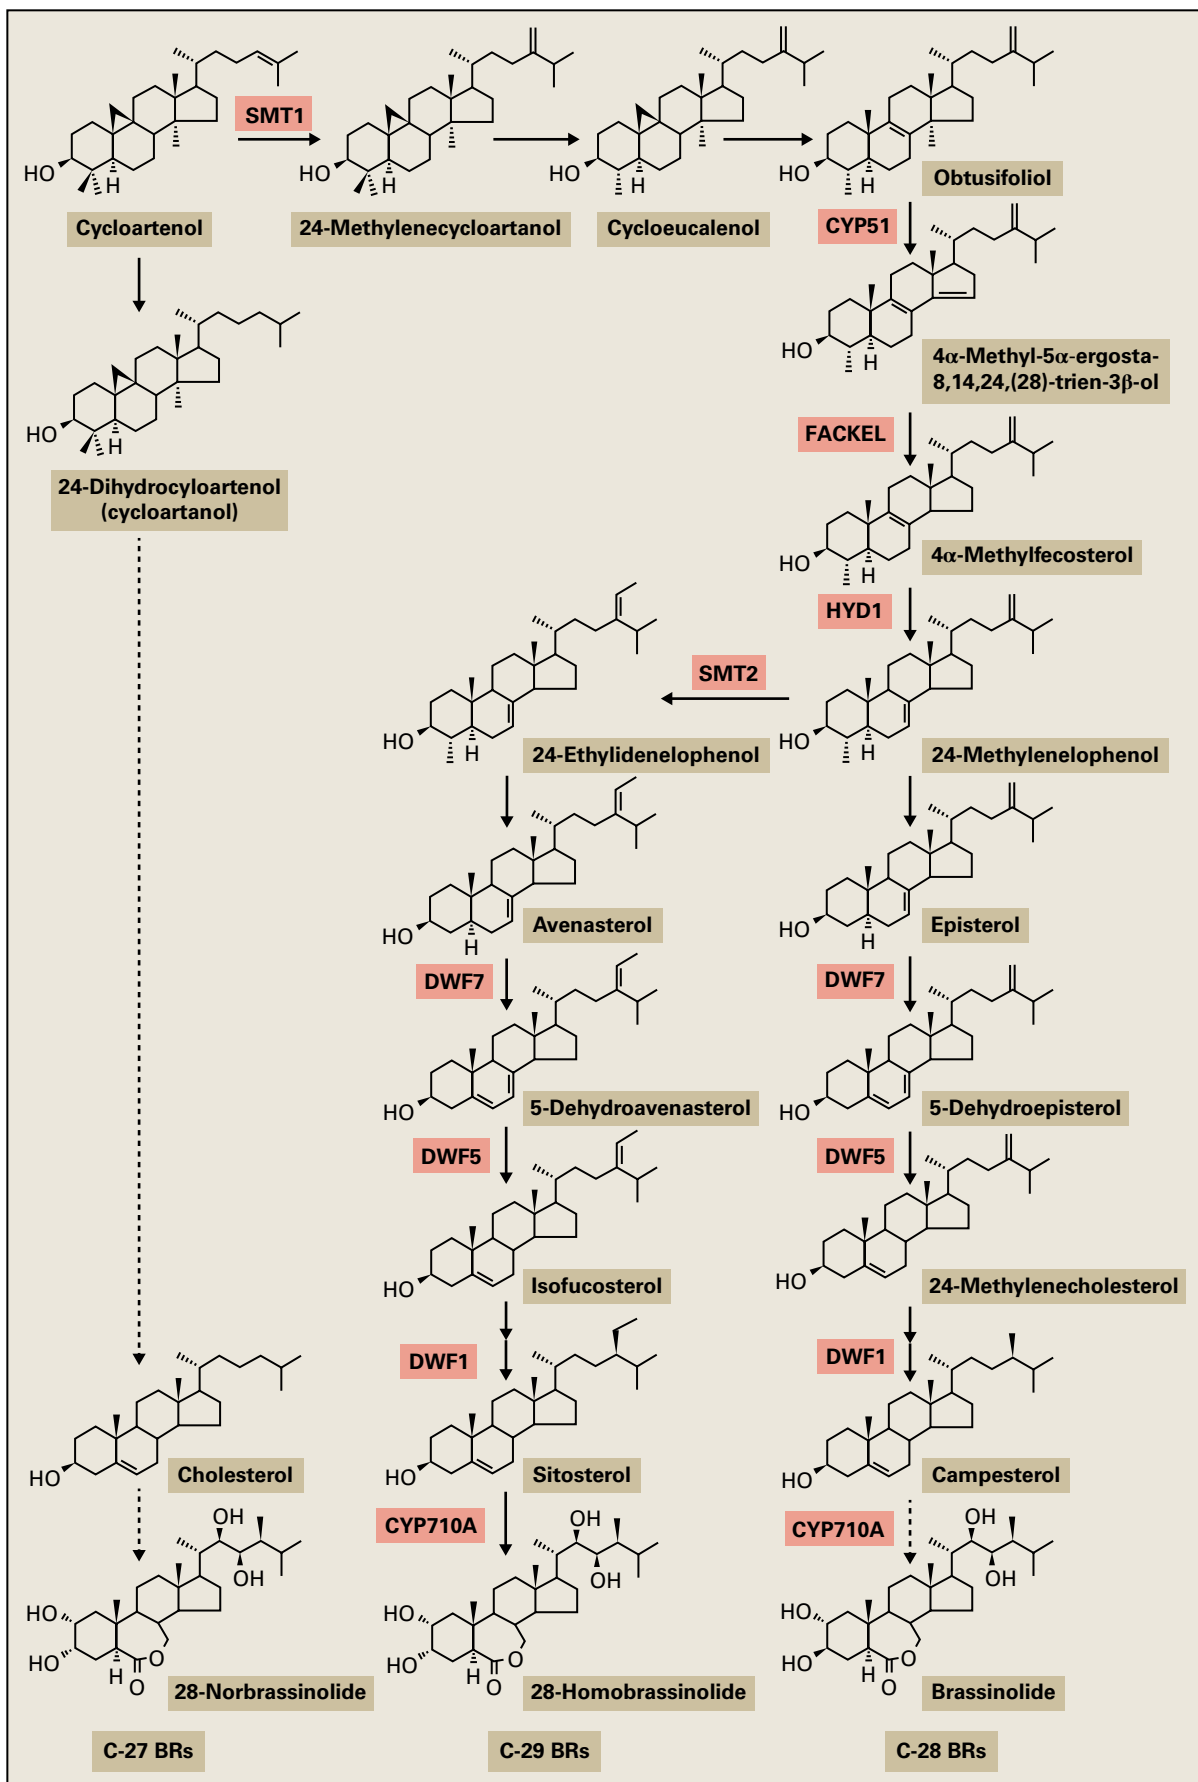

FIGURE 17.57 Biosynthesis of sterols in vascular plants and biosynthetic lesions in Arabidopsis mutants. The biosynthesis of sterols in vascular plants is not fully understood, especially the synthesis of cholesterol. Broken lines indicate multiple steps. Sites where Arabidopsis gene products act on the pathway are indicated: CYP51; CYP710A; DWF1, DWARF1; DWF5, DWARF5; DWF7, DWARF7, FACKEL; HYD1, HYDRA1; SMT1, STEROL METHYLTRANSFERASE1; SMT2, STEROL METHYLTRANSFERASE2.

enzymes and affinity for different substrates are also providing novel insights into the order of reactions. A consensus is emerging that there is no single definitive route to BL synthesis, however the most likely route is via the late C-6 oxidation of BRs as described in the following sections.

The first step

The first step in the synthesis of BL is conversion of campesterol to its 22-hydroxylated product (22S)-22-hydroxy-campesterol (Fig. 17.58). The *Arabidopsis DWARF4* gene encodes a CYP450 enzyme, CYP90B, and this more readily hydroxylates campesterol rather than campestanol, which therefore places it as the first reaction in the conversion of campesterol to BL. (22S)-22-hydroxy-campesterol is then converted to the C-2 ketone by CYP90A1 and the keto moiety is a substrate for the 5 α -reductase activity of DEETIOLATED2 (DET2). The reduction of the D4 bond is impaired in the *det2* dwarf mutant of *Arabidopsis* and this reaction is analogous to the conversion of testosterone to dihydrotestosterone in animals. The amino acid sequence deduced from the *DET2* gene shares 40% homology with a mammalian steroid 5 α -reductase, which catalyzes the NADPH-dependent conversion of testosterone to dihydrotestosterone.

C-23 hydroxylation

Previously CYP90A encoded by the *Constitutive photomorphogenic and dwarfism (Cpd)* gene was thought to be the C-23 hydroxylase in BL synthesis. This is no longer the case and CYP450s, CYP90C, and CYP90D catalyze C-23 hydroxylation of BRs (Fig. 17.58). In *Arabidopsis* these enzymes have redundant function as only *cyp90C* and *cyp90D* double mutants have a strong dwarfing phenotype. Recombinant enzyme assays indicate that both CYP90C1 and CYP90D1 are able to convert (22S,24R)-22-hydroxyergost-4-en-3-one, (22S,24R)-22-hydroxy-5 α -ergostan-3-one, and 3-*epi*-6-deoxocathasterone to their C23-hydroxylated products. But they showed limited conversion of (22S)-22-hydroxycampesterol and 6-deoxocathasterone. This indicates a new preferred synthesis route leading to the production of BL that shortcuts the need to synthesize intermediates such as 6-deoxocathasterone and 6-deoxoteasterone that were present in previous pathways (Fig. 17.58).

C-6 oxidation

The *S. lycopersicum Dwarf* gene was cloned by transposon tagging and found to encode a CYP450 enzyme CYP85A1. This enzyme catalyzed the conversion of 6-deoxocastasterone to castasterone (CS). CYP85A3 in *S. lycopersicum* is a CYP85A1 homolog that is fruit specific and can convert 6-deoxocastasterone to BL. In *Arabidopsis* CYP85A1 and CYP85A2 exhibit overlapping function, with single loss of function mutations having weak or no phenotype. Biochemical analysis indicates CYP85A1 can synthesize CS whereas CYP85A2 can make both CS and BL.

Transcriptional feedback regulation of BL synthesis

Transcripts encoding CYP85A1, CYP85A2, CYP90B1, CYP90C1, and CYP901 from *Arabidopsis* are downregulated by bioactive BRs. Feedback regulation requires a functional

BRASSINOSTEROID-INSENSITIVE1 (BRI1) receptor as mutants lacking the receptor have defective feedback regulation with very high P450 transcript levels and BR accumulation observed. Binding of the BRASSINAZOLE RESISTANT1 (BZR1) transcription factor, a transcription factor involved in BR signaling (see Chapter 18), has identified a specific BR-response element to which BZR1 binds as a repressor. This response element has also been identified in the promoters of the other P450 genes in BR synthesis indicating coordinated repression of BR synthesis genes.

17.6.4 Chemical inhibitors have been used to dissect pathways of BR biosynthesis

The use of inhibitors of plant hormone biosynthesis complements studies with biosynthetic mutants in helping to elucidate metabolic pathways. They also provide phenotypic evidence for the role the hormone plays in growth and development in species for which mutants are difficult to generate. Triazoles, such as uniconazole and paclobutrazol (see Fig. 17.8), inhibit *ent*-kaurene oxidase, a CYP450 involved in GA biosynthesis (see Fig. 17.7). Modification of uniconazole in which the *tert*-butyl group is replaced by a phenyl group generated brassinazole, a strong inhibitor of BR synthesis (Fig. 17.8). Treatment of plants with brassinazole generates phenotypes similar to BR-synthesis mutants by inhibiting the C-22 hydroxylase reaction catalyzed by CYP90B.

17.6.5 BR metabolism routes have been identified

Mutants and genes

Both molecular genetic and chemical approaches have helped elucidate mechanisms of BR metabolism. Activation tagged mutants leading to over expression of CYP734A1 and CYP72B1 generates phenotypes similar to the BR-deficient dwarf mutants. CYP734A1 overexpression mutants accumulate C-26 hydroxylated BRs and the recombinant enzyme has been shown to have C-26 hydroxylase activity. CYP72B1 overexpression mutants do not accumulate C-26 hydroxylated BRs and its function is yet to be defined. CYP734A1 transcript levels are under positive feedback regulation by BRs whereas CYP72B1 transcription does not seem to be affected.

Molecular genetic techniques have also revealed the importance of glycosylation and sulfonation in BR metabolism. Analysis of UDP-glycosyltransferases (UGTs) has shown that plant steroids can act as substrates, and in *Arabidopsis* 23-O-glucosylation of BL and CS is observed. Transgenic plants overexpressing UGT73C5 contained reduced amounts of BRs and displayed BR-deficient phenotypes that can be rescued by exogenous application of BRs. Sulfonation of BRs by recombinant plant steroid sulfotransferase has been observed although the substrate range of these enzymes is limited and BR-sulfates have not been observed in plants.

FIGURE 17.58 Biosynthesis of BL from campesterol. Intermediates with turquoise background are those originally observed as the early C-6 oxidation pathway. Intermediates with pink background indicate most likely synthesis route. Location and class of CYP450 enzymes are provided: 85A1, C-6 oxidase (nonlactonizing); 85A2, C-6 oxidase (lactone – BL formation); 90B, C-22 hydroxylase; 90C/D, C-23 hydroxylase; DET2, DEETIOLATED2 = 5 α -reductase; CYP90A1, C-3 oxidation. Broken arrows indicate probable multienzyme catalyzed reaction with other intervening intermediates, solid arrows indicate single step.

FIGURE 17.59 Metabolism of castasterone (CS) and BL. In addition to the metabolites indicated, water-soluble metabolites are formed from CS and BL, but their structures have not been determined.

Analysis of metabolites

Molecular genetic approaches are complemented with experiments focused on chemical analysis of metabolism products of BRs including CS and BL. This has provided further mechanisms of BR deactivation (Fig. 17.59) although many water-soluble metabolites with undetermined structures are also formed. Metabolism of 24-epicastasterone and 24-epibrassinolide, though rare in plants, has been investigated in most detail (Figs. 17.60 and 17.61). From these studies, four basic reaction sequences have been identified, the type of metabolism observed being dependent on plant species and BR used.

Epimerization of the 2- and 3-hydroxyls, followed by glucosylation or esterification

The α -hydroxyls on the A-ring often epimerize to form β -hydroxyls. 3-Epicastasterone is found as a minor metabolite of CS in tobacco and rice seedlings (see Fig. 17.59). 3-Epimerization has also been observed following application of 24-epicastasterone and 24-epibrassinolide to cell cultures of *S. lycopersicum* and serradella (*Ornithopus sativus*) (Figs. 17.60 and 17.61). 2-Epimerization is observed when *Cucumis sativus*

seedlings metabolize 24-epibrassinolide (Fig. 17.61). Because 2-epicastasterone, 3-epicastasterone, and 2,3-diepicastasterone are major endogenous BRs in *P. vulgaris* seeds, and all are less active biologically than CS, epimerization of the 2- and 3-hydroxyls appears to be a general deactivation reaction.

After 3-epimerization, the resulting 3β -hydroxyl group is esterified with lauric, myristic, or palmitic acids in *Ornithopus* cells (Figs. 17.60 and 17.61). Lily (*Lilium* sp.) pollen contains teasterone-3-O-esters conjugated with lauric and myristic acids. However, no acyl conjugates of typhasterol, CS, and BL are known to occur naturally, suggesting that only the 3β -hydroxyl is susceptible to conjugation with fatty acids. In *S. lycopersicum* cells, 3-epimerization is not followed by esterification but with glucosylation of either the 2α - or the 3β -hydroxyl group. Accordingly, 3-epimerization to form a 3β -hydroxyl group precedes further conjugation.

Hydroxylation of C-20 and successive side chain cleavage

Hydroxylation of C-20 has been observed after application of 24-epicastasterone and 24-epibrassinolide to *Ornithopus* cells

FIGURE 17.60 Metabolism of 24-epicastasterone. *Present as glycoside(s) in *S. lycopersicum* cells. **Identified as the free form in *Ornithopus* cells.

(Figs. 17.60 and 17.61). 20-Hydroxylation probably occurs after 3-epimerization and is followed by cleavage of the bond between C-20 and C-22, which yields pregnane derivatives. A pregnane-6,20-dione derived from 24-epicastasterone undergoes further reduction of the 6-keto group to form a 6 β -hydroxyl moiety.

Glucosylation of C-23 hydroxyl group

In *Vigna radiata* cuttings, BL is converted almost exclusively to its 23-O-glucoside, while CS is converted to nonglycosidic

metabolites (see Fig. 17.59). 23-O-glucosides of 25-methyl-dolichosterone and its 2-epimer are endogenous components in immature seeds of *P. vulgaris*. 23-O-glucosylation, therefore, appears to be an important deactivation step in some legumes.

Hydroxylation of C-25 and C-26 and subsequent glucosylation

In cultured cells of *S. lycopersicum*, 24-epimers of CS and BL are not metabolized to 23-O-glucosides. Instead, the C-25 or

FIGURE 17.61 Metabolism of 24-epibrassinolide.

C-26 positions are subjected to hydroxylation followed by glucosylation (Figs. 17.60 and 17.61). Thus, modification of the BR side chain may be determined by whether there is a 24 α - or 24 β -methyl group present. Other possibilities cannot be ruled out, however, as metabolism of the α - and β -isomers have not been examined in the same plant species. 25-Hydroxy-3,24-diepicastasterone is derived from 24-epicastasterone in *S. lycopersicum* cells, while 25-hydroxy-3,24-diepicastasterone is produced from 24-epibrassinolide in *Ornithopus* cells.

In the *O. sativa* lamina inclination assay (see Fig. 17.54), 25-hydroxylation increases biological activity of 24-epibrassinolide 10-fold, whereas 26-hydroxylation reduces activity. 25-Hydroxy BRs are inactive when applied to *Arabidopsis* BR-mutants. 25-Hydroxy-BL has not been detected in plants and among the naturally occurring BRs, BL exhibits the most biological activity.

17.7 Polyamines

Polyamines (PAs) are organic polycations commonly found in both prokaryotes and eukaryotes. Because of their polycationic nature, PAs have a high affinity for anionic constituents such as DNA, RNA, phospholipids, and acidic proteins, as well as anionic groups in membranes and cell walls. PAs stimulate many reactions involved in the synthesis of DNA, RNA, and proteins, and are essential for the growth and development of living cells. PAs elicit diverse physiological responses in plants, including cell division, tuber formation, root initiation, embryogenesis, flower development, fruit ripening, and stress tolerance. Because PAs are much more abundant in plants than other hormones, and because millimolar concentrations of PAs are required to induce a biological response, PAs may not have a truly hormonal role. Instead, as is the case in animals, they appear to participate, directly or indirectly, in

FIGURE 17.62 Structures of PAs. Putrescine, spermidine, and spermine are commonly found in plants.

several key processes and metabolic pathways, which are essential for normal growth and development.

The PAs found most frequently in plants and other organisms are putrescine, spermidine, and spermine (Fig. 17.62). In addition, several uncommon PAs, such as homospermidine, norspermidine, norspermine, thermospermine, and cadaverine, have been found in plants. Although cadaverine is present at lower concentrations than the other PAs, it is a common constituent of legumes. Plant PAs occur both as free amines and as amide conjugates of hydroxycinnamic acids such as *p*-coumaric, ferulic, and caffeic acids. These conjugates represent a significant portion of the total PA pool. Participation of conjugates in various cellular processes is seen in the association between

hydroxycinnamic acid amide accumulation and flowering, seed and fruit development, and hypersensitive responses to viral and fungal infections.

17.7.1 The first step of polyamine synthesis is decarboxylation of arginine or ornithine

The first step of PA biosynthesis is decarboxylation of the amino acids Arg or ornithine (Orn), which is catalyzed by Arg decarboxylase (ADC) or Orn decarboxylase (ODC) (Fig. 17.63). Putrescine synthesis from Arg requires three enzymatic steps catalyzed by ADC, agmatine iminohydrolase, and *N*-carbamoylputrescine amidohydrolase, but putrescine can also be directly made by Orn decarboxylation. Since ODC in plants is usually less active than ADC, Arg decarboxylation is the major pathway for putrescine synthesis. In *S. lycopersicum* roots, expression pattern of ODC is different from ADC in terms of response to sucrose, CK, and auxin, suggesting a differentiation of physiological role between the two pathways. On the other hand, there are two ADC genes (*ADC1* and *ADC2*) but no ODC gene in *Arabidopsis*, indicating that PAs are exclusively produced via ADC in *Arabidopsis*. Seeds from an ADC double mutant are abnormal and fail to germinate.

Despite some conflicting evidence, ODC enzymes from *H. vulgare*, jute (*Corchorus* spp.), and *S. lycopersicum* generally exhibit end-product inhibition in the presence of putrescine, spermidine, or spermine. However, ADC enzymes from *A. sativa*, *O. sativa*, *C. sativus*, and *Lathyrus sativus* are inhibited by agmatine but are relatively insensitive to PAs. Environmental stresses increase ADC activity, upregulating putrescine production. Abiotic stresses, such as low temperatures, high salt, and dehydration, as well as ABA treatment, induce expression of *ADC1* or *ADC2* in *Arabidopsis*. The potent enzyme inhibitors α -difluoromethylarginine and α -difluoromethylornithine irreversibly inhibit ADC and ODC, respectively.

17.7.2 Putrescine is converted to spermidine and spermine

Spermidine synthase catalyzes the conversion of putrescine to spermidine, and spermine synthase converts spermidine to spermine (Fig. 17.63). Both enzymes transfer an aminopropyl group from decarboxylated *S*-adenosyl-L-methionine (dSAM) to their respective substrates. *S*-Adenosyl-L-methionine decarboxylase (SAM decarboxylase) converts SAM to dSAM. The synthesis of dSAM is inhibited by spermidine but increases in response to increasing putrescine. Because SAM is also a precursor of ethylene, and because PAs and ethylene inhibit each other's biosynthesis, control of the fate of SAM may significantly influence plant growth (see Section 17.5.4).

FIGURE 17.63 Biosynthesis of putrescine, spermidine, and spermine. In most plants, arginine decarboxylase is more active than ornithine decarboxylase. Thermospermine could be synthesized in some plant species.

FIGURE 17.64 Biosynthesis of cadaverine. The responsible genes for cadaverine synthesis have not been identified in plants.

In *Arabidopsis*, there are two genes for spermidine synthase (*SPDS1* and *SPDS2*) and two for spermine synthase (*ACL5* and *SPMS*). Recent studies have demonstrated that *ACL5* catalyzes synthesis of thermospermine rather than spermine. A loss-of-function mutant of *ACL5* has severe defects in stem elongation, but exogenous application of thermospermine, but not spermine, rescues the phenotype, indicating that thermospermine is required for normal stem elongation in *Arabidopsis*.

17.7.3 Cadaverine is synthesized from Lys or L-homoarginine

Cadaverine synthesis from L-Lys is catalyzed by Lys decarboxylase (Fig. 17.64). Lys decarboxylase activity is low in most plant tissue but in some leguminous species Lys decarboxylase activity increases with the accumulation of quinolizidine alkaloids, which are synthesized from cadaverine. In *L. sativus*, cadaverine is produced either from Lys or from L-homoarginine by way of homoagmatine (Fig. 17.64). Both conversions are catalyzed by a single decarboxylase that is distinct from Arg decarboxylase and Lys decarboxylase. The genes encoding cadaverine synthesis have not been identified in plants.

17.7.4 Polyamines are degraded by oxidative deamination

PAs are catabolized by oxidative deamination catalyzed by diamine oxidase and polyamine oxidase (Fig. 17.65). Diamine oxidase, a copper-containing enzyme, has a high affinity for diamines such as putrescine and cadaverine. The terminal (primary) amino groups are subjected to oxidative deamination, resulting in the co-production of aminoaldehyde, hydrogen peroxide, and ammonia. The aminoaldehydes derived from putrescine and cadaverine cyclize spontaneously

to yield 1-pyrroline and 1-piperidine, respectively. PAs are precursors of various important alkaloids, and diamine oxidases participate in the biosynthesis of alkaloids containing a heterocyclic ring.

A second class of plant flavin enzymes, polyamine oxidases, catabolize spermidine and spermine, by oxidation of secondary amino groups, forming hydrogen peroxide, 1,3-diaminopropane, and aminoaldehydes. The aminoaldehydes derived from spermidine and spermine are 4-aminobutyraldehyde and 4-(3-aminopropyl)aminobutyraldehyde, respectively. A part of PA degradation appears to occur in the apoplast, as polyamine oxidase activity is detected in the cell wall fraction. Hydrogen peroxide generated by these oxidases may be involved in lignifying cell walls.

There are five *Arabidopsis* genes for polyamine oxidase (*PAO1* to *PAO5*). *PAO1* and *PAO4* convert spermine to spermidine, and *PAO3* converts spermine to spermidine and spermidine to putrescine. These lines of evidence indicate an involvement of these polyamine oxidases in back-conversion pathways, which have been demonstrated in mammals. In addition, *PAO2*, *PAO3*, and *PAO4* are localized in peroxisomes, suggesting a novel role for peroxisomes in PA metabolism. The hydrogen peroxide produced by these oxidases is unlikely to play a specialized role in cell function because peroxisomes efficiently eliminate hydrogen peroxide.

17.8 Jasmonic acid

Jasmonic acid (JA) and related compounds, often referred to as jasmonates collectively, were initially isolated as inhibitors of plant growth. Later, they have been shown to regulate various physiological processes in plants, including development of flowers and defense responses against herbivores and fungal pathogens. Jasmonates are similar structurally to prostaglandins, autacoidal hormones that exhibit various biological activities in mammals (Fig. 17.66). Both jasmonates and prostaglandins are derived from fatty acids.

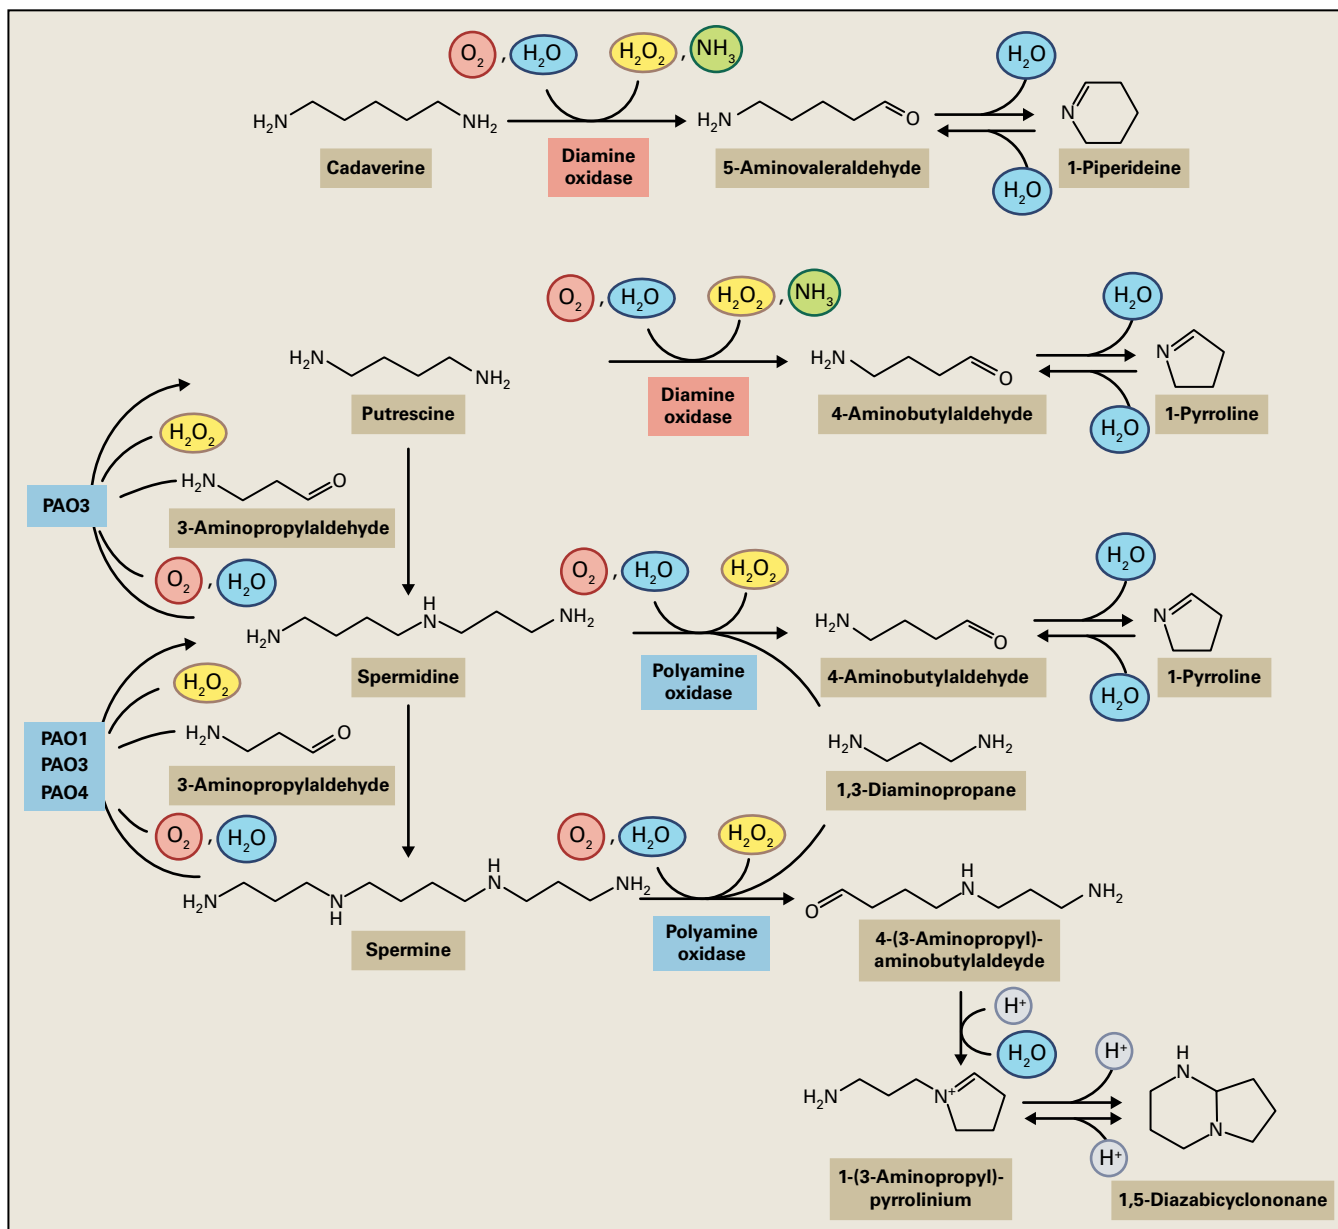

FIGURE 17.65 Catabolism of PAs by diamine oxidases and polyamine oxidases. Some *Arabidopsis* polyamine oxidases (PAO1, PAO3, PAO4) may be involved in PA back-conversion pathways.

Methyl jasmonate is well known in the perfume industry as a fragrant component of the essential oils of jasmine (*Jasminum grandiflorum*).

In 1971, JA was isolated from culture filtrates of a fungus, *Botryodiplodi theobromae*, as a plant growth inhibitor. Cucurbitic acid (Fig. 17.66) was isolated from immature pumpkin (*Cucurbita* sp.) seeds in 1977 and identified as a new type of growth inhibitor, different from ABA. In the early 1980s, JA and methyl jasmonate were detected as senescence-promoting or growth-retarding substances in many plant species, including *Artemisia absinthium* (wormwood), *Vicia faba*, *P. vulgaris*, *Dolichos lablab*, and *Castanea crenata*. In 1989, the 12-O- β -glucoside of tuberonic acid (12-hydroxy-(+)-7-isojasmonic acid; Fig. 17.66) was characterized as a potato tuber-inducing factor.

(-)-JA and methyl (-)-jasmonate are the major jasmonates isolated from plant tissues. Their naturally occurring stereoisomers, (+)-7-isojasmonic acid and methyl (+)-7-isojasmonate, also appear to be active agents in plants because they exhibit higher biological activity in some, but not all, test systems. In vitro, (+)-7-isojasmonic acid is unstable and is isomerized by treatment with acid, base, or heat to form a 9:1 equilibrium mixture of (-)-JA: (+)-7-isojasmonic acid, because the carbonyl group at C-6 can tautomerize to an enol by utilizing the proton from C-7. To what extent this chemical process is involved in conversion of (+)-7-isojasmonic acid to (-)-JA in plants is unclear. Whether (-)-JA occurs naturally or is an artifact derived from (+)-7-isojasmonic acid has been the subject of debate. However, identification of the *trans*-alkyl compound, 6-*epi*-7-isocucurbitic acid (which does not

FIGURE 17.66 Structures of JA and its derivatives. The structure of prostaglandin E1, a mammalian autacoidal hormone, is also shown.

possess the C-6 carbonyl group; Fig. 17.66), in plant extracts supports the view that (–)-JA is an endogenous constituent of plant tissues.

17.8.1 Jasmonates inhibit growth processes in many tissues and are essential for reproductive development and pathogen resistance

Exogenous JA was first reported to inhibit the growth of *O. sativa*, *T. aestivum*, and *L. sativa* seedlings; it was subsequently shown to inhibit seed and pollen germination, retard root growth, and promote the curling of tendrils. JA content is high in vegetative sink tissues, and the compound regulates accumulation of vegetative storage proteins during seed development in *Glycine max* and *Arabidopsis*.

Arabidopsis mutants severely defective in JA biosynthesis or response are male sterile. Fertility of such JA synthesis mutants can be rescued by exogenous JA treatment. In *Arabidopsis* JA-deficient mutants, anther filaments do not elongate sufficiently to a position above the stigma, suggesting

that JA plays a role in coordinating the timing of growth and development of floral organs. In addition, anther dehiscence does not occur at the time of flower opening and the majority of mutant pollen grains are not viable in JA-deficient mutants.

JA plays an important role in plant resistance to insects and necrotrophic pathogens. Plants accumulate JA and its derivatives when they are wounded or treated with pathogen-derived elicitors (oligosaccharides). Exogenous treatment with JA activates expression of hundreds of defense-related genes. Changes in gene expression result in upregulation of synthesis of defense-related proteins and metabolites, including antifungal proteins, antifeedants, phytoalexins, and volatiles that attract predatory insects. JA treatment also downregulates expression of genes encoding enzymes involved in growth and primary metabolism, including photosynthesis, so that resources can be used for defense.

17.8.2 Jasmonates are synthesized from α -linolenic acid

The first step of JA biosynthesis is release of α -linolenic acid, a C_{18} poly-unsaturated fatty acid, from plastid membrane lipid by lipase (Fig. 17.67). This enzyme was first discovered using the *Arabidopsis defective in anther dehiscence 1 (dad1)* mutant, defective in flower development due to JA-deficiency. α -Linolenic acid is converted to 13-hydroperoxylinolenic acid by 13-lipoxygenase, and then allene oxide synthase (AOS) catalyzes the formation of 12,13(*S*)-epoxylinolenic acid. AOS is a plastid-localized CYP450 enzyme with several unusual characteristics. Unlike the majority of CYP450 enzymes which act as monooxygenases, AOS does not require oxygen and is therefore not an oxidase, nor does it require NADPH or P450 reductase. 12,13(*S*)-epoxylinolenic acid, the product of AOS, is rapidly cyclized by the enzyme allene oxide cyclase (AOC), yielding 12-oxo-*cis*-10,15-phytodienoic acid (OPDA), a cyclopentanone derivative. AOC also is a plastid-localized enzyme carrying an amino-terminal plastid-targeting sequence.

The second stage of JA biosynthesis occurs in the peroxisome, suggesting that OPDA produced in the plastid is first exported from this organelle and then imported into the peroxisome for subsequent metabolic conversions. The mechanism for this export is not understood, whereas import into peroxisomes of *Arabidopsis* is partly dependent on the ATP-cassette transporter PXA1/CTS. In the peroxisome, OPDA is first converted to 3-oxo-2-(*cis*-2'-pentenyl) cyclopentane-1-octanoic acid (OPC-8:0) by OPDA reductase (OPR) (Fig. 17.67). This enzyme was first purified from *Corydalis sempervirens*. Subsequent reverse genetic studies in *Arabidopsis* showed that a specific isoform encoded by the OPR3 gene participates in JA synthesis. OPC-8:0 is activated by a carboxyl-CoA ligase, which is encoded by the *OPCL1* gene in *Arabidopsis*, and then converted to (+)-7-isojasmonic acid by three rounds of β -oxidation (see Fig. 17.67 and Chapter 8.8.5). β -Oxidation in plants is catalyzed by

FIGURE 17.67 Biosynthesis of jasmonoyl-isoleucine in plants. The first step of jasmonoyl-isoleucine biosynthesis is release of α -linolenic acid from plastid membrane lipid. Enzymes and metabolic conversions that occur in the plastid and the peroxisome are shown in green and blue, respectively. Subcellular localization of JAR1 has not been determined experimentally, but it is thought to be a cytosolic enzyme because of a lack of any apparent organelle targeting sequence. OPDA, 12-oxo-*cis*-10,15-phytodienoic acid; OPC, 3-oxo-2-(*cis*-2'-pentenyl)-cyclopentane-1-octanoic acid.

acyl-CoA oxidase, a multifunctional protein (which exhibits 2-*trans*-enoyl-CoA hydratase, L-3-hydroxyacyl-CoA dehydrogenase, D-3-hydroxyacyl-CoA epimerase, and $\Delta^3\Delta^2$ -enoyl-CoA isomerase activities), as well as a L-3-ketoacyl-CoA thiolase.

17.8.3 Jasmonoyl-isoleucine is an active hormone in the jasmonate signaling pathway

JA is subjected to an amide-linked conjugation to isoleucine (Ile) and other amino acids to yield jasmonoyl-isoleucine (JA-Ile) and other jasmonoyl-amino acid conjugates, respectively (Fig. 17.67). In *Arabidopsis*, these conjugation reactions are catalyzed by an enzyme encoded by the *JAR1* (*JASMONATE RESISTANT 1*) locus. *JAR1* belongs to a large gene family encoding enzymes that adenylate a carboxyl group of the substrate followed by an exchange with a second substrate, which, in the case of *JAR1*, is an amino acid. Similar reactions are catalyzed by a subset of GH3 family proteins for synthesis of amino acid conjugates of IAA (see Section 17.4.8).

jar1 mutants were isolated because of their resistance to exogenous JA in a root growth inhibition assay. The *jar1* phenotype suggests that conversion of JA to JA-Ile is required to activate the JA signaling pathway. Recently, researchers have found that JA-Ile stimulates binding of the F-box protein CORONATINE-INSENSITIVE 1 (COI1) to jasmonate ZIM domain (JAZ) proteins, a class of negative regulators of JA signaling. The COI1-JAZ interaction triggered by JA-Ile promotes the ubiquitination-dependent degradation of JAZ proteins by the 26S proteasome. Studies with *coi1* mutants have shown that COI1 is required for most, if not all, JA responses. Taken together, these results indicate that COI1 is a critical perception component of the JA signal. Unlike JA-Ile, other jasmonate compounds, including (–)-JA, methyl (–)-jasmonate and OPDA are unable to activate COI1-JAZ interaction in vitro. These findings indicate that JA-Ile, as well as other JA-amino acid conjugates that also promoted COI1-JAZ interactions, act as active hormones in the JA signaling pathway.

Evidence suggests that JA-Ile synthesis is under positive feedback regulation. Many genes that encode JA-Ile biosynthesis enzymes are positively regulated by JA treatment, including 13-lipoxygenase, AOS, AOC, OPDA reductase (OPR3), and *JAR1* (Fig. 17.67).

17.8.4 Coronatine is a bacterial toxin that activates jasmonate signaling

Coronatine (CO) is a phytotoxin produced by some plant pathogenic bacteria. There is evidence that CO exerts its virulence effects by activating JA signaling in host plants. The structural similarity of CO to JA-Ile supports the idea that

FIGURE 17.68 Structural similarity between coronatine, a bacterial toxin (left) and jasmonoyl-isoleucine (right). To highlight the similarity, these structures are superimposed (center).

FIGURE 17.69 Metabolism of JA in plants. JA is metabolized through modification of the carboxyl group (blue), C-12 oxidation (orange) or the reduction of C-6 ketone (green). 12-Hydroxy-(+)-7-isojasmonic acid is further metabolized to conjugates.

this toxin acts as a molecular mimic of JA-Ile (Fig. 17.68). This hypothesis has been proven by recent experiments showing that CO binds directly to COI1-JAZ complexes *in vitro* even more effectively than does JA-Ile. CO appears to reduce the effectiveness of salicylic acid-dependent disease resistance responses by activating the JA signaling pathway.

17.8.5 JA is metabolized to various products via multiple pathways

Besides being converted to amino acid conjugates, JA can undergo several other modification reactions (Fig. 17.69). So far, only a few enzymes involved in these reactions have been identified, and the biological roles of these modifications are not fully understood. JA is converted to volatile methyl jasmonate by an SAM-dependent carboxyl methyltransferase. Methyl jasmonate is thought to act as an airborne signal in interplant communication, being released in response to wounding and other abiotic stresses. Another volatile compound, *cis*-jasmone, is synthesized from JA by decarboxylation (Fig. 17.69), but the enzyme responsible for this reaction has not been clarified. Gene expression profiling of

cis-jasmone-regulated genes in *Arabidopsis* revealed a unique and more limited set of genes upregulated by *cis*-jasmone treatment in comparison with methyl jasmonate treatment, suggesting a unique role of *cis*-jasmone in defense responses. The carboxyl group of JA can also be modified through conjugation with glucose to give jasmonoyl-1-β-glucose in cell cultures of tobacco and tomato.

12-Hydroxy-(+)-7-isojasmonic acid is also known as tuberonic acid (see Fig. 17.66) because of its tuber-inducing activity in potato, whereas its glucoside appears to be the transport form. Systematic investigation of the biochemical functions of *Arabidopsis* sulfotransferases identified an enzyme, designated as AtST2a, that catalyzes sulfonation of 12-hydroxy-(+)-7-isojasmonic acid using 3'-phosphoadenosine 5'-phosphosulfate as a sulfate donor (Fig. 17.69). Recent survey of 12-hydroxy-(+)-7-isojasmonic acid and its sulfonated and glucosylated derivatives demonstrated that these compounds are constituents of various organs of many plant species. Thus, 12-hydroxylation of JA and subsequent glucosylation and sulfonation appears to be a widespread JA metabolic route in plants. Reduction of the C-6 keto group of the cyclopentanone ring leads to the formation of cucurbitic acid.

17.9 Salicylic acid

Salicylic acid (SA) (see Fig. 17.1) is far better known for its medicinal properties (Box 17.1) than for its regulatory roles in plants. Although many physiological effects of SA application have been reported, only a few have been shown to be physiologically important in plants, for example, the regulatory role of SA in thermogenesis of various species and in the response of plants to pathogens.

17.9.1 Salicylic acid can retard senescence of petals and induce flowering

Soluble aspirin tablets disintegrate rapidly in water, and the acetylsalicylic acid is converted to SA. Adding aspirin to a vase of water containing cut flowers will retard senescence of petals and make flowers last longer. This is probably a

consequence of reduced rates of ethylene biosynthesis, in light of reports that SA blocks the conversion of ACC to ethylene. SA also induces flowering in the duckweeds *Lemna gibba*, *Spirodela polyrrhiza*, and *Wolffia microscopia* when these long-day plants are grown under a noninductive short day photoperiod (Chapter 19). This effect is not specific, however, and related phenolics also can stimulate flowering in these and other species. Furthermore, because SA concentrations are similar in vegetative and induced tissues, the compound is unlikely to be an endogenous flower-inducing signal.

17.9.2 Salicylic acid regulates thermogenesis in voodoo lily

Clear evidence linking endogenous SA with a regulatory role in plants was first obtained during studies on thermogenesis in flowers of voodoo lily (*Sauromatum guttatum*). During thermogenesis, much of the electron flow in mitochondria is

BOX 17.1

Salicylic acid has been used as an analgesic for more than 2,000 years

Since the 4th century BC, plants such as willow, myrtle, poplar and meadowsweet have been used to relieve pain caused by a variety of conditions, including diseases of the eye, rheumatism, childbirth and fever. The active component remained unknown until the 19th century when SA and related compounds, such as methyl salicylate, saligenin, and their glycosides, were isolated from willow and other plant sources. Oil of wintergreen extracted from the American plant, *Gaultheria procumbens*, was an especially rich source of methyl salicylate and was a widely used analgesic during the mid-19th century.

In 1858, salicylic acid was chemically synthesized in Germany, and its commercial production began in 1874 at one tenth the cost of making wintergreen oil. However, the sharp bitter taste and gastric irritation associated with SA made long term use difficult. This problem was overcome in the 1890s, when clinical tests carried out by the German pharmaceutical company Frederick Bayer and Co. showed that these side effects could be avoided by replacing SA with its acetylated derivative. In 1898, acetylsalicylic acid was given the trade name aspirin. Within one year of its launch, aspirin began to be manufactured in tablet form, rather than as a powder, and sales soon swelled to amazing proportions.

More than 100 years later, aspirin tablets are still sold widely as a ready remedy for many conditions, including the common cold, headache, fevers, and rheumatoid arthritis. Aspirin is also increasingly used to prevent and

treat heart attacks and cerebral thrombosis. The beneficial effects ascribed to acetylsalicylic acid include retarding production of prostaglandins, which promote blood clotting. Moreover, a growing number of discerning airline passengers are taking a precautionary aspirin tablet prior to departure to lessen the risks, albeit relatively small, of blood clots and coronary problems associated with long flights. The current world production of aspirin is many thousands of tons per year, and average consumption in developed countries is about 100 tablets per person per annum.

Methyl salicylate

Saligenin

Acetylsalicylic acid

diverted from the cytochrome respiration pathway to the cyanide-insensitive nonphosphorylating electron transport pathway unique to plant mitochondria (Chapter 14). Also, the glycolytic pathways and Krebs cycle enzymes, which provide substrates for alternative oxidase, are activated. Energy released by electron flow through this alternative respiratory pathway is not conserved as chemical energy but is released as heat. The flower of *S. guttatum* develops from a corm and can reach more than 70 cm in height (see Box 14.2). On the day of anthesis, the spathe unfolds and shortly afterwards the upper spadix begins to generate heat, volatilizing pungent amines and indoles that attract insect pollinators. The temperature of the spadix can increase to 14°C above ambient by early afternoon but falls to normal values by evening. A second burst of thermogenicity begins in the lower spadix in late evening and ends early next morning after an increase in temperature of more than 10°C (Fig. 17.70). In 1937 it was proposed that thermogenesis in *S. guttatum* was initiated by “calorigen,” a water-soluble substance produced in the staminate flower primordia positioned between the upper and lower spadix. In 1987, calorigen was identified as SA when it was shown that treating immature spadix sections with as little as 0.12 µg of SA per gram fresh weight caused their temperatures to rise by as much as 12°C. Large increases in endogenous concentrations of SA occur immediately prior to onset of thermogenicity in both upper and lower spadix.

17.9.3 Salicylic acid production is associated with disease resistance

More widespread interest in SA was generated when it was closely linked to the hypersensitive response, a disease resistance mechanism in which plants restrict spread of fungal, bacterial or viral pathogens by producing necrotic

FIGURE 17.70 The response of the *Sauromatum guttatum* appendix (upper spadix) to application of SA or a crude extract of male flowers of the same species. Both exogenous treatments result in a marked increase in appendix temperature.

lesions around the initial point of penetration (Fig. 17.71). This localized cell death often is associated with changes in healthy, distant parts of plants that enhance resistance to secondary infection by a broad range of pathogens. Increased resistance, which develops over a period of several days to a week following initial pathogen invasion, is referred to as systemic acquired resistance (SAR). Associated with hypersensitive response and SAR is synthesis of five or more families of serologically distinct, pathogenesis-related (PR) proteins. Two of these families encode the hydrolytic β -1,3-glucanases and chitinases. While the precise function of other families of PR proteins is not well understood, their expression is associated with resistance to a large number of viral, fungal, and bacterial pathogens.

The indication that SA was involved in plant defense against disease came with the finding that SA treatment of the leaves of Tobacco Mosaic Virus (TMV)-susceptible tobacco (*N. tabacum* cv. Xanthi *n*) induced the accumulation of PR proteins and enhanced resistance to TMV infection. It has now been shown that SA treatment also induces SAR against many pathogens in a variety of plants. In the TMV-resistant tobacco cultivar Xanthi-*nc*, but not the susceptible Xanthi-*n*, the endogenous SA pool increases about 40-fold in TMV-inoculated leaves and about 10-fold in uninfected leaves of the same plant. The steep rise in SA content parallels or precedes induction of PR protein gene expression in both inoculated and uninoculated leaves of TMV-resistant plants. Endogenous SA, therefore, appears to play a key role in signal transduction leading to activation of genes encoding PR proteins and in establishing the hypersensitive response and SAR. Studies with *C. sativus* and *S. tuberosum*, and other species indicate that involvement of SA in these responses is not unique to *N. tabacum*.

Despite arguments that SA acts as the primary long distance signal translocated in the phloem from the site of pathogen invasion to uninfected leaves where it initiates

FIGURE 17.71 Necrotic lesions on the leaf of resistant *Nicotiana tabacum* formed in response to infection with TMV. Source: J. Draper, University of Wales, Aberystwyth, UK; previously unpublished.

FIGURE 17.72 The *Pseudomonas putida nahG* gene product catalyzes the metabolism of SA to catechol.

development of the SAR response, grafting studies with wild-type and TMV-susceptible transgenic Xanthi-*nc* tobacco plants have refuted this hypothesis. Accumulation of SA is prevented in transgenic plants expressing the *Ps. putida nahG* gene, the product of which catalyzes the conversion of SA to catechol (Fig. 17.72). This research indicates that local infection leads to the production of an unidentified mobile signal that is transported to distal tissues, where it initiates the accumulation of SA required for induction of SAR.

17.9.4 Two distinct pathways exist for the biosynthesis of salicylic acid in plants

In 1993, SA biosynthesis in *N. tabacum* was proposed to involve a side branch of the phenylpropanoid pathway, which converts *trans*-cinnamic acid to benzoic acid (BA), the latter undergoing 2-hydroxylation to form SA (Fig. 17.73). It was suggested that after TMV-inoculation, a large pool of benzoic conjugate (100 $\mu\text{g/g}$ fresh weight) is hydrolyzed, releasing BA, which activates BA 2-hydroxylase (BA2H), responsible for catalyzing the conversion of BA to SA. BA2H has been partially purified and shown to have characteristic features of NADPH-dependent CYP450 monooxygenases, with the exception of being a soluble protein, unlike typical P450 enzymes that are membrane bound. No gene encoding BA2H has been identified. More recent work has suggested that the rate-limiting step in SA biosynthesis is the conversion of *trans*-cinnamic acid to BA, involving a β -oxidation pathway in which *trans*-cinnamoyl-CoA is the first of four intermediates (Fig. 17.73). Indirect evidence supports involvement of *trans*-cinnamic acid as a key intermediate in SA biosynthesis: TMV inoculation of leaves of transgenic Xanthi-*nc* plants, in which phenylalanine ammonia lyase activity is suppressed, exhibit a four-fold lower increase in SA than do inoculated leaves of wild-type plants.

SA is produced as a biosynthetic precursor of a siderophore (iron-chelating compound) by some bacteria, where SA is synthesized from chorismate. In bacteria, chorismate is first converted to isochorismate by isochorismate synthase (ICS), which is then converted to SA and pyruvate by isochorismate pyruvate lyase (IPL). There is evidence that a large fraction of SA in *Arabidopsis* is synthesized from isochorismate as in bacteria: the *ics1/sid2* mutant defective in ICS has been shown to

accumulate only 5-10% of SA of wild type after pathogen infection (Fig. 17.73). So far, no IPL activity has been reported in plants. The discovery of the isochorismate pathway in *Arabidopsis* poses the question of relative contributions of the BA- and isochorismate-dependent pathways. The two pathways may operate under different conditions, although this is not likely to be the case in *Arabidopsis* as the *ics1/sid2* mutant fails to accumulate SA in response to various SA-inducing environmental cues. The relative contribution of the two pathways might differ in plant species. In SA synthesis upon exposure to ozone in *N. tabacum*, radiolabeled BA is incorporated into SA and the *ICS* gene (unique in the genome) is not expressed, suggesting the operation of the BA-dependent pathway. By contrast, in *Arabidopsis* the same ozone treatment led to an induction of the *ICS1* gene.

17.9.5 Methyl salicylate may play a role as a mobile signal in systemic acquired resistance

In both healthy and infected tobacco leaves, the main SA metabolites are SA 2-O- β -glucoside (SAG) and SA β -glucosyl ester (SGE), with the latter occurring transiently and in smaller quantities than the former (Fig. 17.73). UDP glucose-dependent glucosyltransferases that catalyze the formation of SAG and SGE have been identified in *N. tabacum* and *Arabidopsis*. SGE is readily converted back to SA by SA β -glucosidase, which has been partially characterized in *N. tabacum* leaves.

The carboxyl group of SA is methylated to form methyl salicylate (MeSA) by a carboxyl methyltransferase that uses SAM as methyl donor (Fig. 17.73). This enzyme has been identified in several plant species, including *Arabidopsis*, *N. tabacum*, and *Clarkia breweri*. MeSA is converted back to SA by MeSA esterase, SABP2, which was initially purified as a high-affinity SA binding protein from *N. tabacum*. The amino acid sequence of the SABP2 protein indicates that it is a member of the α/β hydrolase superfamily, which shares a conserved α/β core domain and catalyzes hydrolysis of different substrates. Analysis of the crystal structures of SABP2, alone and in complex with SA, revealed an active site typical of α/β hydrolases, with Ser, His, and Asp residues as the catalytic triad. SA is bound in the active site and acts as a potent product inhibitor of catalysis. An amino acid substitution of Ala¹³ to Leu of SABP2 (A13L) results in loss of SA-binding activity without losing its catalytic function as MeSA esterase. Thus, this mutant version of SABP2 is insensitive to product inhibition by SA.

Using the A13L mutant of SABP2, evidence has been provided that MeSA esterase activity of SABP2 is required for SAR signaling in systemic *N. tabacum* leaves. In transgenic *N. tabacum* plants with elevated MeSA esterase activity in infected leaves, MeSA concentrations do not increase in infected leaves, phloem exudates and systemic leaves. Furthermore, SAR is blocked when SA methyl transferase

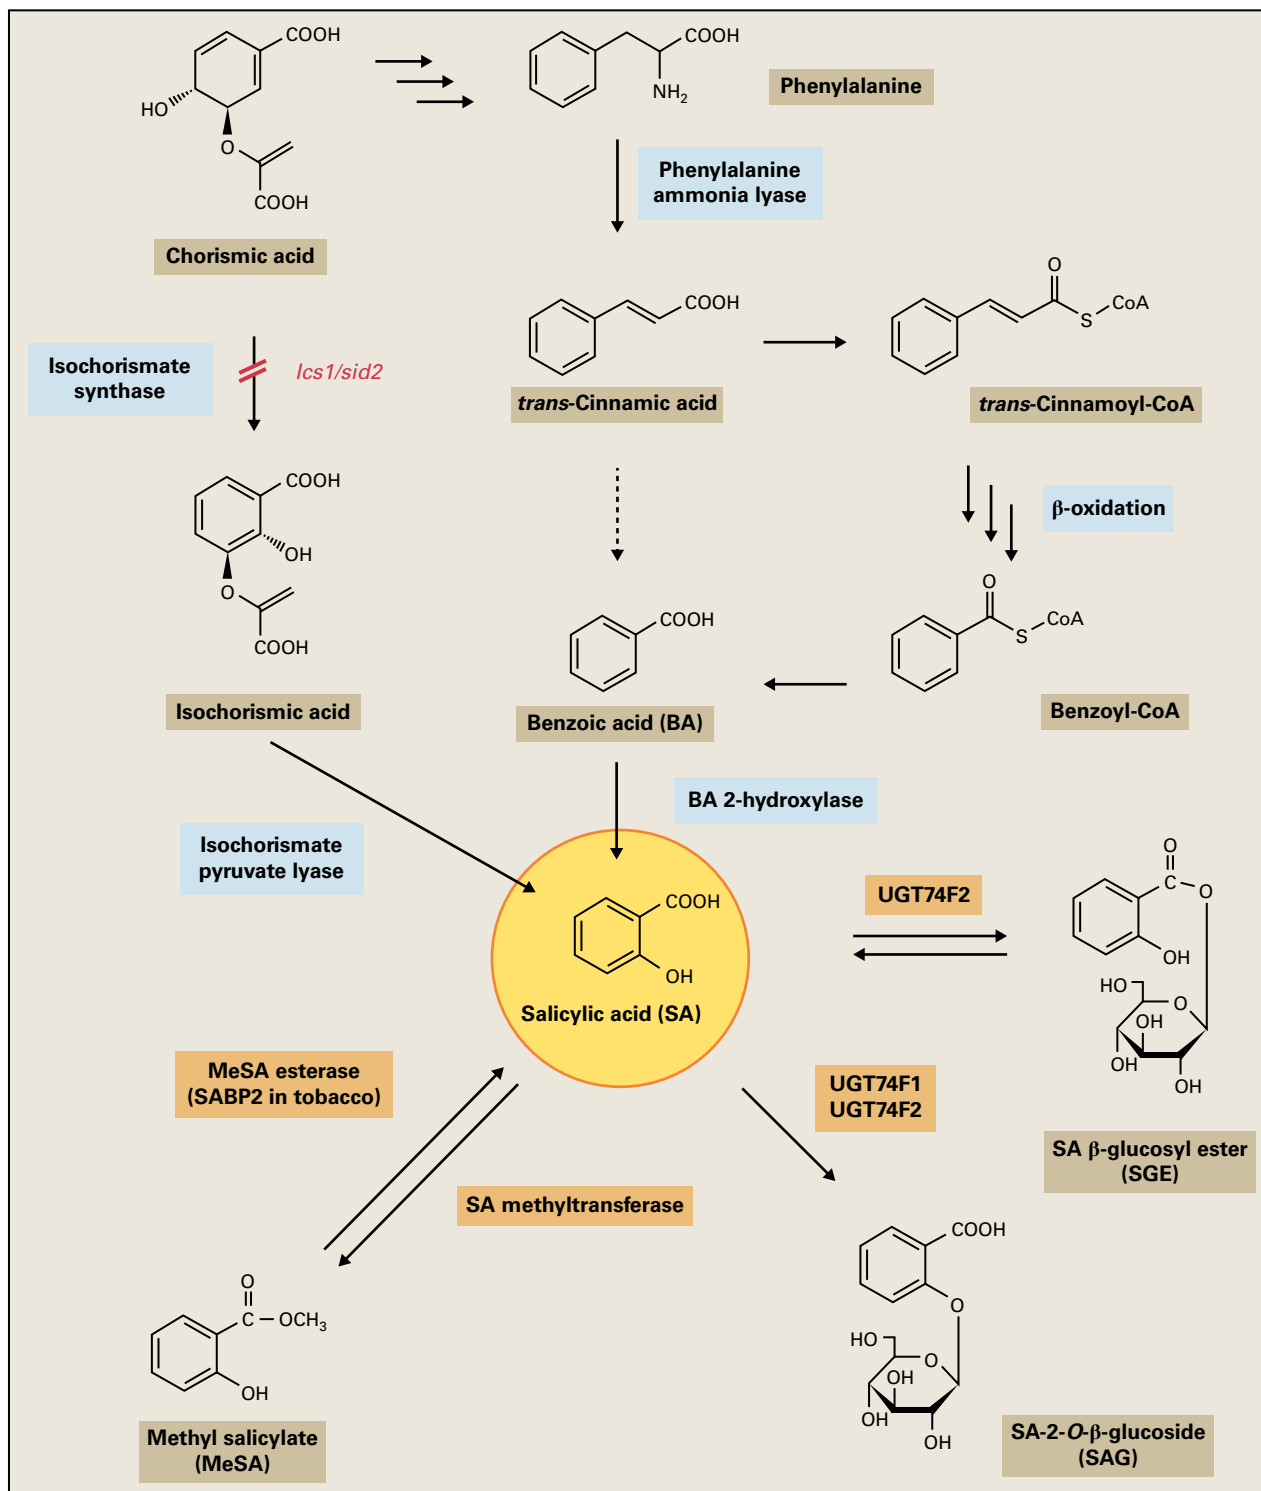

FIGURE 17.73 Proposed SA biosynthesis and metabolism pathways in plants. Current evidence suggests *trans*-cinnamic acid is converted to BA by way of the β -oxidation pathway. A CoA-independent route for the conversion of *trans*-cinnamic acid to BA may also exist (dashed arrow). In *Arabidopsis*, studies using mutants defective in isochorismate synthase (*ics1/sid2*) demonstrate that the majority of SA is synthesized by way of isochorismic acid. For the conversion of chorismic acid to phenylalanine, see Chapter 7. In *Arabidopsis*, UDP-glucose-dependent glucosyl-transferases, designated as UGT74F1 and UGT74G2, catalyze the formation of SA β -glucosyl ester (SGE) and SA-2-O- β -glucoside (SAG).

(which converts SA to MeSA) is silenced in infected leaves, and MeSA treatment of lower leaves induced SAR in upper untreated leaves. Therefore, MeSA has been proposed to be an essential part of the SAR signal in tobacco. However, more

recent work has shown that *Arabidopsis* mutants defective in expression of a SA methyltransferase gene are devoid of pathogen-induced MeSA accumulation but still show increased SA concentrations in systemic leaves and develop

FIGURE 17.74 Structures of naturally occurring strigolactones (SLs) and a synthetic SL analog, GR24.

SAR upon local inoculation of a pathogen, suggesting that MeSA is dispensable for SAR in *Arabidopsis*. Thus, whether MeSA is a common mobile signal for SAR in plants is still under debate and requires further investigations.

17.10 Strigolactones

Parasitic plants of the *Striga*, *Orobanche*, and *Alectra* genera (Orobanchaceae) are root parasites that cause losses in crop yields in many parts of the world. Control of these parasitic plants is difficult because they produce a huge number of seeds that remain viable in soil for many years until they detect germination stimulants released from host roots. A pure crystalline germination stimulant of *Striga* seeds was isolated in 1966 from cotton root exudates. This stimulant, termed strigol, has a characteristic chemical structure, including two lactone rings linked via an enol ether bridge (Fig. 17.74). Later, diverse strigol-related compounds, collectively called **strigolactones (SLs)**, were isolated as germination stimulants of parasite seeds in root exudates of various plant species (Fig. 17.74).

Until recently, a biological function of SLs in host plants was unknown. It was discovered in 2005 that SLs are plant-derived signals that induce hyphal branching of arbuscular mycorrhizal fungi (AM fungi), a phenomenon that is observed at the initial stage of colonization (Fig. 17.75). This symbiotic interaction is observed in more than 80% of terrestrial plants. Since AM fungi facilitate the uptake of water and mineral nutrients such as phosphate and nitrate by host plants, it is considered that plants evolved to produce SLs to enable AM fungi to colonize their roots. Parasitic plants are thought to abuse these chemical signals to recognize the vicinity of a potential host plant (Fig. 17.75). Studies using various SLs and their synthetic analogs suggest that the structure of the CD rings of SLs is crucial for their biological activity.

FIGURE 17.75 SLs are released from roots and act as chemical signals in communication with root parasite seeds and arbuscular mycorrhizal (AM) fungi in the rhizosphere. They also act as endogenous regulators of shoot branching in plants.

Extensive survey of SLs revealed their occurrence in root exudates of a wide variety of plant species, including non-hosts of AM fungi (e.g., brassicaceae, of which *Arabidopsis* is a member). These findings suggested that SLs might have unidentified role(s) in plants. In 2008, it became apparent that SLs were not just chemical signals in the rhizosphere but also endogenous regulators of shoot branching.

17.10.1 Genetic studies suggested a novel carotenoid-derived signal inhibits shoot branching

Shoot branching involves the formation of axillary buds in the axils of leaves and subsequent outgrowth of the buds. In many species, only a small proportion of buds grow to form branches, with both the timing and extent of bud activation being tightly regulated by endogenous and environmental factors. The participation of auxin and CK in the regulation of axillary bud activity has long been known (see Fig. 17.37). Besides these two hormones, studies with excessive shoot branching mutants suggested the involvement of a novel hormone-like compound in inhibiting outgrowth of axillary buds. These mutants include *ramosus* (*rms*) of *P. sativum*, *decreased apical dominance* (*dad*) of *Petunia*, *more axillary growth* (*max*) of *Arabidopsis* and particular *dwarf* (*d*) mutants of *O. sativa*. Grafting experiments suggest that some of these mutations affect genes required for synthesis of this hormone, while others are required for perception or transduction of the signal. For example, the excessive shoot branching phenotype of *max1*, *max3*, and *max4* mutants is rescued when grafted onto wild type rootstock, while the *max2* scion on wild-type rootstock still produces excessive branching (Fig. 17.76). These results suggest that *MAX1*, *MAX3*, and *MAX4* are required for the synthesis of a root-derived graft-transmissible signal that inhibits axillary bud outgrowth, while *MAX2* is involved in perception or transduction of this signal in shoots. Since a *max4* rootstock does not cause excessive branching in wild type scion, the shoot branching inhibitor synthesized in the scion (shoot) is also sufficient to prevent excessive shoot branching (Fig. 17.76).

FIGURE 17.76 Arabidopsis *max* mutants produce more branches in comparison with wild type (WT) (upper panel). The branching phenotype of *max1*, *max3* and *max4* shoots, but not that of *max2* shoots, are rescued when grafted onto a WT rootstock (lower panel).

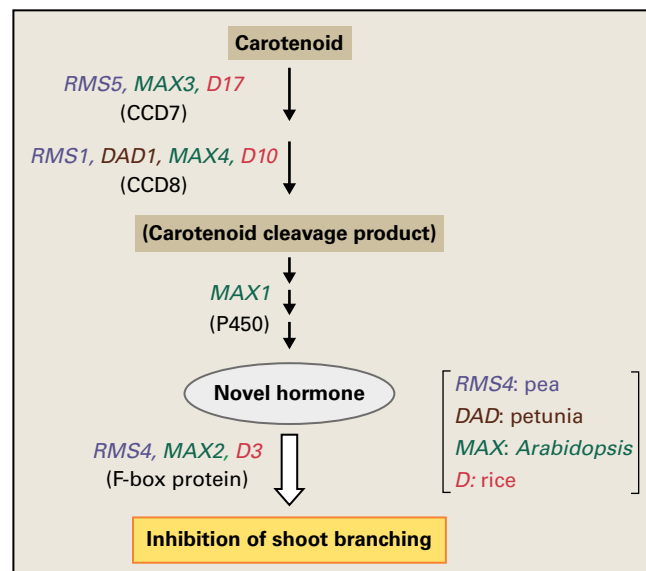

FIGURE 17.77 A hypothetical pathway for the novel shoot branching inhibitor hormone. Carotenoid cleavage dioxygenases (CCDs) and a CYP450 are required for synthesis, whereas an F-box protein is probably involved in perception or transduction of the hormonal signal.

This idea was supported by the molecular identification of *Arabidopsis* *MAX* genes and several *RMS*, *DAD*, and *D* loci in *P. sativum*, *Petunia*, and *O. sativa*. *MAX3*, *RMS5*, and *D17* encode carotenoid cleavage dioxygenase 7 (CCD7), while *MAX4*, *RMS1*, *D10*, and *DAD1* encode another subclass of CCDs designated as CCD8 (Fig. 17.77). *MAX1* encodes a protein in the CYP450 monooxygenase superfamily, of which members are typically involved in metabolism of lipophilic small molecules, as discussed earlier. These findings are consistent with the idea that *MAX1*, *MAX3* and *MAX4* participate in biosynthesis of a carotenoid-derived hormone-like compound. *MAX2*, *RMS4*, and *D3* are orthologous members of the F-box protein family, which are known to function as substrate recognition subunits of SCF ubiquitin E3 ligase for proteasome-mediated proteolysis. Some members of this protein family include *TIR1*, *GID2/SLY1* and *COI1*, all of which are components of hormone perception or signaling (see Chapter 18), suggesting that *max2*, *rms4* and *d3* mutants are defective in a response to the novel hormone.

17.10.2 Strigolactone inhibits shoot branching

Recently, SLs have been shown to inhibit shoot branching in the proposed *RMS/DAD/MAX/D* pathway (Fig. 17.78). Two lines of evidence support this idea. First, SL concentrations in root exudates and in roots are significantly decreased in the *ccd7* and *ccd8* mutants of *P. sativum* and *O. sativa*. Second, axillary bud outgrowth in *ccd7* and *ccd8* mutants of *P. sativum*, *O. sativa* and *Arabidopsis* is inhibited by exogenous SL.

FIGURE 17.78 The excessive branching (tillering) and semi-dwarf phenotypes of the *O. sativa* *d10* mutant are fully complemented by exogenous GR24, a synthetic SL analog (supplied at 1 μ M in the hydroponic culture media). In contrast, the *d3* mutant is insensitive to GR24.

FIGURE 17.79 Oxidative cleavage reactions catalyzed by recombinant CCD7 and CCD8 proteins *in vitro* or in bacterial cells using β -carotene as a substrate. Note that CCD7 can use other carotenoids as substrates and the exact reactions catalyzed by these CCDs in planta has not been conclusive.

Figure 17.78 illustrates the branching phenotype as well as plant height of the *O. sativa* *ccd8/d10* mutant that was nearly fully complemented by including GR24 in culture media. In contrast, *P. sativum* and *O. sativa* branching mutants characterized as lacking a response to the branching inhibitor (*rms4*, *max2*, and *d3*, see Fig. 17.77) were insensitive to exogenous GR24 (Fig. 17.78), and were not deficient in SLs. These results indicate that the inhibitory effect of SLs on shoot branching is specific to the proposed RMS/D pathway. It is not known whether SL itself is an active form of this hormone class, because application of an SL analog might be metabolized in plants and converted to an active compound. Together, current data indicate that SLs act as a new class of branch-inhibiting hormones or their biosynthetic precursors.

17.10.3 Strigolactone biosynthesis pathway remains to be elucidated

Until recently, the biosynthetic origin of SLs was unknown, although their chemical structures suggested that they are terpenoids. In recent studies using chemical inhibitors and mutants of *S. lycopersicum* and *Z. mays*, SLs were shown to be derived from carotenoids. This is consistent with the discovery that carotenoid cleavage dioxygenases, CCD7 and CCD8, participate in SL biosynthesis. Recombinant CCD7 and CCD8 proteins from *Arabidopsis* and *O. sativa* sequentially cleave β -carotene, forming a C_{18} apocarotenoid *in vitro* and in bacterial cells (Fig. 17.79). However, CCD7 could also use other carotenoid substrates, and the exact reactions catalyzed

by these CCDs in planta have not been identified. MAX1, a CYP450 monooxygenase named CYP711A1 potentially catalyzes a later step of SL biosynthesis, although its substrate and product are unknown. Considering the chemical structure of SLs, more enzymes are likely to be required for their biosynthesis from a carotenoid-cleavage product.

17.10.4 Strigolactone biosynthesis is under feedback regulation

In *O. sativa*, *P. sativum*, and *Petunia*, genes encoding CCD8 are highly upregulated in the SL-deficient and -insensitive mutant backgrounds, suggesting feedback regulation of CCD8 expression. Consistent with this, *CCD8/D10* gene expression is downregulated by SL treatment in *O. sativa*. Furthermore, SL levels are substantially increased in the SL-insensitive *O. sativa d3* mutant in comparison with wild type. These results indicate that there is

a link between SL action and biosynthesis in these plant species, as previously recognized for other plant hormones.

17.10.5 Strigolactone production is elevated under mineral nutrient deficiency

The amounts of SLs released from roots are drastically increased under deficiency of phosphate or nitrate in hosts of AM fungi. This is thought to be an adaptive response of plants under nutrient deficiency in order to maximize the symbiotic interaction with AM fungi, which assist the uptake of mineral nutrients by the host plant. This idea is supported by the observation that *Lupinus albus* (white lupin), a nonhost of AM fungi, does not increase SL production in response to phosphate deficiency, unlike the mycotrophic *Trifolium pratense*. These results indicate that SL production is closely related to the strategy of plants for mineral nutrient acquisition.

Summary

A battery of endogenous hormones regulate plant growth and responses to environmental stimuli, including GAs, ABA, CKs, IAA, ethylene, BRs, PAs, JA, SA, and SLs. Most of these compounds are present in plant tissues at low concentrations (nanogram or sub-nanogram per gram fresh weight) and pool sizes are tightly controlled by various biosynthetic, catabolic, and conjugation pathways. To date, the major biosynthesis routes for these hormones have been elucidated and most of the genes encoding enzymes in these pathways have been identified. Combinations of different experimental approaches, including chemistry, biochemistry, molecular biology, and genetics, have contributed to these achievements. The use of hormone-deficient and -overproduction mutants has been particularly powerful in the isolation of new genes, as well as in understanding the biochemical function of gene products.

Although these hormones are diverse in their chemical structures, there are some common features in their biosynthetic and catabolic pathways. Members of the CYP450 monooxygenase superfamily are frequently involved in the biosynthesis and/or deactivation of various hormones, including GAs, ABA, CKs, IAA, BRs, JA, and SLs. Methylation of a carboxyl group by SAM-dependent methyl transferases also participates in homeostasis of multiple hormones discussed in this chapter. With the exception of ethylene, conjugation with glucose or an amino acid commonly occurs in many hormone metabolism pathways. However, in all cases, hormone conjugation is only one of many routes for deactivation. At least in some cases, hormone conjugates are thought to function as a storage form, from which a free, bioactive hormone can be released upon hydrolysis. It has

long been assumed that hormone conjugates are not bioactive per se in plants. However, a recent finding that JA-Ile (and some other amino acid conjugates of JA) might act as an active signal in the JA response pathway provides a new view regarding the role of hormone conjugation.

Studies have shown that the major part of hormone biosynthetic and catabolic pathways are conserved in diverse plant species, but in some cases, species-specific biosynthesis routes have been found, including one of the IAA pathways in *Arabidopsis*, which relates to the production of indole glucosinolates as secondary metabolites in this species. Increasing evidence suggests that many hormones, if not all, function as intermediates between the perception of environmental signals and resulting alterations in growth and developmental patterns. Examples include light-regulation of GA₁ concentrations in lettuce seeds, an increase in ABA concentrations under water stress, and JA accumulation in response to wounding. In addition, hormone concentrations are regulated by the action of other hormones.

There is emerging evidence suggesting that hormone concentrations in plants are determined as a consequence of multiple layers of regulation. For example, in both GA and BR pathways, negative feedback regulation involves a change in accumulation of particular mRNAs encoding biosynthesis and inactivating enzymes. However, as shown for ACS in ethylene biosynthesis, hormone homeostasis can also be controlled by turnover of the enzyme through protein modification. Advances in hormone biosynthesis research have started to expand our understanding of how plants utilize multiple classes of hormones to regulate their growth and development under changing environmental conditions.

Signal Transduction

Ottoline Leyser and Stephen Day

Introduction

Plant cells detect a wide range of signals that originate either within the plant or the surrounding environment, and they use this information to regulate their behavior. In all cases, the responses of cells rely on **signal transduction**—the process by which information is transferred from the site(s) of perception to the site(s) of response. Investigations over recent years have provided detailed molecular descriptions for several intracellular signal transduction pathways, tracing the interactions that link signal perception to cellular responses. In addition, the research reveals how combinations of pathways interact to allow cells to integrate multiple sources of information.

18.1 Characteristics of signal perception, transduction, and integration in plants

18.1.1 Plant cells monitor a continuous, complex stream of information

Plants regulate their biology in accordance with diverse environmental and internal cues. In the physical environment, plant cells detect gravity, temperature, local distributions of soil nutrients and water, and mechanical forces such as wind, the pressure between the root and soil, and internal tension or

compression. They also sense the concentrations of gases such as carbon dioxide, oxygen, and ozone as well as the intensity, direction, and spectral quality of light; indeed, through the perception of light and temperature, they sense the time of day and the time of year. In the biotic environment, cells sense the presence of pathogens, herbivores, neighboring plants, and symbiotic bacteria and fungi. Internally, plants monitor their developmental stage, health, and water, nutrient, and photosynthate status. In addition, signaling interactions between cells in developing regions of the plant determine patterns of cells, tissues, and organs, while long-range signals control larger patterns of development. Somehow, plants organize appropriate local and systemic responses to each of these signals (Fig. 18.1).

Plant responses to these diverse categories of information interact and feed back on each other. For example, at the vegetative shoot apex, local cell-to-cell signaling first determines the pattern of leaf initiation and then, within each developing leaf, controls the arrangement of cell types. These patterning processes need no external help, since isolated shoot apices or individual leaf primordia can produce normal, if small, shoots and leaves in tissue culture. In real life, however, developing regions such as the shoot apex are in continuous communication with the rest of the plant through long-range signals carried in the vascular tissue. This allows the plant to modulate larger patterns of development, such as the balance of shoot to root growth, or the decision to flower. As each region of the plant responds to such signals, it may alter its own signaling patterns; the transition of an axillary bud from dormancy to growth, for example, is linked to the initiation of auxin export from the bud into the main stem.

FIGURE 18.1 External information that affects plant physiology, defense, and development comes from many aspects of the plant's physical and biological environments. Almost all external signals can vary in intensity, sometimes from minute to minute.

Regardless of how complex they become, all plant responses to internal and environmental signals begin at the level of the individual cell. This chapter, therefore, considers signal perception, transduction, and integration from the cellular perspective. This section discusses the characteristics of signaling mechanisms operating in eukaryotic cells, plant cells in particular. Subsequent sections consider specific plant signaling pathways and examples of intracellular signal integration in detail.

18.1.2 Chains of signal-transducing molecules connect perception to response

Plants perceive environmental information that is both physical (e.g., light intensity and temperature) and chemical (e.g., water availability and nutrient concentration). Signals operating within and between plant cells are mostly chemical, although exceptions can be made for electrical events at membranes and physical forces generated by tissue growth.

Regardless of signal type, plant cells perceive most environmental information and most intercellular signals at dedicated **receptor proteins**. Signal perception results in a change in receptor protein activity, typically to regulate an

FIGURE 18.2 Plant signal perception, transduction, and response. An extracellular signal is shown binding to a plasma membrane receptor protein. The receptor controls the activity of an intracellular transduction pathway that regulates cell responses to the signal. Overall, information inherent to the signal is transferred from the site of perception to sites of response within the cell. Note that the cell wall is not shown for clarity.

intracellular signal transduction pathway (Fig. 18.2). Operation of the transduction pathway then depends on interactions between its component signal-transducing molecules, which often result in covalent modifications and/or allosteric changes. For example, some receptor proteins respond to signal perception by activating intracellular protein **kinases**, enzymes that phosphorylate proteins. Phosphorylation typically causes an allosteric change in the target protein that can change its activity to induce either a change in cell behavior or downstream signaling. Interactions within a transduction pathway often also lead to movement of signaling molecules within the cell, for example through release of a signaling protein from an anchoring complex or opening of ion channels. In such ways, transduction pathways transfer information inherent to the perceived signal through the cell to the sites of response.

Many pathways also eventually regulate the synthesis, activity, or stability of **transcription factors**, proteins that regulate gene transcription. This may reflect a central role for transcriptional control in establishing overall patterns of cellular behavior. Research has, however, focused on transcriptional regulation; gene expression is also regulated at other levels, and not all cellular responses require changes in gene activity.

Some transduction pathways also act on cytoplasmic or membrane components, often leading to very rapid responses. For example, germinating pollen tubes grow at tens to hundreds of nanometers per second, and they are steered through the style to the ovule by signals perceived by

plasma membrane receptors. The receptors induce a cytoplasmic signal transduction pathway responsible for aligning the cytoskeleton at the tube tip and, hence, determining the direction of growth. Similarly, changes in guard cell osmotic potential and, therefore, turgor can open or close stomata over a period of minutes—a process mediated by the regulation of ion flux via plasma membrane channels in response to factors such as light, the hormone abscisic acid (ABA), and carbon dioxide concentration (see Section 18.9).

18.1.3 Signal transduction in plant cells evolved from ancient signaling mechanisms

The classes of signaling molecules and types of signaling interactions present in plant cells also exist, with varying degrees of overlap, in prokaryotes, animals, and fungi. Intracellular signal transduction mechanisms are, therefore, evolutionarily ancient. In contrast, most of the molecules that carry intercellular signals within a plant are unique to the plant kingdom, reflecting independent evolution of multicellularity in the different eukaryotic kingdoms.

The diversity of extracellular signals and conservation of intracellular transduction mechanisms are reflected in the structure of receptor proteins. For example, receptor proteins in the plasma membrane often possess an extracellular **ligand-binding domain** that captures the signal, a transmembrane domain that anchors it within the membrane, and an intracellular **effector domain** that interacts with downstream signaling components. Ligand-binding domains have diverse structures, reflecting the wide range of extracellular signals, whereas effector domains are typically highly conserved within and between species. Transferring receptor proteins between kingdoms can demonstrate this. For example, the yeast (*Saccharomyces cerevisiae*) receptor protein SLN1 is required for osmoregulation, and loss-of-function mutations in the receptor are lethal. Mutant yeast can be rescued by transformation with the *Arabidopsis* gene for the cytokinin receptor, CRE1, but only if they are also given a cytokinin supply to activate the receptor (Fig. 18.3). CRE1

FIGURE 18.3 CRE1, a plant cytokinin receptor, can substitute for the yeast receptor SLN1, which is required in yeast for osmoregulation. Yeast *sln1* mutants lacking SLN1 die, and mutants expressing a CRE1 transgene survive, but only if cytokinin is present to activate the CRE1 receptor.

and SLN1 are both histidine kinases that act through the two-component system (see Section 18.5), and despite responding to very different external signals, their effector domains (represented by the kinase receiver domain, see Section 18.5) are sufficiently similar for CRE1 to interact with the necessary downstream signaling pathway in yeast.

The same phenomenon occurs at the level of individual cells within a species: diverse extracellular signals activate similar intracellular signal transduction pathways. Combined with the ancient origin of intracellular signaling mechanisms, this has led to the concept of **signaling cassettes**, modular signal transduction mechanisms that are frequently conserved within and between diverse organisms and that process a wide range of upstream signals to trigger a wide range of downstream responses. Examples discussed in this chapter include kinase cascades and two-component mechanisms.

18.1.4 Diverse transduction pathways share common characteristics

A huge variety of signal transduction pathways occur in plant cells. They display diversity both in their molecular constituents and in the interactions that occur between those constituents. There are, however, some common themes.

Signals are almost always progressively amplified as information travels along a pathway. An individual kinase, for example, can phosphorylate many copies of its target protein, and opening of a single membrane calcium channel allows flux of multiple calcium ions. In a special case of signal amplification, large-scale activation of gene transcription is often achieved through the activity of **transcriptional cascades**. For example, the perception of light as a seedling emerges from the soil leads to the accumulation of a handful of master transcription factors (see Section 18.7.3). These then induce transcription from genes encoding secondary transcription factors, which may induce transcription from other transcription factor genes. Collectively, the transcription factors in the cascade regulate the expression of thousands of downstream genes required for the seedling's growth as an autotroph.

Transduction pathways can continue after the initiating signal has ended, with the duration of signaling tightly regulated by inactivating mechanisms such as dephosphorylation of phosphorylated proteins. In contrast, if the initiating signal persists, feedback mechanisms often reduce the activity of the associated transduction pathway, leading to desensitization of the cell to the signal.

When a component of a pathway has several downstream targets, the pathway branches and a single perceived cue leads to diverse responses that may occur in different compartments of the cell. The complexity of the intracellular signaling network is also greatly increased by the fact that many signaling components are encoded by multigene families. Often, family members have similar, but nonidentical activities, and cellular responses are modulated by differential expression of genes within a family. The phytochrome light receptors

provide a clear example. As described in Section 18.7, phytochromes are divided into two subgroups: light-labile phytochrome (phyA, the concentration of which falls in the light) and light-stable phytochrome (phyB–E, which have similar concentrations in light and darkness). Accumulation of light-labile phyA in dark-grown seedlings gives cells an extreme, but transient sensitivity to light that is not seen in mature shoots, in which lower levels of light-stable phytochromes predominate.

Cell-to-cell variation in the expression of receptors and signaling intermediates may help explain one of the abiding puzzles in the study of plant signal transduction—that a small group of classical plant hormones mediates a huge range of processes in plant development, physiology, and defense. For example, auxin functions in mechanisms that establish the polarity of the embryo, initiate and maintain the apical meristems of the shoot and root, determine sites of leaf initiation and the pattern of vascular development, mediate tropic movements, regulate the degree of shoot branching and the balance of shoot to root growth, and initiate regeneration after wounding. For such diverse functions to occur in response to individual signals, different cell types must respond in different ways. In a simple example, treatment with indole-3-acetic acid (IAA, the major naturally occurring plant auxin) at concentrations of about 10^{-7} M stimulates elongation of cells in the shoot, but inhibits elongation of cells in the root. Cell-to-cell or temporal variations in the expression of the signal transduction network also likely underlie the phenomenon of **competence**, the ability of a cell (or tissue or organ) to respond to a signal with a particular development outcome.

18.1.5 Interactions between transduction pathways allow signal integration

Signaling pathways initiated by different cues interact with each other. Indeed, few, if any, discrete pathways exist in plant cells. Instead, most known pathways interact with other pathways in ways that both regulate cellular responses and feed back onto the structure and behavior of the signaling network.

Signal transduction pathways may interact because they converge onto the same signaling intermediates, or onto the same response molecules, to regulate a common process. For example, in the control of stomatal aperture, intracellular signals initiated by light and ABA converge to regulate guard cell plasma membrane proton pumps, the activities of which regulate membrane polarization and form a key step in the transduction of both signals. In this case, the two signals have conflicting effects on the pump: light upregulates the activity of the pump to promote stomatal opening, whereas ABA blocks the pump to induce stomatal closure (see Section 18.9).

Pathways also interact through the regulation of one pathway by a component of another. Considering stomata once more, light activates the proton pump by causing its phosphorylation. This pathway is inhibited by ABA signaling through

a mechanism that appears to require the ABA signaling intermediate, hydrogen peroxide; ABA signaling both regulates the proton pump directly and interferes with the transduction pathway that links light perception to pump activity. In a conceptually similar manner, the response to a signal can include changes in the synthesis, perception, or transduction of one or more other signals. For example, auxin and ethylene mutually stimulate each other's synthesis.

Through interactions such as these, signals perceived by different receptors, and representing different information acquired by the cell, are integrated while being processed by a complex and continually adjusting signal transduction network. This allows cells to integrate multiple sources of information rapidly, for example, to modulate their response to local environmental cues (such as guard cell light exposure) according to intercellular signals relating to the status of the plant as a whole (such as ABA as an indicator of water stress).

The convergence of signal transduction onto common signaling intermediates and response molecules allows signal integration but also risks loss of **specificity**, the extent to which distinct signals are able to induce distinct responses. For example, as discussed in Section 18.3, calcium ions (Ca^{2+}) are signaling intermediates downstream of a wide range of different receptors. This raises the question of how the cell achieves the appropriate response to each perceived cue when it is using identical signaling components in multiple contexts.

Part of the answer is through the compartmentalization of signaling pathways coupled to rapid inactivation of signaling components. A signal transduction pathway may be restricted to the cytosol, to a particular class of organelle, or to the nucleus. When this is the case, damaging interactions can be avoided if those signaling intermediates that can diffuse between compartments are inactivated rapidly relative to the rate of diffusion. A similar phenomenon occurs on a smaller physical scale through the regulated binding of signaling components to scaffold proteins, facilitating interactions between components within a transduction pathway while limiting interactions between pathways. This is believed to occur in **mitogen-activated protein kinase (MAPK) cascades**, where it is thought to help divide the multitude of possible cascades into defined signaling cassettes (see Section 18.3.2).

18.1.6 Signaling mechanisms in plant cells can be grouped according to multiple criteria

Descriptions of intracellular signaling in plants may be organized according to cellular location and the class of signaling mechanism, or they may be arranged signal by signal or discussed with respect to particular cellular responses. This chapter uses all three approaches according to which best suits the available data. Section 18.2 considers signal perception at the plasma membrane, including research on

the perception of brassinosteroids, bacterial flagellin, CLE peptides, ABA, and mechanical forces. Section 18.3 then considers the functions of second messengers and kinase cascades in signal transduction and integration.

Sections 18.4 to 18.7 consider the perception and transduction of individual signals; they discuss how cells respond to the hormones ethylene, cytokinin, and auxin and how signal transduction follows light perception by phytochromes. These are among the best understood transduction pathways in plant cells. Signaling by gibberellins is discussed in Section 18.8 in relation to signal integration by DELLA proteins during seedling responses to light. Section 18.9 then considers the integration of light, ABA-, and CO₂ signaling in the control of stomatal aperture. This is far from an exhaustive survey of signal transduction in plant cells, but hopefully it provides a framework for understanding related areas of research.

18.2 Overview of signal perception at the plasma membrane

18.2.1 The plasma membrane is a major site of signal perception

Plant cells have two routes by which they are able to communicate with one another: the **apoplast**, formed by the interconnected cell walls of the plant, and the **symplast**, the cytoplasmic continuum created by strands of cytoplasm connecting neighboring cells via plasmodesmata. Molecular transport through the apoplast and symplast is discussed in detail in Chapter 15. With respect to intercellular signaling, the apoplast is associated with the transmission of signals such as the plant hormones and signal peptides, which require conventional receptor proteins. In contrast, signaling via the symplast allows regulated movement of RNAs and transcription factor proteins, which can induce responses in the receiving cell more directly.

For signals arriving at the cell through the apoplast, the plasma membrane is a major site of perception; indeed, large and hydrophilic molecules that lack a membrane import channel can only be perceived by plasma membrane receptors. Receptors at the membrane also perceive some physical signals, for example mechanical force (see Section 18.2.4) and blue light (via phototropins, see Box 18.2).

Plasma membrane receptors are divided into three major groups distinguished by how they interact with intracellular signaling components: receptor kinases, G protein-coupled receptors, and ion channel receptors. The receptor kinases are by far the largest group of membrane receptors in plants, and they transduce extracellular signals through phosphorylation of intracellular targets (see Section 18.2.2). G protein-coupled receptors regulate trimeric GTP-binding

proteins (**G proteins**) located on the inner surface of the membrane (see Section 18.2.3). Lastly, ion channel receptors regulate membrane ion channels and, thus, ion fluxes into or out of the cell (see Section 18.2.4).

Despite the importance of signal perception at the plasma membrane, it should be noted that small, lipophilic molecules can cross the membrane and be perceived in the cytoplasm or nucleus. This is the case for ethylene, which is detected by receptors on the endoplasmic reticulum membrane (see Section 18.4), and for the hormones auxin and gibberellin, which are perceived by soluble receptors that interact with the cell's protein degradation machinery (see Sections 18.6 and 18.8). Similarly, the plasma membrane is no barrier to many physical cues; the phytochrome and cryptochrome families of photoreceptors, for example, are intracellular, having both cytoplasmic and nuclear locations, depending on the light conditions and the particular family member (see Section 18.7, see Box 18.2).

18.2.2 Signaling by the largest group of membrane receptor kinases can involve both receptor heterodimerization and receptor endocytosis

Phosphorylation is the most common posttranslational modification used by cells to regulate protein activity. Catalyzed by **kinases**, phosphorylation can alter protein stability, subcellular location, binding properties, enzyme activity, and susceptibility to subsequent modifications. Furthermore, single proteins may be phosphorylated at multiple amino acid residues, sometimes by different kinases and with different effects, enabling integration of separate signal transduction pathways. Consequently, it is not surprising that kinases and **phosphatases** (which dephosphorylate proteins) play vital roles in signal transduction in all organisms.

In plants, signal perception appears to rely heavily on plasma membrane **receptor-like kinases** (RLKs), a family of over 600 proteins in *Arabidopsis* and over 1,100 in rice (*Oryza sativa*) that typically phosphorylate target proteins on serine and threonine residues. RLKs possess an extracellular domain that provides potential ligand-binding sites, a transmembrane domain, and an intracellular kinase domain. They act in a wide range of processes, including hormone perception, development, defense, symbiosis, and pollen tube germination and guidance. The best understood of the signal transduction mechanisms mediated by RLKs is the perception of brassinosteroids (BRs). RLKs also function in the perception of **CLE peptides** (CLAVATA3/ENDOSPERM SURROUNDING REGION, Box 18.1).

BRs are a group of steroid hormones that function in a variety of cellular and developmental contexts, such as promotion of cell elongation during etiolation of dark-grown seedlings. Research on the RLKs required for BR perception and on other, closely related RLKs has revealed multiple,

BOX
18.1

CLE peptide signals act in several developmental contexts

The **CLE peptides**, named after CLAVATA3 (*CLV3*)/ENDOSPERM SURROUNDING REGION (*ESR*), were discovered through research on the control of the size of the *Arabidopsis* shoot apical meristem (SAM). The SAM is composed of a central zone (CZ) and a peripheral zone (PZ) (panel A). Cells in the CZ act as stem cells for shoot development; they divide to supply cells to the PZ, in which cells both divide and differentiate to initiate the structures of the shoot.

The size of the CZ and, therefore, of the whole SAM is regulated by a feedback loop acting on the genes *WUSCHEL* (*WUS*) and *CLAVATA3* (*CLV3*). *WUS* is expressed in a small group of cells deep in the CZ and is required for the production of a signal that confers stem cell identity throughout the CZ. At least in part, this signal consists of the *WUS* protein—a transcription factor that is transported between meristem cells via plasmodesmata (see Section 11.5.1).

In the upper CZ layers, *WUS* activates transcription from *CLV3*, which encodes a small protein that is processed to produce a secreted, 13 amino acid CLE peptide. The *CLV3* CLE peptide acts as a short-range signal perceived by cells deeper in the CZ (panel B; cell wall not shown). In the current model, perception of the *CLV3* CLE peptide occurs at two receptors: a homodimer of the *CLV1* protein, and a heterodimer consisting of the *CLV2* and *CORYNE* (*CRN*) proteins. *CLV1* is a LRR-receptor-like kinase (see Section 18.2.2), and *CLV2* and *CRN* are related proteins. *CLV2* resembles *CLV1* but lacks an intracellular kinase domain. In contrast, *CRN* possesses a kinase domain but lacks a full extracellular domain. The *CLV2/CRN* heterodimer therefore has the necessary domains for signal perception and transduction. Signals from the *CLV1* and *CLV2/CRN* receptors converge to down regulate *WUS* expression. This completes the feedback loop and creates a mechanism in which SAM size is determined by the balance of *WUS* expression, which acts to promote CZ identity and hence SAM growth, and *CLV3* signaling, which limits *WUS* activity.

In total over 30 genes encoding proteins likely to produce secreted CLE peptides have been identified in *Arabidopsis*. The genes are expressed in a variety of tissues, and CLE peptides have been implicated in the regulation of root apical meristem activity and in vascular

differentiation. Although *CLV1* expression is confined to the SAM, *CLV2* and *CRN* are both expressed in a wide range of tissues. Therefore, the *CLV2/CRN* receptor may function beyond the CZ of the SAM and in the perception of other CLE peptides. Supporting this, both *crn* and *clv2* mutants have defects in stamen and anther development.

A

B

pairwise interactions between RLKs. The results of such research also indicate receptor endocytosis may have a key role in the regulation of signal transduction from RLKs.

BRs bind to the extracellular domain of the BR receptor BRASSINOSTEROID INSENSITIVE1 (*BRI1*) (Fig. 18.4). *BRI1* is a member of the largest subgroup of RLKs, those in which

the extracellular domain contains leucine-rich repeats (LRRs), which consist of a series of repeated motifs of 20–29 amino acid residues rich in leucines, thought to function in protein–protein interactions. As steroid molecules, BRs are unlikely targets for a LRR; in *BRI1*, however, the LRR is interrupted by a 70-amino acid ‘island domain’ that is likely the site of BR binding.

FIGURE 18.4 Brassinosteroids (BR) bind to the BRI1 receptor, causing dissociation of the inhibitor BKI1 and heterodimerization and reciprocal phosphorylation of BRI1 and BAK1. BRI1 phosphorylates BSKs, inducing signal transduction pathways that lead to accumulation of unphosphorylated forms of the BZR1 and BES1 transcription factors in the nucleus and consequent changes in gene transcription. Note that the cell wall is not shown for clarity.

BRI1 exists in the plasma membrane as a homodimer associated with the inhibitory protein BKI1 (BRI1 KINASE INHIBITOR1). BR binding induces the dissociation of BKI1 from the receptor, probably induced by phosphorylation of BKI1 by BRI1, and leads to the loss of BKI1 from the plasma membrane. Freed from BKI1 inhibition, BRI1 phosphorylates downstream targets. In addition, the BRI1 homodimer splits, and BRI1 forms heterodimers with another LRR-RLK called BAK1 (BRI1-ASSOCIATED KINASE1). Reciprocal phosphorylation within the heterodimer—of BAK1 by BRI1 and then of BRI1 by BAK1—subsequently enhances signaling from BRI1. BAK1 has a truncated extracellular domain containing only a short LRR domain and no island domain, and it does not appear to have a ligand-binding function.

The signal transduction pathway downstream of BRI1 is not fully known. In the current model, BRI1 phosphorylates and activates a small family of kinases (BSK1, BSK2, and BSK3) that induce downstream BR responses through their

own kinase activities. The targets of the BSKs are unknown; however, downstream responses are mediated through the regulation of a family of transcription factors that includes BZR1 and BES1. The activity of these transcription factors is downregulated through phosphorylation by the kinase BIN2 and upregulated through dephosphorylation by the phosphatase BSU1. Phosphorylation inhibits the activity of BZR1 and BES1 by multiple mechanisms, including the retention of the two transcription factors in the cytoplasm, an increase in their rate of degradation, and a reduction in their DNA binding ability. Following BR perception, BIN2 is inhibited and BSU1 is stimulated, leading to accumulation of unphosphorylated BZR1 and BES1 in the nucleus and regulation of BR-responsive genes (e.g., the inhibition of transcription from the *DWF4* gene).

The tomato (*Solanum lycopersicum*) homolog of BRI1 acts both as the BR receptor and as the receptor for the defense signal **systemin**, an 18 amino acid peptide produced by tomatoes and other Solanaceae in response to insect attack and that acts as a systemic signal capable of inducing defense-related genes. The ability of tomato BRI1 to bind two different signals raises the question of how specificity is maintained to differentiate responses to BRs and to systemin. One possibility is that systemin binding induces interaction with an LRR-RLK other than BAK1.

BRI1 is likely to signal from both the plasma membrane and endosomes (intracellular vesicles created by endocytosis; see Chapter 1). Both BRI1 and BAK1 are removed from the plasma membrane into endosomal membranes and then cycled back to the plasma membrane via transport vesicles budding off from recycling endosomes (Fig. 18.5). BRI1 cycling is constitutive and is not affected by either BR binding or the loss of BAK1 function. Treatment with brefeldin A, an inhibitor of endosomal trafficking, causes accumulation of BRI1 in endosomes and increases signaling through the BR pathway, suggesting a role for signaling from endosomal BRI1. The use of endosomes for signal transduction from plasma membrane receptors increases the membrane area available for signaling interactions. Furthermore, for typical elongated, differentiated plant cells in which the central vacuole occupies most of the cell volume, receptor endocytosis may help ensure even signaling strengths from different regions of the plasma membrane. As the resultant endosomes are circulated around the cell by cytoplasmic streaming, receptors activated at all parts of the plasma membrane are brought into the proximity of the nucleus.

Moving away from BR signaling, research on other functions of BAK1 suggests multiple interactions between pairs (at least) of plasma membrane RLKs. In addition to BRI1, BAK1 associates with the receptor for bacterial flagellin, an LRR-RLK called FLS2 (FLAGELLIN-SENSITIVE2). FLS2 induces a range of defense responses after flagellin binding. Similar to the case for BRI1, ligand binding to FLS2 induces association of FLS2 with BAK1, which promotes signaling by the receptor. Unlike BRI1, however, FLS2 is not constitutively cycled through endosomes. Instead, FLS2 endocytosis

FIGURE 18.5 *BRI1* and *FLS2* receptors activated by binding to BR and flagellin, respectively, signal from both the plasma membrane and, after endocytosis, endosomal membranes. Following endocytosis of both the inactive (not shown) and activated forms of *BRI1*, endosomal *BRI1* is recycled to the plasma membrane. In contrast, only active *FLS2* undergoes endocytosis, and endosomal *FLS2* is targeted for destruction in lysosomes. Note that the cell wall is not shown for clarity.

is induced by flagellin binding, and although *FLS2* is also believed to signal from endosomes, the receptor is not recycled; instead endosomal *FLS2* is eventually destroyed (Fig. 18.5).

The functions of kinases closely related to BAK1 demonstrate further levels of complexity (Fig. 18.6). BAK1 is a member of a family of five LRR-RLKs called SERKs (SOMATIC EMBRYOGENESIS RECEPTOR-LIKE KINASES). BAK1 is SERK3. SERK1 acts redundantly with BAK1 as a co-receptor for *BRI1*. However, SERK1, together with SERK2 also functions in the development of microspores in the anther, a process that does not appear to require BAK1. Lastly, mutational analysis shows that with SERK4, BAK1 has a BR-independent role in controlling the cell death response. The functions of SERK5 are unknown.

In addition to RLKs, plants possess histidine kinase receptors. These include the receptors for ethylene and cytokinin and constitute a separate group of kinases derived from bacterial two-component systems. Histidine kinase receptors are discussed in detail in Sections 18.4 and 18.5.

18.2.3 Plant cells possess a small group of putative G protein-coupled receptors

G protein-coupled receptors (GPCRs) regulate the activity of trimeric GTP-binding proteins (**G proteins**) (Fig. 18.7). These consist of $G\alpha$, $G\beta$, and $G\gamma$ subunits, and as trimers, they are inactive and bound at the $G\alpha$ subunit by a molecule

of GDP. GPCRs possess an extracellular ligand-binding domain, a transmembrane domain composed of seven hydrophobic helices, and an intracellular domain that interacts with inactive G protein trimers. Ligand binding by the receptor induces the $G\alpha$ subunit of the trimer to release its bound GDP molecule and bind a molecule of GTP instead. This activates the G protein, which uncouples from the receptor and dissociates into the $G\alpha$ subunit and a $G\beta/\gamma$ dimer.

$G\alpha$ and $G\gamma$ both have short, covalently attached lipid tails that anchor them to the inside of the plasma membrane so that $G\alpha$ and the $G\beta/\gamma$ dimer diffuse on the membrane to activate downstream signaling proteins. A single ligand-bound GPCR can amplify a signal by activating multiple G proteins. Signaling is terminated by the hydrolysis of bound GTP to GDP by $G\alpha$ (which has GTPase activity), and this process is stimulated by **GTPase activating proteins (GAPs)**. GDP-bound $G\alpha$ reassociates with the $G\beta/\gamma$ dimer to form an inactive trimer, which then binds a GPCR to complete the cycle.

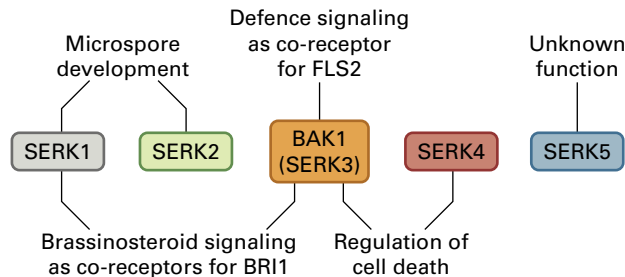

FIGURE 18.6 The SERK family of LRR-RLKs have multiple and overlapping functions.

FIGURE 18.7 Regulation of heterotrimeric G proteins. (A) Ligand binding by a G protein-coupled receptor (GPCR) induces the $G\alpha$ subunit of the heterotrimeric G protein to exchange GDP for GTP. This leads to the dissociation of the G protein into active $G\alpha$ and $G\beta/\gamma$ subunits that regulate the activity of downstream effector proteins ($G\beta/\gamma$ activity not shown). (B) $G\alpha$ is inactivated by the hydrolysis of bound GTP to GDP, which is stimulated by a GTPase activating protein (GAP). Inactive $G\alpha$ binds to the $G\beta/\gamma$ dimer, reconstituting the inactive heterotrimeric G protein. Note that the cell wall is not shown for clarity.

The alternation of $G\alpha$ between an active GTP-bound and an inactive GDP-bound form is a general feature of the GTP-binding protein superfamily. The superfamily includes GTP-binding initiation and elongation factors that act in protein synthesis, and also the **small** or **monomeric G proteins**, whose functions include signal transduction, organelle trafficking, and cytoskeleton assembly. The regulation of

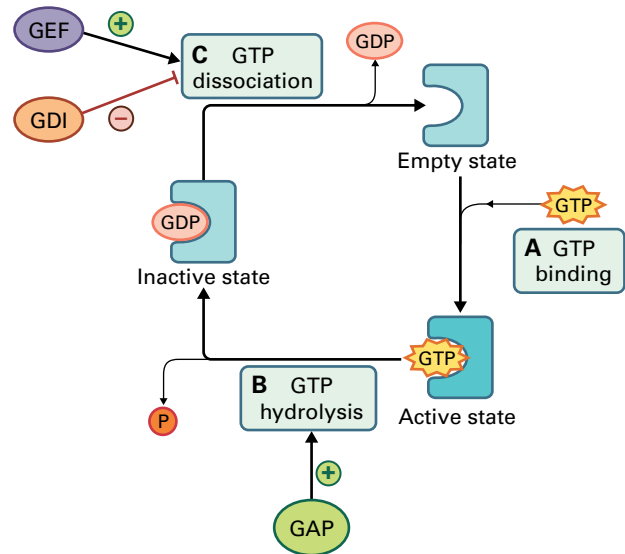

FIGURE 18.8 (A) Monomeric G proteins are converted from an empty state to an active state by GTP binding. (B) They are inactivated by GTP hydrolysis, which is stimulated by a GTPase activating protein (GAP). (C) GDP release, which is inhibited by GDP dissociation inhibitors (GDIs) and stimulated by guanine nucleotide exchange factors (GEFs), returns the G protein to its empty state and allows reactivation.

monomeric G proteins has parallels with the regulation of $G\alpha$ activity (Fig. 18.8). Monomeric G proteins are activated by **guanine nucleotide exchange factors** (GEFs), which induce the exchange of GDP for GTP, a function equivalent to that of GPCRs. As is the case for regulation of $G\alpha$ activity, the hydrolysis of GTP to GDP by monomeric G proteins is stimulated by GAPs. Lastly, **GDP dissociation inhibitors** (GDIs) prevent the spontaneous release of GDP by monomeric G proteins, a role played by the $G\beta/\gamma$ dimer in trimeric G proteins.

A sharp contrast exists between the extent of GPCR signaling in plants and animals. Mammals possess between 500 and 1,000 GPCRs, depending on the species, together with multiple copies of the G protein subunits and a wide range of G protein-regulated signal transducing proteins, including kinases, ion channels, and enzymes involved in the production or destruction of second messengers such as cyclic nucleotides. In contrast, analysis of the *Arabidopsis* genome has identified only a handful of putative GPCRs. Unequivocal roles for the function of these GPCRs are currently lacking. Furthermore, *Arabidopsis* possesses only one $G\alpha$ -, one $G\beta$ -, and two $G\gamma$ -encoding genes. The nature of the signaling proteins acting downstream of $G\alpha$ and the $G\beta/\gamma$ dimer in plants is uncertain.

18.2.4 Ion channel receptors can perceive mechanical stimuli

Ion channels are water-filled pores created by conformational changes in multisubunit, membrane-spanning proteins. They allow inorganic ions to flow across membranes, down their electrochemical gradients. Pore diameter and the charges on the amino acid residues that line the pore determine which ions are able to use a channel (see Chapter 3 for more details).

Ion channels can be regulated by binding either extracellular or intracellular ligands and by changes in voltage across the membrane or by mechanical force. In the plant plasma membrane, no identified ion channel proteins function as receptors for extracellular ligands; mechanosensing calcium ion channels, however, play a role in plant responses to physical forces.

Plants display developmental responses to gravity, touch, soil pressure, wind, and the stresses imposed by their own weight and tissue growth. Mechanical stimulation results in an immediate and transient increase in cytosolic calcium ion concentration. Though this suggests the existence of mechanosensing ion channels, the identity of such channels has yet to be confirmed. One candidate is the MID1 COMPLEMENTING ACTIVITY1 (MCA1) protein of *Arabidopsis*. MCA1 is believed to be a plasma membrane calcium ion channel that responds to mechanical stimulation, and the roots of *mca1* loss-of-function mutants are unable to penetrate harder agar growth media, implying an abnormal response to pressure.

18.3 Intracellular signal transduction, amplification, and integration via second messengers and MAPK cascades

18.3.1 Second messengers act as diffusible signals within the cell

Second messengers are diffusible, intracellular signals that are typically synthesized or released in a transient, but concentrated pulse following primary signal perception. They provide a means of rapidly relaying signals to downstream transduction components. Second messengers include small molecules and mineral ions that diffuse through the cytosol, as well as lipid-based signaling molecules that diffuse within membranes. Here, we consider two cytosolic second messengers: cyclic nucleotides and calcium ions (Ca^{2+}).

The term second messenger was first used to describe **cyclic 3',5'-adenosine monophosphate** (cAMP) after the discovery in the late 1950s that cAMP mediated signal transduction in response to a number of animal hormones. In the canonical pathway, hormone perception by an animal G protein-coupled receptor (see Section 18.2.3) leads to activation, via the G protein's $G\alpha$ subunit, of a plasma membrane **adenylyl cyclase**. This enzyme catalyzes the conversion of ATP to cAMP (Fig. 18.9), which in turn diffuses to activate cytosolic **cAMP-dependent protein kinase** (PKA). PKA phosphorylates downstream target proteins to activate appropriate transduction pathways. Animal cells also use **cGMP** as a second messenger; it is produced by **guanylyl cyclase** and activates **cGMP-dependent protein kinase** (PKG). In addition to activating PKA and PKG, cyclic nucleotides in animal cells act by opening plasma membrane **cyclic nucleotide-gated ion channels** (CNGCs), which allow nonselective influx of the Ca^{2+} , K^+ , and Na^+ cations. The cyclic nucleotide signal is terminated by the conversion of cAMP and cGMP into their noncyclic forms by phosphodiesterases.

Cyclic nucleotides have more restricted roles in plant cells than in animal cells. Importantly, no plant homologs of PKA or PKG have been found, and cyclic nucleotide signaling in plant cells may, therefore, be limited to the regulation of CNGCs. Like those found in animal cells, plant CNGCs are nonspecific cation channels. They have been implicated in various processes, including gibberellic acid (GA) and phytochrome signaling, pollen tube growth, cell cycle control, and stress and defense signaling. For example, pathogen infection induces rapid cAMP production and the influx of Ca^{2+} into plant cells, which is believed to occur through CNGCs. Spikes in cytosolic Ca^{2+} concentration are associated with a variety of defense responses, such as the expression of defense-related genes and the induction of programmed cell death.

FIGURE 18.9 Synthesis and degradation of cyclic 3',5'-AMP by adenylyl cyclase and cyclic AMP phosphodiesterase. cAMP is shown as a structural formula and as a space-filling model.

Ca^{2+} is a far more significant second messenger in plant cells than are the cyclic nucleotides. Cells maintain very low resting cytosolic Ca^{2+} concentrations $[Ca^{2+}]_{\text{cyt}}$ of around 100–350 nM while sustaining large Ca^{2+} stores in the vacuole and endoplasmic reticulum (ER) at concentrations of about 1–2 mM (Fig. 18.10). In the cell wall, Ca^{2+} concentration is estimated at about 0.5–1 mM. $[Ca^{2+}]_{\text{cyt}}$ is measured using cells transformed to produce Ca^{2+} -responsive luminescent or fluorescent dyes. This approach has shown spikes of $[Ca^{2+}]_{\text{cyt}}$ reaching approximately 1 μM can occur in response to a huge range of biotic and abiotic stimuli including pathogen infection (as above), nodulation factors, the hormones GA and ABA, red and blue light, UV-B radiation, low and high temperature, touch, wind, changes in the gravity vector, and anaerobic, drought and salt stress.

$[Ca^{2+}]_{\text{cyt}}$ spikes result from the opening of Ca^{2+} -permeable channels in the plasma membrane, ER membrane, or vacuolar membrane (tonoplast). Reflecting the complexity of stimuli that induce $[Ca^{2+}]_{\text{cyt}}$ spikes, there are several Ca^{2+} -permeable channels, which are gated by mechanical stimuli (see Section 18.2.4),

by changes in the membrane electrical potential, or by ligands such as cyclic nucleotides (for the plasma membrane CNGCs), and the second messengers inositol trisphosphate (IP_3) and cyclic ADP-ribose (for channels on internal membranes).

$[Ca^{2+}]_{\text{cyt}}$ regulation of downstream signaling is largely mediated by Ca^{2+} -sensitive protein kinases. Plant cells contain kinases that bind Ca^{2+} directly as well as kinases that are regulated by the Ca^{2+} -binding **calmodulin** proteins (CaMs) and by binding to both Ca^{2+} and CaMs. The Ca^{2+} signal is terminated by membrane Ca^{2+} pumps (Ca^{2+} ATPases) and proton/calcium exchangers (antiports) that return $[Ca^{2+}]_{\text{cyt}}$ to its resting level (Fig. 18.10).

Ca^{2+} signaling illustrates one of the main questions facing research on second messengers, the problem of signal specificity (see Section 18.1.4). With so many stimuli leading to $[Ca^{2+}]_{\text{cyt}}$ spikes, and the large number of Ca^{2+} - and/or CaM-regulated kinases activating diverse downstream pathways, how does Ca^{2+} signaling link each stimulus to its appropriate response? There are several possibilities.

FIGURE 18.10 Interactions of intracellular and extracellular Ca^{2+} in cell signaling. The concentration of free Ca^{2+} is much lower in the cytosol than in the cell wall or organelles. When the cell is signaled, channels in various organelles and/or the plasma membrane open to allow Ca^{2+} to enter the cytosol by diffusion down its electrochemical gradient. Ca^{2+} ATPases (Ca^{2+} pumps) and $\text{Ca}^{2+}/\text{H}^+$ antiports return the cytosolic concentration to its resting value.

First, responses may depend on the spatial pattern of the Ca^{2+} signal. As a result of Ca^{2+} uptake by organelles and Ca^{2+} binding by proteins, the rate at which Ca^{2+} diffuses in the cytoplasm is at least two orders of magnitude below that of Ca^{2+} diffusing in a simple solution. This allows spatial segregation of $[\text{Ca}^{2+}]_{\text{cyt}}$ changes, for example in the formation of standing gradients of $[\text{Ca}^{2+}]_{\text{cyt}}$, which are important in directing the growth of root hairs and pollen tubes (Fig. 18.11).

Next, information may also be encoded in the temporal pattern of $[\text{Ca}^{2+}]_{\text{cyt}}$ changes. During the regulation of stomatal aperture, for example, $[\text{Ca}^{2+}]_{\text{cyt}}$ oscillates, and the correct period of oscillation is required for signaling (see Section 18.9). In some cases, an increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ may be necessary, but is insufficient for a response, which means the presence or absence of other signaling molecules determine whether the response occurs.

Lastly, it is unlikely that all cells produce all components of the Ca^{2+} signal transduction machinery at all times. Signal specificity may depend in part of the subset of the Ca^{2+} -related signaling apparatus that is expressed by the individual cell.

FIGURE 18.11 Pollen tubes maintain a standing gradient of cytosolic $[\text{Ca}^{2+}]_{\text{cyt}}$ in their tip region. The standing gradient is essential for growth and results from a tip-associated cluster of Ca^{2+} channels. Pollen tubes can be loaded with $[\text{Ca}^{2+}]$ -sensitive fluorescent dyes such as indo-1 or fura-2 for quantification of free $[\text{Ca}^{2+}]$ by fluorescence microscopy.

18.3.2 MAPK cascades function in diverse signal transduction pathways

MAPK cascades exist in all eukaryotic cells and represent a classic example of a signaling cassette, a conserved modular transduction mechanism that processes multiple upstream signals to trigger multiple downstream responses. The core cascade consists of a series of three kinases: a MAPK, a **MAPK kinase** (MAPKK), and a **MAPKK kinase** (MAPKKK) (Fig. 18.12). MAPKKK phosphorylates and activates MAPKK, which in turn phosphorylates and activates MAPK. The active MAPK may translocate to a different part of the cell and phosphorylate downstream transduction components, such as other kinases, metabolic enzymes, or transcription factors to regulate their activity. Signaling through the cascade is induced by activation of the MAPKKK, which can occur by a variety of mechanisms, for example, phosphorylation by an upstream kinase or binding by a monomeric G protein. Signaling is attenuated by the appropriate phosphatases.

In plants, MAPK cascades have been implicated in diverse processes, including jasmonic acid (JA) and ABA signal transduction, formation of the division plate during cell division, regulation of asymmetric divisions during embryogenesis and stomatal patterning, and cellular responses to abiotic stresses and pathogens. Underlying these numerous functions is a complex network of kinases, consisting in *Arabidopsis* of about 60 MAPKKKs, 10 MAPKKs, and 20 MAPKs. This gives the potential for thousands of MAPK cascade-forming combinations. Individual upstream signals can activate multiple MAPK cascades, and individual kinases can be activated by

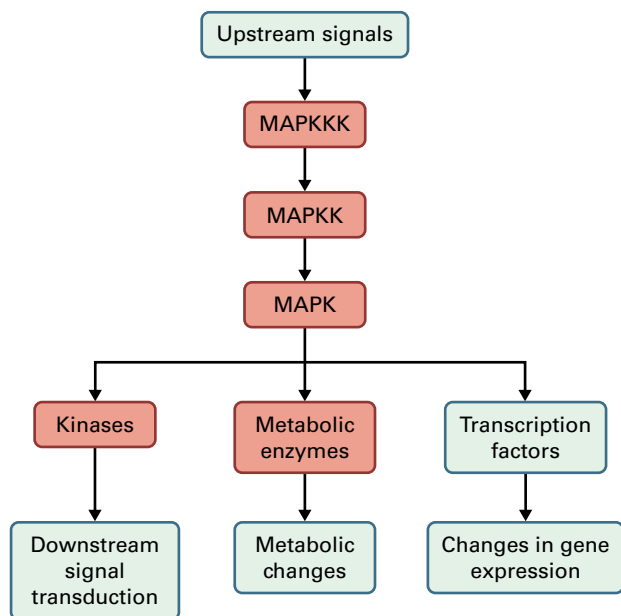

FIGURE 18.12 Mitogen-activated protein kinase (MAPK) cascades are signaling modules found in all eukaryotic cells. Upstream signals activate a MAPK kinase kinase (MAPKKK), which phosphorylates and activates a MAPK kinase (MAPKK). In turn, the MAPKK phosphorylates and activates a MAPK, which may phosphorylate a variety of downstream targets.

multiple upstream signals, indicating the network handles both diverging and converging transduction pathways. There is an “hourglass” pattern to the number of kinases existing at each level: a large number of MAPKKKs activate a much smaller number of MAPKKs, which in turn activate a somewhat larger number of MAPKs.

A good example of divergent signaling through the network of MAPK cascades is provided by the response to bacterial flagellin. As discussed in Section 18.2.2, flagellin detection by the cell surface receptor FLS2 induces a variety of defense mechanisms in *Arabidopsis*. These are mediated in part through MAPK cascades that result in increases in the activity of at least three MAPKs (MPK3, MPK4, and MPK6), each with different effects on downstream signaling (Fig. 18.13). For example, MPK3 phosphorylates and activates the transcription factor VIP1, causing VIP1 to translocate from the cytoplasm to the nucleus, where it activates defense-related genes. Inactive MPK4 exists as a nuclear complex with the transcription factor WRKY33. Active MPK4 phosphorylates a substrate protein called MKS1, leading to an MKS1/WRKY33-containing complex that dissociates from MPK4, allowing WRKY33 to induce transcription from a distinct set of defense-related genes. Lastly, MPK6 phosphorylates and stabilizes ACS6, an enzyme in the ethylene biosynthetic pathway, which leads to increased ethylene production.

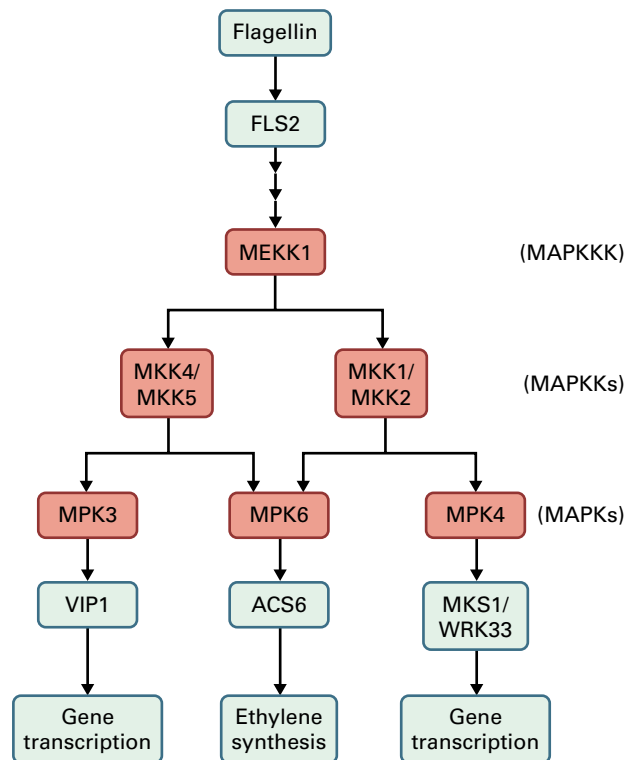

FIGURE 18.13 Divergent signaling in response to flagellin. Flagellin binding to the cell surface receptor FLS2 leads to the activation of the MAPKKK MEKK1. Signaling through MKK1, MKK4, and MKK5, MEKK1 activity results in that activation of three MAPKs—MPK3, MPK4, and MPK6—with different effects on downstream signaling (see text).

MPK6 illustrates well the extent of signal convergence through MAPK cascades. In addition to the flagellin response, changes in MPK6 activity have been reported in response to hydrogen peroxide, ozone, cold, drought, touch, wounding, JA, and ABA. Furthermore, MPK6 (with MPK3) is activated downstream of the MAPKKK YODA, which functions in embryogenesis and stomatal patterning. Reflecting this convergence of signals, MPK6 can functionally interact with at least five MAPKKs.

These data suggest MAPK cascades form a signaling network in which individual kinases have multiple inputs and outputs. As discussed in Section 18.1.4, this raises the question of how signal specificity is maintained. Specificity may be improved through selective colocalization of kinases into cascade-forming combinations to restrict the extent of kinase interactions. There are several examples in yeast and animal cells of specific cascades formed by the binding of the appropriate kinases to cellular scaffold proteins. Another mechanism may be selective repression of some cascades by phosphatases to allow only certain transduction pathways to operate. Phosphatases that target particular MAPKs have been identified in *Arabidopsis*.

Finally, interactions between kinase cascades may allow cells to integrate the information they receive and so tailor responses to their individual circumstances. For example, in tobacco (*Nicotiana tabacum*), the MAPKs WIPK (homologous to *Arabidopsis* MPK3) and SIPK (homologous to MPK6) activate a variety of defense mechanisms in response to wounding and pathogens. Transcription of the *WIPK* gene is promoted by the activity of SIPK, leading to accumulation of WIPK protein and an increase in WIPK activity. Hence, signaling through the MAPK cascade network can feed back to modulate network structure, in this case providing the cell with a mechanism to ramp up defense-related signaling.

18.4 Ethylene signal transduction

18.4.1 Ethylene participates in stress responses, developmental transitions, and patterning events

Ethylene (C_2H_4) can be synthesized throughout the plant, and its production increases rapidly following abiotic or biotic stresses, such as physical force, wounding, drought, flooding, herbivory, and disease. Responses to stress-induced ethylene include changes in growth habit, strengthening of cell walls, and expression of defense-related genes. Ethylene production is also developmentally regulated, and ethylene signaling can trigger developmental transitions. For example, increased ethylene synthesis promotes senescence and abscission of leaves and flowers, and in many species, fruit ripening. Lastly, ethylene plays a role in pattern formation in developing organs; in the *Arabidopsis* root, for example, ethylene influences the size of the meristematic zone and the arrangement of root hairs.

Research on ethylene signal transduction has largely focused on the responses of dark-grown *Arabidopsis* seedlings to the gas. These include tightening of the seedling apical hook, reduction in hypocotyl elongation, and increased hypocotyl thickness, a combination called the **triple response** (Fig. 18.14). The triple response has provided researchers with a clear phenotype to use in screens for mutations and treatments that affect ethylene signaling. In the natural environment, the triple response enhances the seedling's ability to grow through compacted soil, which both stimulates ethylene production by mechanical force and inhibits ethylene diffusion.

FIGURE 18.14 Dark-grown *Arabidopsis* seedlings showing the induction of the triple response by ethylene. (A) Ethylene treatment reduces shoot elongation, increases shoot thickness, and causes a tightening of the apical hook. (B) Dominant mutations in ethylene receptor genes cause ethylene insensitivity. (C) In contrast, mutants with loss of function of multiple ethylene receptors show a constitutive ethylene response.

18.4.2 Ethylene is perceived by receptor complexes at the endoplasmic reticulum

As a small, nonpolar, gaseous molecule, ethylene can diffuse from cell to cell both in solution and through air spaces. It is also possible that vascular transport of the immediate precursor to ethylene, 1-aminocyclopropane-1-carboxylic acid (ACC), can transmit the ethylene signal over long distances.

In *Arabidopsis*, ethylene perception depends on five related receptors located at the ER membrane: ETHYLENE RESPONSE1 and 2 (ETR1 and ETR2), ETHYLENE RESPONSE SENSOR1 and 2 (ERS1 and ERS2), and ETHYLENE INSENSITIVE4 (EIN4). These receptors were identified by single dominant mutations that reduce ethylene binding and result in the loss of ethylene responses by the plant (Fig. 18.14). This is a surprising result, since each ethylene-insensitive mutant still possesses four genes encoding wild-type receptors. Furthermore, recessive, null mutations in any one receptor have no phenotypic effect, showing that the ethylene receptors are functionally redundant. However, loss of the function of multiple receptors leads to a constitutive ethylene response, the opposite phenotype to that induced by the dominant mutations (Fig. 18.14).

Together, these data suggest a counterintuitive model for ethylene perception in which the receptors are active in the absence of ethylene and are inactivated by ethylene binding (Fig. 18.15). The dominant mutations prevent ethylene binding and so lock a receptor in its active state, producing a constitutive 'no ethylene' signal and, hence, a loss of ethylene response. In contrast, multiple null mutants have significantly reduced receptor activity even in the absence of ethylene, resulting in constitutive ethylene responses.

The ethylene receptors exist as homo- and heterodimers and bind to ethylene via a copper cofactor. They have homology to histidine kinase receptors that act in bacterial two-component systems; however, histidine kinase activity does not appear to be necessary for ethylene signaling. Section 18.5 discusses two-component systems with reference to cytokinin signaling and gives details of the structures and subtypes of the ethylene receptors in that context.

The ethylene receptors form complexes at the ER membrane with the downstream signaling protein CONSTITUTIVE TRIPLE RESPONSE1 (CTR1). CTR1 was defined by loss-of-function mutations that cause a constitutive triple response, indicating CTR1 inhibits ethylene responses. Both the presence of CTR1 at the ER and its ability to suppress ethylene responses depend on binding between CTR1 and the receptors. Mutated CTR1 that cannot bind to receptors is cytosolic and inactive, resulting in a constitutive triple response. These data suggest that in the absence of ethylene, ethylene receptors activate bound CTR1, which acts to prevent ethylene responses. Ethylene binding, however, prevents the receptors from activating CTR1 and so allows ethylene responses to occur (Fig. 18.15).

The precise mechanism of ethylene signal transduction after perception at the ER membrane by receptor-CTR1 complexes is uncertain. CTR1 is homologous to mammalian RAF kinases, MAPKKKs that initiate MAPK signaling cascades (see Section 18.3.2), and mutations that abolish CTR1 kinase function result in constitutive ethylene responses, indicating kinase activity is required for CTR1 to inhibit ethylene signaling. This suggests a MAPK cascade functions in ethylene signaling, but conclusive evidence is lacking.

FIGURE 18.15 Ethylene signal transduction by receptor-CTR1 complexes. (A) In the absence of ethylene, ethylene receptors at the ER membrane activate bound CTR1, which inhibits ethylene responses. (B) Ethylene binding prevents the receptors from activating CTR1, allowing ethylene responses to occur. (C) Dominant receptor mutants are unable to bind ethylene, resulting in constitutive CTR1 activity and suppression of ethylene responses. (D) Loss of multiple receptors reduces binding and activation of CTR1, resulting in permanent ethylene responses.

18.4.3 Ethylene responses depend on the EIN3 family of transcription factors

Mutant analysis has identified positive regulators of ethylene responses downstream of CTR1, notably the EIN2 and EIN3 proteins (Fig. 18.16). Loss of EIN2 function results in complete ethylene insensitivity, demonstrating EIN2 is absolutely required to induce ethylene responses. EIN2 is an ER-tethered protein the phosphorylation of which is dependent on CTR1. Ethylene results in its dephosphorylation and cleavage, and the resulting C-terminal cleavage product translocates to the nucleus, where it can activate EIN3.

EIN3 is a transcription factor that induces gene expression in response to ethylene signals transduced through EIN2. Together with the related proteins EIN3-LIKE1 (EIL1) and EIL2, it appears necessary for the induction of most transcriptional responses to ethylene. For example, double mutants lacking functional EIN3 and EIL1 display virtually no changes in gene transcription after ethylene treatment. Among the genes induced by EIN3 and the EILs are more transcription factors (e.g., ERF1) that induce other ethylene responsive genes, allowing rapid amplification of the ethylene signal and activation of hundreds of genes in response to ethylene perception (Fig. 18.16).

EIN3 activity is controlled through the regulation of EIN3 protein stability. EIN3 is bound by F-box proteins (see Section 18.6) EBF1 and EBF2, which prevent its activity by targeting it for destruction. Ethylene signaling prevents EBF1 and EBF2 from inducing EIN3 destruction, leading to accumulation of EIN3 and induction of ethylene-responsive genes. One mechanism by which this may be achieved is by destruction of the EBF1 and EBF2 mRNAs through action of the EIN5 protein (also called XRN4), an exoribonuclease required for full ethylene response. EIN3 stability may also be regulated by phosphorylation of EIN3, and EIN3 can be phosphorylated at two sites, one that increases and another that decreases its half-life.

Interestingly, one of the genes directly induced by EIN3 encodes EBF2, creating a negative feedback cycle in which EIN3 promotes its own destruction. It is tempting to speculate this mechanism enables ethylene signaling to switch off rapidly once ethylene is no longer present. An effective off-switch could be particularly important for ethylene signal transduction because ethylene appears to bind tightly to its receptors. For example, the half-life of ethylene dissociation from the ETR2 receptor as measured in transgenic yeast is approximately 10 hours.

18.4.4 Ethylene signaling interacts with other signaling mechanisms

Points of interaction have been identified between ethylene signal transduction and other signaling mechanisms in the plant (Fig. 18.16). For example, whereas ethylene promotes

FIGURE 18.16 Ethylene signal transduction. Ethylene binding prevents ethylene receptors from activating CTR1, thus preventing CTR1 from inhibiting the activity of downstream components, such as EIN2. The transduction of the inhibitory signal from CTR1 to EIN2 may involve a kinase cascade. EIN2 promotes the activity of EIN3 and EIL transcription factors by preventing protein degradation induced by EBF1 and EBF2. This may occur in part by activation of EIN5, which degrades EBF1 and EBF2 mRNAs. EIN3 and EILs promote the expression of ethylene responsive genes, including downstream transcription factors such as ERF1, and the negative regulator EBF2. Glucose signaling enhances EIN3 degradation. Jasmonic acid (JA) signaling promotes the expression of ERF1. Lines ending in an arrow head indicate positive regulation. Lines ending in a bar indicate negative regulation.

EIN3 stability, glucose promotes EIN3 destruction. The mechanism by which glucose affects EIN3 stability is unknown, but the glucose-induced signals may counteract ethylene responses. Since ethylene signaling commonly leads to a reduction in both plant stature and leaf size, this provides a means by which abundant glucose produced by photosynthesis could promote plant growth.

Immediately downstream of EIN3, the ERF1 transcription factor provides another point of interaction. As described above, expression of the *ERF1* gene is directly induced by EIN3. *ERF1* is also activated by signals induced by JA, a hormone involved in regulating plant defense against herbivores. Ethylene and JA are synergistic in their activation of *ERF1*, and since the synthesis of both hormones is induced by wounding from herbivores, they combine to amplify the plant's response.

In addition to interactions during ethylene signal transduction, cross-regulation between ethylene and other hormones occurs at the level of hormone synthesis. The best-understood case is the interaction between ethylene and auxin. As stated above, the immediate precursor of ethylene is ACC. Auxin promotes the expression of ACC synthase and in doing so induces ethylene production. Similarly, ethylene promotes transcription of genes required for auxin biosynthesis in *Arabidopsis* roots. Therefore, some of the effects of auxin and ethylene on the plant may be due in part to the mutual induction of each other's synthesis.

18.5 Cytokinin signal transduction

18.5.1 The cytokinin signal is transduced by proteins derived from bacterial two-component systems

Cytokinins are signaling molecules related to adenine that function in a range of processes including seed development and germination, development at the shoot and root apical meristems, vascular patterning, shoot branching, leaf senescence, circadian rhythms, stress responses, and interactions with pathogens and nodulating bacteria. Cytokinin signal transduction involves a mechanism derived from the bacterial **two-component system**, a major signal transduction module that regulates responses to a wide range of physical and molecular stimuli in prokaryotes.

The basic two-component system consists of two proteins, a **histidine kinase** and a **response regulator** (Fig. 18.17). The

FIGURE 18.17 The two-component system and its multistep derivative. (A) The two-component system consists of a histidine kinase and response regulator. On activation of the input domain by ligand binding or other processes, the histidine kinase autophosphorylates a histidine residue in the transmitter domain. This phosphoryl group is then transferred to a conserved aspartate residue in the receiver domain of the response regulator, resulting in the activation of the neighboring output domain. (B) In the multi-step derivative, the histidine kinase often contains its own receiver domain, and phosphotransfer to the response regulator is mediated by a histidine phosphotransfer protein. The phosphoryl group moves from the transmitter domain to the receiver domain of the histidine kinase, then to a histidine phosphotransfer protein, and then to the response regulator. All phosphotransfers in the two systems can also occur in the reverse direction.

histidine kinase exists as a dimer and may be membrane spanning or soluble. Each kinase monomer possesses two domains: an input domain and a transmitter domain. The input domains of the two monomers are responsible for signal perception, following which the monomers reciprocally phosphorylate a histidine residue in each other's transmitter domain. Therefore, signal perception leads to autophosphorylation of the histidine kinase.

The response regulator also contains two domains, a receiver domain and an output domain. Phosphoryl groups are transferred from autophosphorylated histidine kinases to an aspartate residue in the receiver domain of response regulators. This activates the output domain of the response regulator, leading to onward signaling (e.g., induction of gene transcription by response regulators that act as transcription factors).

Though this basic system is only found in prokaryotes, an evolutionary derivative consisting of a multistep phosphorelay with three components occurs in prokaryotes, plants, and fungi, but not animals (Fig. 18.17). In the multistep system, the histidine kinase often contains its own receiver domain, to which the phosphoryl group is transferred after autophosphorylation. Rather than the phosphoryl group then moving directly from the kinase to the response regulator, this phosphotransfer occurs via an intermediate called a **histidine phosphotransfer protein** (HPT). HPTs share similarities with the transmitter domain of the histidine kinase, indicating the multistep system evolved using protein domains already present in the basic system. In both the basic and multistep systems, all phosphotransfers can occur in both directions (e.g., from the response regulator to the histidine kinase in the basic system). Signal transduction, therefore, depends on the balance of 'forward' and 'reverse' phosphotransfers.

18.5.2 Cytokinin is one of several signals transduced by two-component systems in *Arabidopsis*

Genome analysis reveals *Arabidopsis* has 11 putative histidine kinases, five functional HPTs (*Arabidopsis* histidine-containing phosphotransfer factors, **AHPs**), and 23 response regulators (*Arabidopsis* response regulators, **ARRs**). Three of the histidine kinases, all AHPs, and virtually all ARR genes have been implicated in cytokinin signaling (Fig. 18.18).

The three cytokinin receptors of *Arabidopsis*, ARABIDOPSIS HISTIDINE KINASE2 and 3 (AHK2 and AHK3) and CYTOKININ RESPONSE1 (CRE1, also called AHK4), are plasma membrane histidine kinases. Each has an extracellular input domain that binds cytokinins, a transmitter domain, and a receiver domain. Cytokinin binding induces autophosphorylation. Phosphoryl groups are then transferred via the receiver domain to AHPs, inducing AHP movement from the membrane into the nucleus and the subsequent transfer of phosphoryl groups to the "type-B" subfamily of ARR genes. *Arabidopsis* also produces a pseudo-AHP, called AHP6, which lacks the histidine residue required to receive a

FIGURE 18.18 Signaling mediated by two-component-derived proteins in *Arabidopsis*. During cytokinin signaling, histidine kinase receptors bind cytokinins and initiate a phosphorelay that activates type-B ARR genes, which induce transcription of cytokinin-responsive genes. Signal transduction is inhibited by AHP6, a pseudo-AHP that is thought to compete with genuine AHPs for access to the receptors. Other histidine kinases (ETR1, AHK1, AHK5, and CKI1) probably also signal through the phosphorelay mechanism. Type-A ARR genes are activated by the phosphorelay initiated by cytokinin receptors, are induced at the level of transcription by type-B ARR genes, and in some cases are stabilized by cytokinin signaling (not shown). Type-A ARR genes inhibit cytokinin signaling by an unknown mechanism, resulting in negative feedback. Some type-A ARR genes also interact with phyB and mediate phyB's input into circadian rhythms. Note that cell wall is not shown for clarity.

phosphate group transferred from a cytokinin receptor. AHP6 acts as an inhibitor of cytokinin signaling, perhaps by competing with genuine AHPs for access to the receptors.

Type-B ARR genes are transcription factors, and in response to phosphorylation by AHPs, they function in a partially redundant fashion to induce transcription from cytokinin-responsive genes. In addition to type-B ARR genes, *Arabidopsis* possesses type-A ARR genes, which are unable to bind DNA and do not induce transcription. Type-A ARR genes are activated as direct targets of phosphotransfer from AHPs, and in response they act as negative regulators of cytokinin signaling. The biochemical mechanism of type-A ARR action is unknown. Interestingly, type-B ARR genes induce transcription from type-A ARR genes in response to cytokinin, and cytokinin signaling also increases the half-life of some type-A ARR proteins. Therefore, cytokinin promotes both the activity and abundance

of type-A ARRs, creating a negative feedback loop that dampens cytokinin signaling (Fig. 18.18).

Apart from the three cytokinin receptors, five of the remaining eight putative histidine kinases in *Arabidopsis* are the ethylene receptors (ETR1, ETR2, ERS1, ERS2, and EIN4, see Section 18.4). These have a membrane-spanning input domain that binds ethylene via a copper cofactor and a histidine kinase transmitter domain; however, the histidine kinase domain is only functional in two ethylene receptors (ETR1 and ERS1). In addition, mutant analysis indicates kinase activity in ETR1 and ERS1 is not needed for ethylene signaling. The picture is further complicated by the fact that only three of the five receptors (ETR1, ETR2, and EIN4) possess a receiver domain of the two-component type. Hence ETR1, but no other ethylene receptor, has both histidine kinase activity and a receiver domain. This may allow ETR1 to interact with the downstream two-component-derived elements—AHPs and through them, ARRs—but currently the extent and role of such signaling are unclear.

The final three histidine kinases in *Arabidopsis* are AHK1, AHK5, and CKI1. All possess a functional input domain, histidine kinase, and receiver domain and are, therefore, likely to signal through AHPs and ARRs, creating possible interactions with cytokinin (and ETR1) signaling (Fig. 18.18). CKI1 is required for megagametophyte development, and AHK1 and AHK5 both appear to mediate stress responses: AHK1 acts as a positive regulator of drought and salt responses, while AHK5 regulates stomatal closure (see Section 18.9) in response to hydrogen peroxide, which is produced following a variety of stresses.

Finally, two-component-derived proteins also transduce signals that are not perceived by histidine kinases. Phytochrome B (phyB, see Section 18.7) interacts with ARR3 and ARR4 (type-A ARRs) in *Arabidopsis* (Fig. 18.18). These mediate the input of phyB into the circadian oscillator in a manner independent of cytokinin signaling. Double mutants lacking ARR3 and ARR4 function also have circadian abnormalities under blue light and continual darkness, conditions in which phyB is inactive. Hence, the two response regulators likely have additional roles in regulating circadian rhythms. Interestingly, the central oscillator of the clock involves pseudo-response regulators, proteins related to ARRs but lacking the ability to accept a phosphoryl group from AHPs.

18.6 Integration of auxin signaling and transport

18.6.1 Complex patterns of auxin flux and accumulation direct key events in plant development

Auxin was discovered in the early 20th century through investigations into seedling phototropism. The predominant auxin in plants is **IAA**, and the list of its known functions now

includes numerous other aspects of plant development. In addition to acting in the regulation of tropisms, auxin functions in patterning the embryo, controlling development at both the root and shoot apical meristems, and coordinating regeneration after wounding. Over a larger scale, auxin acts in the control of both lateral root initiation and bud outgrowth and forms part of the mechanism that coordinates root and shoot growth.

The developmental roles of auxin rely on complex patterns of intercellular auxin transport and accumulation. During embryogenesis in *Arabidopsis*, for example, auxin transport from the basal to the apical cell of the two-cell embryo created by zygotic division is thought to direct the apical cell towards the formation of the embryo proper, while most derivatives of the basal cell form a supporting, nutritive structure called the suspensor. Later, specification of root development requires a shift in the direction of auxin transport to create an auxin flux running from the presumptive embryonic shoot apex down through the embryo into the suspensor.

Unique among plant hormones, auxin moves between cells by a dedicated transport system composed of an intricate network of transmembrane proteins. This network is regulated by auxin signaling to generate multiple levels of feedback between auxin signal transduction and auxin transport. Together with local synthesis and degradation, such feedback helps to generate both stable and dynamic patterns of auxin flux and accumulation that are required for development. Auxin transport is also regulated by developmental information and environmental cues in ways that coordinate development with internal and external information.

The following sections consider auxin signal transduction, intercellular auxin transport, and the feedback between the two.

18.6.2 Transduction of intracellular auxin is mediated by targeted protein degradation

Auxin enters cells by both passive movement and active transport (see Section 18.6.4). Within the cell, auxin is perceived by a small family of soluble, nuclear receptors that act in protein complexes involved in targeting proteins for degradation (Fig. 18.19).

In eukaryotic cells, proteins are tagged for destruction by sequential conjugation with the small protein **ubiquitin** to attach a poly-ubiquitin chain. Once tagged in this way, proteins can be recognized and destroyed by the **26S proteasome**, a large complex of proteolytic enzymes. Addition of ubiquitin is a multistep process. First, a high-energy thioester bond is formed between ubiquitin and an **E1 ubiquitin-activating enzyme** by a mechanism that requires ATP hydrolysis. The ubiquitin is then transferred to an **E2 ubiquitin-conjugating enzyme**, to which it also attaches via a thioester bond. The ubiquitin-carrying E2 and the target protein are then brought together by an **E3 ubiquitin-protein ligase**, which catalyzes the transfer of the ubiquitin molecule to the target.

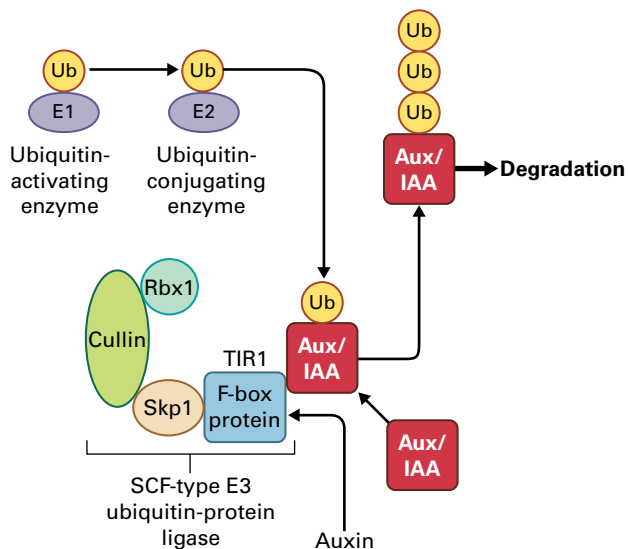

FIGURE 18.19 Targeted protein degradation mediates auxin signal transduction. Auxin binding to the F-box protein TIR1 enhances interaction between TIR1 and Aux/IAA proteins. This allows polyubiquitination of Aux/IAA proteins through the sequential actions of E1, E2, and E3 enzymes and so targets Aux/IAs for degradation. Ub, ubiquitin.

Plants possess multiple E3 enzymes, which occur in distinct families. With respect to auxin signal transduction, the E3 enzymes of interest are multiprotein **SCF complexes** (named after three of their major constituents: a **Skp1** protein, a **Cullin** protein, and an **F-box** protein). A fourth subunit called **Rbx1** forms a dimer with Cullin, and the Cullin–Rbx1 dimer transfers the ubiquitin to the target protein (see Section 10.6). The target protein associates with the complex via the F-box protein, while Skp1 acts as a scaffold to connect the other subunits (Fig. 18.19). Therefore, the F-box protein is what gives an SCF complex its specificity for target proteins.

Intracellular auxin signal transduction involves the binding of auxin to members of a small family of F-box proteins that function as auxin receptors. The family consists of TIR1 (TRANSPORT INHIBITOR RESISTANT1) and related AUXIN SIGNALING F-BOX PROTEINS AFB1, AFB2, and AFB3. These are among about 700 F-box proteins in the *Arabidopsis* genome. In addition to the auxin receptors, these include the **zeitlupe** photoreceptors, which function in the regulation of the circadian clock (Box 18.2), proteins that act in signal transduction of gibberellins (see Section 18.8) and the defense-related hormone JA.

Of the auxin receptors, TIR1 has been studied in the most detail. A soluble, nuclear protein, TIR1 brings a group of short-lived transcriptional repressors called Aux/IAs to the SCF complex for polyubiquitination. The association between TIR1 and Aux/IAA occurs at a region of LRRs (see Section 18.2.2) in TIR1. The interaction is enhanced by auxin, which binds to a hydrophobic pocket within the LRR region to increase the size of the binding surface for the Aux/IAA, which docks onto TIR1 directly over the auxin molecule. Inositol hexakisphosphate is a possible cofactor in the

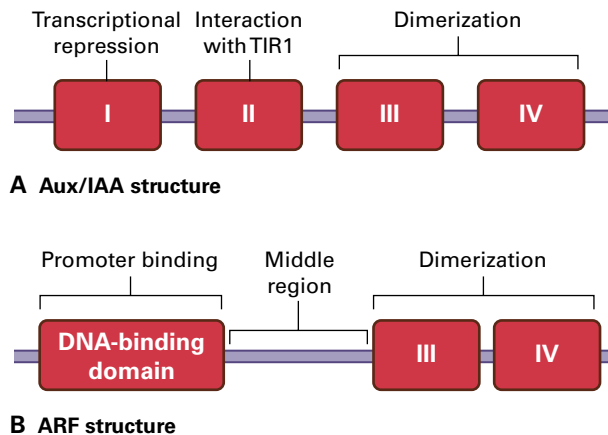

FIGURE 18.20 Structure of Aux/IAs and ARFs. (A) Aux/IAs possess a transcriptional repressor domain (I), a domain required for interaction with TIR1 and the AFB proteins (II), and two dimerization domains (III and IV). (B) ARFs possess a DNA-binding domain, a middle region, and dimerization domains related to those in Aux/IAs.

interaction. Because of its mode of action, auxin has been described as molecular glue that helps Aux/IAs stick to TIR1. As a consequence, auxin increases the rate at which Aux/IAs are targeted for ubiquitination and degradation. Hence, increases in auxin concentration reduce the half-life of Aux/IAA proteins (Fig. 18.19).

Aux/IAs contain four conserved domains (Fig. 18.20). Domain I, at the amino terminus, is a potent transcriptional repressor. Domain II is responsible for the interaction with TIR1 and is required for auxin-induced degradation of Aux/IAs. The carboxyl-terminal domains III and IV are dimerization domains that mediate the formation of Aux/IAA dimers. Domains III and IV are also present in a group of transcription factors called **Auxin response factors** (ARFs, Fig. 18.20) and mediate the formation of both ARF–ARF and ARF–Aux/IAA dimers. Within a cell there is, therefore, a complex pattern of dimerization within and between the Aux/IAA and ARF families, and changes to this pattern are thought to be crucial to auxin signal transduction.

The simplest example arises from the interaction between Aux/IAs and a group of ARFs that act as transcriptional activators (Fig. 18.21). ARFs contain an amino-terminal DNA-binding domain, which can also mediate ARF–ARF dimerization and is separated from the carboxyl-terminal dimerization domains by a middle region (Fig. 18.20). The 22 ARFs in the *Arabidopsis* genome are classified into subgroups according to the composition of the middle region, and a group of five ARFs characterized by a glutamate-rich (Q-rich) middle region act as transcriptional activators. ARFs bind to the promoters of auxin-inducible genes. At low auxin concentrations, the ARFs form heterodimers with Aux/IAs, and the repressor domain of the Aux/IAA prevents gene transcription (Fig. 18.21). Since Aux/IAs lack a DNA-binding domain, they require an ARF to bring them to a promoter region to repress transcription. Auxin reduces Aux/IAA concentration, freeing the Q-rich ARFs from repression

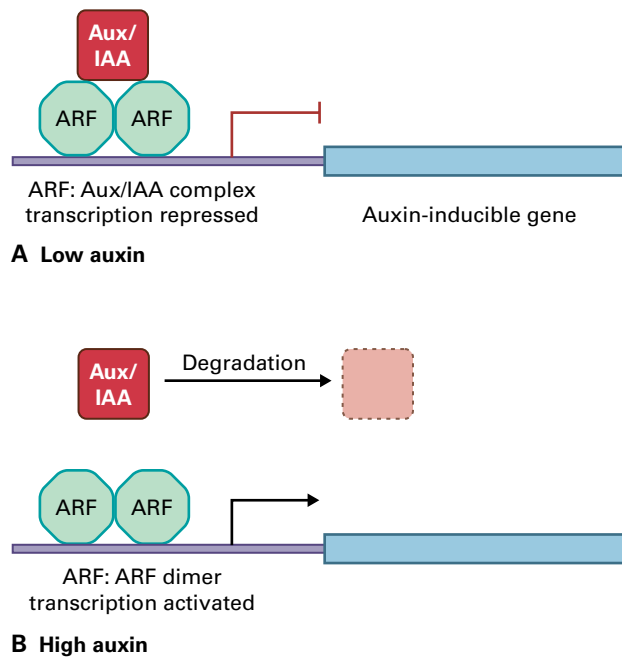

FIGURE 18.21 Auxin-responsive genes are activated by the Q-rich sub-family of ARF proteins. (A) Activation is blocked at low auxin concentration by the formation of an ARF:Aux/IAA complex. (B) High auxin concentrations induce Aux/IAA degradation and so activate transcription.

thereby activating gene transcription. *Aux/IAA* genes are among those induced by this mechanism, as are *GH3* genes which encode auxin-conjugating enzymes responsible for reducing free auxin levels. Therefore, auxin signal transduction includes at least two negative feedback loops that dampen the auxin response.

Unlike the Q-rich ARFs, at least some members of other ARF subgroups act as transcriptional repressors, suggesting auxin responses mediated by Aux/IAAs and ARFs are more complex than simple gene induction. Aux/IAAs also have diverse properties. For example, the half-lives of the 29 *Arabidopsis* Aux/IAAs can vary by an order of magnitude. These data suggest the effects of auxin signaling depend on the particular combinations of ARF and Aux/IAA expressed in individual cells.

18.6.3 Cells may perceive extracellular auxin

In addition to the perception of intracellular auxin by TIR1 and AFBs, there is evidence for a receptor for extracellular auxin. A candidate is a membrane-associated protein called AUXIN-BINDING PROTEIN1 (ABP1).

ABP1 is localized both at the plasma membrane and the ER; however, ABP1 only binds auxin efficiently at extracellular pHs, suggesting it associates with auxin on the outer face of the plasma membrane. Evidence that ABP1 may act as a

receptor for extracellular auxin comes, among other things, from research on the auxin response of protoplasts (tissue-cultured cells lacking a cell wall).

In some contexts, auxin treatment induces very rapid (<1 minute) changes in plasma membrane ion fluxes. In protoplasts, the result is a shift in osmotic potential that causes water intake and protoplast swelling. This effect can be mimicked in the absence of auxin if protoplasts are treated with antibodies that bind to the ABP1 auxin binding site, but can be blocked by antibodies that bind to ABP1 elsewhere. These results support the hypothesis that ABP1 is an auxin receptor. Antibodies bound to the auxin binding site might trigger signal transduction leading to changes in ion fluxes, whereas antibodies binding elsewhere might prevent either auxin binding or subsequent signaling by ABP1.

18.6.4 Auxin signaling regulates the machinery of auxin transport

The polarized flow of auxin through tissues and organs requires auxin movement into and out of successive cells, and this involves both active and passive movement of auxin across the plasma membrane (Fig. 18.22). Active transport of auxin is mediated by at least three classes of membrane transporter proteins: the **AUX1/LIKE AUX1 (AUX/LAX)** family, which act as auxin influx carriers, **ABCB proteins**, which mediate both auxin influx and efflux depending on the protein, and **PIN proteins**, which are believed to function as auxin efflux carriers. In addition, the pH difference between the apoplast (pH 5.5) and the cytoplasm (pH 7) is thought to drive passive movement of auxin into the cell. IAA is a weak acid and exists in both its protonated and ionized forms in the acidic conditions of the wall. Uncharged, protonated IAA can move across the plasma membrane, but once in the neutral cytoplasm, it ionizes and is unable to move back out. Therefore, whereas auxin influx occurs by both passive flow and active transport, the movement of auxin out of the cell is necessarily mediated by efflux carriers.

The polarity of intercellular auxin flux depends largely on the asymmetric distribution of the auxin membrane transport proteins, in particular the PIN proteins. *Arabidopsis* has eight PIN proteins (PIN1–8), several of which are associated with mutant phenotypes that suggest disrupted auxin transport. For example, *pin1* mutants are defective in organ initiation at the shoot apical meristem, a process that requires the auxin flux-driven formation of localized auxin concentration maxima (see below). Techniques such as immunolocalization or the fusion of PIN proteins to reporter proteins demonstrate that PIN polarization in auxin-transporting cells corresponds to the predicted direction of auxin flux. A major feature of auxin movement in the plant, for example, is the transport of auxin synthesized by young leaves in a shoot-to-root direction through xylem parenchyma cells and the vascular cambium.

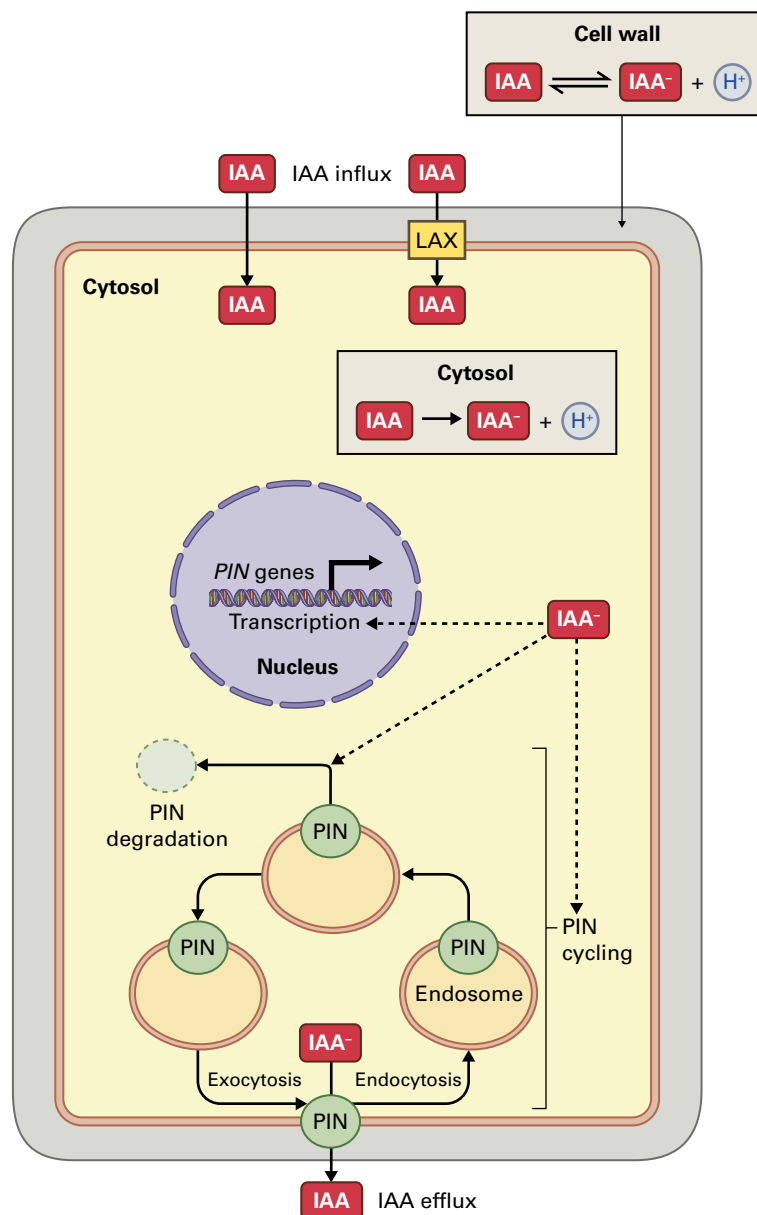

FIGURE 18.22 Auxin (IAA) influx occurs by passive diffusion and by active transport via LAX proteins. Auxin efflux occurs by active transport by PIN proteins, and the distribution of PIN proteins is thought to determine the direction of intercellular auxin flux. Feedback between auxin signaling and auxin transport occurs at multiple levels. For example, auxin signaling regulates the transcription, cycling, and degradation of PIN proteins. Auxin influx and efflux are also mediated by ABCB proteins (not shown).

This auxin flow is known as the **polar transport stream** and is associated with the polarization of PIN1 to the basal (root-facing) membrane of the transporting cells. Auxin is also transported from the shoot to the root by bulk flow through the phloem,

Several levels of interaction have been identified that link the auxin transport machinery to auxin signaling. Auxin treatment induces expression of *PIN* genes and leads to the accumulation of PINs, a mechanism by which increased auxin concentration in a cell could increase auxin efflux activity. In some contexts, however, auxin treatment also reduces the

stability of PIN proteins; therefore, the overall effect of auxin concentration on PIN abundance can be complex.

Auxin signaling also affects the mechanism determining PIN polarization. In some cell types PIN proteins undergo continual cycling between the cell membrane and endosomes (Fig. 18.22). Over the short term, auxin treatment inhibits endocytosis of PIN proteins and so may lead to accumulation of PINs at the plasma membrane and, therefore, promotion of auxin export from the cell. In contrast, longer term auxin treatments can increase PIN internalization. As with PIN abundance, therefore, auxin signaling appears to interact with

FIGURE 18.23 Canalization hypothesis. (A) Cells between an auxin source (top) and sink (bottom) begin to transport auxin in the direction of auxin flux. (B, C) Positive feedback between auxin transport and the capacity for auxin transport causes the channeling of auxin flux into narrow strands of increasingly polarized cells. (D) When auxin concentration rises above a threshold, cells in such strands differentiate into vascular tissue.

PIN cycling in a complex manner that includes both positive and negative regulation.

Auxin also induces transcription from *PINOID* (*PID*), a gene encoding a protein kinase that regulates PIN polarization. *PID* is a serine/threonine kinase that appears to regulate the position of PIN proteins with respect to the apical-to-basal (shoot-to-root) axis of the plant. Loss of *PID* function leads to a consistent shift of apically localized PIN proteins to the basal face of cells. In contrast, constitutive expression of a *PID* transgene can cause basally localized PIN proteins to move to the apical face of cells. *PID* has been shown to phosphorylate PIN proteins directly. Therefore, an intuitive explanation for the data is that PIN proteins phosphorylated by *PID* are targeted to the apical face of the cell, whereas unphosphorylated PINs are directed to the basal face.

In addition to control by auxin signaling, auxin transport is also regulated by cell type and environmental information. For example, epidermal cells at both the root and shoot tips display different auxin transport characteristics to cells in underlying tissues. This is discussed below with respect to leaf initiation. A clear example of environmental influence on auxin flux occurs in tropisms, in which environmentally responsive redirection of auxin transport leads to localized auxin concentration-dependent changes in cell expansion, and causes tropic curvature.

18.6.5 Feedback between auxin signaling and transport is required for both vascular patterning and leaf initiation

The regulation of PIN distribution and concentration by auxin suggests feedback between auxin signaling and auxin transport. A major function of such feedback is in development, which requires robust, partially self-organizing mechanisms for creation of patterns of cells, tissues, and organs. Two well-studied examples of auxin-mediated development are the patterning of vascular tissue and leaf initiation.

The **canalization hypothesis** proposes a positive feedback mechanism that links vascular development to auxin flux (Fig. 18.23). According to this hypothesis, polarized auxin transport by a cell induces an increase in both the polarization and activity of that cell for subsequent auxin transport. With a limited auxin source and a defined auxin sink, this creates competition between cells for auxin and progressive channeling of auxin flux into a narrow file of highly polarized cells that connect the source to the sink. The hypothesis further proposes that, at a certain threshold of auxin concentration, cells in the strand are induced to differentiate into vascular tissue. Monitoring PIN distribution, for example, through use of PINs fused to green fluorescent protein (PIN-GFP), shows canalization in action. In a variety of contexts, vascular differentiation is preceded by the gradual formation cell files expressing increasingly high PIN levels localized according to the predicted direction of auxin flux. These files subsequently differentiate into vascular strands.

In contrast to the stable routes for auxin transport generated during vascular development, organ initiation at the shoot apical meristem depends on repeated changes in auxin flux and accumulation (Fig. 18.24). This is shown by the development of naked pin-like structure at the shoot apex following disruption of auxin flow by auxin transport inhibitors, or in the *pin1* mutant (it was this that gave the PIN genes their name). Leaves can be induced to develop on such pins by local auxin application, suggesting that leaves and other organs are initiated at sites of high auxin concentration.

The pattern of auxin flux in untreated, wild-type meristems has been investigated by real-time imaging of PIN-GFP and by PIN immunolocalization. The results of these studies have led to the proposal that cells in the meristem's epidermal layer distribute PIN proteins such that each cell transports auxin toward the neighbor in the layer with the greatest auxin concentration. The result is a feedback mechanism that generates a convergence of auxin flux to create a local auxin concentration maximum in the epidermis. Cells at this site initiate a leaf. In subepidermal layers at the site of initiation, PIN proteins eventually relocate to the basal cell face and direct auxin flux towards deeper tissues (where it is involved in vascular differentiation in the developing leaf). These fluxes drain

FIGURE 18.24 Leaf initiation. Auxin concentration is shown in red, and polar auxin transport is indicated by arrows. (A) In the meristem epidermis, auxin is transported up its concentration gradient, leading to localized auxin accumulation that defines the leaf initiation site (I1). (B) As the leaf initiates (P1), auxin is transported from epidermis at the leaf tip into subepidermal layers. This drains auxin from the surrounding epidermis, causing redistribution of auxin transport towards the next initiation site.

auxin away from surrounding epidermal cells and so inhibit leaf initiation in the vicinity of the new primordium.

As each leaf is initiated, the change in the pattern of auxin concentration in the epidermis causes a shift in PIN polarization in epidermal cells such that auxin is directed towards the next leaf initiation site. This generates the regular pattern of leaves around the apex (the phyllotaxy). Note that the mechanism requires auxin to be retained in the epidermal layer, which is achieved by the localization of AUX/LAX influx carriers to the epidermal cells.

The hypothesized mechanisms of vascular patterning and leaf initiation show how complex interactions between auxin, its transport, and its signaling can create patterns that regulate plant development. Both the parameters of the interactions and their outcome depend on developmental context. Furthermore, the core mechanisms may be regulated by additional local and long-range signals.

18.7 Signal transduction from phytochromes

18.7.1 A major function of phytochromes is to distinguish between red and far-red light

Phytochromes are present in all green plants, several bacterial groups, and some fungi. They were discovered through investigation into the phenomenon of **red/far-red photoreversibility**. For example, in many species germination is promoted by short exposure to red light (wavelengths of 620–700 nm) but is inhibited if this is followed immediately by exposure to far-red light (wavelengths of about 700–800 nm).

Photoreversibility arises from the interconversion of phytochromes between two isomers with different light-absorbing

properties (Fig. 18.25). Phytochromes are synthesized as an inactive, red light-absorbing isomer called P_R . Light absorption by P_R converts it to an active, far-red-absorbing isomer called P_{FR} (**photoconversion**). Similarly, light absorption by P_{FR} converts it back to P_R . Hence, red light promotes phytochrome responses by converting inactive P_R into active P_{FR} , while far-red light inhibits the same responses by converting P_{FR} back to P_R . In addition to photoconversion, P_{FR} can revert spontaneously to P_R . Although such reversion occurs in light and darkness, it is measured by the fall in P_{FR} concentration in the dark, and so is known as **dark reversion** (Fig. 18.25).

Phytochromes act with other plant photoreceptors to modulate physiology and development (Box 18.2). Photoconversion between P_R and P_{FR} allows phytochromes to provide information about the ratio of red to far-red light (R:FR ratio) in the plant's environment. This is biologically relevant because leaves absorb most red light, whereas they transmit most far-red light. Therefore, a low R:FR ratio indicates shading from competitors, which has a variety of developmental effects, depending on the species. In weedy plants such as *Arabidopsis*, low R:FR inhibits seed germination and induces shade escape responses during plant growth. Phytochrome-mediated responses also include seedling photomorphogenesis, flowering, and control of the circadian clock.

Phytochromes are soluble proteins and are dimers in which each subunit is bound to a molecule of phytychromobilin, a linear tetrapyrrole that functions as the light-absorbing chromophore (Fig. 18.25). Light absorption by phytychromobilin causes its isomerization and subsequent changes to both the absorption spectrum of the chromophore and the conformation of the phytochrome protein. Although the absorption peaks of P_R (about 660 nm) and P_{FR} (about 730 nm) are in the red and far-red regions of the spectrum respectively, both isomers absorb some light at all wavelengths from UV-B to far-red (Fig. 18.26). Therefore, no wavelength of illumination fully drives phytochromes into existing purely as P_R or P_{FR} .

Plants produce several different phytochromes. *Arabidopsis*, for example, contains five different phytochromes (phyA–E) that possess identical chromophores and show the same absorption spectra in their P_R and P_{FR} forms, but have different apoproteins and display overlapping, but distinct functions. The main functional distinction is between **light-labile** and **light-stable** phytochromes; in *Arabidopsis*, only phyA is light labile, and the other four phytochromes are light stable.

Light-labile phytochromes are the predominant form in imbibed seeds and in seedlings kept in continual darkness. Tests on *Arabidopsis* show that in these circumstances, the *PHYA* gene is strongly expressed, resulting in the accumulation of high concentrations of the phytochrome's P_R isomer (P_{RA}). This causes extreme light sensitivity, because even very low light exposures generate sufficient P_{FR} to induce responses. This is true across the entire P_R absorption spectrum. Hence, after several days in darkness, imbibed *Arabidopsis* seeds germinate following brief exposures to even UV-B or far-red light. Obviously, these responses do not show photoreversibility (Fig. 18.26).

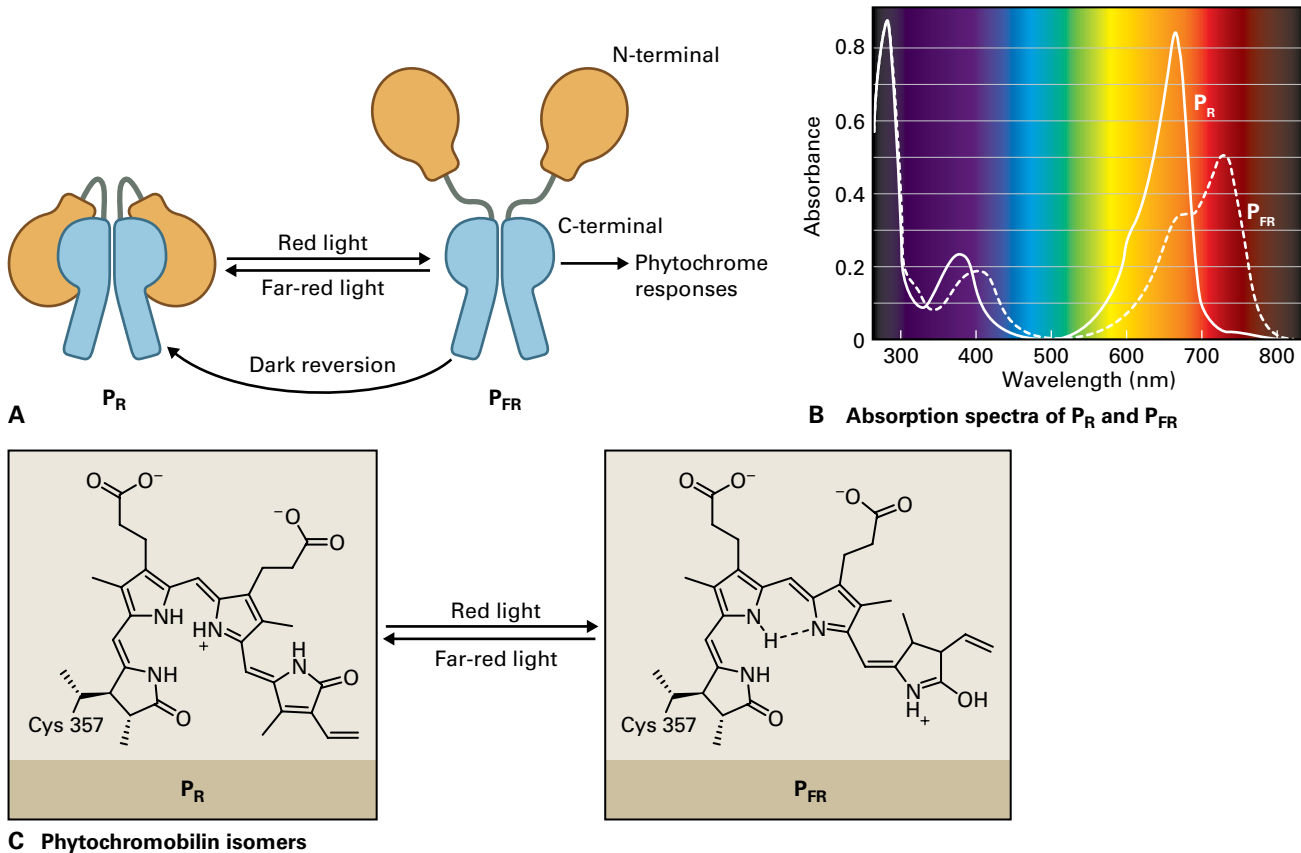

FIGURE 18.25 Phytochromes exist as dimers and undergo photoconversion between inactive P_R and active P_{FR} . (A) P_{FR} also reverts in a light-independent manner to P_R (dark reversion). When P_R converts to P_{FR} , phytochromes undergo a conformational change that is believed to involve the unfolding of the N-terminus from the C-terminus. (B) Absorption spectra for P_R and P_{FR} show peaks for red (around 660 nm) and far-red (around 730 nm), respectively. (C) The phytochrome chromophore is a linear tetrapyrrole called phytychromobilin that undergoes light-induced isomerization.

BOX 18.2

Plant photoreceptors

The **action spectra** of light-regulated responses demonstrate plants are highly sensitive to UV-B radiation (wavelengths from about 280 nm to 320 nm), UV-A radiation (from about 320 nm to 380 nm), blue light (from about 380 nm to 500 nm), red light (from about 620 nm to 700 nm), and far-red light (from about 700 nm to 800 nm). It is, therefore, at these wavelengths that plant photoreceptors are most sensitive. UV-B radiation is detected by the UV RESISTANCE LOCUS 8 (UVR8) protein. UV-A and blue wavelengths are detected by **cryptochromes**, **phototropins**, and the recently discovered **zeitlupes**. Responses to red and far-red light are mediated by **phytochromes**. It has also been proposed that plants may possess receptors for green light (wavelengths from about 500 nm to 600 nm); however, responses to green light are often subtle and are sometimes mediated by cryptochromes and phytochromes, both of which display a degree of sensitivity to this region of the spectrum.

Most photoreceptors consist of proteins bound to light-absorbing pigments called chromophores, which give a photoreceptor its spectral sensitivity. In response to light absorption by the chromophore, the photoreceptor protein regulates downstream signaling. Phytochromes and cryptochromes are both soluble receptors that function primarily in the nucleus to regulate the activity of transcription factors (see Section 18.7). These two classes of photoreceptor combine to regulate developmental responses to light intensity, such as the de-etiolation (photomorphogenesis) of seedlings on reaching the soil surface. As described in Section 18.7, phytochromes also mediate responses to variations in the spectral quality of light that indicate shading by other plants.

Zeitlupes are light-responsive F-box proteins (see Section 18.6.2) that target proteins that function in the circadian clock and the photoperiodic regulation of flowering for degradation. Both the circadian clock and the initiation

of flowering are also regulated by signaling initiated by cryptochromes and phytochromes. UVR8 is a **β -propeller protein** (characterized by a propeller-like domain of flat 'blades' around a central channel). In the absence of UV-B, UVR8 exists as a homodimer. On UV-B absorption, the dimer dissociates and UVR8 monomers interact with nuclear proteins to induce UV acclimation and morphological responses such as reduced hypocotyl elongation.

Phototropins are plasma membrane-associated protein kinases responsible for regulating phototropism and light-induced chloroplast movement. They also function in the control of stomatal aperture (see Section 18.9) and in the regulation of hypocotyl and leaf expansion. Light absorption by phototropins causes their autophosphorylation and induces signal transduction pathways that lead to the redistribution of PIN auxin efflux carriers necessary for directional growth (see Section 18.6.3) and to the changes in plasma membrane ion fluxes that regulate guard cell turgor (see Section 18.9.2).

Signal transduction pathways from different photoreceptors interact, allowing integration of information from the light environment. For example, although phototropism is primarily mediated by phototropins, the amplitude of phototropic bending is modulated by cryptochrome and phytochrome signaling. As discussed in Section 18.7.3, the plasma membrane-associated protein PKS1 interacts with both phyA and phototropin1 and may allow phytochrome signaling to influence phototropic responses. There are also direct and indirect interactions between phytochromes and cryptochromes. For example, phytochromes phosphorylate cryptochromes *in vitro*, and both phytochromes and cryptochromes inhibit the activity of the protein COP1, which acts as a negative regulator of light responses (see Section 18.7.3). UVR8 also interacts with COP1. In contrast to the action of phytochromes and cryptochromes, however, this leads to COP1 accumulation, which promotes UV-B induced responses.

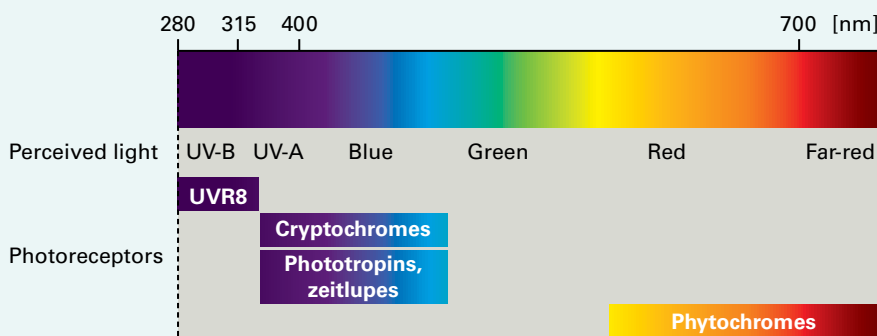

FIGURE 18.26 Action spectra for the *phyA*- and *phyB*-induced germination of *Arabidopsis* seeds. The action spectrum for *phyB* was determined with seeds imbibed in water for very short periods and is reversible by exposure to far-red light. The action spectrum for *phyA* was determined using seeds imbibed in water for 2 days in darkness. *phyA*-induced germination is extremely light-sensitive and does not display photoreversibility.

Prolonged light exposure and the conversion of P_{FR} to P_{RA} cause *phyA* concentration to drop approximately 100-fold. This occurs partly because the P_{FR} protein is rapidly degraded and partly because light inhibits *PHYA* transcription in a process that is itself mediated by phytochrome signaling. Despite the fall in concentration, *phyA* still functions in light-grown plants. In contrast to *phyA*, the light-stable phytochromes (*phyB*–*E*) have about the same concentrations in both light and darkness and are the major group found in mature plants.

18.7.2 Phytochromes in the P_{FR} form are translocated into the nucleus

Because phytochromes are synthesized in the inactive, P_R form, this is the only isomer present in seedlings germinated in continual darkness. Immunolocalization and the use of fluorescently-labeled phytochromes suggest that, under these

conditions, phytochromes are exclusively cytosolic. However, exposure to light and the conversion of P_R to P_{FR} causes movement of phytochromes from the cytosol into the nucleus.

Research on *Arabidopsis* indicates that the kinetics and mechanism of this process differ between phyA and phyB (Fig. 18.27). Phytochromes are too large to diffuse passively through nuclear pores and so require active transport across the nuclear membrane. In the case of phyB, this is conceptually simple. PhyB possesses a nuclear localization sequence (NLS) that is believed to be uncovered by the conformational change occurring as P_R B converts to P_{FR} B. This allows binding by nuclear import proteins and trafficking of phyB across the nuclear membrane in a process that takes place over a period of hours. In contrast, phyA lacks a NLS, and P_{FR} A depends on the proteins FHY1 and FHL for nuclear import. These act redundantly to bind specifically to P_{FR} A and, via their own NLSs, traffic it into the nucleus. Nuclear import of P_{FR} A is extremely rapid, detectable within minutes of light exposure.

FIGURE 18.27 Conversion of cytoplasmic P_R to P_{FR} induces movement of phytochromes into the nucleus. Nuclear import of P_{FR} B is mediated by import proteins binding to the phyB nuclear localization sequence. In contrast, phyA lacks a nuclear localization sequence, and nuclear import of P_{FR} A requires the proteins FHY1 and FHL. Conversion of nuclear P_{FR} to P_R induces translocation of phytochromes back to the cytoplasm.

Furthermore, because of the high concentration of phyA in dark-grown seedlings, both red and far-red light produce sufficient P_{FR} A for its accumulation in the nucleus to be observed.

Within the nucleus, both phyA and phyB accumulate in a speckled pattern, which has led to the hypothesis that phytochromes act in the nucleus as components of large signaling complexes. Consistent with this, the speckles—usually called **nuclear bodies** (NBs)—associated with P_{FR} B disappear upon exposure to far-red light and, hence, the conversion of P_{FR} to P_R . Furthermore, NBs have a circadian pattern: they disappear at night and re-form shortly *before* dawn, indicating regulation by the circadian clock and suggesting a point of integration between light- and clock-signaling. Lastly, the reversion of P_{FR} B to P_R B by exposure to far-red light also causes phyB to be exported from the nucleus, suggesting that, while cytosolic P_{FR} is imported into the nucleus, nuclear P_R is exported back to the cytosol. Notice that, because photoconversion is extremely rapid relative to phytochrome trafficking, both forms are present in both the cytosol and the nucleus of light-grown plants.

18.7.3 Phytochromes regulate transcription factor stability

Some phytochrome-mediated responses are extremely rapid and almost certainly depend on signal transduction within the cytoplasm. For example, phytochrome-induced cytoplasmic streaming in *Vallisneria* (eelgrass) has been recorded within 2.5 seconds of light exposure. Phytochromes have serine/threonine kinase activity and may, therefore, initiate cytoplasmic signal transduction through phosphorylation of downstream signaling proteins. A candidate effector is PKS1, a plasma membrane-associated protein of unknown biochemical function that is phosphorylated by phytochromes and is required for normal phyA-induced responses. PKS1 also interacts with the photoreceptor phototropin1, which is required for phototropism (Box 18.2). This may form part of the mechanism by which phytochrome signaling modulates the extent of phototropic curvature.

Despite evidence of cytoplasmic signal transduction, mutations that prevent nuclear import of a phytochrome also block most responses mediated by that phytochrome. For example, movement of phyA into the nucleus is completely blocked in the *hy1/fhl* double mutant of *Arabidopsis*. Mutant seeds lose the phyA-induced germination response, and mutant seedlings lose phyA-mediated de-etiolation responses, indicating these are mediated by nuclear signaling. Consistent with a primarily nuclear role for phytochromes, phytochrome signaling is associated with extensive changes in gene expression. In the most dramatic case, phytochrome signaling changes the expression of over 10% of the *Arabidopsis* transcriptome during the initial exposure of seedlings to light.

Phytochrome-mediated changes in gene expression appear to depend largely on modulation of transcription factor stability. In brief, phytochrome signaling both promotes the

FIGURE 18.28 Phytochromes regulate the stability of transcription factors in the nucleus. In the P_{FR} form, phytochromes induce phosphorylation and ubiquitin-linked degradation of PIFs, transcription factors that inhibit light responses. P_{FR} also inhibits the activity of COP1, which ubiquitinates the transcription factors HFR1, HY5, and LAF1, which promote light responses. In doing so, P_{FR} increases the stability of HFR1, HY5, and LAF1, leading to induction of light-responsive genes.

degradation of transcription factors that act as negative regulators of light responses and stabilizes the transcription factors that act as positive regulators (Fig. 18.28).

The main class of negative regulators is the phytochrome-interacting factors (PIFs), which bind specifically to P_{FR} . PIFs are basic helix-loop-helix (bHLH) transcription factors. In *Arabidopsis*, they consist of a family of 15 proteins, of which at least six function in phytochrome signaling with overlapping, but varied roles. PIF3 was the first PIF identified and has been studied in detail. It promotes etiolation in dark-grown seedlings by inducing expression of etiolation-related genes. Upon light exposure, PIF3 colocalizes with phytochromes in NBs and is subsequently degraded, resulting in the inhibition of etiolation and promotion of photomorphogenic development. PIF3 degradation correlates with the phosphorylation of PIF3 and depends on its ubiquitination and subsequent targeting to the 26S proteasome (see Section 18.6.2). One model of phytochrome action is that phytochromes induce PIF phosphorylation to direct PIFs to an E3 ubiquitin protein

ligase for ubiquitination (see Section 18.6.2). Phytochromes can phosphorylate PIFs *in vitro*.

While promoting ubiquitination of PIFs, phytochrome signaling inhibits ubiquitination of the transcription factors HY5, LAF1, and HFR1, which promote expression of light-inducible genes (Fig. 18.28). In darkness, HY5, LAF1, and HFR1 are ubiquitinated by the E3 enzyme COP1 and are, therefore, degraded by the 26S proteasome. Interestingly, COP1-dependent ubiquitination is also responsible for phyA degradation in the light. Phytochromes bind to COP1 and inhibit its activity, partly by causing exclusion of COP1 from the nucleus. The consequence is accumulation of HY5, LAF1, and HFR1 and the induction of light-responsive genes.

Phytochrome activity is affected by phosphorylation. Phytochromes autophosphorylate and do so more actively in the P_{FR} than P_R form. They are also phosphorylated by other, unknown kinases. The consequence of phosphorylation appears to be a decrease in P_{FR} activity through changes in phytochrome stability and in the affinity of phytochromes for interacting partners, such as PIF3. Phytochromes can be dephosphorylated by a type 5 protein phosphatase (PAPP5). The combination of phytochrome phosphorylation and dephosphorylation may, therefore, provide cells with a means of controlling the amplitude of the phytochrome signal.

18.8 Gibberellin signal transduction and its integration with phytochrome signaling during seedling development

Gibberellins (GAs, gibberellic acid) are a group of tetracyclic, diterpenoid hormones that function in a wide range of developmental processes, including germination, stem elongation, leaf expansion, the initiation of flowering, and floral development. GAs are synthesized in many parts of the plant and, in general, promote developmental transitions and growth. Mutants with reduced GA synthesis and plants or seeds treated with GA biosynthesis inhibitors display poor germination, are dwarfed, and flower late (Fig. 18.29). This section describes GA signal transduction and then considers the integration of gibberellin- and phytochrome-signaling during seedling development.

18.8.1 Gibberellin signal transduction depends on degradation of DELLA proteins

In a striking parallel with auxin signal transduction (see Section 18.6), GA signaling is mediated by the ubiquitination-dependent degradation of proteins that function as negative

FIGURE 18.29 Arabidopsis mutants with altered gibberellin (GA) synthesis or response. Chemical inhibition of GA synthesis (A) and disruption of GA biosynthesis by the *ga1* mutation (B) both result in dwarf, late-flowering plants. *ga1* mutants are rescued by addition of GA or by DELLA loss-of-function mutation *rga* (C). The *gai* mutation results in constitutive DELLA activity that causes a dwarf phenotype (D) that is not rescued by GA treatment (E).

regulators of growth, in this case, the **DELLA proteins** (DELLAs). GA is perceived by soluble GA-insensitive dwarf1 proteins (**GID1 proteins**, Fig. 18.30), originally identified through the *gid1* mutant of rice (*Oryza sativa*). The *Arabidopsis* genome encodes three functionally redundant GA receptors, GID1a–c. GID1 proteins bind GA, and this enhances their interaction with DELLAs. In turn, the GID1-DELLA interaction promotes association between DELLAs and a family of F-box proteins related to SLEEPY1 (SLY1) in *Arabidopsis* and

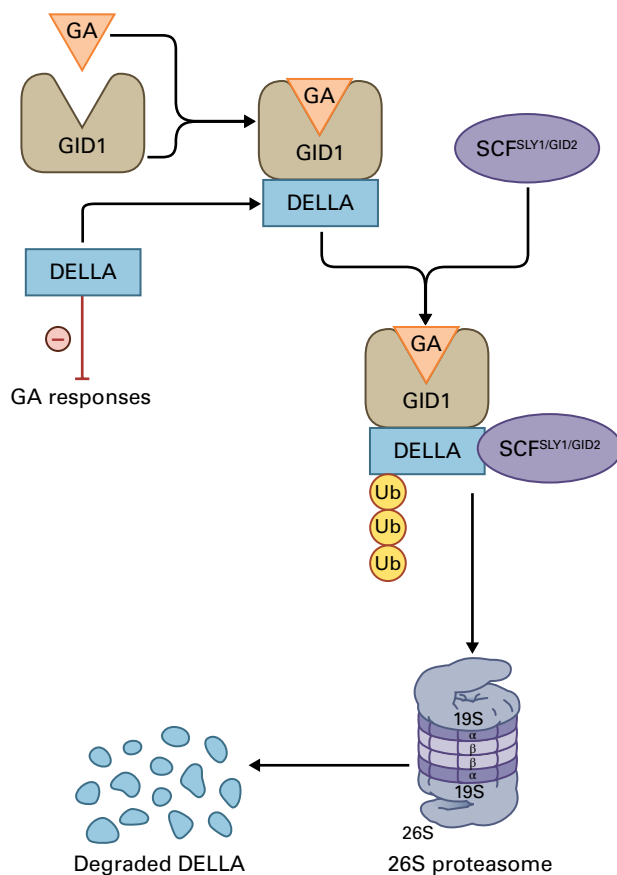

FIGURE 18.30 GA-mediated degradation of DELLA proteins relieves DELLA inhibition of GA responses. GA-binding by the receptor GID1 promotes binding between GID1 and DELLAs, which favors interaction between DELLAs and SCF complexes containing the F-box protein SLY1/GID2 ($SCF^{SLY1/GID2}$). $SCF^{SLY1/GID2}$ ubiquitinates DELLA proteins and so targets them for destruction by the 26S proteasome.

its homolog GID2 in rice. This leads to ubiquitination of DELLA proteins by SLY1/GID2-containing SCF complexes and the subsequent degradation of the DELLAs by the 26S proteasome (Fig. 18.30). For details of F-box proteins, SCF complexes, and ubiquitination-mediated protein degradation, see Section 18.6.2.

The function of DELLA proteins as negative regulators of GA signaling and inhibitors of plant growth is demonstrated by the phenotype of loss-of-function mutations in DELLA genes (see Fig. 18.29). For example, the GA biosynthesis mutant *ga1* (*gibberellic acid1*) of *Arabidopsis* has severely reduced GA levels and a dwarf, late-flowering phenotype. However, *ga1* mutants are partially rescued by loss of function of the DELLA gene *RGA* (*REPRESSOR-OF-ga1-3*). These data can be explained by assuming that *RGA* acts to repress growth and delay flowering, and that *RGA* function is inhibited by GA.

DELLAs are soluble, nuclear proteins that belong to the GRAS family (from GAI [see later], RGA, and SCARECROW) of plant regulatory proteins. They share a C-terminal GRAS domain with other members of the family but possess a unique N-terminal DELLA domain (Fig. 18.31), named after

FIGURE 18.31 DELLA protein structure. DELLA proteins belong to the GRAS family of plant regulatory proteins. The C-terminal GRAS domain is the functional domain determining DELLA activity. The N-terminal DELLA domain contains the conserved DELLA and VHYNP motifs (named after the first five amino acids in each), which are essential for interaction with GID1 and, therefore, for GA-induced DELLA protein degradation.

a conserved amino acid sequence near the N-terminus (D E L L and A are the single-letter abbreviations of the first five amino acid residues in this sequence). The DELLA domain also contains a conserved VHYNP sequence, and both the DELLA and VHYNP sequences are required for the interaction between DELLA proteins and GID1s. Mutations that disrupt either sequence cause a dominant, GA-insensitive dwarf phenotype due to the inability of GA to induce degradation of the mutant DELLA protein. Study of such mutations led to the identification of the first known DELLA protein, GAI (GA-insensitive) of *Arabidopsis* (see Fig. 18.29). A similar mutation in the wheat (*Triticum aestivum*) DELLA gene *Reduced height1* is responsible for the semi-dwarf wheat varieties that enabled the yield gain underlying the “green revolution” of the 1960s and 1970s.

The rice genome encodes only a single DELLA protein (SLR1). In contrast, *Arabidopsis* encodes five DELLA proteins (RGA, GAI, RGA-LIKE1 (RGL1), RGL2, and RGL3), and analysis of the interaction between DELLA loss-of-function mutations and the *gal-3* extreme GA-biosynthetic mutant has revealed some specialization of function within the *Arabidopsis* DELLA family. For example, there is a clear distinction between the roles of GAI and RGA and that of RGL2. *gal-3* mutants do not germinate without GA treatment, and they grow into extremely dwarfed, late-flowering plants with abnormal floral development. Combined loss of GAI and RGA functions rescues the dwarf and late-flowering aspects of the *gal-3* phenotype but does not enable GA-independent germination. In contrast, loss of RGL2 permits *gal-3* seeds to germinate without added GA but does not rescue vegetative growth or flowering time. These and other experiments indicate GAI and RGA are the main repressors of vegetative growth and flowering, whereas RGL2 is the primary repressor of germination.

18.8.2 DELLAs have a dual function in the nucleus

DELLA proteins appear to act in two distinct ways in the nucleus: they promote transcription from target genes and inhibit the activities of at least some phytochrome-interacting factors (PIFs, see Section 18.7.3). The interaction between DELLAs and PIFs is considered in Section 18.8.3. Here, we

FIGURE 18.32 Induction of transcription by DELLA proteins. In the current model of DELLA protein action, DELLAs induce transcription by binding to and activating a separate transcription factor. Genes induced by DELLAs include those encoding GA biosynthetic enzymes (GA3ox1 and GA20ox2), GA receptors (GID1a and GID1b), and XERICO, which promotes ABA synthesis.

discuss the role of DELLA proteins in enhancing gene transcription, in particular genes involved in GA signaling.

The use of an inducible DELLA transgene (encoding a GA-insensitive version of RGA) has led to the identification of 14 genes from which transcription is rapidly promoted by DELLA activity in *Arabidopsis*. Supporting a role for DELLAs in inducing transcription is the observation that the DELLA protein associates with the promoters of eight of these genes. DELLA proteins, however, lack an identified DNA-binding domain, so it is likely DELLAs promote gene expression by associating with a separate DNA-binding protein or transcription factor (Fig. 18.32).

Interestingly, among the genes identified as DELLA targets are two GA biosynthetic genes (GA3ox1 and GA20ox2) and two GA receptor genes (GID1a and GID1b). By promoting the expression of these genes, DELLAs increase both GA synthesis and GA sensitivity, creating a negative feedback loop in which DELLA activity increases GA signal transduction and, therefore, leads to DELLA degradation (Fig. 18.32). This is consistent with other evidence for feedback in GA signaling. For example, in *Arabidopsis*, GA treatment or increased GA signaling due to mutation cause a decrease in transcription from genes encoding GA biosynthetic enzymes and the upregulation of genes encoding enzymes that inactive GAs. In contrast, GA deficiency or mutations that inhibit GA signaling have roughly the opposite effect.

Putative DELLA targets also include the XERICO gene, which is thought to promote ABA synthesis. This represents a point of interaction in the generally antagonistic relationship between GA and ABA signaling (Box 18.3).

18.8.3 DELLAs and PIFs act antagonistically during seedling photomorphogenesis

In flowering plants, seedlings grown in continual darkness display **etiolation**, a developmental program characterized by reduced root growth, a rapidly elongating stem (hypocotyl or epicotyl) that ends in an apical hook, and folded, unexpanded

BOX
18.3

Antagonistic regulation of germination and stress responses by GA and ABA

GA and ABA often act antagonistically. For example, germination in many species requires biosynthesis of gibberellins and subsequent GA signaling. In contrast, ABA inhibits germination and mutations that cause ABA deficiency can rescue the nongerminating phenotype of GA-deficient mutants.

In both the seed and in growing plants, ABA and GA reciprocally suppress each other's synthesis and promote each other's degradation. Hence, seeds of GA deficient *ga1* mutants of *Arabidopsis* accumulate higher concentrations of ABA, while in the ABA-deficient mutant *aba2*, seeds contain higher levels of GA. This suggests a model for the control of germination in which GA and ABA are responsible for two competing positive feedback loops. Initially, ABA signaling dominates over GA signaling, with high ABA levels and low GA levels maintained by the ABA effects on GA synthesis and degradation. Subsequently, germination is induced by factors that create a switch to dominance by GA signaling, with high GA levels and low ABA levels maintained by the GA effects on ABA metabolism (A).

The antagonism between GA and ABA during germination is reflected in the functions of the *Arabidopsis* DELLA protein RGL2 (see Section 18.8 and (B)), which acts to suppress germination in part by promoting ABA synthesis. RGL2 is thought to induce transcription from the gene *XERICO* which encodes an E3 ubiquitin ligase (see Section 18.6.2). Overexpression of *XERICO* leads to increased concentrations of ABA, suggesting the *XERICO* protein targets an inhibitor of ABA synthesis for ubiquitination and, therefore, degradation. Hence, by inducing *XERICO* synthesis, RGL2 increases ABA concentration in the seed, whereas by inducing RGL2 degradation (see Section 18.8), GA depresses ABA levels. Interestingly, an increase in ABA concentration in the seed leads to an increase in both RGL2 mRNA and protein, suggesting positive feedback between ABA and RGL2. Downstream of RGL2, ABA

promotes expression of the *ABI5* gene, which encodes a transcription factor that inhibits germination. Interestingly, the antagonistic effects of ABA and GA on germination are recapitulated during plant responses to adverse conditions such as salt stress, drought, and extremes of temperature. These abiotic stresses lead to an adaptive reduction in growth rate that appears to depend largely on the action of DELLA proteins. For example, salt stress leads to a reduction in GA levels and a consequent increase in DELLA concentrations. Furthermore, mutants such as *ga1* with reduced GA synthesis or *gai* with constitutive DELLA activity have increased salt tolerance. In contrast, mutants with loss of DELLA function do not restrain growth fully in response to salt and have reduced survival rates during salt stress. Salt stress also promotes ABA synthesis. ABA induces stress-related genes independently of GA-signaling. In addition, however, ABA induces DELLA accumulation by inhibiting GA synthesis.

leaves or cotyledons around an inactive shoot apical meristem. This pattern of development maximizes upward growth to bring the seedling shoot to the soil surface. Once in the light, seedlings display **photomorphogenesis** (de-etiolation). Stem elongation slows rapidly, the apical hook unfolds, the leaves or cotyledons expand and develop chloroplasts, the shoot apical meristem becomes active, and root growth accelerates (Fig. 18.33).

Comparing germination and photomorphogenesis, it is clear that there is a change in the effects of light on GA-regulated processes. Consider an *Arabidopsis* seed and seedling. During germination, light-promoted GA synthesis and

signaling lead to cell elongation in the embryonic root and hypocotyl. In contrast, in an etiolated seedling, light exposure reduces GA synthesis and signaling in the hypocotyl, reducing cell elongation. The situation in other organs is more complex; for example, cotyledon expansion is promoted by light and GAs, but largely occurs in the photomorphogenic seedling rather than during germination.

Another difference between germination and photomorphogenesis is that whereas light-induced germination is primarily mediated by phytochromes, seedling photomorphogenesis is induced by light perceived at both phytochromes and cryptochromes (UV-A/blue light receptors, Box 18.2).

In both cases, light perception inhibits the activity of the E3 ubiquitin ligase COP1, which results in accumulation of transcription factors such as HY5, LAF1, and HFR1 (see Section 18.7.3). These transcription factors then induce expression of light-responsive genes. At the same time, phytochromes induce ubiquitination and destruction of PIF transcription factors, which act in darkness to promote expression of etiolation-related genes (see Section 18.7.3).

The change in the effect of light on GA signaling between germination and photomorphogenesis occurs largely at the level of GA metabolism. Light promotes GA synthesis in the seed but inhibits GA synthesis in the etiolated seedling (Fig. 18.34). For example, blue light inhibits the GA biosynthetic genes *GA3ox1* and *GA20ox1* and promotes expression of the GA-inactivating gene *GA2ox1* in *Arabidopsis* seedlings. Similarly, light causes a rapid reduction in the concentration of bioactive GA in etiolated pea (*Pisum sativum*) seedlings;

consistent with this finding, GA-deficient seedlings display a partially photomorphogenic phenotype in darkness.

In addition to the effect of light on GA concentration, recently it has been discovered that phytochrome and GA signaling have antagonist effects on PIF activity in the seedling (Fig. 18.34). DELLA proteins bind both PIF3 and PIF4 in *Arabidopsis*, which prevents the PIFs from binding the promoters of their target genes and, hence, prevents PIF-induced etiolation. In darkness, however, high GA levels promote etiolation by leading to the degradation of DELLAs, which permits PIF3 and PIF4 activity. In the light, the fall in GA concentration leads to the accumulation of DELLAs, which block PIF3 and PIF4. In combination with the phytochrome-mediated destruction of PIFs, this induces the switch from etiolation to photomorphogenesis.

18.8.4 The GA signal transduction pathway evolved in stages

The GA signal transduction pathway and the antagonistic roles of DELLAs and GA in regulating growth are conserved across angiosperms (flowering plants) and gymnosperms (conifers). Stages in the evolution of GA signal transduction have been revealed by research on interactions between *GID1* homologs and DELLA proteins in the moss *Physcomitrella patens* and in the lycophyte *Selaginella kraussiana*.

Mosses are nonvascular plants that evolved approximately 430 million years ago, whereas lycophytes are primitive vascular plants and appeared about 400 million years ago (Fig. 18.35). Genome analysis shows that both *P. patens* and *S. kraussiana* possess *GID1* homologs and DELLA proteins; however, GA signaling appears to be absent in moss and highly limited in *Selaginella*.

FIGURE 18.33 Characteristics of etiolated and photomorphogenic seedlings.

FIGURE 18.34 Direct interactions between DELLAs and PIFs during seedling photomorphogenesis. (A) In darkness, high gibberellin (GA) levels lead to the degradation of DELLA proteins, allowing PIF transcription factors to induce transcription from etiolation-related genes. (B) Light causes a fall in GA concentration in the seedling, resulting in accumulation of DELLA proteins in the nucleus. DELLAs bind directly to PIFs to prevent PIF-induced gene transcription. In addition, light induces movement of phytochromes into the nucleus and phytochrome-mediated degradation of PIF proteins. As a result, the seedling switches from etiolation to photomorphogenesis.

FIGURE 18.35 Evolution of the *GID1/DELLA* interaction and of *DELLA* function. (A) *DELLAs* and *GID1*-like proteins evolved before the divergence of bryophytes, but in bryophytes they do not interact. (B) Subsequently, but before the evolution of lycophytes, *GA* synthesis, *GID1-GA* binding, and *GA*-promoted *GID1/DELLA* interaction arose. (C) Before the evolution of seed plants (gymnosperms and angiosperms), and perhaps before the evolution of ferns, *DELLAs* gained a growth-suppressing function.

Moss produces no known bioactive GAs and has no clear response to exogenously applied GAs. Consistent with this, there is no interaction between *GID1*-like proteins and *DELLA* homologs in moss, which lack the required *DELLA* and *VHYNP* sequence (see above). It is likely that moss does not perceive GA and lacks a GA signal transduction pathway; the moss *GID1* homologs and *DELLA* proteins must, therefore, have (unknown) GA-independent functions.

GID1 and *DELLA* proteins in *S. kraussiana* do interact, and their interaction is promoted by GA. Therefore, the initial steps of GA signal transduction in lycophytes are similar to those in flowering plants. Furthermore, GA treatment downregulates transcription from the *GID1* gene of *S. kraussiana*, paralleling the negative feedback observed in GA signal transduction in *Arabidopsis* (see Section 18.8.2). Unlike the case in flowering plants, however, GA does not stimulate the growth of lycophytes, and it is thought that *DELLA* proteins do not inhibit lycophyte (or moss) growth. It is currently unclear what function(s) GA has in lycophytes.

Interestingly, *DELLA* genes from both *P. patens* and *S. kraussiana* can suppress growth when expressed in *Arabidopsis*. This indicates the evolution of growth suppression by *DELLAs* depended on changes in downstream interacting components such as *PIFs* and *DELLA*-regulated genes rather than on changes in the structure of the *DELLAs* themselves. In a similar vein, *DELLAs* from both *Arabidopsis* and *S. kraussiana* can interact with a *GID1*-like protein from moss, showing the evolution of this interaction depended largely on changes in *DELLA* structure rather than *GID1* structure. Nonetheless, a change in *GID1* structure was required between the evolution of mosses and the evolution of vascular plants to

allow GA binding by *GID1* and, therefore, *GID1*'s function as a receptor.

These experiments suggest the following model for the evolution and of the *GID1/DELLA* interaction and its consequences (Fig. 18.35). In moss, GA signal transduction is absent, but *GID1* homologs and *DELLAs* are present and presumably have other functions. Prior to the evolution of lycophytes, *GID1* gained the ability to bind GA, *DELLA* proteins gained the ability to bind *GID1*, and GA stimulation of the *GID1/DELLA* interaction arose. The growth-restraint function of *DELLAs* appeared after the divergence of lycophytes but before the evolution of seed plants (gymnosperms and angiosperms). It remains unclear at what point in this series the ubiquitination of *DELLAs* by F-box proteins—and its promotion by GA—evolved.

18.9 Integration of light, ABA, and CO₂ signals in the regulation of stomatal aperture

18.9.1 An intricate signal transduction network regulates stomatal aperture

Stomata allow diffusion of both carbon dioxide into the leaf for photosynthesis and water out of the leaf, driving the transpiration stream. The size of the stomatal pore is governed by

FIGURE 18.36 Blue light induces an increase in guard cell turgor. Blue light absorption by phototropins results the activation of a plasma membrane H⁺-ATPase, leading to membrane hyperpolarization and consequent activation of voltage-sensitive K_{in} channels. K⁺ influx is balanced by anion influx and synthesis, causing accumulation of K⁺ salts and increased turgor. In the afternoon, sucrose replaces K⁺ salts as the osmoticum. Note that the cell wall is not shown for clarity.

a combination endogenous and environmental factors including light, carbon dioxide, humidity, hormones (in particular ABA), temperature, ozone, and the plant's internal clock and water status. These combine to regulate stomatal aperture in a way that provides a compromise between CO₂ uptake and excessive water loss.

The stomatal pore varies in size because of turgor changes in the two, flanking guard cells. Owing to the pattern of microfibrils in guard cell walls, an increase in turgor causes guard cells to elongate and forces them to bend outwards, which opens the pore. Conversely, a decrease in turgor shortens guard cells and closes stomata. These changes are accompanied by substantial variation in guard cell volume and require extensive vesicle trafficking between the cytoplasm and the plasma membrane to increase or decrease plasma membrane surface area.

There has been much research into the mechanisms that regulate guard cell turgor and into the signal transduction network that ties these mechanisms to endogenous and environmental signals. Here we consider the integration of signal transduction in response to light, ABA, and CO₂ concentration.

18.9.2 Light-induced stomatal opening depends on phototropin signaling

In most species, stomata open in response to light. Action spectra and mutational analysis demonstrate this depends on blue/UV-A wavelengths perceived by phototropins (Box 18.2). On absorbing light, guard cell phototropins initiate a signal transduction pathway that activates plasma

membrane proton pumps (H⁺-ATPases) that pump protons out of the cytosol and into the apoplast (Fig. 18.36). This increases the potential difference between the cytosol and apoplast, causing hyperpolarization of the plasma membrane, which activates membrane-spanning, voltage-gated potassium intake channels (K_{in}⁺), triggering an influx of potassium ions (K⁺) down their electrochemical gradient from the apoplast into the cytosol. The increase in cytosolic K⁺ concentration is balanced by the accumulation of malate and anions such as Cl⁻, and NO₃⁻, which are imported across the plasma membrane. Malate is also synthesized within the guard cells from starch. For a detailed discussion of ion transport, see Chapter 3.

Plasma membrane ion fluxes are matched by ion fluxes across vacuolar membranes. This leads to the accumulation of potassium salts in the cytosol and vacuoles and, therefore, an overall lowering of the guard cell's water potential. Consequent water uptake increases the guard cell's turgor and causes stomatal opening. Under natural conditions, accumulated potassium salts are replaced during the morning by sucrose, which is responsible for maintaining guard cell turgor through the day.

The transduction pathway that links light perception by phototropins to the activation of the H⁺-ATPase is currently incompletely understood (Fig. 18.37). In response to blue light, the H⁺-ATPase is phosphorylated on serine and threonine residues in its C-terminus. This is followed by the binding of a 14-3-3 protein to the same domain. 14-3-3 proteins can cause changes in target protein activity or protein relocation, and can also act as a scaffold to allow protein-protein interactions. Binding by the 14-3-3 protein in response to H⁺-ATPase phosphorylation is absolutely required for induction of proton pumping.

FIGURE 18.37 Signal transduction from phototropins to the H^+ -ATPase in the guard cell. Absorption of blue light induces phototropin autophosphorylation and association with a 14-3-3 protein. This initiates a signal transduction pathway that includes a type 1 protein phosphatase (PP1), and a protein kinase that phosphorylates the H^+ -ATPase. Phosphorylation induces binding of a 14-3-3 protein and activation of the H^+ -ATPase. Phototropin signaling may also involve an increase in cytosolic calcium concentration. Note that the cell wall is not shown for clarity.

Phototropins are membrane-associated kinases, and their kinase activity is stimulated by light absorption causing autophosphorylation that initiates downstream signaling. There is no evidence that phototropins directly phosphorylate the H^+ -ATPase; therefore, other signaling components must transduce the signal from phototropins to the proton pump. Interestingly, these include a 14-3-3 protein that binds to phototropin after the photoreceptor autophosphorylates. Given binding between a 14-3-3 protein and the H^+ -ATPase, this raises the possibility of the formation of a complex containing phototropin, 14-3-3 proteins, and the H^+ -ATPase.

A type 1 protein phosphatase (PP1) is also implicated in the transduction pathway. Chemical inhibition of PP1 activity suppresses blue light-induced phosphorylation of the H^+ -ATPase and stomatal opening. Similarly, light-induced opening is reduced in plants expressing a dominant, inactive form of PP1. These experiments suggest that PP1 acts as a positive regulator of the pathway linking phototropins to activation of the proton pump. The transduction pathway may also involve changes in cytosolic Ca^{2+} concentration (see Section 18.9.4). Ultimately, signaling from phototropins must lead to activation of the protein kinase responsible for phosphorylating the H^+ -ATPase.

18.9.3 An ABA-induced rise in cytosolic Ca^{2+} concentration induces stomatal closure

ABA acts as a signal to induce stomatal closure. Synthesized in water-stressed leaves, ABA is also produced in roots in response to soil dryness and may be transported to the shoot in the transpiration stream. Grafting experiments between wild-type plants and ABA-deficient mutants, however, indicate

ABA synthesis is required only in the shoot for root water stress to induce stomatal closure. This suggests water-stressed roots transmit an ABA-independent signal that induces ABA synthesis in the shoot and consequent stomatal closure. It has been proposed that the root-to-shoot signal could be drought-induced changes in hydraulic force in the xylem. Such changes transmit very rapidly from the root to xylem capillaries in the leaf and could be detectable by mechanosensitive ion channels in leaf cells.

ABA causes stomata to close by reversing the accumulation of potassium salts in guard cells and inducing the conversion of sugars into starch. The resulting fall in solute concentration leads to loss of water from the guard cell into the apoplast by osmosis, a fall in guard cell turgor, and closing of the stomatal pore.

ABA signaling in guard cells is largely mediated through the second messenger Ca^{2+} (Fig. 18.38). Acting through an incompletely understood network of signaling intermediates, ABA induces release of calcium ions from internal stores such as the ER and activates plasma membrane Ca^{2+} influx channels. The consequent rise in Ca^{2+} concentration in the guard cell cytosol, $[Ca^{2+}]_{\text{cyt}}$, inactivates the plasma membrane H^+ -ATPase and, therefore, prevents proton pumping out of the cell. Increased $[Ca^{2+}]_{\text{cyt}}$ also activates plasma membrane anion efflux channels, and these two effects combine to depolarize the membrane. Membrane depolarization closes voltage-sensitive K^+ channels but opens K^+ channels. In addition, K^+ channels are inhibited directly by the rise in $[Ca^{2+}]_{\text{cyt}}$. Overall, therefore, the increase in $[Ca^{2+}]_{\text{cyt}}$ causes the net efflux of anions and K^+ from the cell, leading to a fall in guard cell turgor.

Despite a clear role for $[Ca^{2+}]_{\text{cyt}}$ in the guard cell response to ABA, not all guard cells display measurable increases in $[Ca^{2+}]_{\text{cyt}}$ after ABA treatment. This suggests ABA may induce stomatal closure by both Ca^{2+} -dependent and Ca^{2+} -independent

FIGURE 18.38 ABA induces efflux of K^+ salts from the guard cell. ABA activates Ca^{2+} influx channels and induces Ca^{2+} release from internal stores, leading to a rise in cytosolic Ca^{2+} concentration, $[Ca^{2+}]_{\text{cyt}}$. This inhibits the H^+ -ATPase and activates anion efflux channels leading to membrane depolarization. Depolarization inhibits K^+ channels and activates K^+ channels. K^+ channels are also inhibited directly by Ca^{2+} . In addition, ABA causes an increase in cytosolic pH, which promotes anion efflux- and K^+ channels. Note that for clarity the cell wall is not shown.

pathways, and also that the significance of the two pathways may vary between guard cells. The proposed Ca^{2+} -independent pathway may involve ABA-induced changes in cytosolic pH (Fig. 18.38). ABA causes an alkalization of the guard cell cytosol, increasing the pH by 0.1–0.3 units. This promotes activity both of plasma membrane anion efflux channels and K^+ channels, and so should also induce a loss of guard cell turgor. A role for a change in pH is supported by the fact that ABA-induced stomatal opening is blocked by treating guard cells with the weak acid sodium butyrate to prevent alkalization of the cytosol.

Comparing the effects of ABA and blue light suggests that the respective signal transduction pathways compete for control of guard cell turgor via their antagonistic effects on plasma membrane ion transport proteins and plasma membrane polarization. In addition, ABA inhibits signal transduction between phototropins and the H^+ -ATPase, countering blue light-induced phosphorylation and activation of the proton pump. This inhibition appears to depend on the production of hydrogen peroxide (H_2O_2) in response to ABA.

18.9.4 Oscillations in cytosolic calcium ion concentration are associated with both ABA and CO_2 signaling in guard cells

Although a simple ABA-induced increase in $[Ca^{2+}]_{\text{cyt}}$ is sufficient to cause stomatal closure, the mechanism of $[Ca^{2+}]_{\text{cyt}}$ signaling over the longer term is more complex. Prolonged ABA exposure induces slow oscillations of $[Ca^{2+}]_{\text{cyt}}$ in guard

cells, and combining long-term monitoring of $[Ca^{2+}]_{\text{cyt}}$ by fluorescent indicators with experimental manipulation of $[Ca^{2+}]_{\text{cyt}}$ through alteration of external ion concentrations shows these oscillations are required to keep stomata closed. A sustained high $[Ca^{2+}]_{\text{cyt}}$ does not maintain closure, whereas slow $[Ca^{2+}]_{\text{cyt}}$ oscillations do (Fig. 18.39). The optimal oscillation rate measured in *Arabidopsis* is about one peak in $[Ca^{2+}]_{\text{cyt}}$ per 10 minutes, pointing to a dynamic component in the downstream interpretation of Ca^{2+} concentration.

Understanding calcium signaling in the guard cell is further complicated by the effect of CO_2 concentration on $[Ca^{2+}]_{\text{cyt}}$ oscillations (Fig. 18.39). High CO_2 is associated with a slow rate of $[Ca^{2+}]_{\text{cyt}}$ oscillation (measured at about one peak per 10 minutes), and this is linked to stomatal closure. However, low CO_2 concentration is associated with more rapid $[Ca^{2+}]_{\text{cyt}}$ oscillations (measured at about two peaks per 10 minutes), and this is associated with stomatal opening. Therefore, $[Ca^{2+}]_{\text{cyt}}$ oscillations appear able to induce stomata to open, to close, or to stay closed depending on the rate of oscillation and the upstream signal.

The induction of slow $[Ca^{2+}]_{\text{cyt}}$ oscillations by ABA or high CO_2 in *Arabidopsis* requires the *GROWTH CONTROLLED BY ABA2 (GCA2)* locus (Fig. 18.39). Loss-of-function *gca2* mutants have reduced stomatal closure in response to both ABA and high CO_2 , and this is associated with impaired regulation of $[Ca^{2+}]_{\text{cyt}}$ oscillations. In contrast, the HT1 protein kinase functions in CO_2 signal transduction but not in ABA signaling. Stomata of loss-of-function *ht1* mutants close in both high and low CO_2 but are still responsive to ABA. This indicates HT1 acts as a negative regulator of CO_2 -induced stomatal closure. The mechanism by which plant cells perceive CO_2 concentration has yet to be discovered.

FIGURE 18.39 Effects of ABA and CO_2 on Ca^{2+} concentration in the guard cell cytosol, $[Ca^{2+}]_{cyt}$. ABA induces an immediate rise in $[Ca^{2+}]_{cyt}$ which is associated with ABA-induced stomatal closure. ABA also induces a long-term pattern of slow $[Ca^{2+}]_{cyt}$ oscillations, which are required for ABA maintenance of stomatal closure. Slow $[Ca^{2+}]_{cyt}$ oscillations are also induced by high CO_2 and are associated with high CO_2 -induced stomatal closure. In contrast, low CO_2 causes rapid $[Ca^{2+}]_{cyt}$ oscillations, and these are associated with low CO_2 -induced stomatal opening. GCA2 is required for ABA and high CO_2 to induce slow $[Ca^{2+}]_{cyt}$ oscillations.

Finally, blue light absorption by phototropin in *Arabidopsis* and tobacco seedlings causes a transient increase in $[Ca^{2+}]_{cyt}$, and inhibition of calcium signaling in guard cells by calmodulin antagonists (see Section 18.3.1) inhibits blue-light-induced proton pumping and stomatal opening. Therefore, it is possible $[Ca^{2+}]_{cyt}$ also induces stomata to open in response to blue light.

For calcium signaling to lead to either an increase or a decrease in guard cell turgor, individual ion channels must display different responses to different patterns of $[Ca^{2+}]_{cyt}$ changes. To help explain how this could be achieved, it has been proposed that the Ca^{2+} -sensitivity of key signal transduction components may be regulated according to prior signaling patterns in the guard cell. In support of this idea, activation of plasma membrane anion efflux channels in guard cell protoplasts by elevated $[Ca^{2+}]_{cyt}$ requires pre-exposure of the protoplasts to a high external Ca^{2+} concentration.

Summary

Plant development, physiology, and defense are flexible processes regulated by numerous internal and external cues. At the cellular level, detection of physical and chemical signals by receptor proteins initiates

18.10 Prospects

In recent years there have been several successes in the hunt for core mechanisms by which plant cells perceive and transduce individual signals. This work will continue, not least because new intercellular signaling molecules continue to be discovered. Alongside research on individual transduction pathways, however, knowledge of signaling mechanisms in plant cells has become sufficiently sophisticated to allow development of models that describe interactions between signaling pathways and also the modulation of signaling networks over time.

As increasing numbers of signaling components and interactions between them are taken into consideration, the systems being described will become too complex for intuitive understanding. At that stage, investigating the properties of a signaling system will require formal modeling accompanied by computer simulation. This has already begun in a few cases. Computer simulation allows models to be tested by comparing the behavior of the theoretical system with its real life counterpart. Models that faithfully reproduce the behavior of the living system can then be subjected to novel constraints or perturbations to develop hypotheses and suggest experiments.

Most recent advances in our understanding of signal transduction in plants have come from model species such as *Arabidopsis thaliana*. The application of this knowledge to less laboratory friendly but more agriculturally significant species may have practical benefits, for example in areas such as drought tolerance. Increasing the number of species studied also allows evolutionary insights into signaling mechanisms. This has already been achieved with respect to the evolution of some individual signaling components; for example, revealing different domain structures and signaling mechanisms of phytochromes in plants, bacteria and fungi and also showing patterns of evolution of the phytochrome family within plants. Comparisons between taxa can also reveal differences in signaling interactions, for example the stepwise evolution of the GID1/DELLA interaction and of DELLA-mediated growth suppression in land plants (see Section 18.8.4). As research into signal transduction networks progresses, it should be possible to extend results such as these to encompass the evolution of larger signaling systems and also to map more accurately the timing of signaling innovations during plant evolution.

intracellular transduction pathways that control cell behavior. In addition, transduction pathways initiated by separate signals and perceived by distinct receptors interact to form a signaling network that integrates the

acquired information. Above the cellular level, short- and long-range intercellular signaling coordinates the activity of tissues, organs, and the plant as a whole. Cellular and intercellular aspects of signaling are tightly coupled, feeding back on each other as cells regulate the synthesis of hormones and other intercellular signals in accordance with the signals they receive.

Recent years have seen rapid advances in our understanding of intracellular signal transduction in plants, with mechanisms of perception, transduction, and response identified for several signals. Of particular interest is the widespread role of the regulation of protein degradation: for example, as mediated by phytochromes and by the auxin and GA receptors, and also functioning in the modulation of ethylene signaling. Given that over 5% of the *Arabidopsis* genome encodes proteins with homology to known mediators of ubiquitination-dependent proteolysis, it is probable that targeted protein degradation acts in many other signal transduction pathways. By a similar argument, it is likely

that the more than 600 RLKs encoded by the *Arabidopsis* genome have a major, although currently poorly understood, role in signal perception.

There has also been progress in understanding the mechanisms by which responses to different signals are integrated, for example via the network of MAPK cascades, during the integration of GA and light signals, or in the regulation of stomatal aperture. Fewer details, however, are available on how signal integration is achieved without the loss of signal specificity, the ability of a particular signal to induce a particular response. Perhaps the most famous example of this is the convergence of signaling mechanisms on the regulation of cytosolic Ca^{2+} concentration. Here it is thought specificity may emerge from the temporal and spatial patterns of Ca^{2+} concentration (see Sections 18.3.1 and 18.9.4). The twin problems of explaining signal integration and signal specificity are likely to become increasingly important as models of intracellular signaling networks grow more complex.

Molecular Regulation of Reproductive Development

Ueli Grossniklaus

Introduction

Flower and seed formation represents an important phase in the life cycle of plants (Fig. 19.1). Flowers contain the reproductive organs producing the gametes that are central to sexual propagation, which culminates in the formation of seeds. A strict control of flowering time ensures the formation of as many seeds as possible, which is critical for the competitive advantage of a plant in its natural habitat, as well as in an agricultural setting. The importance of plant reproduction is demonstrated by the agricultural importance of fruit and seed crops, with cereals contributing as much as 80–90% of the world's calorie supply.

This chapter describes how the plant integrates external and internal signals to decide when to flower. It also explains how flower morphogenesis is controlled, how gametes are formed in the reproductive floral organs, and how the gametes unite to form the next generation, the developing embryo. While other plant species are considered, this chapter focuses on genetic studies in the model species *Arabidopsis thaliana*, through which much of the molecular basis of plant reproductive development has been unravelled.

19.1 The transition from vegetative to reproductive development

19.1.1 The first step in sexual plant reproduction is the decision to flower

The decision to flower marks the transition from vegetative to reproductive growth and is a key decision in the life cycle of plants. While growing vegetatively, the shoot apical meristem produces leaves with axillary meristems, which can form indeterminate secondary shoots. During the transition to flowering, the apical meristem is reprogrammed to an inflorescence meristem, which produces floral meristems on its flanks. The floral meristems, in turn, produce floral organs that form a single flower and are, therefore, determinate because they form a defined number of organs. This shift in meristem identity represents a major developmental change.

Precise timing of the decision to flower is crucial to guarantee reproductive success. It not only ensures that conditions

FIGURE 19.1 The life cycle of a flowering plant, which involves the alternation of haploid (gametophytic) and diploid (sporophytic) generations. The haploid meiotic products produced in anthers (microspores) and ovules (megaspores) undergo several division cycles to form multicellular gametophytes, the pollen grain (male gametophyte) and embryo sac (female gametophyte), respectively.

are favorable for reproduction, it also optimizes the availability of mating partners. A good example of this is the synchronous flowering of some cactus species, which open their flowers only for a few hours in a short time window. Synchronous flowering both enhances the chance for cross-pollination and reduces the proportion of seeds lost to

predators. Moreover, the manipulation of flowering time through breeding has expanded the cultivation range and yield of many crops. For example, winter varieties of wheat (*Triticum aestivum*) and canola (*Brassica napus*) are sown in autumn and then overwinter in the vegetative phase. The extended vegetative growth period leads to yields that,

FIGURE 19.2 Winter and spring varieties of crop plants. The same variety of wheat either sown in autumn (left) or spring (right) illustrates the advantage of an extended vegetative growth period.

Source: <http://www.islandgrains.com/whats-the-difference-between-spring-wheat-and-winter-wheat/>.

depending on crop and cultivar, can be 50–100% higher than those of varieties sown in spring (Fig. 19.2). It is not surprising, then, that the timing of the decision to flower is under several levels of control.

19.1.2 Induction of flowering integrates external and internal cues

Before a plant starts to flower, it must accumulate enough resources to sustain seed development, and it must ensure that the environmental conditions are favorable for reproductive success. The plant must first generate enough leaves to produce sufficient photosynthate to support seed formation, which requires a significant amount of metabolic resources. In addition, flowering should be optimized with respect to environmental conditions, such as light, temperature, and the availability of water. Thus, plants must integrate environmental cues with internal conditions, and this requires complex gene regulatory networks.

Indeed, a large number of mutants have been identified that alter flowering time in *Arabidopsis*, and the physiological, genetic, and molecular analyses of these mutants have shown that flowering time is influenced by day length (**photoperiod**), light quality, ambient temperature, exposure to long periods of cold (**vernalization**), as well as developmental and hormonal signals. For example, studies with *Arabidopsis* mutants and natural varieties (accessions) uncovered the roles of both photoperiod and vernalization in the control of flowering time. Plants exposed to long days (16 hours of light) rather than short days (8 hours of light) flower much earlier, and mutations that disrupt the response to photoperiod cause plants to flower late under long days, but they have no effect under

short days (Fig. 19.3). Some *Arabidopsis* accessions flower early if they are vernalized. This is particularly true for accessions that grow farther north (at higher latitudes), while accessions from more southern regions do not require vernalization, indicating that this is an adaptation to cold climates. However, *Arabidopsis* plants eventually flower even under short days and without vernalization, a response that requires the genes of the autonomous pathway. Plants with mutations affecting this branch of regulation flower later under both long and short days but respond to vernalization (Fig. 19.3). Finally, flowering time in *Arabidopsis* is also controlled by ambient temperature and the phytohormone gibberellin, which promotes flowering, particularly under short day conditions.

Together, genetic analyses in *Arabidopsis* have identified five distinct but interconnected pathways that regulate flowering time: the photoperiod, vernalization, autonomous, thermosensory, and gibberellin pathways.

19.1.3 Photoperiod is an important regulator of floral induction

At moderate to high latitudes, photoperiod is a reliable indicator of the season, so it is not surprising that most plants use day length as a cue for flowering. At the beginning of the 20th century, scientists found that certain varieties of tobacco (*Nicotiana tabacum*) flower during the short days in the southern United States but fail to flower in the longer days farther north. In contrast, ryegrass (*Lolium perenne*) only flowers under long days. Similar experiments showed that photoperiod regulates flowering time in a wide variety of plants, and three major behaviors in response to day length (photoperiodism) could be distinguished (Fig. 19.4).

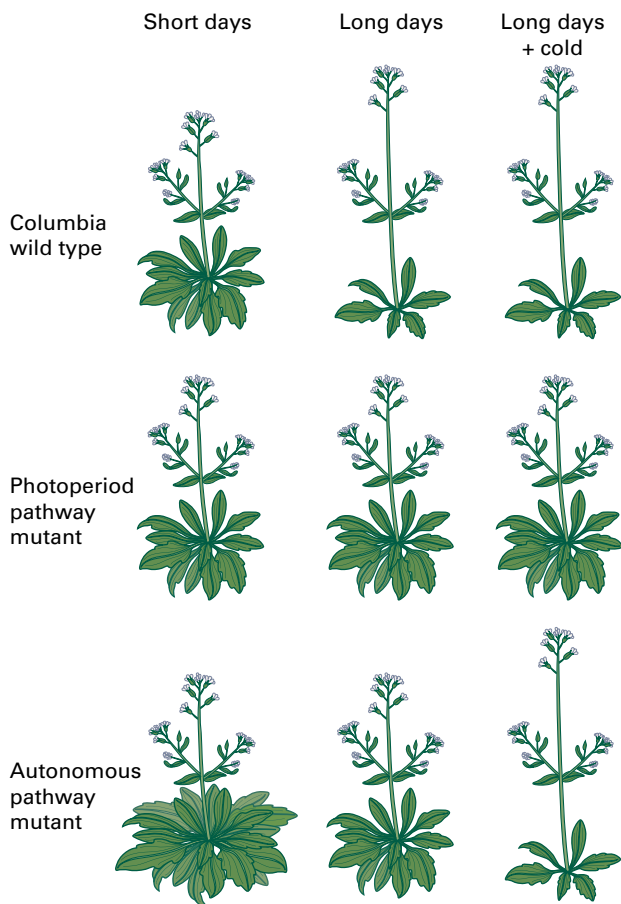

FIGURE 19.3 Response of *Arabidopsis* plants to environmental conditions. Columbia wild-type plants flower late under short days and early under long days, a response not affected by vernalization. Plants with mutations affecting the photoperiod pathway are indistinguishable from the wild type under short day conditions, but flower late under long days, irrespective of vernalization. In contrast, plants with mutations affecting the autonomous pathway flower later than the wild type under both short and long days but this phenotype is overcome by vernalization.

Long-day plants, such as clover (*Trifolium pratense*) and oat (*Avena sativa*) are induced to flower after exposure to long days and short nights, and the opposite is true for **short-day plants**, for example, coffee (*Coffea arabica*) and hemp (*Cannabis sativa*), which flower under short days and long nights. **Day-neutral plants**, such as tomato (*Solanum lycopersicum*) and cucumber (*Cucumis sativus*), flower regardless of the photoperiod. As mentioned above, many species, including *Arabidopsis* and snapdragon (*Antirrhinum majus*), eventually flower even under noninductive photoperiods (facultative long- and short-day plants), whereas others, such as clover, have an absolute photoperiod requirement (obligate long- and short-day plants). Finally, some plants have a complex requirement for a specific combination of long and short days to induce flowering.

In most cases, plants measure the duration of the night (dark) rather than the day (light). This was demonstrated by breaking the night with a short period of light. In cocklebur

(*Xanthium strumarium*), a short-day plant, breaking the dark period for as little as 5 minutes with light is enough to prevent flowering. Most long-day plants are less sensitive to a break in the dark period, but many will flower under short days with a light period of 30–60 minutes during the night (Fig. 19.4). In addition to photoperiod, flowering time is also modulated by the quality of light.

19.1.4 Phytochromes and cryptochromes detect photoperiod

Plants have a variety of photoreceptors, and two types, phytochromes (red light receptors) and cryptochromes (blue light receptors), are required for photoperiodism. The *Arabidopsis* genome encodes five phytochromes (PHYA to PHYE), whose functions are distinct but also overlap. Phytochromes absorb red and far-red light and control various developmental processes, including germination, internode elongation, shade avoidance, entrainment of the plant's circadian clock, and flowering (see Chapter 18). *Arabidopsis* has two cryptochromes (CRY1 and CRY2) that, besides being involved in floral induction, also play a role in the entrainment of the circadian clock and phototropism.

The discovery that floral induction in short-day plants could be prevented by a short disruption of the dark period with light allowed an investigation into the wavelengths of light that are perceived by the plant. Disruption with red light blocked the transition to flowering, but this effect could be reversed by following exposure to red light with exposure to far-red light. This reversible behavior implied an involvement of phytochromes in the control of flowering time. Indeed, *Arabidopsis phyA* mutants flower somewhat later than the wild type and do not respond to disruption of the dark period. The situation, however, is complex: While *PHYA* seems to promote flowering, *PHYB* delays it, as evidenced by the early flowering phenotype of *phyB* mutants, and other phytochromes also contribute to the repression of flowering. Cryptochromes are also involved in photoperiodism: *Arabidopsis cry2* mutants flower later than the wild type under inductive long days. Thus, in *Arabidopsis* and its relatives, both *PHYA* and *CRY2* promote flowering, whereas in other plants this role is taken by *PHYA* alone; for example, mutants that lack *PHYA* in pea (*Pisum sativum*), a long-day plant, are insensitive to photoperiod and flower at the same time under long- and short-day conditions.

19.1.5 Mobile signals control floral induction

The discovery of photoperiodism opened the door to many experimental manipulations and the physiological dissection of the transition to flowering. Since floral induction leads to a reprogramming of the shoot apical meristem, an important

FIGURE 19.4 Plant responses to different photoperiods (1–3). A short-day day plant requires a dark period of more than 12 hours, while a long-day plant requires one of less than 12 hours. A long-day plant can be induced to flower if the long night is interrupted by a light flash. A day-neutral plant flowers irrespective of photoperiod.

question to address was whether day length is sensed directly in the shoot apex or in other parts of the plant. In experiments with spinach (*Spinacia oleraceae*), a short-day plant, exposure of only the leaves to the inductive photoperiod induced flowering, whereas exposure of the shoot apex to short days did not. These results indicated the photoperiod was measured in the leaves, but how does this lead to the reprogramming events in the shoot apex?

A series of grafting experiments addressed this question. Grafting a single leaf of a beefsteak plant (*Perilla crispa*) that was exposed to the inducing photoperiod onto an uninduced stock causes the plant to flower (Fig. 19.5). Thus, a mobile signal, referred to as **florigen**, is transported from the induced leaf to the uninduced shoot apex through the phloem. The same leaf can be sequentially grafted onto other vegetative rootstocks and induce flowering in six to seven plants. This suggests that, once induced, the leaf continuously produces the mobile signal that controls the flowering status of the plant.

The molecular identity of florigen was not unveiled for decades until molecular genetic experiments in *Arabidopsis* identified the protein encoded by *FLOWERING LOCUS T* (*FT*) as a major component of the mobile signal that induces flowering. *FT* contains a phosphatidylethanolamine-binding domain, which in mammals is involved in kinase signaling and appears to mediate protein–protein interactions. In *Arabidopsis*, *FT* is synthesized in the leaf upon floral induction and moves to the shoot apex (Fig. 19.6). There, it interacts with a bZIP transcription factor encoded by *FLOWERING*

LOCUS D (*FD*) to regulate target genes that mediate the reprogramming of the meristem to produce flowers.

19.1.6 Photoperiod controls the activity of *CONSTANS*

To measure the length of the day, the plant must compare it with an internal standard. Many physiological processes follow a circadian rhythm, an oscillatory behavior with a period of approximately 1 day. This allows an organism to anticipate periodic changes in the environment and adjust its physiological activities accordingly. In plants, up to 60% of genes are regulated by the circadian clock, which influences many aspects of development, such as flower opening, leaf movements, stomatal opening, and many other processes, including the decision to flower.

It was proposed that flowering is induced when a rhythmic process under the control of the circadian clock is sensitive to light at a particular time of the day, in other words when exposure to light and this process coincide (**external coincidence model**). Indeed, many mutations in *Arabidopsis* affect the photoperiod pathway; they delay flowering under long but not under short days, and are interlinked with the circadian clock; they either affect its entrainment, are components of the clock itself, or are regulated by it. The last one is true for *CONSTANS* (*CO*), a key regulator of flowering whose mRNA

FIGURE 19.5 Permanent photoinduction by leaves of the beefsteak plant (*Perilla crispata*). (A) Induction of a single leaf by short days (light green) can induce flowering. (B) If the same leaf is grafted onto a plant that was kept under noninductive conditions, it can induce flowering of that plant, indicating the production of a flower promoting, mobile signal in the induced leaf. (C) The grafting process can be repeated with the same effect, indicating the induction of the mobile signal is permanent. Grafting of (D) a noninduced leaf or (E) a flowering apex does not induce flowering of the host plant.

FIGURE 19.6 *FT* protein is the florigen. *FT* is produced in the leaf under an inductive photoperiod. It is transported via the phloem to the shoot apex where it forms a heterodimer with *FD* to regulate target genes that control the reprogramming into an inflorescence meristem.

starts to accumulate at dusk and reaches a maximum during the dark period under short days (Fig. 19.7).

CO transcription is not only under the control of the circadian clock, but is also regulated by a blue light-dependent

complex involving GIGANTEA (*GI*) and the FLAVIN-BINDING, KELCH REPEAT, F-BOX1 (*FKF1*) protein, the last one mediating protein degradation. Accumulation of the *GI*-*FKF1* complex in the late afternoon leads to degradation of CYCLING DOF FACTOR1 (*CDF1*), a repressor of *CO*, thereby activating *CO* expression at dusk. In the dark, however, *CO* protein is unstable and fails to accumulate. In contrast, under long days, *CO* mRNA reaches a peak at the end of the day and is translated in the light. Exposure to blue and far-red light, which promotes flowering in *Arabidopsis* via *CRY2* and *PHYA*, stabilizes the *CO* protein, which thus accumulates under long days and activates its target gene *FT* (Fig. 19.7). *CO* expression and consequently the activation of *FT* occur in the companion cells of the phloem, through which the *FT* protein is subsequently transported to the shoot apex. As a consequence, *Arabidopsis* flowers only when *CO* transcription and translation coincide with exposure to light as it occurs under long days. The rhythmic accumulation of the *CO* protein and its sensitivity to light thus provide the molecular basis for the external coincidence model.

Orthologs of *CO* and *FT*, *Heading date 1* (*Hd1*) and *Heading date 3a* (*Hd3a*), also control flowering in rice (*Oryza sativa*), despite rice being a short-day plant. While *Hd1* regulates the expression of *Hd3a* in rice as do *CO* and *FT* in *Arabidopsis*, the molecular mechanisms differ. *Hd1* acts as transcriptional repressor of *Hd3a* under long days, and as an

FIGURE 19.7 *CO* is a central regulator of the photoperiod pathway. (A) *CO* is regulated through output of the circadian clock and the photoreceptors *PHYA* and *CRY2*. (B) Under short days, *CO* mRNA accumulates in the dark but the protein is degraded such that it does not accumulate to activate *FT*. (C) Under long days, *CO* mRNA accumulation occurs during the light and the *CO* protein is stabilized by the activity of the photoreceptors such that *FT* transcription is activated.

activator of *Hd3a* under short days. Thus, *Hd3a*, the *FT* ortholog inducing flowering, is only produced under short days in rice.

19.1.7 The vernalization and autonomous pathways converge on the regulation of *FLOWERING LOCUS C*

Many plants growing at higher latitudes require vernalization, a 4- to 12-week exposure to cold that usually occurs during winter. Vernalization ensures that plants do not flower prematurely in late summer, when the photoperiod may be inductive for flowering but seed formation could be compromised by frost. However, even *Arabidopsis* accessions that require vernalization eventually flower in the absence of the cold treatment (flowering in these cases is promoted by the autonomous pathway), whereas other plants, such as some varieties of cabbage (*Brassica oleraceae*), have an absolute vernalization requirement (Fig. 19.8).

Once an annual plant undergoes vernalization, it “remembers” the cold treatment throughout its life (through many mitotic cell divisions). This is demonstrated in experiments with pennycress (*Thlaspi arvense*), where leaves can be removed after vernalization and used to regenerate plants *in vitro*. The regenerated plants show a flowering behavior as if they had been vernalized; their progeny, however, do not flower, indicating that the following generation requires vernalization. Thus, the memory of vernalization is maintained over many mitotic divisions, but not through meiosis.

Unlike photoperiod, which is detected in leaves, vernalization relies on events in the shoot apex. This can be shown by specifically treating the shoot apex or leaves of celery plants (*Apium graveolens*) with cold. Only when the shoot apex is subjected to cold does the plant show a typical vernalization response.

The genetic basis of vernalization was first dissected in *Arabidopsis* by crossing winter-annual accessions (germinate in autumn and require vernalization to flower in spring) with summer annual accessions (germinate in spring and flower

in the same season without vernalization). The vernalization-requiring accessions had active alleles of the *FRIGIDA* (*FRI*) and *FLOWERING LOCUS C* (*FLC*) loci, whereas summer-annuals had inactive alleles of these genes. The *FLC* gene encodes a transcription factor of the MADS domain family (see Chapter 9), and its expression is regulated by *FRI*. Mutations in *FRI* cause reduced *FLC* expression and early flowering, as do mutations in other regulators of *FLC*, for instance *FRIGIDA LIKE1* (*FRL1*), *FRIGIDA ESSENTIAL1* (*FES1*), *SUPPRESSOR OF FRI4* (*SUF4*), and *FLC EXPRESSOR* (*FLX*). These regulatory proteins form a multisubunit activator complex that recruits the general transcription machinery and chromatin modification factors (see Section 19.1.8) to the *FLC* locus. *FLC* is a potent repressor of flowering: plants with high levels of *FLC* expression, for instance winter-annuals with active *FLC* and *FRI* alleles, flower late. Vernalization reduces *FLC* expression and thus results in earlier flowering (Fig. 19.9).

The response of *FLC* to cold exposure is gradual: the longer the cold treatment, the greater the reduction in *FLC* expression. This explains why vernalization is quantitative, with short exposures to cold promoting flowering less than long exposures. However, *FLC* is not only downregulated by vernalization, also the autonomous pathway affects *FLC* expression. With increasing age of the plant, *FLC* expression levels drop gradually, such that they eventually are low enough to allow flowering.

In conclusion, a range of external and internal signals converge on *FLC* and regulate its expression, which ultimately controls the transition to flowering.

19.1.8 *Arabidopsis* mutants allowed dissecting the molecular basis for the cellular memory of vernalization

The stable transmission of vernalization through mitotic divisions implies that a cellular memory mechanism allows cells to remember the exposure to cold. In fact, once *FLC* has been downregulated by vernalization, its expression level remains low even after the plant has been returned to a warm

FIGURE 19.8 Vernalization requirements in cabbage. The plant on the left is a 5-year-old winter variety that has not been exposed to cold and thus never flowered. In contrast, the summer variety shown by the child flowers without vernalization.

Source: R. Amasino, University of Wisconsin-Madison; previously unpublished.

temperature. Since the low expression state of *FLC* is maintained over many cell divisions even in the absence of the cold stimulus, this can be viewed as an epigenetic phenomenon.

Genetic screens for *Arabidopsis* mutants that flower late even after vernalization allowed the dissection of the molecular basis of this process. In one mutant, *vernalization insensitive3* (*vin3*), *FLC* expression is not reduced during vernalization, and this gene is required for initiating *FLC* repression during cold exposure. Indeed, expression of *VIN3* increases during the cold (i.e., it is vernalization induced), but

FIGURE 19.9 *FLC* is repressed by vernalization. (A) *FLC* is a strong repressor of flowering that is activated by *FRI* and shows high expression in the absence of a cold treatment as shown in the Northern blot on the right. (B) Vernalization represses *FLC* (see Northern blot) so that the plant initiates flowering.

it is insufficient to cause vernalization when overexpressed. Other mutants, including *vernalization2* (*vrn2*), do not affect downregulation of *FLC* itself but its maintenance, as *FLC* levels increase again after returning *vrn2* mutants to warm temperature. Thus, *VRN2* can be viewed as part of the cellular memory system.

The molecular characterization of these genes revealed that they affect histone modifications that lead to a silenced chromatin organization (see Chapter 9). *VIN3* encodes a plant homeodomain (PHD) domain, which is often found in proteins modifying chromatin. *VRN2* is a homolog of *Drosophila* Suppressor of zeste 12, a component of the highly conserved **Polycomb repressive complex 2** (PRC2). The PRC2 complex is conserved between animals and plants and has histone H3 lysine 27 trimethylation (H3K27me3) activity that is mediated by homologs of the *Drosophila* histone methyltransferase Enhancer of zeste [E(Z)] (Box 19.1).

19.1.9 Integration of signals controls expression of meristem identity genes

In addition to the photoperiod, vernalization, and autonomous pathways, ambient temperature and gibberellins also control flowering. Ultimately, all these activities lead to a reprogramming of the vegetative apical meristem to an **inflorescence meristem**.

For this to occur, all the activities of the different flowering pathways must be integrated in the shoot apex. This is achieved by regulation of floral integrator genes, which are targets of multiple floral pathways. For instance, *FT* is

Polycomb complexes occur in both plants and animals

PRC2 complexes are highly conserved during evolution and are found in vertebrates, invertebrates, and plants. They consist of four conserved core subunits and some variably associated proteins. PRC2 maintains target genes in a repressed state through its histone methyltransferase activity, which is mediated by *Drosophila* E(Z) and its homologs. In plants, there are three E(Z) homologs, CURLY LEAF (CLF), MEDEA (MEA), and SWINGER (SWN), and at least three different PRC2 complexes have been identified through their function in distinct developmental processes.

For instance during vernalization, the VRN-PRC2 complex containing the core subunits VRN2, FERTILIZATION

INDEPENDENT ENDOSPERM (FIE), MULTISUPPRESSOR OF IRA1 (MSI1), and the histone methyltransferases CLF or SWN place H3K27me3 marks on the *FLC* locus, thereby silencing its expression (see below). A dimer of the two PHD domain proteins VRN5 and VIN3, the latter being induced by cold, enhances VRN-PRC2 activity and stably represses the *FLC* locus. At some point during the reproductive cycle, however, the repressive H3K27me3 histone marks have to be erased, as the progeny of a vernalized plant does not flower early. This erasure occurs during early embryogenesis, but the molecular mechanisms involved are currently not well understood.

FIGURE 19.10 Integration of the various flowering pathways. The transition from vegetative to reproductive growth is controlled by four major pathways whose activities are integrated through the regulation of FT and SOC1 that, in turn, activate the meristem identity genes AP1 and LFY.

activated by CO, but at the same time, it is repressed by FLC and regulators of the thermosensory pathway. Similarly, the MADS box gene *SUPPRESSOR OF OVEREXPRESSION OF CONSTANS1* (*SOC1*) is repressed by FLC but activated by FT and the gibberellin pathway (Fig. 19.10). In this way, information from the different pathways is integrated and leads to the reprogramming of the shoot meristem through the activation of specific genes in the apex, including *LEAFY* (*LFY*) and *APETALA1* (*AP1*). Both these genes are activated by FT and SOC1 and ultimately confer floral identity to the primordia produced by the meristem. They encode transcription factors of the MADS domain and LFY-FLO family, respectively, and mutations in them cause partial transformation of flowers to shoots.

19.2 The molecular basis of flower development

The development of flowers is one of the most intensively studied developmental processes. Although work in various plants, including snapdragon (*A. majus*), rice (*O. sativa*), tobacco (*N. tabacum*), and petunia (*Petunia hybrida*), has contributed to our understanding of the molecular genetic basis of flower development, most of the molecular work has been performed using *Arabidopsis*.

19.2.1 Inflorescence architecture is determined by *LEAFY*

Once the vegetative meristem has been reprogrammed into an inflorescence meristem, it produces new meristems that give rise to either secondary inflorescences or flowers

(Fig. 19.11). An inflorescence is indeterminate if it continues to produce flowers throughout the life of the plant; it is determinate if the apical meristem produces a certain number of flowers and then converts into a floral meristem itself, thereby terminating the inflorescence. In its extreme form, as in tulips (*Tulipa gesneriana*) and many other Liliaceae, the reproductive meristem produces only a single, terminal flower.

The identity of the floral meristem is determined by the function of two closely related genes that encode the AP1 and CAULIFLOWER (*CAL*) transcription factors. Whereas *ap1* mutants have phenotypes that reveal aspects of the gene's function as both a meristem and floral organ identity gene, *cal* single mutants look like the wild type. In an *ap1 cal* double mutant, however, the function of both genes in determining floral meristem identity is dramatically revealed: instead of producing floral meristems, the apical meristem of the double mutant produces inflorescence meristems, which in turn produce inflorescence meristems again, giving rise to a mass of inflorescence meristems, but no flowers (Fig. 19.12). Such apices look like tiny cauliflowers and, indeed, cauliflower and romanesco broccoli are two of the cultivated forms of *B. oleracea* that have a similar phenotype.

Whether a primordium produces a flower depends on the action of another transcription factor, LFY, which is encoded by a highly conserved gene that controls floral meristem identity in angiosperms and possibly also in gymnosperms (expression of LFY homologs is induced in their reproductive cones). In an *lfy* mutant, the cells that should produce a flower meristem instead form a shoot that produces leaves. Conversely, constitutive overexpression of LFY transforms the apical meristem into a floral meristem after the transition to flowering, resulting in the formation of a single, terminal flower. A similar phenotype is observed in *terminal flower1* (*tf1*) mutants. In this mutant, LFY is expressed in the inflorescence meristem, causing its conversion into a floral meristem. LFY controls the expression of

FIGURE 19.11 Diagram of an *Arabidopsis* plant and flower. (A) Before flowering, the vegetative meristem produces rosette leaves. After floral induction, the primary inflorescence meristem produces cauline leaves with secondary inflorescences emerging from their axils, and flowers. (B) Schematic representation of flower with longitudinal and transverse sections. The first and second whorls produce sterile floral organs, the sepals and petals. The third and fourth whorls produce reproductive organs, the stamens and carpels.

FIGURE 19.12 Meristem identity genes control inflorescence development. (A) shows an *Arabidopsis* wild-type inflorescence, while two redundant floral meristem identity genes are mutated, both in the *ap1 cal* double mutant of *Arabidopsis* (B) and in cauliflower (C). Source: A. Bolanos, S. Hofstetter and H.P. Schöb, University of Zurich; previously unpublished.

regulatory genes that are required for flower formation, including *API* and *CAL*, and it is expressed very early in the cells that form a floral meristem. The regulatory interactions, however, are complex, and *LFY* itself is activated through the redundant function of *API*, *CAL*, and *FRUITFUL* (*FUL*), resulting in a positive feedback loop.

In an indeterminate wild-type inflorescence meristem, *LFY* is only expressed in the cells that will form a floral meristem but not in the apex, where it is normally repressed by *TFL1* (Fig. 19.13). This explains why mutations disrupting *TFL1* or the constitutive expression of *LFY* both lead to the formation of terminal flowers. A change in expression of *LFY* and/or *TFL1* may give rise to a variety of inflorescence architectures by altering the determinacy of inflorescence meristems.

19.2.2 Diverse floral morphologies have a common body plan

There is tremendous diversity of floral morphologies, and the abrupt appearance and rapid diversification of flowering plants in the mid-Cretaceous led to Charles Darwin's metaphor of the "abominable mystery." This enormous and beautiful diversity, however, is solely based on variations of a common theme: all flowers, as diverse as they may appear, have a common body plan and develop in very similar ways.

All plants have the same arrangement of floral organs, namely (from outside to inside) sepals, petals, stamens, and carpels, and all arranged in concentric whorls, starting at the periphery of the floral meristem and moving towards its

center (see Figs. 19.11 and 19.14). Once a group of cells is determined to form a floral meristem, floral organs are sequentially formed. In *Arabidopsis*, four **sepals** are formed in the outermost whorl (whorl 1), followed by four **petals** in whorl 2. Sepals and petals are sterile organs and together make up the **perianth**, which is often specifically shaped and colored to attract pollinators and protects the reproductive organs in the center of the flower. In *Arabidopsis*, the reproductive organs are represented by the six **stamens**, which develop in whorl 3, and the two **carpels** that originate from the innermost whorl (whorl 4) and fuse to form the **gynoecium**, which harbors the ovules (see Fig. 19.11). As the floral meristem produces a more or less defined number of organs in the four whorls and the production of new cells

stops thereafter, it is a determinate meristem. Consistent with this, the *WUSCHEL* (*WUS*) gene, which is required for stem cell maintenance in meristems, becomes repressed in the floral meristem once the primordia of the reproductive organs are formed.

Flowers can also lack organs, however, or the organs may be modified to look more like another organ of the flower. For instance, in many members of the Liliaceae, the sepals are colorful and petal-like, so the organs of the perianth look alike and are often referred to as tepals (Fig. 19.15). Even in grasses, which do have unusual flowers, the typical arrangement of the floral organs can still be seen. The **lodicules** occupy the position of the petals, whereas two dimorphic organs, the **palea** and **lemma**, can be viewed as the equivalents of sepals (Fig. 19.15).

This extraordinary conservation of the floral body plan suggests that the underlying molecular mechanisms are also shared. Accordingly, the genes controlling floral organ identity are highly conserved, and differences in their regulation can explain the morphological variety seen in flowers.

19.2.3 The ABC model determines organ identity

The genes controlling floral organ identity were identified through studies of homeotic mutations, which transform one organ into another and are, thus, involved in determining the identity of these organs. A well-known homeotic mutation, which has attracted the attention of horticulturists, leads to the replacement of the reproductive organs by perianth organs, thereby forming a filled or double flower (Fig. 19.16). The first such double flower mutant of *Arabidopsis* was described in 1873, and consistent with the highly conserved organization of flowers, mutations with similar phenotypes in *Arabidopsis* and snapdragon affect homologous genes.

FIGURE 19.13 Regulatory interactions between genes conferring identity to inflorescence and floral meristems. *LFY* and *AP1/CAL* are expressed in floral meristems and positively regulate each other. *TFL1* is expressed in the apex of the inflorescence meristem and engages in negative regulatory interactions with the floral meristem identity genes *LFY* and *AP1/CAL*, preventing the termination of the shoot apex in a flower.

Source: A. Hedhly, University of Zurich; previously unpublished.

FIGURE 19.17 The original ABC mutants. Each mutant shows homeotic transformations, that is the transformation of one organ into another. The B-class mutants *ap3* and *pi* look identical, while the A-class mutant *ap1* has a floral meristem identity phenotype in addition to the homeotic phenotype shown here for *ap2*. The C-class mutant *ag* affects floral meristem determinacy in addition to organ identity. The organs are color-coded: sepals, green; petals, yellow; stamens, red; carpels, blue.

Homeotic mutants in *Arabidopsis* always affect two adjacent whorls. For instance, in *agamous* (*ag*), the mutation producing double flowers, the sepals in whorl 3 are replaced by petals, and the gynoecium in whorl 4 is replaced by another

flower, so the pattern sepals–petals–petals is reiterated several times (Fig. 19.17). This phenotype shows that *AG* not only controls floral organ identity, but is also responsible for the determinate nature of the flower. In an *ag* mutant, *WUS* is not

FIGURE 19.18 ABC model for floral organ specification. Functional domains of the A- (dark green), B- (orange), and C-class (purple) genes encompass two whorls and their specific combinations specify organ identity in each of the four whorls.

repressed after the initiation of floral primordia in the inner whorls, and thus the stem cell pool in the floral meristem is maintained and produces additional organs. Also the homeotic mutants *pistillata* (*pi*) and *apetala3* (*ap3*), which have identical phenotypes, affect two whorls: petals in whorl 2 are replaced by sepals, and stamens in whorl 3 by carpels. Finally, the two outermost whorls are affected in the homeotic mutants *ap1* and *apetala2* (*ap2*) (Fig. 19.17).

In addition to determining inflorescence meristem identity, *API* also plays a role in specifying floral organ identity. While the sepals in *ap1* mutants are converted to leaf-like organs that produce secondary and tertiary flowers in their axils, the petals are usually missing and occasionally replaced by stamens or mosaic organs. In *ap2* mutants, sepals in whorl 1 are converted to carpels and stamens replace the petals in whorl 2 (Fig. 19.17). In addition, *ap2* flowers have often fewer organs than wild-type flowers and sometimes all organs in whorl 2 are missing. This phenotype indicates that *AP2* not only determines the identity of floral organs, but also specifies the number of organ primordia that are formed.

Based on the organ identity phenotypes observed in these homeotic mutants, the original **ABC model** for flower development (Fig. 19.18) was formulated. In this model, the genes controlling floral organ identity are subdivided into three classes: A-class genes (*API*, *AP2*) are active in whorls 1 and 2, B-class genes (*PI*, *AP3*) in whorls 2 and 3, and C-class genes (*AG*) in whorls 3 and 4. The domains in which each class of homeotic genes is active partially overlap, such that each whorl has a unique combination of activities that determines the identity of the organs it usually forms. Class A alone determines sepal identity, classes A and B together specify petal identity, classes B and C confer stamen identity, while class C alone is needed to form carpels. Moreover, classes A and C act antagonistically, that is they repress each other's activity. Thus, if C class activity is missing in whorls 3 and 4, A-function extends into these whorls and vice versa.

This simple model for the combinatorial function of the A-, B-, and C-class genes can explain the observed phenotypes in single mutants and faithfully predicts those of double mutants (Fig. 19.19). For instance, if A-function is lost, then C-function extends into whorls 1 and 2, such that carpels are formed in whorls 1 and 4, which now only express the C-function gene *AG*, while stamens are formed in whorls 2

and 3, which express both C- and B-function. If both A- and B-function are removed, only the C-function is expressed in all four whorls, leading to the formation of a flower with carpels in all whorls. Using combinations of homeotic mutants and transgenic plants that overexpress a homeotic gene in all four whorls, any floral organ can be made in any position in a predictable way. For example, if an A-class mutant is combined with a transgene that leads to overexpression of the B-class genes throughout the flower meristem, flowers with only stamens develop, controlled by the combination of C- and B-class genes now present in all four whorls (Fig. 19.19).

Some phenotypes, however, cannot be predicted on the basis of the ABC model. A triple mutant that expresses neither A-, nor B-, nor C-class genes produces flowers that have leaf-like organs in all whorls, illustrating that floral organs are modified leaves. The ABC model also does not make predictions for the phenotype of a double mutant affecting A- and C-class genes, as B-class genes usually act in combination with either A- or C-class genes. It turns out that such mutants have leaf-like organs in whorl 1, which does not express any of the homeotic genes, and leaf-like organs with stamenoid characters in whorl 2, because it expresses B-class genes that are involved in stamen formation. This pattern is then reiterated as the flower meristem loses its determinacy in the C-class mutant *ag*.

Although subsequent molecular analyses have added layers of complexity to the original ABC model, the model has proven robust in predicting phenotypes of (multiple) mutants and transgenic lines and explaining the diversity of floral morphologies found in nature. For example, the model predicts that in tulips and other Liliaceae, which have petal-like organs in whorls 1 and 2, the B-function extends into whorl 1. Indeed, B-class genes in tulips are expressed in whorl 1, such that petal-like organs form in this whorl under the control of A- and B-class genes.

19.2.4 Organ specification is explained by the molecular quartet model

The homeotic genes described above all encode transcription factors, which is consistent with their function in specifying organ identity. It is thought that each combination of A-, B-,

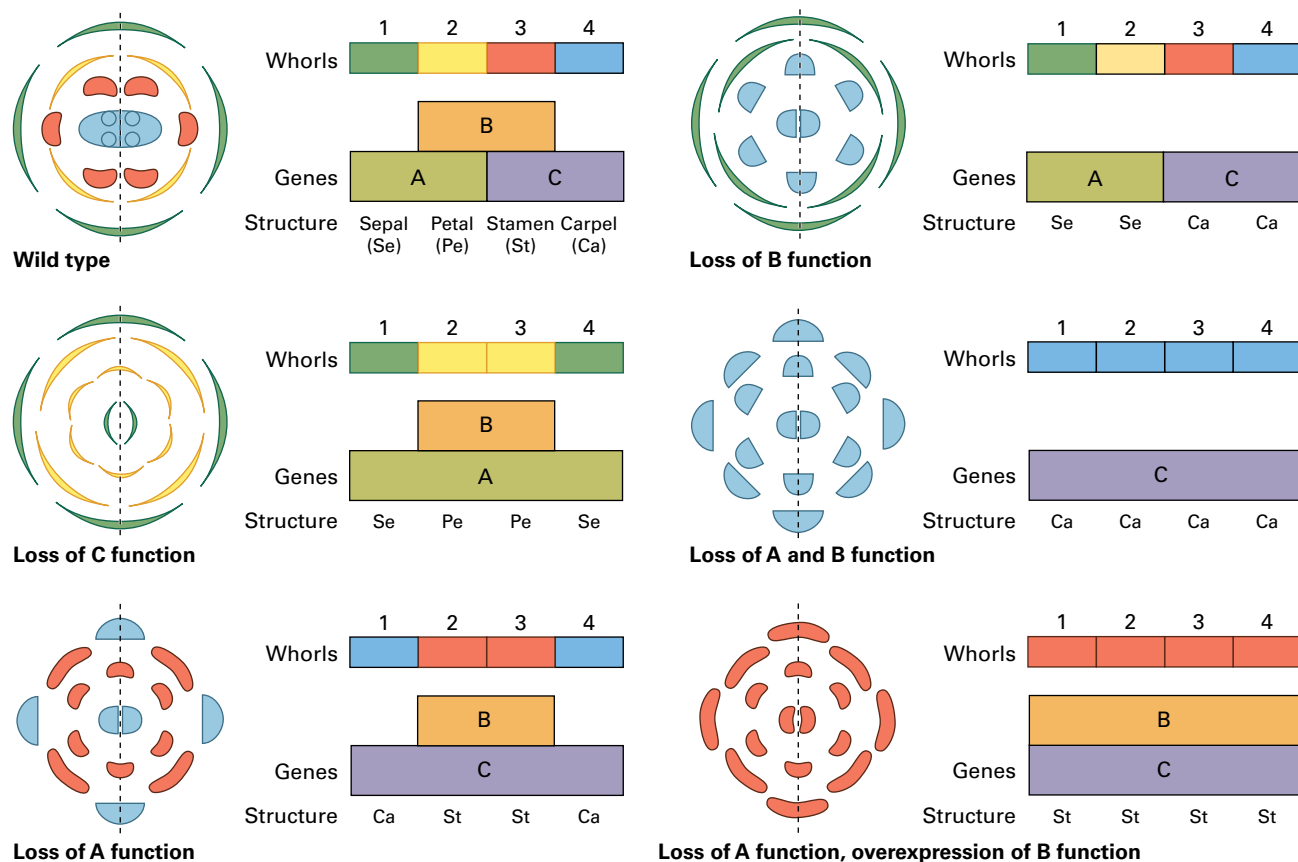

FIGURE 19.19 Mutant phenotypes of single and multiple mutants based on the ABC model. The ABC model postulates that A and C functions are antagonistic. When C-function is missing, A-function expands into whorls 3 and 4 leading to the formation of petals in whorl 3, where B-function is present, and sepals in whorl 4. Conversely, if A-function is lost, C-function extends into whorls 1 and 2, leading to the formation of carpels and stamens. Based on the ABC model, double mutant phenotypes can be accurately predicted as described in the text. However, additional functions of the homeotic genes can lead to modified phenotypes, e.g. combinations with *ag* have indeterminate flowers and *ap2* mutants often lack organs in whorl 2.

or C-class transcription factors regulates a set of target genes required for the development of the corresponding organ.

All homeotic genes except *AP2* encode MADS-domain transcription factors (see Chapter 9), which are characterized by a highly conserved, N-terminal DNA-binding domain. The 56–60 amino acid MADS-domain occurs in plant, animal, and fungal proteins and binds DNA sequences with similarity to the CC[A/T]₆GG motif, also known as CARG-box (Fig. 19.20). *AP2* differs from the others in that it was the founding member of a transcription factor family unique to plants that contains an AP2 DNA-binding domain. The MADS-domain proteins bind DNA as multimeric complexes; for example, *AP3* and *PI* proteins can bind to a CARG-box only if both proteins are part of the multimeric complex, providing a molecular explanation for why the corresponding mutants have identical phenotypes.

The molecular and genetic characterization of plant homeotic genes revealed that they function similarly to the homeotic genes in animals. In both cases, specific combinations of transcription factors specify the identity of organs or segments, respectively. In the case of animals, all homeotic genes encode homeodomain transcription factors, whereas plant homeotic genes encode transcription factors belonging

to the MADS-domain or AP2 DNA-binding domain family. The floral organ identity genes are conserved throughout angiosperms, and homologs with corresponding functions have been identified in many plants.

With the exception of *AP2*, which is expressed in all four whorls, floral organ identity genes are expressed in the domains predicted by the ABC model. For example, the B-class genes *PI* and *AP3* are expressed in whorls 2 and 3, and C-class gene *AG* in whorls 3 and 4 (Fig. 19.21). This correspondence of function and expression domains suggests that homeotic genes are primarily regulated at the transcriptional level.

The difference between the expression pattern of *AP2* and its functional domain can be explained by the expression of microRNA *miR172* in whorls 3 and 4 (see Chapter 6). This microRNA targets *AP2* mRNA and prevents its translation into a protein (Fig. 19.22), such that the *AP2* protein is present only in whorls 1 and 2, in a pattern complementary to that of the *AG* protein as expected based on the ABC model. A refined analysis of the *AP2*, *AG*, and *miR172* expression patterns has shown that *AP2* accumulates mostly in whorls 1 and 2 and only partially overlaps with *miR172* in the center of the flower. Also, *AP2* never completely expands into the

center of *ag* mutant flowers. Thus, the original ABC model must be further modified so that *AP2* and *AG* do not act in a mutually exclusive fashion; instead, the decision to form petals or stamens may depend on their relative abundance in whorls 2 and 3.

While the manipulation of homeotic genes changes floral organ identity, A-, B-, and C-class genes are insufficient for converting a leaf into a floral organ. However, when they are expressed together with the *SEPALATA* genes (*SEP1*, *SEP2*, *SEP3*), vegetative and cauline leaves are converted into floral organs, their identity depending on which combination of A-, B-, and C-class genes are co-expressed with *SEP1/2/3*. The *SEP*

FIGURE 19.20 MADS-domain proteins bind DNA. Structure of a dimer formed by two MADS-domains binding to a CAAT-box on DNA.

genes are redundant, and only the triple *sep1/2/3* mutant produces flowers in which all organs are converted into sepals. Thus, *SEP1/2/3* are required for the normal development of petals, stamens, and carpels, and are referred to as E-class genes (the D-class is involved in ovule identity, see Section 19.4.1). During early flower development, *SEP1* and *SEP2* are expressed in all four whorls, while *SEP3* is only expressed in whorls 2, 3, and 4.

Like most other homeotic genes, the *SEP* genes encode MADS-domain transcription factors that interact with other MADS-domain proteins. To explain the known combinatorial interactions, it was suggested that they form complexes consisting of four proteins (“floral quartets”). Each quartet consists of a set of MADS-domain proteins specifying a particular organ and controls a set of target genes required for its formation (Fig. 19.23). For instance, the quartet directing petal development would contain the A-class protein *AP1*, the B-class proteins *PI* and *AP3*, and a *SEP* protein. In whorl 4, however, two *SEP* proteins would form a quartet with two *AG* proteins, which specify carpel development. Indeed, the existence of multimeric protein complexes as proposed in the floral quartet model was demonstrated in *planta*.

19.2.5 A number of factors regulate the expression of floral homeotic genes

Most of the flower organ identity genes are expressed in specific domains of the floral meristem that give rise to the organs they control. The homeotic genes are activated by *LFY* and *AP1*, which are, therefore, important for both specifying the identity of the flower meristem and activating organ identity genes during the early stages of flower development. During these early stages, however, both *AP1* and *LFY* are expressed throughout the floral meristem, while their B- and C-class target genes are only expressed in specific domains. Therefore, other factors must be involved in controlling the specific expression domains of the homeotic genes.

For instance, *LFY* activates the C-class gene *AG*, but this requires the homeodomain transcription factor *WUS*

FIGURE 19.21 Expression patterns of floral homeotic genes. The MADS-box genes *AP1*, *AP3*, *PI*, and *AG* are expressed in two adjacent whorls as expected based on the ABC model. *AP2*, however, is expressed in all four whorls throughout flower development. This raises questions regarding the function of *AP2*, which was predicted to act antagonistically to *AG* and, based on the original ABC model, should not be coexpressed with *AG* in whorls 3 and 4.

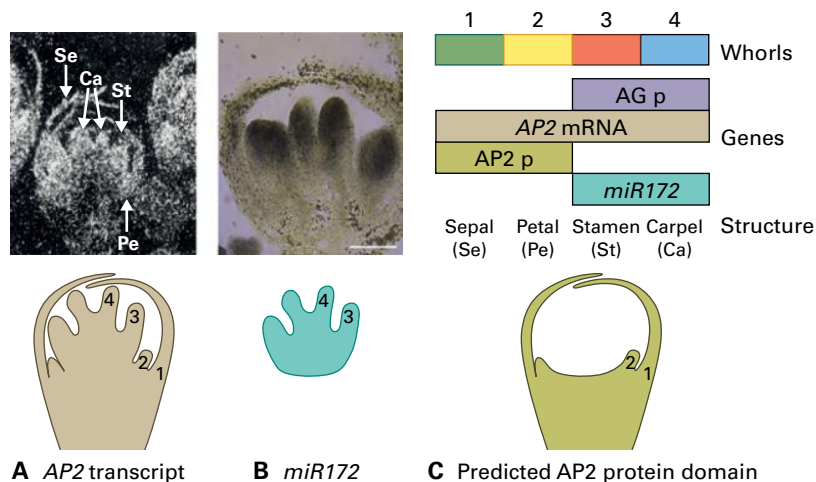

FIGURE 19.22 *AP2* is regulated by a microRNA. *AP2* is expressed in all four whorls (A), although it supposedly acts antagonistically with *AG* and should thus repress *AG* in whorls 3 and 4. This conundrum is resolved by the expression of *miR172* in whorls 3 and 4 (B), where it prevents the translation of *AP2*. Thus, the *AP2* and *AG* proteins do not co-occur in whorls 3 and 4, and act antagonistically as expected (C).

FIGURE 19.23 Quartet model for floral organ identity. The homeotic proteins form tetrameric complexes that involve between two and four distinct proteins. In each whorl, a specific combination of proteins forms a quartet, which regulates specific target genes that are required to form the specified organ.

(see Chapter 11) as co-factor. *WUS* is expressed early during flower development, prior to *AG*. *LFY* and *WUS* activate *AG* in whorls 3 and 4 by binding to *cis*-regulatory elements in the second intron of the *AG* gene. However, *AG* is also regulated by A-class genes, as A- and C-class act antagonistically. While mutations in *AP1* do not affect *AG* expression, *AG* is misexpressed in whorls 1 and 2 of *ap2* mutants, leading to homeotic transformations. Thus, *AP2* controls the spatial expression pattern of *AG*. Genes that are involved in regulating the spatial expression domain of homeotic genes are referred to as **cadastral genes**; therefore, *AP2* is both a homeotic and a cadastral gene. Since *AP1* expression expands into whorls 3 and 4 in an *ag* mutant, *AG* has three functions: It is a homeotic, cadastral, and floral determinacy gene.

Once floral homeotic gene expression patterns have been established through the action of the floral meristem identity and cadastral genes, they must be maintained, and this is

achieved by *Polycomb* group (PcG) and *trithorax* group (TrxG) genes. PcG genes encode a heterogeneous group of proteins that form repressive multiprotein complexes. In *Drosophila*, they were originally defined through their requirement for maintaining homeotic genes in a repressed state. TrxG genes, on the other hand, are required to maintain their active state of gene expression. In a *curly leaf* (*clf*) mutant, for instance, repression of *AG* in whorls 1 and 2 is not maintained later during flower development, and *AG* is expressed ectopically in leaves. *CLF* encodes a homolog of the *Drosophila* histone methyltransferase E(Z) and is part of the PRC2 complexes (see Chapter 11 and Box 19.1) that regulate homeotic gene expression (EMF-PRC2) and the floral repressor *FLC* (VRN-PRC2). Interestingly, in mutants of *ATX1*, an *Arabidopsis* gene similar to *Drosophila trithorax*, the expression of floral homeotic genes is reduced. *ATX1* also encodes a histone methyltransferase, but it is responsible for the trimethylation of histone H3 lysine 4 (H3K4me3), which is associated with active chromatin and acts antagonistically to H3K27me3. Thus, PcG and TrxG proteins are required to maintain homeotic genes in a repressed or active state of expression in both animals and plants.

These highly conserved multiprotein complexes must have an ancient origin that predates the separation of the plant and animal lineages. However, multicellularity and, therefore, the function of homeotic genes evolved separately in animals and plants, suggesting that PcG and TrxG regulatory modules were recruited independently to regulate homeotic genes in these two lineages (Fig. 19.24). This is an example of convergent evolution, as PRC2 complexes have not only been recruited to regulate homeotic genes in animals and plants, but also regulate genomic imprinting in both lineages (see Section 19.10).

In animals, another complex consisting of PcG proteins, ***Polycomb* repressive complex 1** (PRC1), is required to stabilize the silenced state of PRC2 target genes through the monoubiquitylation of histone H2A. Only a few of the genes encoding components of *Drosophila* PRC1 are conserved in plant genomes. Among them are the RING-finger proteins

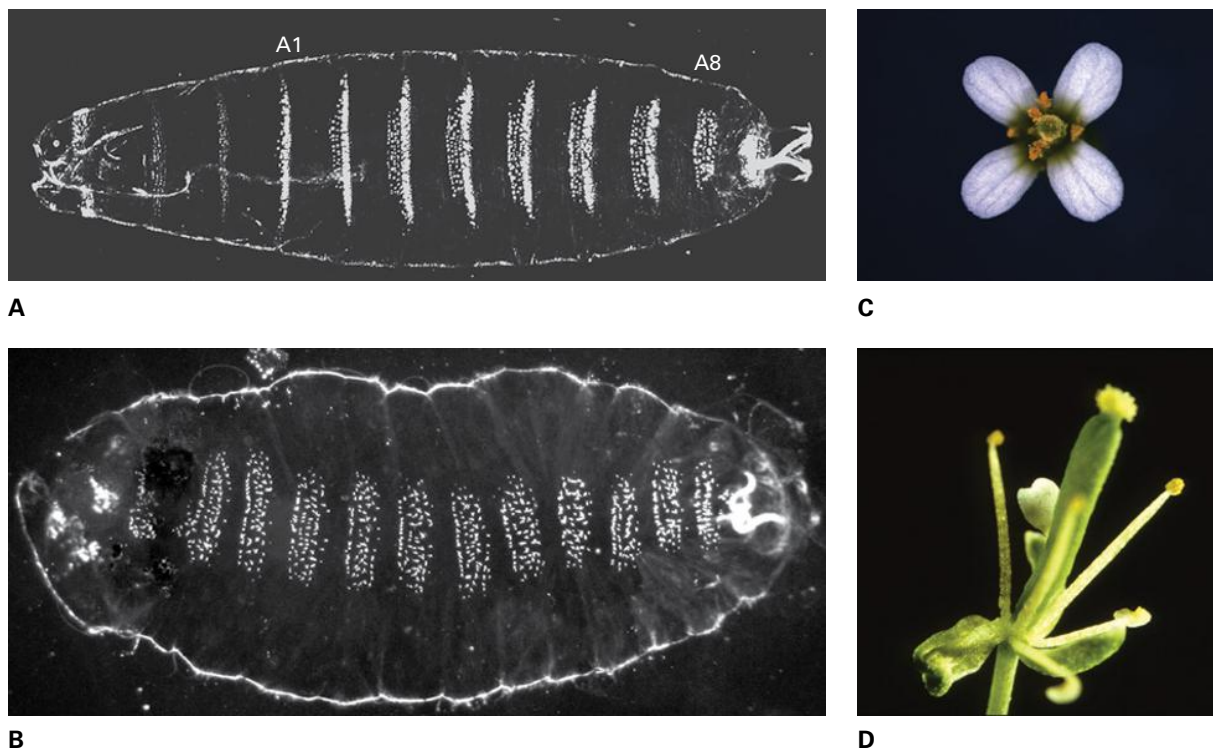

FIGURE 19.24 Homeotic phenotypes in PcG mutants. PcG proteins are highly conserved and play similar roles in plants and animals where they have been independently recruited to regulate homeotic genes. (A) *Drosophila* wild type larvae where each abdominal segment (A1–A8) has a distinct cuticle pattern. (B) *Drosophila su(z)12* larvae where all segments are homeotically transformed and have A8 identity. (C) *Arabidopsis* wild-type flower. (D) *Arabidopsis clf* flower with homeotic organ transformations.

RING1A and RING1B, which mediate H2A monoubiquitination and, when disrupted, show phenotypes similar to those observed in PRC2 mutants. This suggests that, in addition to PRC2, which is highly conserved, complexes with functions similar to those of PRC1 also exist in plants.

19.3 The formation of male gametes

19.3.1 Gamete development in plants is strikingly different from that in animals

Once the plant has produced flowers, a key event in plant reproduction takes place in the floral reproductive organs (the anthers and ovules): the transition from the diploid **sporophytic** to the haploid **gametophytic** generation.

There are many striking differences in the reproduction of animals and plants. In plants, meiosis produces **spores**, whereas in animals meiosis is intimately connected to gamete production. In fact, the spore-producing sporophyte represents the dominant phase of the life cycle in flowering plants, while the gamete-producing **gametophytes** consist of only a few cells, and their development depends on resources from the sporophyte (see Fig. 19.1). However, this is not true for all plants. In mosses and

liverworts, for example, the gametophytes are free-living, photosynthetically active organisms that represent the dominant phase of the life cycle (Fig. 19.25). What is common to all gametophytes, however, is that they are multicellular, form from haploid spores through mitotic divisions, and only subsequently produce the gametes. This is in contrast to animals, where the meiotic products differentiate directly into gametes.

In plants, there is no early separation of soma and germline. Rather, any sporophytic cell can give rise to a gametophyte and so somatic mutations can sometimes be inherited. The first cells to eventually give rise to a gamete are the archesporios that differentiate in the anther and ovule. Thus, these cells can be viewed as the first cells of the plant equivalent of the germline, which is only established late in development and independently in each reproductive organ.

19.3.2 During anther development, cells are set aside that eventually give rise to pollen

The stamen, the male reproductive organ of flowering plants, typically consists of a stalk-like filament and an anther. Formation of the haploid microspores (**microsporogenesis**) and pollen development (**microgametogenesis**) take place within the anther. The development of anthers and male gametophytes is highly conserved among angiosperms, with

FIGURE 19.25 Life cycle of the moss *Physcomitrella patens*. Gametophytes are free-living organisms that produce gametes in specialized reproductive organs. Fertilization of the egg cell by a motile sperm forms a zygote, which develops into a sporophyte that is dependent on the gametophyte. Sporogenesis produces spores that initiate the gametophytic generation.

only minor differences among certain plant families. Therefore, the molecular insights into male reproductive processes gained from model species can be directly translated to crop plants, a fact that has been exploited in several biotechnological applications. Male sterile mutants are useful in the production of hybrid seeds, which are widely used in agriculture because crosses involving a male sterile parent, serving as the female, are much easier to conduct on a large scale.

During anther development, cells are set aside that will eventually give rise to pollen. The first step in this process is the specification of four subepidermal cells into archesporia, which eventually form the four-lobed anthers typical of flowering plants. The subepidermal cells can be traced back to the L2 layer of the shoot meristem, which is thus the layer that gives rise to the germline in plants. In *Arabidopsis* the *SPOROCTELESS/NOZZLE (SPL/NZZ)* gene is required for archesporia formation in both male and female reproductive organs. *SPL/NZZ* is a direct target of *AG* and encodes a transcription factor with similarities to MADS-domain proteins.

Each archesporia divides to form a primary parietal and a primary sporogenous cell. The primary sporogenous cell divides again to produce the **microsporocytes** (also referred to as microspore or pollen mother cell), and it serves as an organizing center in the formation of the pollen sac (microsporangium), in which pollen development takes place. Induced by signals from sporogenous cells, the primary parietal cell divides to form an outer endothelial and an inner

secondary parietal cell, which divides once more to form the cells of the middle and tapetum layer that is in direct contact with the microsporocytes (Fig. 19.26).

The tapetum encloses the pollen sac that contains the microsporocytes. Tapetal cells produce diverse compounds, such as phenolics, flavonols, and proteins that contribute to the formation of the intricate outer wall of the pollen, the exine. The tapetal cells eventually undergo programmed cell death, and some of their cellular components are incorporated into the pollen coat that lines the surface of the mature pollen grain's exine layer (Fig. 19.27). The pollen coat plays a central role in pollen recognition at the stigma surface (see Section 19.5.2). In fact, many mutations that result in male sterility (lack of pollen production) primarily affect the tapetum, indicating that the tapetum plays an essential, noncell autonomous role for pollen development.

19.3.3 Complex cell–cell communication events underlie microsporogenesis

As mentioned in the previous section, during anther development, the two daughter cells of the archesporia adopt different fates: the primary sporogenous cells form the microspore mother cells and, thus, the gametes, whereas the primary parietal cells form the sporophytic tissues of the pollen sac. Using mutants in both *Arabidopsis* and rice (*Oryza sativa*), it

FIGURE 19.26 Development of the pollen sac. (A) A cross section of a young anther primordium showing two of the four enlarged archesporial cells. (B) Asymmetric division in the anther. An archespore (A) differentiates underneath the epidermis (Ep). An asymmetric division forms the primary parietal (PP) and the primary sporogenous (PS) cells. The PS divides to form a pool of microspore mother cells and induces neighboring cells to adopt a PP-like fate ('PP') and PP cells to divide and form endothelial (E) and secondary parietal (SP) cells. The 'PP' cells then undergo the same asymmetric division to form E and SP cells. The 'PP' cells then undergo the same asymmetric division to form E and SP cells, which eventually divide to form the middle (M) and tapetal (T) cell layers surrounding the PS cells (only one cell is shown that already underwent this division). Source: Scott et al. (2004). *Plant Cell* 16:S46.

was shown that this cell fate decision is governed by several signaling cascades.

In the *extra sporogenous cells (exs)/excess microsporocytes1 (ems1)* mutant of *Arabidopsis*, too many microsporocytes are formed at the expense of tapetal cells. This phenotype might be explained if cells that give rise to the tapetal layer adopted instead a microsporocyte fate. *EXC/EMS1* encodes a leucine-rich repeat receptor-like kinase (LRR-RLK; see Chapter 18) that is expressed in the parietal cell lineage. Mutations in another gene, *TAPETAL DETERMINANT1 (TPD1)*, give rise to the same phenotype as *exs/ems1* mutants, but *TPD1* is predominantly expressed in microsporocytes and encodes a secreted protein that interacts with *EXC/EMS1*. This suggests that *TPD1* is a ligand produced in the sporogenous lineage that is recognized by *EXC/EMS1* in the parietal lineage to organize the formation of the pollen sac. The same holds true for the rice orthologs of these two genes. Finally, a double mutant affecting another pair of RLKs, the *SOMATIC EMBRYOGENESIS RECEPTOR-LIKE KINASE1* and 2 (*SERK1*, *SERK2*), shares the same phenotype, illustrating the complexity of cell–cell communication events that regulate this important cell fate decision.

Once the microsporocytes are formed, they undergo two meiotic divisions to produce four haploid microspores. Progression through meiosis requires a suite of genes, many of which are conserved between yeast, animals, and plants. Many sterile mutants in plants are the result of mutations affecting meiosis, and most of these affect both sexes, although a few are sex specific. At the end of meiosis, a tetrad of microspores encased in a callose wall is formed. Individual microspores are

released through digestion of the callose by a tapetum-derived enzyme (callase) (Fig. 19.27).

The free microspore marks the beginning of the gametophytic phase, during which the mature male gametophyte is formed inside the pollen sac. But microspores are surprisingly plastic and, under appropriate conditions, they can form embryos (**androgenesis**) that are haploid. Doubling their chromosomes, which can happen spontaneously or after treatment with colchicine, results in diploid plants with a uniformly homozygous genome. Such an immediate route to homozygosity is of great interest for plant breeders because it circumvents time-consuming, repeated self-fertilization to generate homozygous plants through inbreeding (Box 19.2).

19.3.4 Microgametogenesis involves two rounds of mitosis

Initially, the free microspores are apolar, with a centrally located nucleus surrounded by small vacuoles. Then the microspore expands in a process that is accompanied by the formation of a large vacuole. This results in the formation of a polarized, unicellular microspore, which divides asymmetrically during pollen mitosis I (PM I) to form a bicellular microspore consisting of a large vegetative cell and a small generative cell (Fig. 19.28). The generative cell detaches from the pollen cell wall and becomes internalized, harbored within the cytoplasm of the vegetative cell ("cell within a cell" configuration).

FIGURE 19.27 Diagram of pollen development. Meiosis occurs in the pollen sacs of the anther and produces a tetrad of microspores. Callose digestion releases free microspores that initiate microgametogenesis. The microspore polarizes and undergoes an asymmetric division (PM I) to form a large vegetative and a small generative cell that gets internalized. The generative cell divides once more (PM II) to form the two sperm cells.

As in many other developmental processes in animals and plants, the asymmetric PM I marks the beginning of the distinct developmental fates of the daughter cells. Only the generative cell undergoes pollen mitosis II (PM II) to form the two sperm cells, which contribute to the next generation. The chromatin in the generative cell nucleus is more condensed

than that of the vegetative nucleus and finally reaches the highly condensed state typical of sperm cells (Fig. 19.28). In contrast, the vegetative cell does not divide further, but is responsible for bringing the sperm cells to the female gametes, carrying them in its cytoplasm as cargo. The vegetative cell stores a large variety of mRNAs and proteins that allow an

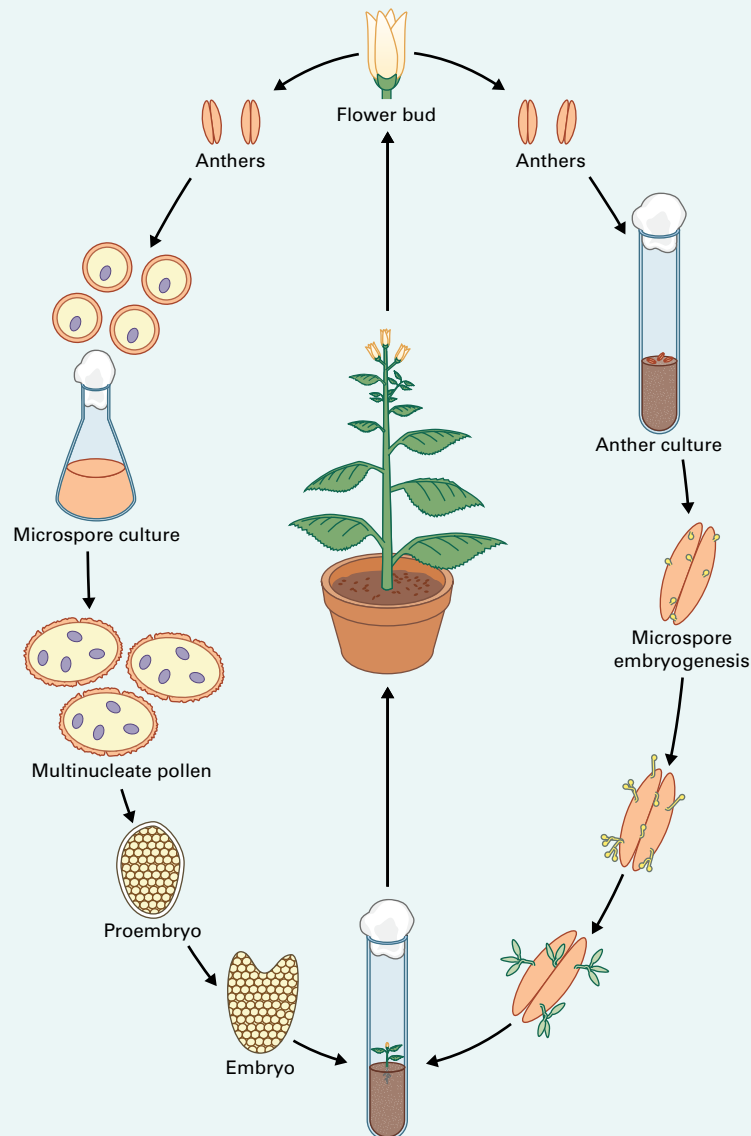

Microspore culture can revert the gametophytic developmental program to a sporophytic program, yielding haploid plants

Cultured anthers or microspores can be used to generate haploid plants. This technique is of interest to plant breeders because doubling the chromosome number of the resulting haploid plants, either spontaneously or by chemical treatment, can generate homozygous diploids.

Flower buds at the appropriate developmental stage are collected and the microspores isolated and cultured. For some plants, microspore culture (left pathway) is inefficient, and the anthers must be cultured instead (right pathway). The sporophytic anther tissue is thought to provide factors required for the development of microspore-derived embryos. Formation of embryos is typically induced by a stress treatment. In some cases, whole plants are grown under stress conditions (such as low temperatures or nitrogen starvation). In other cases, anthers are excised or microspores isolated from a

nonstressed plant; after the isolated tissues or cells are subjected to a stress treatment (e.g., heat shock or starvation for nitrogen and sucrose), they are transferred to a medium containing sucrose and nitrogen to promote further development of microspore-derived embryos.

After stress treatment, microspore embryos arise by one of two developmental pathways. In the first pathway (shown on the left), the vegetative cell of a binucleate pollen grain continues to proliferate, forming a multinucleate pollen grain and eventually an embryo. In the second, the uninucleate microspore undergoes a symmetrical cell division, giving rise to two equal-sized cells that both continue to divide (not shown). Both pathways involve a release of the cell cycle arrest that the vegetative cell undergoes during normal pollen development.

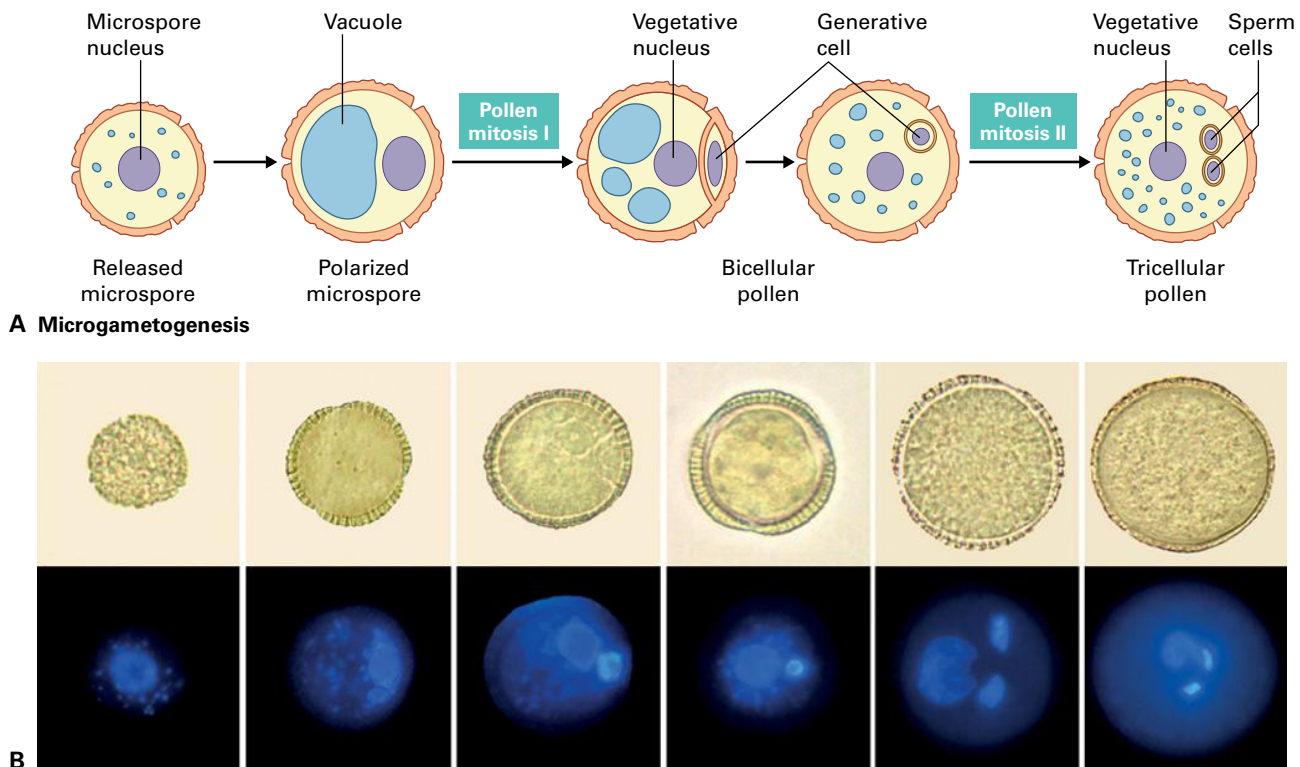

FIGURE 19.28 Microgametogenesis in *Arabidopsis*. Diagrammatic (A), light (B) and fluorescent microscopical (C) representation of the developmental progression through male gametogenesis (see main text for details). The fluorescent pictures show DAPI-stained pollen. The large vegetative nucleus and the two small sperm nuclei with highly condensed chromatin are clearly visible in tricellular pollen. Source: (B) D. Twell, University of Leicester; previously unpublished.

immediate response upon pollination, for example, rapid germination and fast initial pollen tube growth through the female reproductive tissues (see Section 19.5.3). The timing of PM II varies between species: in some plants, like *Arabidopsis*, PM II occurs prior to the release of pollen from the anthers (**anthesis**) such that tricellular pollen is released, but in most plants, like maize (*Zea mays*) and tobacco (*N. tabacum*), PM II takes place after pollen germination on the stigma, and the pollen released at anthesis is bicellular.

The many known male sterile mutations are usually recessive mutations affecting the diploid sporophyte, most often anther development and meiosis. The identification of mutants that affect the haploid phase of development has proven more difficult because even a fully penetrant mutant that affects microgametogenesis produces 50% normal pollen, so these plants appear fully fertile. With the development of efficient insertional mutagenesis systems, however, it became possible to perform large-scale screens for mutants affecting both male and female gametophyte development (Box 19.3).

Characterizations of gametophytic mutants have provided insights into the diverse developmental processes controlling microgametogenesis. For example, in *Arabidopsis* mutations in the A-type cyclin-dependent kinase gene *CDKA;1* (see Chapter 11) or the *F-BOX-LIKE 17* (*FBL17*) gene (see Chapter 18) lead to the formation of pollen with a single sperm-like cell, although this cell can divide later during pollen tube growth. *FBL17* targets the CDK inhibitory proteins KRP6 and KRP7 (see Chapter 11) for degradation by the

ubiquitin–proteasome pathway (see Chapter 10). While these two CDK inhibitors are expressed in both daughter cells after PM I, *FBL17* is only transiently expressed in the generative cell, where it leads to the cell type-specific degradation of KRP6/7, allowing the generative cell to proceed to S-phase. In contrast, *CDKA;1* activity remains inhibited by KRP6/7 in the vegetative cell, thereby blocking cell cycle progression and enforcing the vegetative cell fate (Fig. 19.29).

Mutations in the *RETINOBLASTOMA-RELATED* (*RBR*) gene, which encodes a central regulator of the G1/S transition (see Chapter 11), result in a phenotype opposite that of *cdka;1* and *fbl17*: The vegetative and sometimes the generative cell undergo additional division cycles. As this phenotype depends on *CDKA;1* activity, *RBR* acts downstream of the KRP6/7-mediated inhibition of *CDKA;1*, enforcing cell cycle exit and thus differentiation of the vegetative cell, while promoting cell cycle progression in the generative cell (Fig. 19.29). Mutations disrupting the *DUO POLLEN* (*DUO*) genes also produce bicellular pollen. *DUO1* encodes R2R3 MYB transcription factor (see Chapter 9) specifically expressed in the generative and sperm cells. It is required for the activation of gamete differentiation as well as the progression to the G2/M phase, thereby integrating differentiation and cell cycle control to ensure the production of a pair of fully differentiated sperm cells (Fig. 19.29).

Pollen and sperm cells harbor a complex complement of mRNAs and small RNAs, including microRNAs and natural antisense RNAs (see Chapter 6). For instance, silencing of

Gametophytic mutations can be identified by segregation ratio distortion

Because mutants that are essential for the male or female can only be maintained as heterozygotes, their identification has proven difficult. Heterozygous male gametophytic mutants produce 50% wild-type pollen and appear fully fertile due to the large excess of pollen produced. Female gametophytic mutants also produce 50% normal female gametophytes, leading to apparently normal fruit development because half of the ovules develop into seeds. That half of the ovules remain unfertilized (arrows in B) and that the plant is thus semisterile can only be seen if the fruits are opened. Because chemical mutagenesis leads to a strong reduction of fertility, it was only possible to use this characteristic phenotype once insertional mutagenesis, be it through transposons or T-DNA, became possible. If an insertion disrupts a *FEMALE GAMETOPHYTIC FACTOR* (*FGF*) (A), required for the development or function of the female gametophyte, it will cause semisterility

(B). However, semisterility can be due to other causes, such as chromosomal translocations, partially penetrant sporophytic mutants, or poor growth conditions. Because mutant gametophytes do not pass on the insertion to their progeny, gametophytic mutations are further characterized by segregation ratio distortion (C). A fully penetrant gametophytic mutation that only affects one sex is expected to segregate 1:1 among the progeny, instead of the Mendelian 3:1 ratio. Because insertions usually carry a dominant marker (e.g. conferring kanamycin resistance, *Kan^R*), their segregation can easily be followed. Segregation ratio distortion is a hallmark lethal mutations and its degree can be used to identify zygotic lethal (2:1) and sex-specific gametophyte lethal (1:1) mutants.

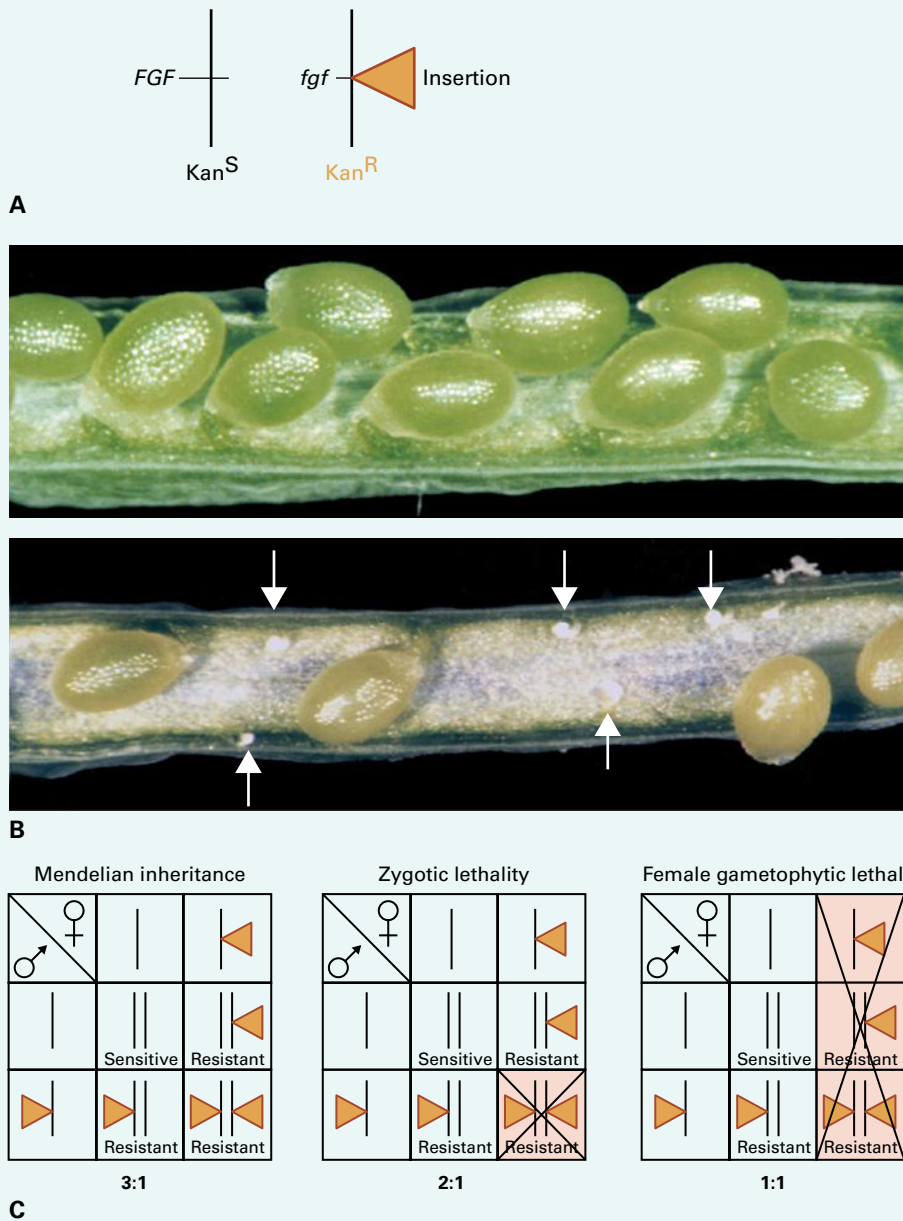

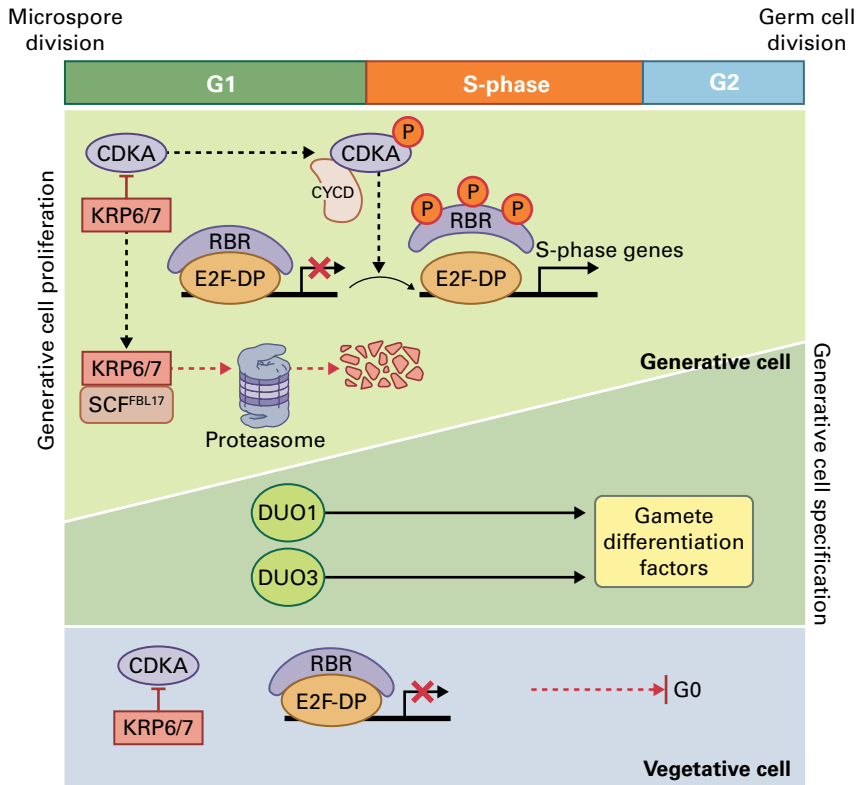

FIGURE 19.29 Relationship between cell cycle progression and cell specification during pollen development. In the vegetative cell, which does not undergo pollen mitosis II, KRP6/7 inhibits CDKA such that RBR remains complexed with E2F/DP inhibiting genes required for the initiation of S-phase. In the generative cell, the FBL17-SCF ubiquitin ligase complex ubiquitinylates KRP6/7 targeting it for degradation and thus releasing the inhibition of CDKA. CDKA can now form a complex with cyclin D (CYCD), which phosphorylates RBR, leading to its release from E2F/DP and the activation of S-phase genes. Concomitantly, the transcription factors DUO1 and DUO3 activate genes required for gamete differentiation.

transposable elements is lost specifically in the vegetative nucleus, leading to the formation of short interfering 21 nucleotide RNAs (21nt siRNA) from the *Athila* retrotransposon. Although produced in the vegetative cell, these 21nt siRNAs preferentially accumulate in the sperm cells, where they may stably silence these transposons from generation to generation. Although the exact mechanisms are unclear, this finding indicates that vegetative and generative cells communicate with each other, possibly through the action of small RNAs.

19.3.5 Cytoplasmic male sterility is caused by mitochondrial defects

Another type of male sterility is caused by mutations in the mitochondrial, rather than the nuclear genome. In most angiosperms, mitochondria are inherited from the cytoplasm of the egg cell. Therefore, such mutations are called cytoplasmic male sterility (CMS) mutations, and they show a purely maternal inheritance that does not conform to Mendel's rule of segregation. CMS is common in wild plant populations and has been reported in more than 150 species, including maize, rice, and bean (*Phaseolus vulgaris*). CMS is of great commercial interest because it facilitates the production of hybrid seeds: If the female parent used to generate F1 hybrids is male sterile (nuclear or CMS), its labor-intensive emasculation can be avoided. However, due to its particular inheritance properties, the progeny of a CMS female is expected to be male sterile, which is detrimental to agricultural use. Therefore, male

sterility in F1 hybrids must be suppressed, and this is achieved by using a male parent that carries a so-called *Restorer of fertility* (*Rf*) gene that is encoded in the nucleus.

In all naturally occurring CMS cases studied, sterility has been traced back to the production of an aberrant protein in the mitochondria, but the exact protein affected depends on the species. Although all cells of the plant carry the same mitochondria, CMS causes defects only in the anther or the pollen, depending on the species or type of CMS. How these aberrant proteins affect male reproductive development is not really understood; however, many *Rf* genes reduce the production of the aberrant mitochondrial protein, thereby restoring fertility.

The first commercially used CMS in maize, CMS-T, was used for hybrid seed production starting in the 1950s, and by 1970 85% of the maize F1 hybrids grown in the USA carried CMS-T. CMS-T, however, was particularly susceptible to the fungus that caused Southern corn leaf blight (*Bipolaris maydis*), which ravaged the USA in 1969–1970, causing tremendous losses in corn yields. For this reason, CMS-T is not used anymore in hybrid seed production. This tragedy illustrates the danger of depending on a small variety of genotypes in agriculture.

The aberrant mitochondrial protein specific to CMS-T is URF13, and it is encoded by a chimeric gene. How it affects tapetum function is unknown. Restoration of CMS-T requires both *Rf1* and *Rf2*, which together abolish the production of the aberrant URF13 protein to restore fertility (Fig. 19.30). The molecular nature of *Rf1* is unknown, but *Rf1* greatly decreases the abundance of *urf13* transcripts, while *Rf2* has no effect on *urf13* transcript accumulation. *Rf2* encodes an

FIGURE 19.30 The CMS-T system of maize. The toxic effect of the URF13 protein (encoded by the mitochondrial genome) is suppressed by the nuclear-encoded Restorer proteins Rf1 (which reduces *urf13* transcripts) and Rf2, an alcohol dehydrogenase (ADH) thought to detoxify the compound induced by the URF13 protein.

FIGURE 19.31 Ovule development is coordinated with megasporogenesis and megagametogenesis. (A) From the nucellus tissue at the tip of the young ovule primordium a subepidermal cell differentiates into the megaspore mother cell (MMC). (B) The nucellus is enveloped by two integuments, and the ovules bend into an anisotropic shape. The surviving functional megaspore (FMS) initiates embryo sac development. (C) The mature ovule has two fully developed integuments that enclose the mature embryo sac with its four cell types: two synergid cells (SC) of which only one is shown, egg cell (EC), central cell (CC), and three antipodal cells (AC).

aldehyde dehydrogenase, and it may be involved in the detoxification of toxins whose production or accumulation is caused by the URF13 protein.

19.4 The formation of female gametes

Female gametes are produced by the embryo sac (haploid female gametophyte), which develops inside the ovule in a coordinated manner with the sporophytic integuments that enclose it. Female gamete formation involves two subsequent developmental processes: **megasporogenesis** generates the haploid spores, and it is followed by **megagametogenesis**,

which forms the mature embryo sac through mitotic divisions of one of these spores.

19.4.1 Ovule development has characteristics of shoot development

Inside the carpels, ovules form as finger-like protrusions from the placenta, and three distinct regions can be distinguished in early ovule primordia (Fig. 19.31): the nucellus region at the apex from which germline cells differentiate, the chalazal region that gives rise to the integuments, and the funicular region that connects the ovule to the placenta. The integuments grow and enclose the nucellus, leaving a small opening, the micropyle, through which the pollen tube enters to effect fertilization (see Section 19.5.5).

After fertilization, the integuments develop into the seed coat, which provides protection for the next generation. The funiculus provides the connection to the mother plant, through which resources required for seed development are transported.

In *Arabidopsis*, ovule identity is conferred on developing primordia through the redundant function of three MADS-box genes. In triple mutants disrupting the *SHATTERPROOF1* and 2 (*SHP1*, *SHP2*) and *SEEDSTICK* (*STK*) genes, ovules are converted to carpels. The same phenotype is observed in petunia if the MADS-box genes *FLORAL BINDING PROTEIN 7* and 11 (*FBP7*, *FBP11*) are downregulated. Overexpression of *FBP11* under a strong constitutive promoter leads to ovule formation on the surfaces of sepals and petals, demonstrating its function as an ovule identity gene (Fig. 19.32). Because these genes only determine the identity of ovules, they are sometimes referred to as D-class genes.

Some *Arabidopsis* mutants exhibit abnormal integuments. In most sporophytic ovule mutants, development of the embryo sac is arrested, suggesting that events occurring in the integuments are required for normal megagametogenesis, possibly through signals that are noncell autonomous. Conversely, ovules lacking an embryo sac may appear normal, though effects on gene expression in sporophytic tissues of the ovule have been detected. This suggests communication between the sporophytic and gametophytic generation during ovule development.

FIGURE 19.32 D-class genes specify ovule identity. (A) Petunia ovules (*ov*) normally form the placenta (*pl*) connected by a funiculus (*fu*). (B) Ectopic ovules (*ov**) induced on sepals by overexpression on the petunia D-class gene *FBP11*.

Source: Colombo et al. (1995). *Plant Cell* 7:1859.

Molecular genetic characterizations of genes involved in ovule development revealed patterning principles that act in both the shoot meristem and the ovule primordium. Indeed, leaf primordia and integuments both form from the flanks of an apex and have a distinct abaxial–adaxial polarity. These similarities are also reflected at the molecular level. For example, *WUS*, which is required for stem cell maintenance in the shoot apex through a noncell autonomous mechanism (see Chapter 11), is also expressed in the nucellus. Lack of *WUS* activity results in a failure to initiate leaves or integuments, indicating that the same signaling module is used to influence adjacent groups of cells. Furthermore, a suite of genes (or their close homologs) plays a role in the establishment of polarity in both integuments and leaves (Fig. 19.33). These include transcription factors of the HD-ZIPIII class of homeodomain proteins on the adaxial side, and of the KANADI (*KAN*) and YABBY class on the abaxial side. For instance, the YABBY gene *INNER NO OUTER* (*INO*) is only expressed in the abaxial region of the outer integument, and *ino* mutations completely abolish the outgrowth of the outer integument.

19.4.2 During megasporogenesis, the diploid megaspore mother cell undergoes meiosis to give rise to four haploid megaspores

Early during ovule development, a single archesporium enlarges and differentiates into the **megaspore mother cell** (MMC), which undergoes two meiotic divisions to form a tetrad of haploid megaspores. This process requires many of the same meiotic genes that also function during microsporogenesis. In most flowering plants, only a single megaspore, the functional megaspore (FMS), survives and forms the embryo sac (monosporic development), whose cells thus share the same genotype.

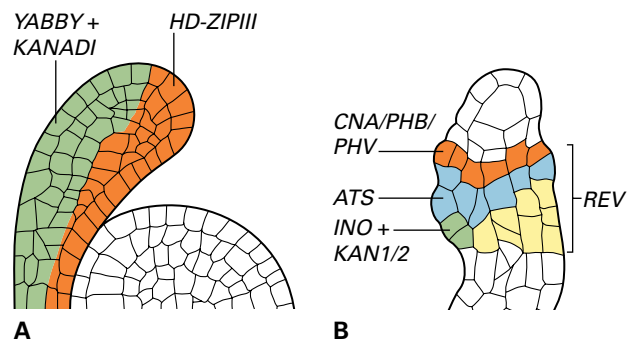

FIGURE 19.33 Establishing polarity of leaves and integuments is based on similar molecules. (A) Leaf polarity is determined by transcription factors specifically expressed in the abaxial (*KAN* and YABBY family) and adaxial (*HD-ZIPIII* family) parts of the primordium. (B) The polarity of integuments is patterned similarly, involving the YABBY factor *INO* and *KAN1/2* on the abaxial side and the HD-ZIPIII factors *PHABULOSA* (*PHB*), *PHAVOLUTA* (*PHV*) and *CORONA* (*CNA*) on the adaxial side. Other factors involved in integument patterning are *REVOLUTA* (*REV*) and *ABERRANT TESTA SHAPE* (*ATS*).

Formation of the MMC requires the SPL/NZZ gene product also involved in microspore formation (see Section 19.3.2), and usually only a single subepidermal cell from the L2 layer acquires this fate. However, in some mutants, such as *multiple archesporial cell 1 (mac1)* in maize and *multiple sporocyte 1 (msp1)* in rice, multiple L2 cells differentiate into an MMC and sometimes even initiate meiosis. This observation suggests that the MMC usually blocks other cells from adopting the same fate through **lateral inhibition**. Lateral inhibition plays an important role in many developmental decisions in animals and plants, and it relies on cell–cell communication. *MSP1* encodes an RLK that binds the peptide TAPETUM DETERMINANT-LIKE 1A, and downregulation of this gene results in a phenotype similar to that of *msp1*.

Recent work in *Arabidopsis* has shown that signaling by small RNAs also plays a role in limiting the number of germline cells. Mutations in *ARGONAUTE 9 (AGO9)* (see Chapter 6), as well as mutations in two other genes involved in small RNA biogenesis or function (*RDR6* and *SGS3*), produce multiple enlarged cells in the nucellus. The same is true for mutations in *MNEME (MEM)*, which encodes an RNA helicase and may also contribute to this pathway (Fig. 19.34). However, unlike in *mac1* and *msp1* mutants, the enlarged

cells in *ago9* and *mem* mutants express FMS-specific markers and are able to initiate gametophyte development without prior meiosis. Thus, these mutants show aspects of apospory, one of the elements of apomixis (see Section 19.4.5).

19.4.3 During megagametogenesis, the FMS divides mitotically to form the embryo sac

Once the haploid FMS is specified, it divides mitotically to form the female gametophyte. Another ARGONAUTE protein, *AGO5*, seems required to initiate this process of megagametogenesis, and neither *AGO5* nor *AGO9* are expressed in the cells that show a phenotype, suggesting noncell autonomous effects. About 70% of flowering plants form an eight-nucleate, seven-celled embryo sac of the *Polygonum* type, though a wide variety of other morphologies have also been described.

In *Arabidopsis* and maize, a *Polygonum* type embryo sac is formed through three mitotic divisions in a syncytium, which are followed by cellularization once eight nuclei have been formed. After the first division, the two nuclei migrate to opposite poles, where they divide two more times in synchrony, separated by a large central vacuole. This yields four

FIGURE 19.34 The plant germline is specified by a small RNA pathway. (A) In an *Arabidopsis* wild-type plant, a single subepidermal cell enlarges and differentiates into a MMC. (B) In *ago9* mutants, two or three enlarged cells form, and some of these can directly give rise to an embryo sac. (C) Two 2-nucleate embryo sacs in the *mem* mutant. (D) Measuring DNA content of the nuclei in (C) shows that one is derived from the normal FMS (1n), the other from an unreduced, enlarged cell (2n).

nuclei at each pole, two of which (the polar nuclei) migrate towards each other and fuse prior to or during fertilization, depending on the species (Fig. 19.35). Concomitantly, cellularization forms seven cells: two gametes and five accessory cells. The accessory cells at the micropylar pole are the two synergids that play a crucial role in fertilization, and at the chalazal pole the three antipodals whose function is not well understood. Next to the synergids is the egg cell, which after fertilization gives rise to the embryo, and in the center, the homodiploid central cell will get fertilized to form the endosperm.

As with pollen development, the use of novel strategies for genetic screens (see Box 19.4) led to the identification of many mutations that disrupt embryo sac development. Gametophytes are haploid, so many of the mutations affect general functions, and mutants arrest during the mitotic phase. Therefore, most molecular analyses have focused on mutants with late phenotypes that either affect cell specification or interfere with fertilization (see Sections 19.5.5 and 19.5.6). Many of the other mutants, however, have provided important insights into basic cellular processes, such as cell cycle regulation, that, due to redundancy, have not been easy to study in other contexts. For example, mutations in proteins affecting DNA replication, licensing of origins of replication, degradation by the ubiquitin–proteasome pathway, chromatin remodeling, and histone acetylation all block mitotic progression through gametogenesis. Mutations in *RBR* lead to extra mitotic divisions in the embryo sac and a failure to express cell type-specific makers, thus connecting cell cycle

control and differentiation processes. *RBR* plays a similar role during male gametophyte development (see Fig. 19.29).

19.4.4 Cell fate determination in the embryo sac relies on positional information and cell–cell communication

The polar nature of the embryo sac and its small number of distinct cell types make it an ideal system for studying fundamental aspects of plant development, such as cell specification and differentiation (Fig. 19.36). Although our understanding of cell fate determination in the female gametophyte is still fragmented, a number of mutants in *Arabidopsis* have provided important insights.

Prior to cellularization, the eight nuclei in the syncytial embryo sac adopt a distinct size that predicts their fate. This observation prompted the hypothesis that the nuclei sense positional information within the embryo sac that ultimately determines their specification. Indeed, cell fates are affected in several mutants with altered positioning of the nuclei. For example, in some embryo sacs of the *eostre* mutant in *Arabidopsis*, only one nucleus occupies the micropylar pole, while two are positioned more centrally, a pattern opposite to that observed in the wild type. Indeed, both nuclei in the more central region can differentiate into egg cells and are competent for fertilization. It was proposed that an auxin gradient specifies cell fates in the embryo sac; however, recent experiments

FIGURE 19.36 Cell type-specific markers expressed in the *Arabidopsis* embryo sac. Enhancer trap lines expressed in (A) the egg apparatus (egg cell and synergids), (B) the synergids, and (C) the egg cell. Source: U. Grossniklaus, University of Zurich; previously unpublished.

could not detect auxin activity inside the female gametophyte. Thus, the molecules that provide this positional information are still unknown.

The analysis of another set of *Arabidopsis* mutants, *lachesis* (*lis*), *clotho* (*clo*), and *atropus* (*ato*), revealed the importance of non-cell autonomous signaling events in preventing accessory cells from adopting a gametic fate. In these mutants, synergid and central cells express egg cell characteristics while losing attributes of their original fate. Moreover, the antipodal cells show aspects of central cell specification. Thus, all cells of the embryo sac can potentially acquire a gametic fate. *LIS* is mainly expressed in the egg and central cell, suggesting that gametic cells prevent accessory cells from adopting this fate through a lateral inhibition mechanism.

LIS, *CLO*, and *ATO* encode components of the core splicing machinery. It is, therefore, likely that their role in lateral inhibition is indirect. *LIS* activity is only required in the egg cell, which thus serves as an organizing center orchestrating cell specification in the embryo sac through non-cell autonomous signals. In maize, *ZmEAL1*, a secreted protein of the defensin-like class and expressed in the egg cell, also affects this process, revealing the role of peptide signals in cell specification.

In summary, studies of mutants affecting specification and differentiation of the cell types in the female gametophyte have uncovered an important role of cell–cell communication and revealed an unexpected developmental plasticity that allows these cells to respond to altered signals.

19.4.5 Apomixis: asexual reproduction through seeds

Sexual reproduction produces new combinations of genotypes and, therefore, genetically and phenotypically variable progeny. Some plants can also produce seeds that are exact

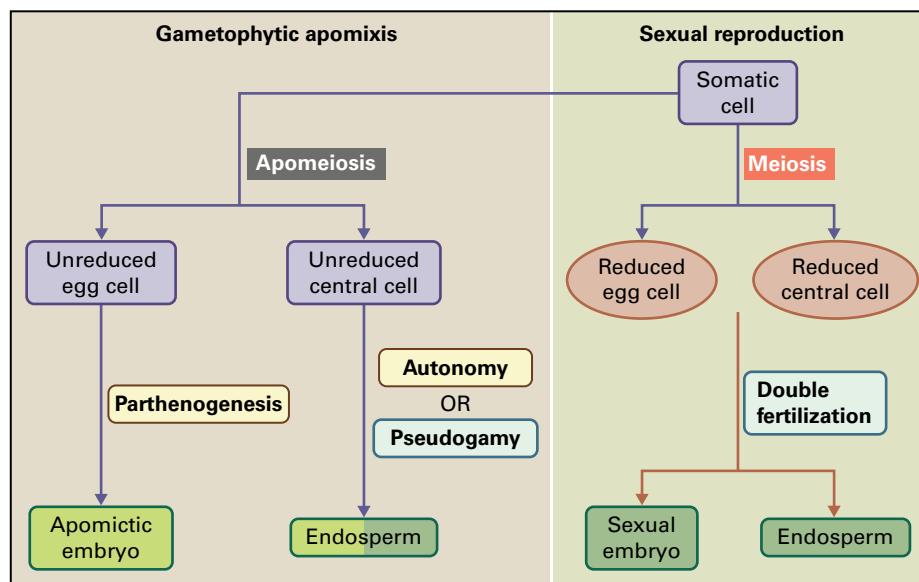

copies of the mother plant through **apomixis**, asexual reproduction through seeds.

Apomixis has great potential for agriculture, because apomictic seeds are clonal and preserve the genotype of the mother. Thus, apomixis can potentially be used to maintain **hybrid vigor** over many generations. Many crops are cultivated as F1 hybrids, produced by crossing two inbred parental lines. Hybrids have higher productivity, but their seeds cannot be stored to be planted in the next year because recombination and segregation break down their uniform, but highly heterozygous genotype. Thus, hybrid seeds must be generated every year, an obstacle that would be circumvented if apomixis could be induced in F1 hybrids.

Apomixis occurs in 500–600 species that belong to about 40 plant families and so is thought to have arisen multiple times during evolution. Consequently, there are also many different ways a clonal seed can be produced. In some species, such as citrus varieties and mango (*Mangifera indica*), an embryo is formed directly from a sporophytic cell of the integuments and invades the embryo sac, competing with the sexually produced embryo. In such **sporophytic apomixis**, a diploid cell gives rise to the next generation, thereby maintaining the maternal genotype. Because this can occur alongside sexual reproduction, sporophytic apomicts often produce a mix of clonal and sexual progeny.

In **gametophytic apomixis**, on the other hand, a female gametophyte is formed from an unreduced cell, thereby preserving the genotype of the mother. Because no meiosis occurs, this is referred to as **apomeiosis** (Fig. 19.37). This can occur in various ways that are broadly classified as diplospory and apospory, which for instance occur in dandelion (*Taraxacum officinale*) and hawkweed (*Hieracium* spp.), respectively. In diplospory, meiosis of the MMC is omitted or aborted, resulting in formation of two unreduced spores, one of which forms the female gametophyte. This is in contrast to

FIGURE 19.37 Schematic representation of gametophytic apomixis and sexual reproduction. In gametophytic apomixis three developmental steps are altered such that meiosis is prevented (apomeiosis), the embryo can develop without fertilization (parthenogenesis), and functional endosperm is formed (autonomy or pseudogamy).

apospory, where a nucellar cell other than the MMC forms the embryo sac. However, to form the next generation, the unreduced egg cell of this embryo sac must also form an embryo in the absence of fertilization (**parthenogenesis**). Finally, seed development cannot proceed normally without the formation of endosperm, the second product of double fertilization in sexual angiosperms. This can either occur through **pseudogamy**, where the endosperm is formed by fertilization, or by **autonomous** endosperm formation, in the absence of fertilization. Both modes of endosperm development in apomicts require developmental adaptations, however. Thus, at least three developmental processes are altered during apomixis in comparison to sexual reproduction: the initiation of embryo sac development from an unreduced cell (apomeiosis), the activation of embryogenesis without fertilization (parthenogenesis), and the production of functional endosperm (Fig. 19.37).

Little is known about the molecular basis of apomixis, but it is under genetic control and often influenced by the environment. In many species, apomeiosis and parthenogenesis are regulated by two independent, dominant loci. Often, these loci are in large blocks of the genome that do not recombine, making map-based cloning approaches difficult. However, screens in *Arabidopsis* and maize have identified mutants that show aspects of apomixis. Various *Arabidopsis* mutants affecting small RNA biogenesis and function (*ago9*, *rdr6*, *sgs3*, and possibly *mem*; see Section 19.4.2) can form unreduced embryo sacs in a process similar to apospory. Other mutants, for example *dyad* and a triple mutant of genes involved in meiosis (the ‘mitosis instead of meiosis’ line *MiMe*), resemble diplospory and form unreduced embryo sacs.

While true apomixis, which does not depend on a specific pollen donor, has not yet been achieved in *Arabidopsis*, a cross of *dyad* or *MiMe* with a special haploid inducer line generates clonal offspring. Similar haploid inducer lines, which eliminate the paternal genome after fertilization through

unknown mechanisms, also exist in maize and have been used for decades to generate maternal haploid progeny. If the chromosome set of such haploid plants is doubled, for example by treatment with colchicine, a homozygous inbred plant is generated. As an alternative to microspore culture (see Box 19.2) this approach is often used in breeding programs.

19.5 Pollination and fertilization

19.5.1 Plants use a variety of strategies to bring sperm and egg cells together

Once gametes are produced, they must fuse to generate the next sporophytic generation. In bryophytes and pteridophytes, the sperm cells produced by antheridia are motile, and fertilization depends on the availability of water. In contrast, seed plants (spermatophytes) produce pollen, which germinates to form a pollen tube that transports the sperm to their target cells. In cycads and ginkgo (*Ginkgo biloba*), the sperm are flagellated and motile, and once released from the pollen tube into an integument-enclosed space, they swim to fertilize the egg cell. In all other seed plants, the sperm cells are not motile and depend on the pollen tube (vegetative cell) for their transport. In gymnosperms, germination and growth of the pollen tube can take months or even years, whereas in angiosperms, pollen tube germination and growth are extremely rapid, which may have contributed to the evolutionary success of the angiosperms. In fact, pollen tubes are the fastest growing cells known, with growth rates as fast as 650 μm per minute in chicory (*Cichorium intybus*).

In angiosperms, many of the processes that lead to successful fertilization require an exchange of signals between the pollen and the female tissues. This starts with the

FIGURE 19.38 Path of the pollen tube from pollination to fertilization. (A) Pollen germinates and grows a pollen tube through the style into the transmitting tract in the septum of the gynoecium, from where it emerges and is guided to the micropyle. (B) As the pollen tube arrives at the micropyle, one of the synergids (SC) starts to degenerate. (C) During pollen tube reception, the pollen tube penetrates the degenerating synergid, where it ruptures and releases the sperm cells to fertilize the egg (EC) and central cell (CC). AC, antipodal.

recognition on the stigma surface (see Section 19.5.2), is followed by directed growth through the transmitting tract (see Section 19.5.3), guidance of the pollen tube into the micropyle (see Section 19.5.4), and pollen tube reception by the female gametophyte (see Section 19.5.5), and concludes with double fertilization whereby one sperm fuses with the egg and the other with the central cell to form the zygote and endosperm, respectively (see Section 19.5.6) (Fig. 19.38).

19.5.2 Pollen grains adhere to the stigma, where they must hydrate before they can germinate

After their formation in the pollen sac, pollen grains are released from the anther in a desiccated state (anthesis or anther dehiscence). Depending on the plant's reproductive strategy, the pollen is transported by wind, insects, birds, or even fruit bats to other flowers, where it adheres to the stigma, the receptive tip of the carpel(s) that form the gynoecium. This initial contact can be crucial for subsequent interactions and can determine whether a compatible interaction occurs. Often, pollen from other species cannot germinate on the stigma, or self-pollen is rejected through a self-incompatibility system to prevent inbreeding (see Section 19.6).

Some species, for example *Arabidopsis* and sunflower (*Helianthus annuus*), have dry stigmas, and adherence of pollen to the stigmatic papillar cell is mediated by components of the pollen exine. This adhesion is strong, but much weaker

with pollen of other plant families, although the underlying chemical interactions are unknown. After this initial contact, the pollen coat, a matrix of long- and short-chain lipids with a small set of proteins, flows onto the papillar cell at the contact site. This contact seems to change the properties of the underlying membrane and enables the flow of water from the papillar cell to the pollen grain, allowing it to hydrate. This process may be mediated by aquaporins (see Chapter 3) in the membrane of the papillar cell.

The pollen coat plays a crucial role in pollen hydration, as was demonstrated by the *eceriferum* mutants in *Arabidopsis*. These mutations affect the biosynthesis of long-chain lipids and waxes, and the mutants are male sterile under dry conditions. If grown under high humidity, however, the male sterile phenotype is suppressed. Hydration activates pollen metabolism and, using the resources stored during pollen development, the pollen germinates and rapidly grows a pollen tube.

In species with wet stigmas, such as tomato, petunia, and lily (*Lilium longiflorum*), water is present in the stigma exudates, so water release may not be as tightly controlled as on a dry stigma. The exudate contains proteins, lipids, polysaccharides, and pigments that support pollen tube growth. In part, however, the lipid-rich exudate may substitute for the function of the pollen coat. Mutants lacking the secreted matrix are female sterile, but sterility can be suppressed by addition of exogenous lipids onto the stigma, which is sufficient for pollen hydration and germination. Thus, also in a wet stigma, access of the pollen to water seems to be regulated and influenced by lipids.

19.5.3 Following germination, the pollen tube grows to reach the embryo sac

Following germination, the pollen tube must grow fast through the stigma and style to reach the embryo sac, where it delivers the two sperm cells to effect double fertilization. As there is usually an excess of pollen over ovules, there is intense competition between growing pollen tubes. Pollen tubes grow only at their tips, and as they grow, their cytoplasm remains in the area behind the tip and callose plugs are formed at regular intervals to seal off the part of the tube left behind. These callose plugs are produced by callose synthase, the exact positioning of which depends on cortical microtubules. The pollen cell wall is unusual and can be divided into an outer cell wall, consisting mainly of pectins, and an inner cell wall, containing callose and cellulose that, however, only gets deposited at some distance from the tip.

Tip growth of the pollen tube depends on turgor pressure, loosening of the cell wall to allow expansion, and a constant supply of cell wall and membrane materials for incorporation at the tip. Vesicle trafficking also provides positional information by delivering specific proteins and lipids to localized membrane domains. For example, when the pollen tube changes growth direction, the delivery of vesicles must be retargeted and membrane homeostasis adjusted. Thus, vesicle

and endomembrane trafficking are regulated to allow a dynamic control of polarized tip growth.

Small GTPases (see Chapter 18) transduce signals from the cell membrane to the cytoskeleton in yeast and animal cells. In plants, the ROP GTPases (see Chapter 5) also affect the dynamics of actin polymerization at the tip of the pollen tube, which is required for the appropriate targeting and fusion of vesicles. Moreover, other target proteins regulated by ROP GTPases are more directly involved in vesicle fusion, for example through controlling a complex that tethers vesicles to the membrane. ROP signaling also affects the levels of intracellular calcium and reactive oxygen species (ROS), which in turn can influence the activity of calcium channels, the actin cytoskeleton, and vesicle trafficking (Fig. 19.39).

Ion fluxes and a calcium gradient at the tip are required for tip growth, and this is consistent with the large number of ion transporters and channels that are expressed in pollen tubes. When pollen tubes alter their growth direction, a reorientation of the maximum of the calcium gradient is the first change that can be detected. Interfering with this calcium gradient blocks tip growth. Later during pollen tube growth, calcium and proton gradients oscillate, and these oscillations are strongly correlated with oscillations in pollen tube growth activity.

FIGURE 19.39 (A) Schematic representation of a growing pollen tube. (B) Signaling events at the tip of a growing pollen tube. The ROP GTPase cycles between a GDP- and GTP-bound state, mediated by the GDP exchange factor GEF and the ROP-GTP activating protein GAP. Activated ROP leads to the production of reactive oxygen species (ROS) by NADPH oxidases (NOX) and calcium influx, and regulates exocytosis and actin dynamics that are central to tip growth.

19.5.4 Pollen tube guidance requires interaction and communication with the female tissues

Pollen tube growth must be directed towards the female gametophyte, and this path requires various interactions with female tissues that provide directional cues. In both lily and *Arabidopsis*, copper-binding proteins known as plantacyanins provide this initial chemotactic guidance. In lily, plantacyanins are secreted by the cells lining the transmitting tract of the wet stigma and can reorient pollen tube growth in vitro, indicating they act as a chemotactic signal. *Arabidopsis* mutants harboring mutations in homologs have normal pollen tube growth likely due to genetic redundancy; however, overexpressing plantacyanin in the stigmatic papillar cells results in a loss of directional growth, and many pollen tubes grow around the papillar cell, unable to find the transmitting tissue. This suggests that plantacyanin overexpression may mask the normal gradients of chemotactic signals and causes pollen tubes to lose their orientation.

In *Arabidopsis*, the pollen tube grows between the cells of the transmitting tissue, present in the septum separating the two carpels, towards the base of the gynoecium. The pollen tubes eventually leave the transmitting tissue at seemingly random positions to grow on the surface of the placental tissue inside the carpel cavity, from where they grow along the funiculus of an ovule to enter the micropylar opening (see Fig. 19.38). In wild-type plants, this process is precise, with every ovule receiving only one pollen tube. This precision is thought to be regulated by several signals that direct pollen tube growth. First, a long-range signal directs pollen tube growth along the funiculus towards the micropylar opening; then, a short-range signal guides the pollen tube inside the micropyle, where it makes contact with the female gametophyte.

Once fertilization has occurred, no other pollen tubes are attracted, suggesting the existence of a repulsive signal. The growth direction of in vitro growing pollen tubes is affected by nitric oxide (NO), a gas with signaling function in both animals and plants. However, whether NO is a

repulsive signal also in planta is not known. The combination of attracting and repulsing signals ensures that only one pollen tube enters a micropyle, thereby preventing the release of more than two sperm, which could cause polyspermy.

In *Arabidopsis* the chemotactic signals are produced by the embryo sac: pollen tube guidance is disrupted in mutants in which the female gametophyte is either absent or arrested. The source of the guidance signal was dissected using a semi-in vitro system with ovules of the wishbone flower (*Torenia fournieri*). In these ovules, the micropylar part of the embryo sac is not enclosed by integuments, so synergids, egg, and part of the central cell are exposed. If such ovules are placed on growth medium, pollen tubes can detect the guidance signals and target the filiform apparatus, a structure secreted by the synergids (Fig. 19.40). However, only pollen tubes that have grown through a stigma, which was cut and placed on the medium so they can grow onto it, are properly guided, whereas pollen tubes germinated in vitro are not. This finding suggests that pollen tubes must be activated through unknown interactions in the stigma, such that they are competent to respond to the guidance cues.

Laser ablation of the cells in the female gametophyte demonstrated that the synergids are the source of the guidance signal. Subsequently, an analysis of genes expressed in the synergids of the wishbone flower identified secreted CRPs with similarities to antimicrobial defensins that are able to attract pollen tubes. Downregulation of two of these CRPs showed that they are required for pollen tube attraction in the semi-in vitro system described above. Thus, these CRPs, named LURE1 and LURE2, serve as guidance signals in this system.

Another micropylar signaling molecule was identified in maize. The *ZmEA1* gene, expressed in the synergids and egg cell, encodes a small protein with a putative transmembrane domain that is cleaved, such that a part of the protein can diffuse into the micropyle. Downregulation of *ZmEA1* in transgenic plants by RNAi interferes with micropylar guidance, demonstrating its importance in this signaling process. How these guidance molecules are perceived by the pollen tube, however, is currently unknown.

FIGURE 19.40 (A–C) Pollen tube guidance in a semi-in vitro system. The exposed embryo sac of *Torenia fournieri* secretes an attractant that guides the pollen tube towards the filiform apparatus between the two synergid cells. The pollen tube targets and penetrates the synergid. Source: Higashiyama et al. (2008). Sex. Plant Reprod. 21:117.

19.5.5 Pollen tube reception requires active communication between male and female gametophytes

Once the pollen tube enters the micropyle, it penetrates one of the synergid cells and ruptures to release the two sperm cells. Subsequently, one sperm fuses with the egg, and the other fuses with the central cell to initiate seed development. The receptive synergid cell initiates a programmed degeneration process, possibly to reduce its turgor pressure and make other cellular adjustments that allow pollen tube discharge. The timing of this degeneration process varies between species: it can start shortly after pollination, which implies the existence of a long-range signal that controls this process, or only once the pollen tube enters the micropyle, as in *Arabidopsis*.

For many years, the rupture of the pollen tube in the synergid cell was considered a purely mechanical process caused by an environment of drastically different osmolarity leading to pollen tube lysis. Identification of the allelic gametophytic *Arabidopsis* mutants *feronia* (*fer*) and *sirène*, however, showed it to be under the control of the female gametophyte. In these mutants, wild-type pollen tubes are attracted to and enter the female gametophyte, but instead of stopping their growth and rupturing to release the sperm cells, they continue to grow inside the embryo sac. This showed that pollen tube reception requires active communication between the male and female gametophytes. *FER* encodes an RLK (see Chapter 18) that is expressed in the synergid cells in which it accumulates in the region around filiform apparatus (Fig. 19.41). Although the putative ligand for *FER* is unknown, it is likely that it is either secreted or present on the surface of the pollen tube.

Several other mutants with a *fer*-like phenotype have been identified, including *nortia* (*nta*) and *turan* (*tun*), which like *FER* were named after Etruscan goddesses of fertility, and *lorelei* (*lre*). The molecular characterization of these genes suggests that complex signaling events occur at the synergid membrane. Whereas *LRE* encodes a putative glycosylphosphatidylinositol-anchored protein and *NTA* belongs to the MLO (MILDEW RESISTANCE LOCUS O) family of seven transmembrane proteins (see Chapter 21), *TUN* encodes a putative UDP-glycosyltransferase superfamily protein, which may be required for glycosylation of the membrane proteins involved in pollen tube reception (see Chapter 4).

The molecular nature of *NTA* revealed interesting parallels between pollen tube reception and fungal infection (see Chapter 21). The first member of the MLO family to be identified was a powdery mildew resistance gene in barley (*Hordeum vulgare*). The wild-type allele is required for a successful penetration of the epidermis by tip-growing fungal hyphae, a function conserved across plant species that in *Arabidopsis* is shared by three redundant MLO proteins (see Chapter 21). This raised the question of whether similar molecular processes are involved in plant defense and plant reproduction. While *NTA* is expressed rather specifically in synergid cells, *FER* is detected in most plant tissues and shows strong expression in epidermal cells. Indeed, homozygous *fer* mutants are resistant to powdery mildew infection,

FIGURE 19.41 Pollen tube reception in *Arabidopsis* requires the *FERONIA* receptor-like kinase. (A, B) Ovules stained with aniline blue to visualize the pollen tubes. In the wild type (A), the pollen tube enters the micropyle and penetrates the synergid where it ruptures. In *fer* mutant female gametophytes (B), the pollen tube fails to rupture and continues to grow inside the embryo sac. In this image, two pollen tubes entered the micropyle. (C, D) The *FER*-GFP fusion protein (green) expressed under the *FER* promoter is visible at high levels in the synergid cells (SC) (C), where it accumulates at the micropylar pole around the filiform apparatus (FA). suggesting that in leaves, *FER*, together with the three redundant *Arabidopsis* MLO proteins, confers susceptibility to the invading fungus, while in the synergid *FER*, together with *NTA*, is required for successful pollen tube reception. Similarities with defense-related processes have also been found for other aspects of plant reproduction. For instance, CRPs that have similarities to defensins serve as signaling molecules in pollen tube guidance, pollen tube rupture, and self-incompatibility (see Section 19.6).

Successful fertilization also relies on the precise timing of pollen tube rupture, which involves the two closest *Arabidopsis* homologs of *FER*, the redundant *ANXUR* (*ANX1/2*) RLKs, both of which are exclusively expressed in pollen. In *anx1/2* double mutants, pollen tubes can germinate in vitro, but they burst soon after germination, while in planta they can grow into the style but only rarely reach the gynoecium. Thus, it appears that *ANX1/2* are required to prevent premature rupture of the pollen tube, and a putative ligand may relieve this repression once it has entered the synergid cell.

Moreover, pollen tube rupture depends on ion transporters, possibly changing the pollen tube's osmolarity and lead to

FIGURE 19.42 Signal exchange during pollen tube reception. In the synergid cells (SC), the membrane proteins FER, NTA and LRE are involved in the perception of a putative ligand produced by the arriving pollen tube. The rupture of the pollen tube is prevented by ANX1/2, the closest homologs of the FER receptor-like kinase. Rupture is presumably induced by secreted signals from the synergids; in maize this is ZmES4 that eventually activates KZM1. See text for details.

lysis. In *Arabidopsis*, pollen tubes of mutants affecting the autoinhibited Ca^{2+} ATPase ACA9 gene can enter the micropyle but fail to burst and discharge their contents, suggesting that Ca^{2+} transport plays an important role in this process (Fig. 19.42). Recent studies in maize have shown that in vitro application of the ZmES4 defensin-like CRP leads to the opening of the inward-rectifying K^+ channel KZM1. ZmES4 is specifically expressed in the embryo sac and its downregulation leads to a failure of pollen tube discharge but leaves guidance unaffected. Together with the fact that ZmES4 acts in a species-specific manner, these observations suggest that ZMES4 serves as a female gametophyte-derived signal that induces pollen tube rupture upon normal reception, releasing the sperm cells to effect double fertilization.

19.5.6 Double fertilization involves two gametic fusion events

When the pollen tube ruptures to release its contents, the two sperm cells remain together and rapidly reach a position between the egg and central cell. The sperm cells remain

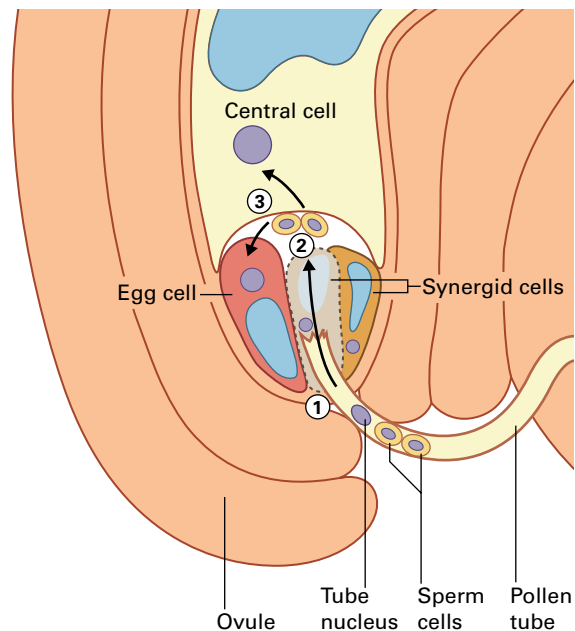

FIGURE 19.43 Sequential steps during double fertilization. (1) The pollen tube penetrates the degenerating synergid, (2) the sperm cells are discharged as the pollen tube ruptures and localize next to egg and central cell, and (3) one sperm cell fuses with the egg and the second with the central cell, followed by karyogamy of maternal and paternal nuclei.

immobile for several minutes before they separate and fertilize the egg and central cell to initiate seed development (Fig. 19.43).

In the male gametophytic *generative cell specific1/hapless2* (*gcs1/hap2*) mutant of *Arabidopsis*, the rapid movement of the sperm cells is normal, but they remain in the position between egg and central cell and do not fuse with the female gametes, indicating that the GCS1 gene product is required for gamete fusion. Interestingly, GCS1 is highly conserved and plays a similar role in gamete fusion in the unicellular green alga *Chlamydomonas reinhardtii* and the malaria parasite *Plasmodium falciparum*.

In an in vitro system using isolated sperm and egg cells from maize, fusion of the gametes triggers Ca^{2+} influx at the site of fusion, and a Ca^{2+} wave subsequently spreads throughout the egg in a manner similar to that in animals. Artificial Ca^{2+} influx caused by the addition of Ca^{2+} ionophores to the egg cell triggers some aspects of egg activation, such as the secretion of cell wall components, indicating that the Ca^{2+} increase is functionally important.

A longstanding question is whether the two sperm cells of flowering plants are functionally equivalent. In the wild leadwort (*Plumbago zeylandica*), for example, the two sperm cells are dimorphic and differ in size and the number of organelles, and the smaller sperm cell always fertilizes the egg cell. This raises the question whether the two sperm cells in other species may not be equivalent either, even though they may not differ in morphology. *Arabidopsis* mutants have shown that its isomorphic sperm cells are functionally equivalent. Some mutants, such as *eostre* and *rbr* (see Section 19.4.4), sometimes produce two egg cells, both of which may be fertilized. Some male gametophytic mutants, on the other hand, produce only one sperm-like cell

that can fertilize either the egg or the central cell. These observations indicate that there is no a priori distinction between the two sperm cells, and this was confirmed in an experiment with a photoconvertible fluorescent protein expressed in the sperm cells, which allowed the differential marking of the two sperm cells in the pollen tube. Observing double fertilization showed that the two sperm fuse randomly with either female gamete, demonstrating their functional equivalence.

The fact that both sperm cells have the potential to fuse with either the egg or the central cell raises the question why polyspermy (events where both sperm cells fuse with the same female gamete) does not occur in plants. In animals, a fast block, relying on membrane depolarization and Ca^{2+} influx, and a slow block, involving the fusion of secretory vesicles and modification of the extracellular matrix, prevent polyspermy. In plants, it is not clear whether similar mechanisms exist, even though a Ca^{2+} wave has been observed after in vitro fertilization. However, the central cell can be fertilized by multiple sperm. In many apomicts, where the egg cell develops parthenogenetically and is not fertilized, the central cell fuses with both sperm cells delivered by the pollen tube to ensure normal endosperm development (see Section 19.7). Therefore, at least the central cell has no fast block to prevent polyspermy.

Such a block may not be necessary if it can somehow be ensured that the two sperm cells fuse with distinct female gametes. Because only a single pollen tube usually enters the micropyle, opportunities for fusion with multiple sperm cells are extremely rare. Indeed, plants limit access of sperm to the embryo sac by preventing the attraction of multiple pollen tubes. In wild-type plants, gene expression in the persisting synergid cell gets rapidly downregulated upon pollen tube reception, and likely also the expression of the pollen tube attractant. However, in *fer* and other *Arabidopsis* mutants that affect pollen tube reception, two or even three pollen tubes can enter the micropyle. This seems to be caused by continued gene expression in the persisting synergid cells of these mutants. Thus, pollen tube rupture or sperm release is required to downregulate gene expression in synergid cells and stop the continued production of the attractant. Fertilization itself causes this downregulation, suggesting noncell autonomous signaling events between the female gametes and the synergid cells. In *gcs1* and *duo1* mutants, in which pollen tubes discharge occurs but the sperm cells do not fuse with the female gametes, additional pollen tubes are attracted to and penetrate the persisting synergid cell. If these additional pollen tubes are wild-type, they can rescue ovules that received defective sperm cells, thereby maximizing reproductive success.

19.6 The molecular basis of self-incompatibility

Plant stigmas are exposed to many types of pollen, and if pollen from a different species fertilizes the egg cell, this usually leads to inviable progeny. In most cases, foreign pollen does

not germinate or, if it does, it cannot interpret the signals that should guide it to the micropyle. If the pollen is from a closely related species, however, it may overcome these prefertilization barriers to interspecific hybridization and eventually reach the degenerating synergid cell.

At this step, however, fertilization can also be blocked if the signals required for pollen tube reception cannot be properly interpreted. For example, in crosses between *A. thaliana* and *A. lyrata*, almost all ovules are targeted by an *A. lyrata* pollen tube, but in about half of them, the pollen tube fails to rupture, showing a phenotype similar to that observed in the *fer* mutant. Fertilization occurs in the remaining half of the ovules, illustrating that sometimes the complex signals can successfully be exchanged if the species are sufficiently close (*A. thaliana* and *A. lyrata* diverged 5–10 million years ago). These hybrid seeds, however, usually abort if they are not rescued through ovule culture, a method that is often used to facilitate wide crosses in breeding programs.

Plants have not only evolved mechanisms to prevent interspecific hybridization, but most species can also prevent self-fertilization. Self-fertilization can lead to inbreeding depression, the counterpart to hybrid vigor, because inbreeding leads to high levels of homozygosity, including that of deleterious alleles. Of course, self-fertilization can also be advantageous because no partner is required for reproduction. Thus, many pioneer plants are self-fertilizing. Based on phylogenetic evidence, however, most self-fertilizing species are evolutionarily “young,” and this mode of reproduction has negative effects for the long-term survival of a species.

Most species rely on a mechanism to prevent self-pollination. For example, the timing of anther dehiscence and stigma receptivity may not coincide (**dichogamy**), preventing germination of self-pollen on the stigma. Alternatively, anther and stigma can be spatially separated to reduce self-pollination (**herkogamy**) (Fig. 19.44). An extreme version of spatial separation is the formation of distinct male and female flowers, either on the same individual as in maize (**monoecy**), or on different individuals (**dioecy**), as in hemp (*C. sativa*) or willow (*Salix alba*). Another mechanism for preventing self-pollination is a **self-incompatibility** system that allows the distinction of self and non-self pollen on the same stigma.

19.6.1 The genetics of self-incompatibility can be complex

Biochemical self-incompatibility systems rely on molecular recognition processes that allow discrimination of self and non-self pollen. Conceptually, such a system must involve at least one pollen factor and one stigma factor. If the factors match, for example, in a molecular interaction that is similar to ligand-receptor recognition, self-fertilization is prevented.

The genetic investigation of self-incompatibility, which was discovered about 200 years ago in early plant hybridization studies, began soon after the rediscovery of Mendel's laws of inheritance. In the 1920s, self-incompatibility was found to be caused by a single locus, now referred to as the

FIGURE 19.44 Heterostyly in *Primula veris*. The thrum morph (left) has the anthers at the top of the tube near the corolla and the stigma in the middle of the tube. In the pin morph (right), the position of anthers and stigma are reversed.

Sterility, or S-locus in most species. The S-locus has numerous alleles (S_1 , S_2 , S_3 , etc.), and incompatibility results whenever both crossing partners carry the same allele. Thus, the S-locus must be highly polymorphic, with every allele of the S-locus differing in sequence from all others; wild cabbage (*B. oleracea*), for example, has more than 50 S-alleles.

Each S-locus allele consists of at least the genes encoding the pollen and the stigma factor, respectively. To prevent the breakdown of self-incompatibility, genes coding male and female factors must be inherited together as a single unit. Therefore, recombination between the two components of the S-locus must be suppressed. How recombination at the S-locus is prevented is not well understood, but the chromosomal rearrangements that characterize different alleles of the S-locus may contribute to this suppression of recombination.

Based on genetic behavior, self-incompatibility can be subdivided into two types. In **gametophytic self-incompatibility** (GSI), self-recognition depends on the genotype of the S-locus carried by the haploid pollen grain, the male gametophyte. If that pollen S-allele matches one of the two S-alleles expressed in the diploid stigmatic tissues, the pollen is rejected (Fig. 19.45). GSI systems are widespread and have been described in over 60 plant families, including the Solanaceae, Rosaceae, and Papaveraceae. In these systems, incompatible pollen tubes usually germinate, but their growth is inhibited in the style before they reach the ovules. In **sporophytic self-incompatibility** (SSI), pollination is usually interrupted early, at pollen hydration or pollen tube germination. The S-locus

FIGURE 19.45 Genetic basis of self-incompatibility. (A) In gametophytic self-incompatibility (GSI), pollen grains that have S-alleles different from those of the female are successful, i.e. the genotype of the male gametophyte matters. On an S_2S_3 stigma, for example, S_1 pollen grows through the style but S_2 and S_3 pollen tubes are arrested. (B) In sporophytic self-incompatibility (SSI), all pollen derived from a male sharing any S-allele with the female fail to germinate, i.e. the genotype of the male sporophyte matters. Because the pollen factor is present in the pollen coat, neither S_1 nor S_2 pollen can germinate on an S_1S_3 stigma, while they are successful on a S_3S_4 stigma.

genotype of the diploid pollen parent, the sporophyte, determines whether pollination is successful. If any of the two S-alleles in the male parent is shared with the female parent, the cross is incompatible (Fig. 19.45). SSI is less common, occurring in the Asteraceae and Brassicaceae, but it includes one of the best-studied examples at the molecular level (*Brassica* spp.).

Although most self-incompatibility systems are controlled by genes within a single S-locus, the situation can be more complex. In rye (*Secale cereale*), for example, the two gametophytically acting loci S and Z control self-incompatibility, and in the tall buttercup (*Ranunculus acris*) self-incompatibility relies on at least four different loci. In the systems we describe in the following sections, however, genes encoded at a single S-locus determine success or failure of pollination, but the underlying molecular mechanisms differ greatly.

19.6.2 Sporophytic self-incompatibility in *Brassica* is mediated by a receptor-like kinase

In the Brassicaceae, the SSI system relies on interactions between the pollen grain and a stigmatic papillar cell. The self-incompatibility reaction is rapid, established within

FIGURE 19.46 The pollen factor is present in the pollen coat. Plants homozygous for an *S*-allele are shown for simplicity. After adhesion of the pollen on the papillar cell, the pollen coat containing pollen coat proteins (PCPs) flows partly onto the stigmatic papillar cell. PCPs can be deposited onto a papillar cell by placing and then removing a pollen grain on it with a micromanipulator. (A) A compatible cross between pollen from an $S_{29}S_{29}$ plant and a $S_{25}S_{25}$ female can be made into (B) an incompatible cross by first placing pollen from an $S_{25}S_{25}$ plant onto the point of adhesion, thus depositing the PCPs that initiate the self-incompatibility response. The same can be achieved by depositing biochemical fractions enriched for 6–8 kDa PCPs onto the papillar cell.

minutes, and is localized on the surface of the papillar cell. This is illustrated by placing pollen grains on individual papillar cells using a micromanipulator. When self-compatible and -incompatible pollen grains are deposited next to each other on a single papillar cell, the incompatible grain does not hydrate, but the compatible grain germinates. Thus, the interaction must be localized to a small region of the papillar cell's surface and does not involve a response of the whole cell. Furthermore, if the nonhydrated pollen is subsequently placed onto a compatible stigma, it can effectively participate in pollination. Therefore, unlike in the systems described below, the SSI system in Brassicaceae does not cause cell death of incompatible pollen.

Once a pollen grain lands on the stigma, a part of the pollen coat flows onto the papillar cell (see Section 19.5.2). The pollen coat contains the pollen factors that determine the specificity of the self-incompatibility interaction. This can be demonstrated by placing a compatible pollen grain on to the same spot where an incompatible pollen grain was placed and then removed. The compatible pollen cannot germinate because the pollen coat material that was left behind initiated an incompatible reaction (Fig. 19.46). The presence of pollen factors in the pollen coat explains the sporophytic nature of the self-incompatibility system in Brassicaceae. The pollen coat contains molecules that were produced by the tapetum. Since the tapetum is diploid, it usually expresses both *S*-alleles of the pollen parent, such that two distinct pollen factors encoded by the two *S*-alleles are expected to be present in the pollen coat.

The self-incompatibility response is mediated by the interaction of an RLK expressed in the papillar cell and a secreted ligand in the pollen coat (Fig. 19.47). The *S*-locus receptor kinase (SRK) is a single-transmembrane serine/threonine kinase that is localized to the plasma membrane of the papillar cell. It binds and recognizes the pollen factor, a small CPR of the defensin class, which is referred to as *S*-locus cysteine-rich protein (SCR) or *S*-locus protein 11 (SP11). Both SRK and SCR/SP11

FIGURE 19.47 Model for SSI in *Brassica* spp. Left, a compatible interaction is shown where SRK is not activated. Right, an incompatible interaction where the SCR/SP11 ligand induces a signaling cascade in the papillar cell. See text for details. Ub, ubiquitin. THL, thioredoxin *h*-like protein; ARC1, Armadillo repeat-containing protein 1; MLPK, *M*-locus protein kinase.

are polymorphic as expected, and at the amino acid level their sequences can differ by as much as 35% for SRK and 70% for SCR/SP11. In fact, several biochemical, genetic, and molecular biological approaches to identify the pollen factor failed, and a genomics approach brought the breakthrough by looking for an anther-expressed polymorphic gene closely linked to SRK.

The specific interaction of SRK and SCR/SP11 variants encoded by the same *S*-allele prevents pollen hydration. That

FIGURE 19.48 Model for the dominant/recessive *S*-alleles in *Brassica rapa*. The dominant S_{11} allele contains the *Smi* gene, which produces a small RNA that is complementary to a sequence in the promoter of the *SCR/SP11* gene of the recessive S_{60} allele. The small RNA leads to the silencing of *SCR/SP11* on the recessive allele by DNA methylation. Blue genes: expressed, red genes: not expressed.

these two proteins are solely responsible for determining the specificity of the interactions has been shown by both loss-of-function and gain-of-function approaches. Downregulation of *SRK* in transgenic plants leads to the breakdown of self-incompatibility in an allele-specific fashion. Conversely, expression of an additional *SRK* or *SCR/SP11* allele confers an additional specificity to stigma or pollen, respectively.

The two proteins are not only required, but sufficient for self-incompatibility, because the transfer of corresponding *SRK* and *SCR/SP11* alleles from *A. lyrata* to *A. thaliana*, which became self-fertilizing less than one million years ago, shows that they are still functional. Although self-fertilization in *A. thaliana* has multiple independent origins, 95% of the European accessions share an inversion in the *SCR/SP11* gene, suggesting a rapid, recent spread of this allele. Thus, the signal transduction components acting downstream of *SRK* all function in self-fertilizing *A. thaliana*. This is consistent with the recent evolution of self-fertilization in this species but also with the fact that these downstream components may also be essential for signaling processes other than self-incompatibility.

While much work has been done to understand the evolution and function of the determining pollen and stigma factors, less is known about the signal transduction cascade induced by binding of *SCR/SP11* to *SRK*. *SRK* forms homodimers in the absence of its ligand, but these are kept in an inactive state by two thioredoxin *h*-like proteins (THL1/2) through a mechanism that is not well understood. Interaction of *SRK* with *SCR/SP11* relieves this inhibition, leading to autophosphorylation of *SRK*. This allows interaction with the Armadillo repeat-containing protein 1 (ARC1), which binds only the phosphorylated form of the intracellular *SRK* kinase domain. How this interaction leads to the inhibition of pollen germination is unknown, but the localization of ARC1 to the proteasome indicates an involvement in protein degradation. Finally, the *M*-locus protein kinase (MLPK), mutations in which render plants self-compatible, is also involved in signal transduction through an unknown mechanism. MLPK is putatively myristoylated and thus likely membrane bound (Fig. 19.47).

Most *S*-alleles are co-dominant but some show dominant/recessive interactions. For example, the *Brassica rapa* S_{11} -allele is dominant over the S_{60} -allele in the pollen, so pollen produced by a $S_{11}S_{60}$ plant can germinate on a stigma expressing the S_{60} -allele. These dominant/recessive interactions may be complex and can differ between the stigma and the pollen. The dominance of the S_{11} -allele in pollen depends on an epigenetic

mechanism. The recently discovered *Smi* gene of the S_{11} -allele encodes a small RNA that acts in *trans* on the *SCR/SP11* gene of the S_{60} -allele, leading to the methylation of its promoter via the RNA-dependent DNA methylation pathway. DNA methylation leads to the silencing of the pollen factor gene *SCR/SP11* of the S_{60} -allele and thus its recessive behavior in pollen (Fig. 19.48).

19.6.3 Gametophytic self-incompatibility in poppy: a signaling cascade leads to cell death of the pollen tube

While the SSI system in *Brassica* spp. acts early during the pollen–stigma interaction, gametophytic systems (GSI) lead to the death of the pollen tube after it germinates. In the field poppy (*Papaver rhoeas*), for example, pollen tubes germinate but die shortly after they penetrate the stigma. The signaling events of the self-incompatibility response in poppy have been characterized in detail, since the response can be recreated in an *in vitro* system, and stigmatic extracts from poppy can efficiently inhibit growth of incompatible pollen tubes. Therefore, the requirements for the self-incompatibility reaction and associated signaling events can be studied by comparing pollen tubes in the presence of stigma extracts from either compatible or incompatible plants.

The ligand that induces cell death in the growing pollen tube is a low-abundance glycoprotein of about 15 kDa that is secreted by stigmatic cells. This stigma factor, referred to as PrsS (*Papaver rhoeas* stigma S), is polymorphic and inhibits pollen tube growth in an allele-specific manner. Although it has no obvious similarity to known ligands, its secreted nature and small size suggest that it is detected by a putative receptor on the pollen tube in an allele-specific manner. This receptor, PrpS (*Papaver rhoeas* pollen S) encodes a novel transmembrane protein of about 21 kDa. As expected, *PrpS* and *PrsS* are polymorphic, and the proteins interact through an extracellular loop of *PrpS*. Downregulation of *PrpS* alleviates pollen tube growth inhibition in an allele-specific manner, demonstrating the crucial role of *PrpS* in the recognition process. A second integral membrane protein, the S-protein binding protein (SBP), may facilitate the interaction between ligand and receptor. It binds *PrpS*, but not in an allele-specific manner, and enhances the effect of *PrpS* to inhibit pollen tube growth in the *in vitro* system.

FIGURE 19.49 Model for GSI in *Papaver rhoaes*. Binding of the stigma factor PrsS to the pollen membrane protein PrpS activates a signaling cascade that leads to the arrest of pollen tube growth by the depolymerization of actin and, ultimately, to programmed cell death. See text for details.

The first response observed after receptor–ligand binding is an influx of Ca^{2+} into the pollen tube, which alters the tip-focused Ca^{2+} gradient that is required for growth (see Section 19.5.3). This increase in Ca^{2+} also disrupts the actin cytoskeleton and induces the Ca^{2+} /calmodulin-dependent phosphorylation of target proteins. Among these are a 26 kDa inorganic pyrophosphatase (p26, IPP) and a 56 kDa mitogen-activated protein kinase (p56, MAPK). Activation of the MAPK cascade eventually leads to the initiation of programmed cell death, characterized by leakage of cytochrome *c* from mitochondria, activation of caspase-like proteases, and degradation of nuclear DNA (Fig. 19.49).

19.6.4 A widespread gametophytic self-incompatibility system involves stylar ribonucleases

A different gametophytic self-incompatibility system that occurs in several families, including Solanaceae, Rosaceae, and Scrophulariaceae, is based on nonspecific ribonucleases, the *S*-locus ribonucleases (S-RNases), which represent the stigma

factors of this system. Incompatible pollen tubes germinate, but their growth is typically arrested in the upper third of the style. The growth of these pollen tubes is slowed, they show abnormal membranes and organelles, and their tips swell and sometimes burst. This is the effect of the abundant S-RNases, which are excreted into the extracellular matrix of the wet stigmas that are characteristic for these families.

Although the S-RNases are nonspecific and degrade diverse RNA molecules, they do this exclusively in self pollen. S-RNases are polymorphic and have two hypervariable regions that are responsible for their *S*-allele specificity. If compatible and incompatible pollen tubes grow in the same style, only incompatible pollen tubes are stopped on their way to the ovules. To explain this allele-specific behavior, it was proposed that only the self S-RNase is taken up into the pollen tube by an allele-specific transporter. This idea was rejected when it was shown that S-RNases are nonspecifically taken up by both self and non-self pollen tubes and, thus, that the processes leading to the allele-specific growth inhibition must take place after the S-RNases entered the pollen tubes. Although the S-RNases were the first factors of any self-incompatibility system to be identified at the molecular level in the late 1980s, it took almost 30 years to understand how this specific action of S-RNases is achieved.

The pollen factor of violet-flowered petunia (*P. inflata*) was isolated in searches for polymorphic genes that were closely linked to the stigma factor, the S-RNase gene. These searches identified the *S*-locus F-box (SLF) protein, which belongs to a cytoplasmic protein family whose members are part of E3 ubiquitin ligase complexes. F-box proteins provide specificity to E3 ubiquitin ligase complexes by binding to specific substrates and targeting them for proteolysis through the ubiquitin–proteasome pathway (see Chapter 10). Indeed, SLF binds to subunits of the E3 ligase complex and also interacts with S-RNases. Although this interaction is not allele-specific, SLF interacts more strongly with non-self S-RNases than with its self S-RNase. The fact that proteasome inhibitors block the growth of compatible, but not incompatible pollen tubes lends further support to the idea that degradation of the S-RNase is required to allow normal pollen tube growth. Based on these observations, it was proposed that all non-self S-RNases are degraded via the proteasome pathway through interactions with SLF, thereby allowing growth of compatible pollen tubes. In contrast, SLF would not interact with the self S-RNase, which would remain active and inhibit the growth of self-pollen tubes.

This model requires the pollen factor SLF to recognize a large number of different S-RNases, except for the one encoded by the same *S*-allele. This is problematic because the degree of polymorphism of *SLF* genes is limited (only 0–15% among nine *SLF* alleles analyzed, much lower than that of the corresponding S-RNase genes, which is 20–60%). Moreover, S-RNase and *SLF* genes do not show the signatures of coevolution expected for the pollen and stigma factors of a self-incompatibility system. Although SLF could be clearly linked to pollen specificity, the fact that the SLF proteins encoded by the *S*₇- and *S*₁₉-alleles of the white moon petunia (*P. axillaris*) are identical in amino acid sequence, despite their genetically distinct behavior in crossing experiments, showed that additional

FIGURE 19.50 Model for GSI in *Petunia* spp. (A) Various S-alleles have a single S-RNase gene encoding the stigma factor but several SLF genes with distinct specificities (anti-S₁, anti-S₂, etc.) that collectively represent the pollen factor. (B) A compatible and (C) an incompatible interaction where no anti-S₁ SLF is present in the pollen such that S₁-RNase is not degraded and arrests pollen tube growth. See text for details.

factors must be involved. The discovery that multiple SLF genes are encoded by each S-allele suggested that they are collectively required to recognize the many different S-RNases. Thus, each SLF must interact only with a small number of non-self S-RNases, but collectively they can recognize a large number (Fig. 19.50).

How and where the S-RNases are degraded is still not well understood, and this process may involve the subcellular compartmentalization and dynamic release of S-RNases. Non-self S-RNases are not degraded after their uptake; rather, they are sequestered into endomembrane vesicles together with a 120-kDa glycoprotein. During subsequent pollen tube growth, these vesicles break down and release the S-RNases in self-pollen tubes but remain intact in non-self pollen tubes. Loss of HT-B, factor 4936, or the 120-kDa glycoprotein, which suppresses the self-incompatibility response, also prevents the breakdown of these vesicles. Thus, cell biological processes, such as subcellular compartmentalization, and biochemical mechanisms including protein degradation, must be integrated to achieve a functional self-incompatibility response.

19.7 Seed development

Following the fusion of sperm and egg cells, the next sporophytic generation begins its development. This occurs within the protective covers of the developing seed, which forms from the ovule after fertilization. Seeds are enclosed in the

developing fruit derived from the gynoecium. Fruits are the major means by which plants disperse their seeds, and many plants depend on animals for their dissemination.

19.7.1 Seed development involves coordination of different compartments

In angiosperms, the fertilized egg (the diploid zygote) develops into the embryo, while the fertilized central cell forms the endosperm, a terminal tissue that nourishes the embryo during its development. In gymnosperms, in contrast, the large multicellular female gametophyte, which is formed prior to fertilization, serves as the embryo-nourishing tissue.

For more than a century, two competing theories have been put forth to explain the evolution of endosperm, but its evolutionary origin is still unclear. The formation of female gametophytes that do not become fertilized in gymnosperms is energetically costly. It was, therefore, proposed that their formation became dependent on fertilization to prevent this waste of energy. In this scenario, the endosperm's evolutionary origin is of gametophytic nature. The second theory suggests the endosperm is of zygotic origin, and that initially a second embryo was formed, which then evolved into endosperm to support the development of its genetic twin. Indeed, although double fertilization was considered a defining feature of angiosperms, two zygotes are formed in Mormon tea (*Ephedra nevadensis*) and paddy oats (*Gnetum gnemon*), both gymnosperms. Thus, double fertilization

FIGURE 19.51 Schematic representation of seed development. Origin and genetic contribution of the maternal and paternal parents to the embryo, endosperm, and seed coat are indicated.

is not unique to angiosperms, but because it is unclear whether it is a derived or primitive feature, this does not allow a decision regarding the evolutionary origin of endosperm.

The embryo and endosperm depend on each other and develop in a coordinated fashion. In addition, they are enclosed in the seed coat, a tissue of maternal origin, which also influences their development (Fig. 19.51). To achieve normal development, the three compartments of the seed must exchange signals and coordinate their development, but little is known about the molecular basis of these interactions. Whereas the endosperm is of great importance for the later phase of embryo development, it does not seem to be absolutely required early on. For instance, if RNA polymerase II is downregulated in the egg and central cell, the embryo develops to the globular stage (see below), while endosperm development is blocked. Similarly, in the *glauce* mutant of *Arabidopsis*, no endosperm is formed but the embryo can develop normally to the globular stage. Thus, during its early development, the embryo does not seem to depend on signals or products from the endosperm.

Important interactions between the seed coat and the endosperm, however, occur both before and after fertilization. For example, seed coat development is repressed by PcG proteins (see Chapter 9) prior to fertilization. Relief of this repression requires fertilization of the central cell, as it is not observed in autonomous endosperm mutants (see Section 19.7.4) that do not affect the maternal tissues. Following fertilization, other pathways control seed coat development. For example, mutants of the *miniseed* (*mini*) and *haiku* (*iku*) class produce small seeds in which endosperm proliferation is reduced. These genes encode components of a signal transduction pathway involving an LRR–RLK (*IKU2*), a WRKY class transcription factor (*MINI3*), and a plant-specific VQ-motif protein (*IKU1*). Although these genes are only expressed in the endosperm, they affect cell elongation in the integuments of the seed coat, suggesting the signals from the endosperm control seed coat development and are important to control seed size. Conversely, another WRKY transcription factor, *TRANSPARENT TESTA GLABRA2* (*TTG2*), functions in the integuments and promotes cell elongation, allowing endosperm proliferation and seed growth. In contrast to *TTG2*, the transcription factors *AP2* and *AUXIN RESPONSE*

FACTOR2 (*ARF2*) restrict cell proliferation in the integuments, thereby physically restricting seed size. Collectively, these interactions illustrate the interdependence of maternal and zygotic tissues during seed development.

19.7.2 Parental effects on seed development can be of sporophytic or gametophytic origin

Parental effects play an important role in seed development. All the compartments of the seed are interdependent, so a mutation affecting a gene with activity in the maternal seed coat can potentially affect the development of either of the two fertilization products. Such a mutation results in a **sporophytic maternal effect** on seed development. Seeds from homozygous mutant mothers would be defective even with a wild-type pollen donor; if the cross were performed in the other direction, however, the seeds would develop normally. This difference in the outcome of reciprocal crosses is the hallmark of a maternal (or paternal) effect mutation.

The gametes themselves may also lack gene products that are important during the later steps of seed development. In this situation, a mutation affecting an activity in the gametophyte leads to aberrant seed development through a **gametophytic maternal effect**. A female gametophyte lethal mutation that blocks the development or function of the embryo sac results in ovules that do not become fertilized and fail to develop into seeds. In a gametophytic maternal effect mutation, however, the female gametes participate in fertilization, and the defect becomes apparent only later on, for example if it leads to seed abortion (Box 19.4). Thus, in a heterozygous gametophytic maternal effect lethal mutation, half of the seeds abort regardless of the contribution of the male; in the reciprocal cross, no phenotype is observed.

The mechanistic basis for a gametophytic maternal effect on seed development can be diverse. First, such a mutation may be **haploinsufficient** in the endosperm; reciprocal crosses with the wild-type result in different genetic compositions of the triploid endosperm with one or two wild-type alleles. If one wild-type allele is not sufficient to sustain normal seed formation, this

BOX
19.4

Phenotypic classes of reproductive mutants

Different classes of female reproductive mutants can be identified by the phenotypes they display in opened, developing siliques. In the wild type (A) nearly 100% of the seeds develop normally (green seeds). In contrast, ovules carrying a mutant allele of a female gametophyte lethal mutation (B) do not develop into seeds. Consequently, in a plant heterozygous for such a mutation only half of the seeds develop normally, whereas the remaining ovules did not get fertilized and are visible as shriveled, white ovules (arrows). In a game-

tophytic maternal effect mutation (C), ovules carrying mutant gametophytes will get fertilized but the seeds abort later during development, such that 50% of the seeds are normal (green) and 50% abort (white or brown seeds). This is in contrast to a zygotic embryo lethal mutation (D) where only homozygous embryos abort, resulting in 25% aborting seeds (white or brown seeds).

Source: U. Grossniklaus, University of Zurich; previously unpublished.

results in a maternal effect on seed development. Second, either one or both of the female gametes may lack a gene product that is deposited and stored, but required only after fertilization. If the lack of this gene product cannot be compensated for by the paternal genome, a gametophytic maternal effect on seed development results and is sometimes referred to as a maternal effect of **cytoplasmic nature**. This situation is typical of maternal effects in many animals, where the large egg cell carries all required products for the initial division cycles of the zygote. Finally, the female gametes may carry specific epigenetic modifications in their genome that result in differential expression after fertilization, sometimes referred to as a maternal effect of **chromosomal nature**. For example, a maternal allele may carry a mark that renders it active after fertilization while the paternally inherited allele remains silent. Thus, the embryo is

functionally hemizygous for this locus. Such parent of origin-dependent effects on gene expression are referred to as **genomic imprinting** (see Section 19.7.5).

The maternal seed coat plays a role in seed dormancy and germination, and maternal effects on seed color and seedling physiology have also been described, but maternal effects were considered unimportant with respect to development. This view was largely based on the fact that plant cells can give rise to embryos in culture, indicating that neither the specialized cytoplasm of the egg cell nor a particular epigenetic configuration of its genome is required for embryogenesis. The discovery of *medea* (*mea*), a gametophytic maternal effect mutation in *Arabidopsis* that is required for normal embryo and endosperm development changed this perception. Seeds that inherit a mutant allele of *mea* through the

FIGURE 19.52 Genetic behavior of the *Arabidopsis* maternal effect mutation *medea* in reciprocal crosses. Seeds derived from mutant female gametophytes (i.e. those inheriting a mutant maternal *mea^m* allele) abort irrespective of the paternal contribution. In contrast, all seeds inheriting the wild-type *MEA^m* allele are normal, even if they inherit a mutant paternal *mea^p* allele.

Source: Baroux et al. (2002). *Adv. Genet.* 46:165.

female gametophyte abort regardless of the contribution of the father (Fig. 19.52). Subsequently, it was found that about half of all mutants that have a gametophytic inheritance pattern (see Box 19.3) show embryo or endosperm phenotypes after fertilization. Thus, maternal effects are widespread and, in contrast to the situation in culture conditions, zygotic embryogenesis seems to require extensive maternal input.

Conceptually, defects in the sperm cells could also lead to paternal effects of cytoplasmic or chromosomal nature. Plant sperm cells contain a diverse set of transcripts, so it is feasible that some of these transcripts are delivered to the zygotic products upon fusion with the female gametes. The *Arabidopsis* *SHORT SUSPENSOR* (*SSP*) gene is transcribed in the sperm cells, but is only translated after delivery to the female gametes. In the zygote, *SSP* activates the *YODA* (*YDA*) MAPK pathway, which regulates the elongation of the zygote and its first asymmetric division. In *ssp* or *yda* mutants, zygote elongation does not occur, and the first division is nearly symmetric. While only homozygous *yda* embryos show this phenotype, *spp* is a paternal effect mutation and the phenotype is only observed if *spp* is inherited from the father. The dependence of zygote elongation on paternal *SSP* activity provides mechanism to ensure that this event only occurs after successful fertilization.

19.7.3 Embryogenesis establishes the main axis of the sporophyte

While gametophytic parental effect mutations clearly show that some input for early development comes from the parents, many more genes are required for embryogenesis, and their mutation can result in embryo lethality (see Box 19.4).

When the zygotic genome becomes active after fertilization is a matter of intense debate. Various lines of evidence suggest that the maternal contribution is important and zygotic genome activation is a gradual process as it was described for animals. Depending on the locus, several division cycles may be required until maternally and paternally inherited genomes are fully active. On the other hand, some genes are active soon after fertilization, and there are examples where both parental genomes seem to be fully active as early as the two-cell stage of embryogenesis. More studies are needed to determine how the timing of zygotic genome activation is controlled and how plant species differ in this regard.

The major function of embryogenesis is to set up the stem cell populations in the embryonic root and shoot meristems. In *Arabidopsis*, the cell divisions during embryogenesis follow a stereotypic pattern, such that it is highly predictable which cells divide and how the division planes will be oriented (Fig. 19.53). However, in many plant species the embryonic cell divisions do not follow a predictable pattern. This suggests that the fate of an embryonic cell is not determined by its lineage, but rather is influenced by its neighbors: cells adopt a fate based on their position in the embryo.

A substantial amount of evidence indicates this is also true in *Arabidopsis*, and that cell specification is flexible during development. In *Arabidopsis*, as in all plants studied to date, the zygote elongates along the micropylar–chalazal axis of the ovule and then divides asymmetrically to form a large, basal cell and a small, apical cell. The apical cell divides further to form the embryo proper, while the basal cell forms the suspensor, connecting the embryo proper to the ovule (Fig. 19.53). Given that the first asymmetric division establishes the apical–basal polarity of the embryo, much effort has gone into understanding the control of this process.

Parental and zygotic factors are both required for zygote elongation and division. Members of the *WUSCHEL-RELATED HOMEODOMAIN* (*WOX*) transcription factor family play an important role at this stage. Transcripts of *WOX2* and *WOX8* are present in both the egg cell and zygote but become restricted to the apical and basal cell, respectively. After division of the zygote, *WOX8*—together with its close homolog *WOX9*—regulates the development of the basal lineage but also, through the noncell autonomous activation of *WOX2*, the apical lineage (Fig. 19.54). Neither single nor multiple mutations in these genes affect the asymmetric division, so the role of these mutations in this process remains obscure.

WOX8 and *WOX9* are directly activated in the zygote by the transcription factor *WRKY2*. In *wrky2* mutants, the egg cell is formed, but the zygote fails to reorganize the polar distribution of the cytoplasm after fertilization, does not elongate properly, and divides symmetrically. These defects are partly overcome when *WOX8* is expressed in the egg cell and early embryo, providing a link between the polarization of the zygote and early embryonic pattern formation (Fig. 19.54). This partial rescue and the fact that *wox8/9* double mutants have a normal zygotic division suggest that additional, yet unknown factors also contribute to this process.

FIGURE 19.53 Embryogenesis in *Arabidopsis*. (A) Schematic representation of development from the zygote to the heart stage, where the main elements of the embryo, i.e. shoot apical meristem (SAM), root apical meristem (RAM), cotyledons (Cot) and hypocotyl (Hyp) are already determined. Lineages of the suspensor (Sus) as well as the upper (Ut) and lower tier (Lt) of the embryo proper (Ep) are indicated. (B–D) Cleared specimen of selected stages. Ac, apical cell; Bc, basal cell; Pd, protoderm; Hy, hypophysis. Source: (B–D) Yadegari et al. (1994). *Plant Cell* 6:1713–1729.

FIGURE 19.54 Control of the asymmetric division of the *Arabidopsis* zygote. (A) Zygote elongation and asymmetric division is controlled by the parallel WOX and YDA pathways. (B) The YDA pathway is activated by the SPP protein, whose RNA is delivered via the sperm cells. WOX homeobox genes show distinct expression patterns along the apical–basal axis of the embryo.

The YDA MAPK pathway mentioned above, which is triggered by paternal SSP supplied by the sperm, also regulates the first asymmetric division. How the two pathways interrelate is not yet entirely clear, but insights have come from the characterization of GROUNDED (GRD), a transcription factor of the RKD family, which is required for YDA signaling but is not a target of the YDA MAPK cascade. However, *grd* and *wox8/9* mutants show a strong synergistic interaction: triple mutants arrest as zygotes or early embryos

without apparent polarity, suggesting they act independently to regulate zygote polarity and elongation (Fig. 19.54).

Once the asymmetric division is achieved, the apical–basal axis of the embryo must be consolidated and reinforced. These subsequent patterning processes depend on the plant hormone auxin. Although auxin is apparently not involved in the first division of the zygote, it rapidly accumulates in the apical cell, once it has formed, as a consequence of polar auxin transport. Members of the PIN-FORMED (PIN) plasma

FIGURE 19.55 Formation of the embryonic root and shoot meristems. Patterning along the apical-basal axis involves the local accumulation of auxin first in the apical cell and its descendants, and then in the hypophysis, which forms the root meristem. Expression of *WUS* and *CLV3* in the young embryo establishes the shoot meristem. See text for details.

membrane protein family function as efflux transporters of auxin (see Chapter 18).

PIN7 is localized at the apical membrane of the basal cell—and initially in the suspensor cells derived from the basal cell—and thus transports auxin into the apical cell (Fig. 19.55). After the first division of the apical cell, PIN1 accumulates at the inner surface of the cells of the embryo proper, leading to the uniform distribution of auxin in the lineage forming the embryo proper. At the early globular stage, a dynamic reorganization of the PIN transporters occurs, such that PIN1 and PIN7 become localized at the basal membrane of embryonic and suspensor cells, respectively. This leads to the accumulation of auxin in the hypophysis, the top-most cell of the suspensor. The hypophysis is the only cell derived from the basal lineage that contributes to the embryo and plays an important role in organizing the embryonic root meristem (Fig. 19.55). This relocation of the PIN proteins depends on *GNOM*, a guanine nucleotide exchange factor for adenosyl ribosylation factors (ARF-GEF), which is involved in the directional delivery of PIN proteins to the plasma membrane. This explains the gross patterning defects in *gnom* mutants, which were isolated in a seminal screen for mutants affecting embryonic pattern formation in *Arabidopsis*. In *gnom* mutants, PINs remain unpolarized and the apical–basal axis of the embryo cannot properly be formed.

The hypophysis not only accumulates auxin, it also shows a high level of cytokinin signaling. The asymmetric division of the hypophysis forms a lens-shaped apical cell, in which cytokinin signaling remains high, and a larger basal cell with high auxin levels. In this cell auxin directly activates the *ARABIDOPSIS RESPONSE REGULATOR* genes *ARR7* and *ARR15*, which are repressors of cytokinin signaling. Thus, the

antagonistic interaction of auxin and cytokinin establish the identity of the lens-shaped cell, which gives rise to the quiescent center cells that organize the embryonic root meristem.

The shoot meristem is formed independently through the establishment and successive refinement of expression domains of regulatory factors. The root and shoot fates of the basal and apical domains in the embryo are determined by complementary master regulators, the *PLETHORA* and *HD-ZIPIII* transcription factors, respectively. Ectopic expression of these regulators in the appropriate genetic background can convert a shoot into a root, and *vice versa*. For example, expression of the *HD-ZIPII* factor *REVOLUTA* in the basal region of the embryo can convert the root into a second shoot. The stem cell niche for the shoot meristem is set up after transverse divisions at the octant stage have formed outer (protoderm, the precursor of the epidermis) and inner cells of the embryo proper. The four apical inner cells begin to express *WUS* and give rise to the organizing center of the embryonic shoot meristem (Fig. 19.55). Slightly later, at the transition stage, when globular embryos lose their radial symmetry and form a bilateral heart stage embryo, *CLAVATA3 (CLV3)* is expressed in the same area. *CLV3* is required to maintain the meristem's stem cell population through a feedback loop with *WUS* (see Chapter 11). Specifying the embryonic shoot meristem between the emerging cotyledons involves many factors, including auxin and the transcription factors *SHOOT MERISTEMLESS* and *CUP SHAPED COTYLEDON1/2*, which regulate each other in a complex way.

The embryo is not only patterned along the apical–basal axis, but the division that forms the protoderm also initiates patterning along the radial axis, eventually forming an epidermal layer, multilayered ground tissue, and the vasculature

in the center. At the heart stage, the body plan of the embryo is fully established: both root and shoot meristems are defined, and the cotyledon primordia and various radial tissues have been set up. What follows are growth and expansion of the cells forming the cotyledons and the hypocotyl to form a torpedo and finally a mature embryo, where the cotyledons and the hypocotyl are approximately of the same length. In *Arabidopsis*, the entire morphogenetic phase starting with the zygote and ending with the fully grown embryo is completed within a week, followed by another week of seed maturation, which is dedicated to processes that prepare the seed for dispersal and germination.

19.7.4 Endosperm development is controlled by maternal and zygotic factors

The second product of fertilization, the endosperm, produces proteins and carbohydrates to support embryogenesis and germination. In many angiosperms, the endosperm is transient in nature: it proliferates during the early phase of seed formation, but is absorbed by the embryo during its growth. This process likely involves some form of programmed cell death and leaves only one or a few cell layers that surround the embryo, including the epidermal layer of the endosperm (**aleurone**). In these cases (including tomato, tobacco, and *Arabidopsis*), the endosperm does not serve a major storage role, rather the embryo itself stores the resources required for germination. In other species, especially the cereals, the endosperm is persistent, contributes up to 80% of the seed mass, and provides the resources required for germination and survival until the seedling is established. Persistent endosperm is one of the most important resources used for food, feed, biofuel, and other industrial materials.

Though many studies have addressed the biosynthesis and mobilization of food reserves in the endosperm, we still know relatively little about the molecular basis of its development. There are two major forms of endosperm development. In some species, for instance in the orange jewelweed (*Impatiens capensis*) and the pukeweed (*Lobelia inflata*), the fertilized endosperm divides to form daughter cells at each division, similar to what occurs during embryogenesis. This cellular type of endosperm development, however, is rare.

Most species have nuclear endosperm development, where the initial divisions of the endosperm occur in a syncytium. Thus, in nuclear endosperm development, as in that of the female gametophyte, the nuclei divide in the absence of cytokinesis (Fig. 19.56). The fertilized central cell nucleus (secondary endosperm) divides prior to the first division of the zygote, and rapid subsequent divisions form the syncytial endosperm (**coenocyte**). The initial divisions are synchronized, but the nuclei in distinct endosperm regions later divide at different rates, forming mitotic domains that correspond to the micropylar, peripheral, and chalazal endosperm (Fig. 19.56). The free nuclear division cycles are followed by cellularization of the endosperm. In *Arabidopsis*, cellularization occurs at the heart stage of embryo development, starting

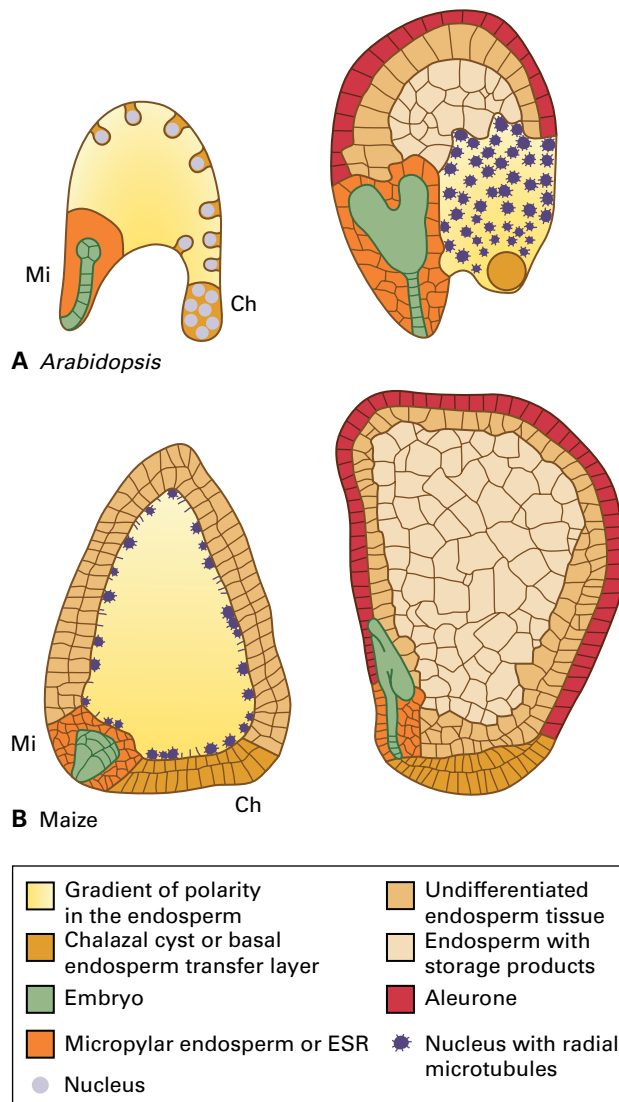

FIGURE 19.56 Endosperm development in *Arabidopsis* (A) and maize (B). Although the endosperm of oil seeds and cereals are anatomically distinct, equivalent domains can be distinguished at the micropylar pole (Mi) around the embryo, at the chalazal pole (Ch), and in between. Endosperm cellularization initiates around the embryo in *Arabidopsis* and then spreads around the periphery towards the chalazal pole, while in maize, cellularization starts at the periphery and progresses to the center. Peripheral nuclei in dense cytoplasmic domains form a radial microtubule network to organize cell wall formation around them.

in the micropylar embryo-surrounding region (ESR) and progressing toward the chalazal pole. In the cereal coenocyte, cellularization starts at the periphery and advances towards the center of the seed until the endosperm cavity is filled. Also in the cereal endosperm, regions with distinct cell fates can be identified: ESR, aleurone, starchy endosperm in the center, and the basal endosperm transfer layer (BETL), which corresponds to the chalazal endosperm of *Arabidopsis* (Fig. 19.56).

Endosperm cellularization is followed by differentiation of specific tissues within the endosperm and, finally, by maturation. During the latter phase, the bulk of the cereal endosperm synthesizes and stores starch and proteins,

FIGURE 19.57 Fertilization-independent endosperm development in the *fis* class mutants. (A) In unpollinated pistils of the wild type, the central cell (arrow points to its nucleus) is arrested until fertilization occurs, while (B) in *mea* embryo sacs, it proliferates in the absence of fertilization but no embryo forms. (C) A wild-type seed from a pollinated pistil with developing embryo (arrow) and endosperm for comparison. Source: Köhler et al. (2003). EMBO J. 22:4804.

while the aleurone accumulates proteins and lipids that are important for germination. Here, only one of these specialized endosperm tissues is discussed, the micropylar endosperm or ESR, which is important for embryogenesis.

The ESR of *Arabidopsis* and cereals is characterized by regionally restricted gene expression. ESR-expressed genes include the sucrose transporter gene *AtSUC5*, which is involved in reserve accumulation in the embryo, and also genes encoding secreted peptides, indicating that signaling is important for ESR function. Indeed, in *Arabidopsis* the endosperm breaks down to provide nutrients and space for the growing embryo. This primarily concerns the ESR and may involve communication between embryo and endosperm. Although the embryo does not appear to influence ESR degeneration (which occurs even in the absence of normal embryo growth, at least in cereals), the endosperm has a strong effect on embryo development. Plants carrying mutations affecting the basic-HLH transcription factor *ZHOUP1* (*ZOU*), which is specifically expressed in the ESR, endosperm is persistent and embryos are small and have an abnormal epidermis. Thus, *ZOU* regulates two distinct processes: ESR degradation and the non-cell autonomous signals for the formation of the embryonic epidermis. The latter is mediated by activating the ESR-expressed *ABNORMAL LEAF SHAPE1* (*ALE1*) gene encoding a subtilisin protease. Such proteases may play a role in the processing of peptide ligands, several of which are expressed in the ESR. Thus, the formation of the embryonic epidermis seems to require an unknown peptide ligand, whose production in the ESR depends on *ZOU* and *ALE1*. The transmission of this signal requires the function of the embryo-expressed RLKs *GASSHO1* and *GASSHO2*, mutations in which also lead to defects in the embryonic epidermis. These examples illustrate the importance of cell–cell communication processes between seed compartments.

The production of endosperm is energetically costly and should be tightly controlled and coordinated with embryo development. Thus, endosperm proliferation is repressed in the absence of fertilization through the action of PcG proteins (see Chapter 9). The FIS–PRC2 complex plays a predominant role in the regulation of female gametophyte and seed development (see Box 19.1). It contains the histone methyltransferase *MEA* and the core subunits *FERTILIZATION-INDEPENDENT SEED2*

(*FIS2*), *FIE*, and *MSI1*. Mutations in any of these four genes, collectively referred to as *fis* class mutants, lead to autonomous endosperm formation in the absence of fertilization (Fig. 19.57). Thus, as in animals where their deregulation can lead to cancer, PRC2 complexes regulate cell proliferation also in plants.

This autonomous, diploid endosperm, however, does not develop normally and fails to cellularize, because the type I MADS-domain transcription factor *AGL62* fails to be down-regulated in *fis* class mutants. In wild-type seeds, the expression of *AGL62* drops just prior to cellularization, and in *agl62* mutants the endosperm cellularizes precociously, suggesting that *AGL62* is important to maintain the syncytial state of the endosperm. Thus, the FIS–PRC2 complex controls the developmental transition from nuclear to cellular endosperm.

Normally, endosperm proliferation is triggered by fertilization, which releases repression by the FIS–PRC2 complex, but the signaling events involved in this release are unknown. In addition to its role prior to fertilization, the FIS–PRC2 complex also plays a role after fertilization. If *fis* class mutants are fertilized by wild-type pollen, all seeds start to develop but abort later during seed development. Both embryo and endosperm show abnormal proliferation, producing enlarged heart stage embryos and overgrowth of the chalazal endosperm. As embryo and endosperm have identical genotypes, however, it is not easy to determine whether the FIS–PRC2 plays a role in both fertilization products, as indicated by the phenotype and mRNA expression patterns of the *FIS* genes, or whether the embryonic defects are a consequence of endosperm failure. In all *fis* class mutants, seed abortion depends solely on the genotype of the embryo sac, thus representing a typical gametophytic maternal effect.

19.7.5 Genomic imprinting involves DNA methylation and PRC2-based repression

Genomic imprinting is the parent-specific marking of a chromosome or gene. This term was coined to describe the observation that paternal X-chromosomes are specifically eliminated during embryogenesis in sciarid flies (*Sciara coprophila*). Thus, these chromosomes must carry a mark, or

imprint, that distinguishes them from maternal chromosomes. The first demonstration of parent-of-origin-dependent behavior for a single gene, rather than an entire chromosome, was made for the *R1* (*colored1*) locus in maize (see Chapter 9). The *R1* locus controls anthocyanin pigmentation in the aleurone, and its alleles show different phenotypes depending on the direction of the parental cross. Inheritance of the *R1* allele from the mother results in full pigmentation of the kernel, whereas inheritance from the father produces kernels with a mottled phenotype, where most aleurone cells fail to express *R1*. A series of genetic experiments performed in the 1960s demonstrated that the *R1* phenotype depends only on parental origin, in other words that *R1* is regulated by genomic imprinting.

In molecular terms, genomic imprinting results in the differential expression of an allele, depending on which parent it is inherited from. Although maternal and paternal alleles of imprinted loci may not differ in sequence and are present in the same nucleus, they are differentially expressed. Thus, they must differ with respect to imprinting marks that were established according to the sex of the parent while the alleles were separated. In plants, this must occur after the lineages for male and female reproductive organs separate, but before fertilization.

Recent work on the mechanisms of imprinting in plants has highlighted several similarities with mammals, in particular the role of DNA methylation and PRC2-based repression. Given that imprinting evolved independently in these lineages, this is a remarkable example of convergent evolution, where similar molecular modules are recruited for the differential regulation of genes. Much of what is known about the molecular basis of imprinted expression comes from the study of a small set of genes in *Arabidopsis*, mainly the maternally expressed *MEA*, *FIS2*, and *FLOWERING WAGENINGEN* (*FWA*) loci, and the paternally expressed *PHERES1* (*PHE1*) gene. Two of the major regulators of imprinted expression are METHYLTRANSFERASE1 (*MET1*), a maintenance DNA methyltransferase that re-establishes methylation in the CG context after replication, and DEMETER (*DME*), a DNA glycosylase that removes methylated cytosines from DNA. Imprinting of *FIS2* and *FWA*, a homeobox gene without apparent function in seed development, is regulated by these two factors. Methylation of cytosines in their 5'-regulatory regions is maintained by *MET1* during sporophytic development, where both alleles are methylated. This is also true during male gametophyte development; paternal alleles in the sperm cells are methylated and not expressed. In the female gametophyte, however, methylation is presumably removed from the maternal alleles by *DME*, which is expressed predominantly in the central cell of the embryo sac. Indeed, *FWA* and *FIS2* are expressed strongly in the central cell, and the maternal alleles are subsequently also active in the endosperm while the paternal alleles are not (Fig. 19.58). Thus, the presence or absence of methylation in the promoters of these genes seems to determine their imprinting status. Indeed, when allele-specific methylation is analyzed 7–8 days after pollination, the parental alleles in the endosperm are differentially methylated.

When exactly the maternal alleles are demethylated is unclear, but the expression of *DME* in the central cell suggests

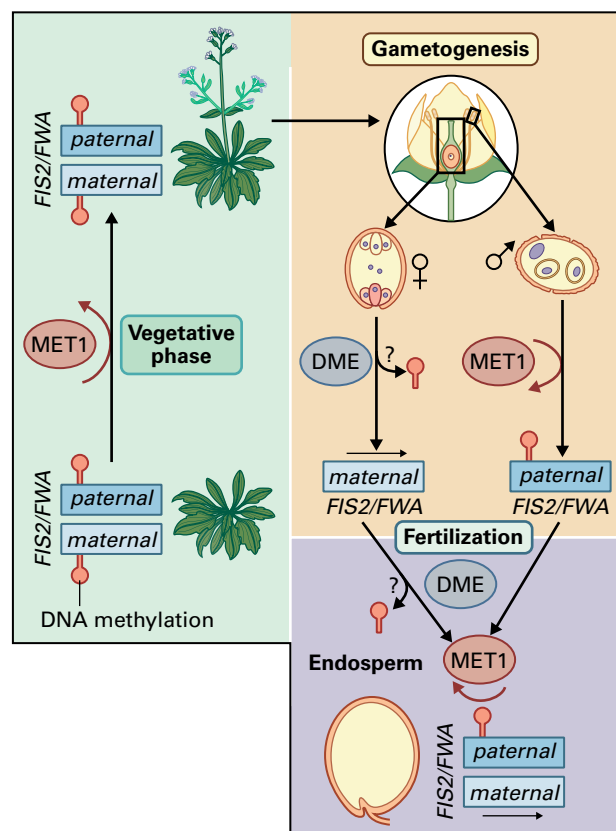

FIGURE 19.58 Model for the regulation of genomic imprinting by DNA-methylation. The *MET1* DNA methyltransferase maintains methylation at the *FIS2* and *FWA* loci throughout sporophytic and pollen development. In the central cell, either before or after fertilization, the DNA glycosylase *DME* removes the methylcytosines, leading to the differential marking and eventually expression of maternal and paternal alleles in the endosperm. See text for details.

that this may occur prior to fertilization. A recent analysis of DNA methylation at the *FWA* locus directly in the central cell showed, however, that it is still methylated. This suggests that *DME* acts only after fertilization and it is unclear how maternal and paternal alleles are marked, causing differential demethylation. A similar situation was described for the *ZmFie2* locus in the endosperm and the *Maternally expressed in embryo1* (*Mee1*) locus in the embryo of maize. In both cases, allele-specific DNA methylation or demethylation, respectively, occurs only after fertilization, and methylation status and expression do not correlate. Thus, at least in some cases, differential DNA methylation does not seem to be the imprint that is inherited from the parents, as it is only established after fertilization, possibly as a consequence of transcription.

The regulation of *MEA* and *PHE1* is more complex and, in addition to DNA methylation, involves repression by the FIS-PRC2 complex. In a *dme* mutant, the maternal *MEA* allele fails to be expressed, suggesting that *DME*-mediated demethylation plays a similar role as it does for *FWA* and *FIS2*. However, if DNA methylation is removed paternally, as in a *met1* mutant, the paternal allele is still silent, while maternal *fis* mutations lead to some expression from the paternal *MEA* allele. These findings suggest the maternally produced FIS-PRC2 complex

represses the paternal *MEA* allele after fertilization in an autorepressive fashion. A more detailed analysis, however, showed that a short piece of the *MEA* promoter devoid of DNA methylation can confer imprinted expression to a reporter gene. This suggests that the role of *DME* is indirect, perhaps by regulating higher order chromatin structure (chromatin loops), and that it is not differential methylation that specifically marks the maternal allele. Furthermore, if both known regulators of the paternal allele, paternal *MET1* and the maternal FIS-PRC2 complex, are lacking, the two parental alleles are still differentially expressed, suggesting that additional, unknown factors are involved in establishing the imprints that mark the parental alleles (Fig. 19.59).

PHE1 was isolated as a direct target gene of *MEA*, which specifically represses the maternal *PHE1* allele. Thus, the FIS-PRC2 complex is involved in allele-specific repression, a function that was also demonstrated in mammals, where PRC2 represses the paternal alleles of selected imprinted

genes. The regulation of *PHE1* is more complex, however, as methylation of repeats that are downstream of the locus is required for efficient repression of the paternal allele by the FIS-PRC2 complex. In the active paternal allele, in contrast, these repeats are methylated. Given that sequences both upstream and downstream of *PHE1* are involved in its regulation, it is possible that they interact by forming a chromatin loop, as has been suggested for the *MEA* locus (Fig. 19.59).

Several hundred additional loci that are candidates for imprinting have been identified in *Arabidopsis*, maize, and rice following advances in sequencing technologies, which allow the profiling of mRNAs in an allele-specific manner. Such profiling approaches have identified genes that show differential expression of the parental alleles in the endosperm. While these are excellent candidates for further studies, different steady-state levels of paternal and maternal transcripts are not sufficient to demonstrate imprinting. The same difference could come about by producing and storing an mRNA in the egg cell

FIGURE 19.59 Model for the role of higher order chromatin organization in the regulation of genomic imprinting. At the *MEA* and *PHE1* loci, chromatin looping has been proposed to play a role in imprinting. (A) Maternal copies of *MEA* are in a loop making them inaccessible to activating imprinting factors. Removal of methylcytosines by *DME* in the central cell opens the loop, allowing access to unknown factors (A) marking the active allele. The paternal copy remains in a loop and is kept silenced by the FIS-PRC2 and additional, unknown repressors (R) in the endosperm. Autorepression of *MEA* reduces expression of the maternal allele after fertilization. (B) At *PHE1* the loops are maintained on the maternal copies, a process involving the FIS-PRC2 and tandem repeats located downstream of *PHE1* that have to remain unmethylated. The paternal *PHE1* allele, where these repeats are methylated, does not form a loop and is active in the endosperm.

or by delivering it to the zygote via the sperm. It is, therefore, important to show that the gene is either not expressed in the gametes or that one parental allele only is actively transcribed after fertilization, an experimentally challenging task.

Genomic imprinting is generally considered to occur in the endosperm, but there are also a few genes that appear to be imprinted in the embryo. The best studied is *Mee1*, a gene of unknown function, which is maternally expressed in maize embryos only after fertilization. However, quite a few more differentially expressed genes in the embryo have been identified and about a dozen were recently shown to show imprinted expression in the *Arabidopsis* embryo. Finally, little is known about the role of imprinted genes, in either endosperm or embryo, as the function of only a handful of imprinted genes is known (see above).

19.7.6 Seed maturation prepares the seed for dispersal and germination

Seed development is not complete when the embryo and endosperm are formed. In fact, seed maturation, the period that follows the morphogenetic phase of seed formation, encompasses many steps that are required to prepare the seed for dispersal (Fig. 19.60).

Seed maturation involves mainly the accumulation of storage products, such as starch, lipids, and proteins, and is followed by seed desiccation. The synthesis of nutrients stored in the seed is crucial for germination and seedling establishment. These resources bridge the period required for the seedling to become photosynthetically active and to be able to acquire nutrients from the soil. The fact that the embryo must survive long periods without water requires extensive changes in its physiology, as it loses up to 90% of the water content. A large number of chaperones, including the family of LATE EMBRYO ABUNDANT (LEA) proteins, play a crucial role in the desiccation process of seeds and pollen, both of which are dispersed in a dry state. The storage

FIGURE 19.60 Physiological changes during seed development. Note the loss in moisture content that occurs during seed maturation and the reduced ability to germinate, which reflects the establishment of seed dormancy at the end of seed maturation.

of nutrients and the establishment of desiccation tolerance are crucial for seed dispersal and the evolutionary success of land plants.

During seed maturation, dormancy is also established. Mature seeds are dormant for a period of time that is specific to the plant species. When dormant, seeds cannot germinate, even under conditions that favor germination. The onset of dormancy during seed maturation and the release of dormancy during germination are both under the control of the phytohormones gibberellin and abscisic acid (ABA). ABA promotes dormancy and prevents germination, whereas gibberellin is required for germination. In mutants deficient for ABA biosynthesis, dormancy is not established and the seeds germinate precociously on the ear or in the seedpod (**vivipary**). Eventually, the balance of these two hormones regulates when a seed germinates.

Germination and seedling establishment are followed by vegetative growth of the plant, which then switches to reproductive growth under the appropriate internal and external conditions. The return to the reproductive phase of development and the formation of flowers closes the circle.

Summary

Plant reproduction is a central process in the plant's life cycle. Flowering, pollination, and fertilization culminate in the formation of seeds, which ensure the propagation of the species but are also the main output of agricultural production. Reproductive success involves interconnected signaling events that control the optimal time for flowering, depends on intricate gene regulatory networks that control floral morphogenesis, necessitates a complex series of cell–cell communication mechanisms to achieve fertilization, and relies on epigenetic regulation to form seeds, the final product of plant reproduction. Tremendous progress has been made over the last

decade in deciphering the molecular mechanisms underlying these diverse developmental processes, chiefly through experiments using *Arabidopsis* as a model system but also through work on other plants.

External and internal signals are integrated to tightly control flowering time, ensuring the formation of as many seeds as possible. Best understood at the molecular level are the regulatory cascades that control two key transcriptional regulators: *CO* by the photoperiod pathway and *FLC* by the vernalization and autonomous pathways. The stable maintenance of repression at *FLC*, and thus the memory of the exposure to cold, relies on

Polycomb complexes, epigenetic regulators conserved from plants to mammals. *CO* and *FLC* integrate various signals and coordinately regulate *LFY* and *API*, which mediate the transition from vegetative to inflorescence meristem identity.

The formation of flowers is one of the best-studied processes in plant development, largely governed by transcriptional networks that regulate organ-specific gene expression. The combinatorial action of homeotic genes, mostly transcription factors of the MADS-domain family, specifies floral organ identity. Expression of these transcription factors is regulated by the meristem identity factors *LFY* and *API*. In turn, the products of homeotic genes form multimeric quartet complexes that regulate downstream genes involved in the development of the different floral organs. Much of floral diversity can be explained by the altered expression patterns of floral homeotic genes, leading to a change in flower morphology.

Because male and female gametophytes develop deeply enclosed in the reproductive organs of the flower, the molecular mechanism controlling their development has long been elusive. Recent advances, however, show that a tight integration of cell cycle control and cell specification is central to male gametophyte development, while signaling via small, secreted proteins seems to be involved in patterning the female gametophyte. Cell–cell communication involving various secreted peptides—many of

which belong to the defensin family of cystein-rich proteins—and cell surface receptors, is even more prominent during pollination and fertilization. Many plant species evolved self-incompatibility systems, allowing them to discriminate self from non-self pollen. The molecular nature of these systems are diverse but well understood at the molecular and cell biological level. After pollen germination, a complex series of cell–cell communication events during pollen tube growth, guidance, and reception ensures successful fertilization.

Finally, double fertilization initiates the formation of seeds, a highly coordinated process that involves interactions of three partners: the maternal seed coat, the embryo, and the endosperm. During embryogenesis, the plant hormone auxin plays a crucial role in setting up the apical–basal axis of the young embryo, which forms the main axis with the root and shoot apical meristems. Normal development of the embryo depends on the formation of endosperm, the second product of fertilization, which provides nutrients and signals to the developing embryo. Endosperm development serves as a paradigm for epigenetic regulation in plants, as it is the major site of genomic imprinting and its proliferation depends on *Polycomb* group complexes. Once the embryo is formed, complex physiological changes ensure that the seeds becomes dormant and can survive in a dry state, allowing long-distance seed dispersal.

Senescence and Cell Death

*Howard Thomas, Helen Ougham,
Luis Mur, and Stefan Jansson*

Introduction

Selective death of cells, tissues and organs is an essential feature of plant development and survival. The controlled death and elimination of parts strongly influences plant shapes, habits, environmental interactions, and adaptations (Fig. 20.1). We see this clearly in the deciduous behavior of temperate trees, for example. The general term for the biological mechanisms underlying terminal events in the lives of plants and their parts is **programmed cell death (PCD)**. PCD includes any process by which protoplasm dies, with or without elimination of the associated cell wall, as part of a genetically determined developmental or adaptive event in the plant life cycle. PCD plays such important roles in plant differentiation and adaptation that the diverse forms and functions of the world's flora could not have evolved without it. Examples include:

- development of unisexual flowers in which cells destined to form male or female parts are selectively deleted
- pollen and egg cell production and post-meiotic development of micro- and megasporophytes
- degeneration of suspensor cells during embryo differentiation
- development of starchy endosperm in cereal grain maturation and death of aleurone cells during germination
- formation of xylem, sclerenchyma, and other specialized cell and tissue types such as epidermal hairs, oil glands, and abscission layers

- generation of complex organ forms, for example, the degeneration of strips of cells (called *lorae*) resulting in the fan-like shape of palm leaves
- senescence of organs, including leaves, roots, flower parts, and the tissues of ripening fruits
- reactions to abiotic stresses, for example aerenchyma formation under anaerobic conditions
- responses to biotic stresses, including the hypersensitive response, in which infection by a pathogen triggers defensive cell death in the host.

20.1 Types of cell death

Although the term PCD usefully encompasses all the ways by which a cell may die in the interests of plant development or survival, it does not tell us anything about mechanisms. In this chapter we survey the range of ways in which plants and their parts initiate, execute, and regulate the processes that lead to cell death.

20.1.1 Modern research on eukaryotic cell death has its roots in animal science

The recent upsurge in the study of cell death in eukaryotes was sparked in the early 1970s by research investigating how animal cells die. Two major types of cell death were identified by

FIGURE 20.1 Programmed cell death (PCD) occurs in many plant cells and tissues and is involved in numerous developmental and adaptive processes, including gamete formation (1); embryo development (2); degeneration of tissues in the seed and fruit (3); tissue and organ development (4 through 6); senescence (7); and responses to environmental signals and pathogens (8 and 9).

this work: **apoptosis**, a highly regulated, energy-dependent process; and **necrosis**, which results from trauma (Fig. 20.2).

Cells undergoing apoptosis shrink and the cytoplasm condenses, although plasma membrane and organellar integrity are retained. The nuclear DNA also condenses and is cleaved into fragments of approximately 50 kbp. Nuclear DNA is often, but not always, further digested by endogenous Ca^{2+} -dependent endonucleases into oligonucleosomal sized fragments. These can be visualized on a gel as a ladder of DNA with fragments of multiples of around 180 bp (Fig. 20.3).

Nuclei in which DNA has been attacked by endonucleases may be detected by terminal dUTP nick end labeling (TUNEL; Fig. 20.4). Fragmentation of nuclear DNA results in the breakdown of chromatin structure and is characteristic of some, but not all, forms of apoptosis. At the same time, the nucleus breaks up and the cell itself is converted into **apoptotic bodies**, small membrane-bound structures containing nuclear debris. These bodies migrate to the margin of the cell and are taken up by adjacent cells through the process of phagocytosis.

FIGURE 20.2 Two types of cell death identified in animal cells. Apoptosis is a form of PCD in which chromatin condenses, the nuclear and plasma membranes bleb, and apoptotic bodies are formed that are eventually engulfed by neighboring phagocytes. Necrosis often occurs when cells are physically damaged; it results in rupture of membranes, release of cellular contents, and tissue inflammation.

FIGURE 20.3 DNA degradation in nuclei of rat thymocytes (lanes 1, 3, and 5) and lymph node cells (lanes 2, 4, and 6) as catalyzed by endogenous Ca^{2+} - and Mg^{2+} -dependent nuclease activity. In the presence of Ca^{2+} and Mg^{2+} , DNA laddering is observed (lanes 1 and 2). Adding the Ca^{2+} chelator EGTA (lanes 3 and 4) or Zn^{2+} (lanes 5 and 6) inhibits DNA degradation. Source: Peitsch et al. (1993) EMBO J. 12(1):371–377.

Additional markers for apoptosis include the formation of mitochondrial permeability transition pores (PTP) and the proteolysis of the DNA-repair enzyme poly (ADP)-ribose polymerase (PARP). PTP formation disrupts mitochondrial function and allows the release of proteins into the cytoplasm,

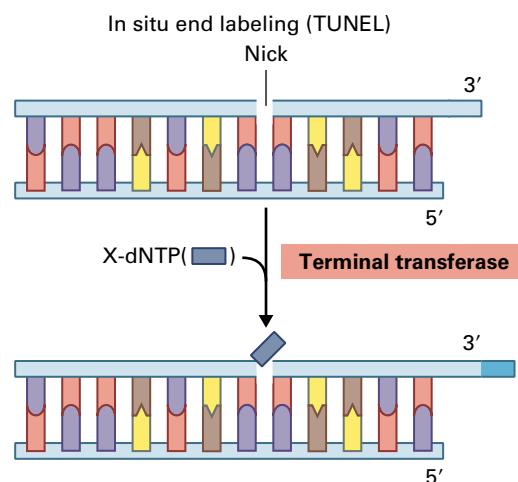

FIGURE 20.4 In the TUNEL assay, terminal deoxynucleotidyl transferase is used to estimate the extent of DNA cleavage, based on the labeling of free 3'-OH ends of DNA with fluorescein-labeled deoxyuridine (X-dNTP) or some other fluorescently labeled nucleotide triphosphate. Note that the TUNEL method estimates only the extent of DNA cleavage and does not provide information on the size of the cleaved product.

of which **cytochrome c** appears to be particularly important. In human cells, cytochrome *c* interacts with a molecular chaperone (Apaf-1) and a procaspase. **Caspases** are a family of cysteine proteases that cleave at specific **aspartate**-containing sites. They participate in both the initiation of apoptosis and the disassembly of cellular contents. Interaction of cytochrome *c*–Apaf-1–procaspase multimers leads to the formation of a wheel-like super-complex known as the **apoptosome**. The procaspase is cleaved into a mature form in an ATP-dependent process, leading to activation of additional caspases and a caspase-dependent nuclease, cleavage of PARP,

and digestion of structural nuclear proteins and several cytoskeletal components.

Animal cells that suffer physical damage die by necrosis, which is a fundamentally different process from apoptosis and which results in rupture of the plasma membrane and endomembranes causing hydrolytic enzymes and other materials to be rapidly released (see Fig. 20.2). Most cellular debris is engulfed by specialized phagocytes. Release of enzymes following trauma results in inflammation, whereas cells that die by apoptosis do not rupture, and therefore do not cause inflammation.

The term apoptosis, although frequently used as a synonym for PCD, has a specific meaning, and its use beyond its well-established context in animal development and pathology should be avoided. Nevertheless, the apoptosis model has influenced concepts of cell and tissue death across all organisms, and established some basic principles recognized in virtually all forms of PCD:

- Non-necrotic cell death is an active process, requiring the orderly operation of metabolism dependent on sources of biological energy.
- Cell death programs in general comprise specific genes that can be modified with predictable consequences for the course of terminal metabolic and cellular events.
- Execution of the program is characterized by cascade processes in which activation of a specific step propagates by turning on downstream actions which in turn invoke further activities and so on.

A terminal PCD process in plants that exhibits these characteristics is sometimes called “apoptosis-like,” but this should not be taken to mean that true apoptosis in the strict sense occurs in plants.

20.1.2 Specific lytic processes dispose of cytoplasm and its components during PCD in plants

Chromatin condensation and DNA laddering do not accompany most types of PCD observed in plants. The presence of the cell wall precludes phagocytosis, by neighboring plant cells, of any structures equivalent to apoptotic bodies. Moreover, no gene sequences with convincing homology to caspases have been reported in plants. There are reports of plant proteases with caspase-like characteristics, for example, endopeptidases of the **vacuolar processing enzyme** (VPE) group, but these so-called “**metacaspases**” have yet to find an agreed physiological role. Metacaspase activity has been measured during some PCD events in plants, including tracheary element formation, pollen death resulting from self-incompatibility, and the hypersensitive response. Inhibitors against mammalian caspases can be effective in suppressing some of these processes.

In the absence of phagocytosis, how do plants eliminate unwanted cytoplasm or whole cells during PCD? The general term for the dissolution of cytoplasm within the cell wall through the action of the cell’s own catabolic machinery is **autolysis**. As described in subsequent sections, plants employ several different kinds of autolytic process during development and adaptation. One way that some plant cells can dispose of their cellular contents is through **autophagy**, a death process in which the cell “eats itself” from within. Vesicles are produced that engulf portions of the cytosol, including intact organelles. These vesicles, called **autophagosomes**, are taken up by the central vacuole of the cell (Fig. 20.5A), or in some cases fuse with lysosomes (lytic vesicles; Fig. 20.5B), and are broken down by hydrolases. Blocking the action of proteolytic enzymes by treatment with inhibitory chemicals such as E-64 or concanamycin A (CMA), disrupts autophagic pathways and results in accumulation of autophagic bodies (Fig. 20.5A,B). Autophagosomes have been observed in senescing corolla cells of Japanese morning glory (*Ipomoea tricolor*, Fig. 20.5C) and during sucrose starvation of cultured *Nicotiana tabacum* BY-2 cells (Fig. 20.5D shows autophagic bodies in the vacuole of a CMA-treated cell).

Mechanistically, autophagy involves distinctive stages: (i) vesicle induction; (ii) vesicle expansion; (iii) tonoplast docking and fusion; and (iv) digestion. Molecular components regulating autophagy have been particularly well described in yeast, but homologs of most of these **autophagic genes** (*ATG*) are also present in *Arabidopsis* (Table 20.1) and other plant species. Initiation of autophagy is regulated by a target of rapamycin (TOR) kinase. Under normal conditions TOR kinase phosphorylates ATG1 kinase and accessory proteins, leading to their inactivation. To initiate autophagy, TOR kinase is inactivated, allowing ATG1 to interact with several ATG proteins, leading ultimately to the formation of a vacuolar-sorting complex that includes a phosphatidylinositol 3-kinase (PI3-K) protein. This is a key vesicle nucleation step in which tubular **pre-autophagic structures** (PASs) are formed, possibly from the endoplasmic reticulum (ER). PASs coalesce to form a cage that captures a portion of the cytoplasm. This late expansion phase is aided by many ATG proteins, with a key event being the linking of the vesicle to cytoskeletal microtubules via an ATG8 conjugate to a lipophilic phosphatidylethanolamine moiety allowing targeting to the vacuole.

Another important feature is the addition to the autophagosome of a protein complex consisting of ATG5, ATG12, and ATG16. The exact function of this complex is unknown, but it is required for vesicle expansion. Docking/fusion involves formation of a receptor complex including VT11, a vesicle-located Soluble *N*-ethylmaleimide-sensitive factor Adaptor protein **RE**ceptor (v-SNARE, see Chapter 4), coming together with a vacuolar membrane syntaxin protein, VAM3. Once within the vacuole (Fig. 20.5), breakdown involves several enzymes that in plants include VPE-type metacaspases (see Section 20.7.1).

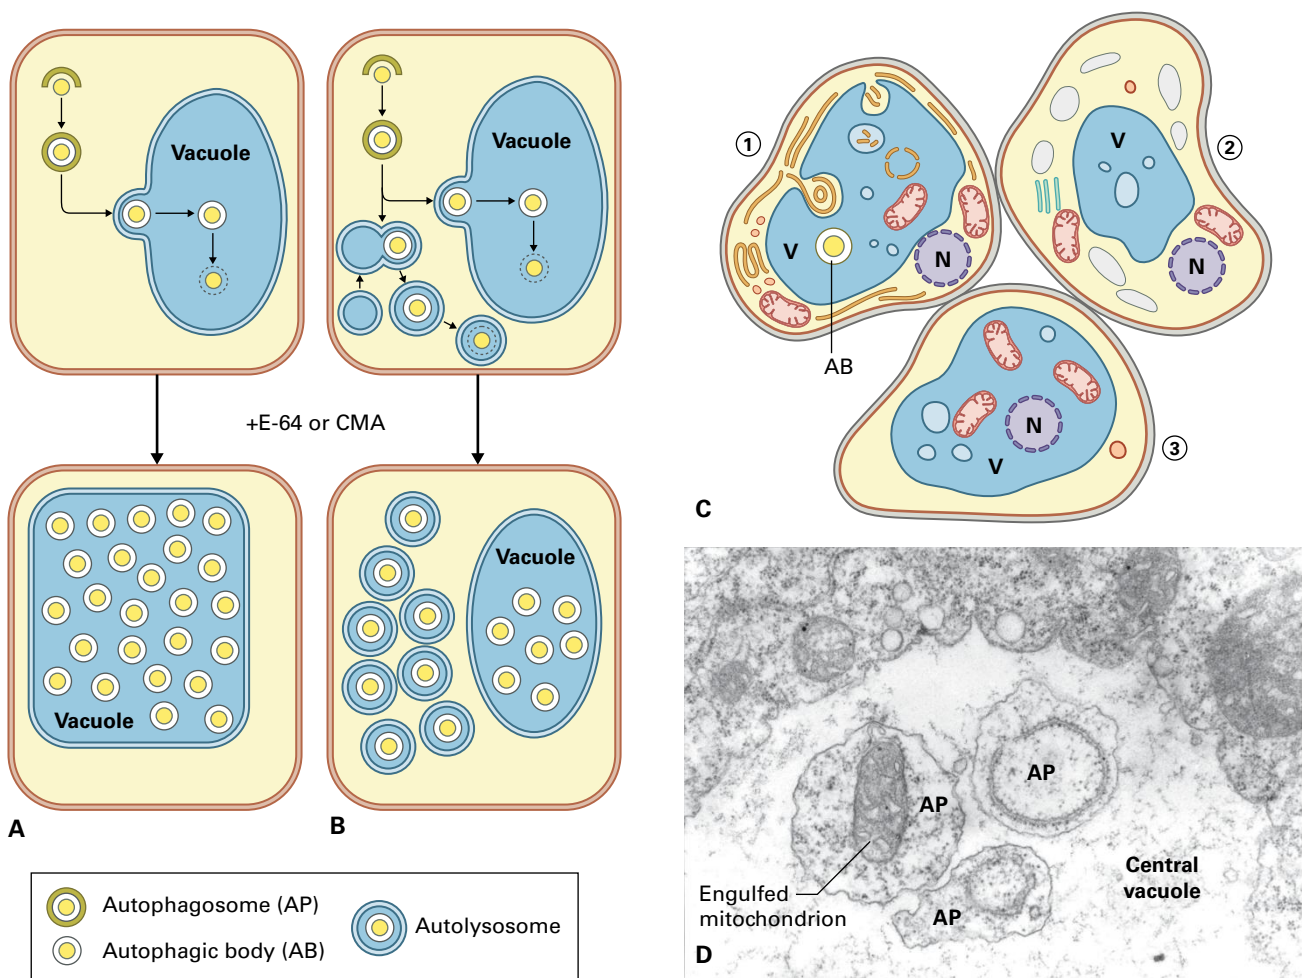

FIGURE 20.5 Autophagy pathways in plant cells. (A) Induction of autophagy in Arabidopsis and many other species results in formation of a double-membrane autophagosome around a portion of cytoplasm. The outer membrane fuses with the tonoplast and the inner membrane and contents enter the lumen of the vacuole (Vac) and are degraded (upper panel). Treatment with inhibitors of vacuolar proteases (E-64, CMA) results in accumulation of autophagic bodies inside the vacuole (lower panel). (B) In tobacco (*Nicotiana* spp.) an additional autophagy pathway operates, in which autophagosome contents are degraded by fusion with small lysosomes in the vacuole (upper panel). Treatment with E-64 or CMA leads to accumulation of autolysosomes in the cytoplasm as well as autophagic bodies in the vacuole (lower panel). (C) Autophagy in some dying senescing corolla cells of *Ipomoea tricolor*. The three cells shown represent different stages of PCD, 1 being the earliest, and 2 and 3 later stages of autophagy. AB, autophagic body; N, nucleus; V, vacuole. (D) Transmission electron micrograph of part of a sucrose-starved cell from a culture of the tobacco (*Nicotiana tabacum*) cell line BY-2 (bright yellow-2) treated with CMA, showing autophagosomes accumulated in the central vacuole, one of which has engulfed an entire mitochondrion.

20.1.3 Plant cells remain viable during most of the developmental program that leads to cell death

An understanding of PCD requires a clear distinction to be made between processes that lead to death, during which time cells are viable, and the final act of death. In some cases the phase preceding death can be arrested or even reversed. Senescence of green (mesophyll) cells of leaves is a case in point. Mesophyll cells remain viable until almost all of the leaf's resources have been exported. While their plastids and other organelles are salvaged, senescing leaves remain turgid, indicating the continued integrity of membranes, cell compartments, and water relations. Wilting as a result of loss of cellular turgor and consequent cell death is a late event in leaf senescence. In comparison to the time-scale of the senescence phase, the terminal autolytic process of declining viability itself is probably very rapid.

Cell death in plants permits developmental and biochemical plasticity. Almost all phases of the plant life cycle are influenced by PCD. The following sections will describe some instances of PCD that occur during plant development, starting with seed germination and proceeding through vegetative and reproductive development.

20.2 PCD during seed development and germination

The seeds and fruits of many species are albuminous, that is, they store reserve materials to support germination in endosperm, the product of the second fertilization event when one of the two pollen grain nuclei fuses with the polar nuclei of the female gametophyte. Cereal endosperm comprises two cell types: **starchy endosperm** and **aleurone**. Aleurone cells are derived from maternal tissue, and studies of maize (*Zea mays*) mutants and transgenics show that their identity is determined by their peripheral location at the surface of the starchy endosperm. Both starchy endosperm and aleurone undergo developmentally regulated PCD but follow distinctly different routes. In mature grain, the starchy endosperm is dead, but unlike almost all other eukaryotic cells that undergo PCD, the contents of these cells are not broken down but are preserved, in a desiccated or mummified state. When grain germinates, hydrolytic enzymes are secreted by the scutellum and aleurone layer, and the entire starchy endosperm is degraded. PCD processes during the development of endosperm and aleurone in albuminous seeds of eudicots and other monocots are similar to those described below for cereals.

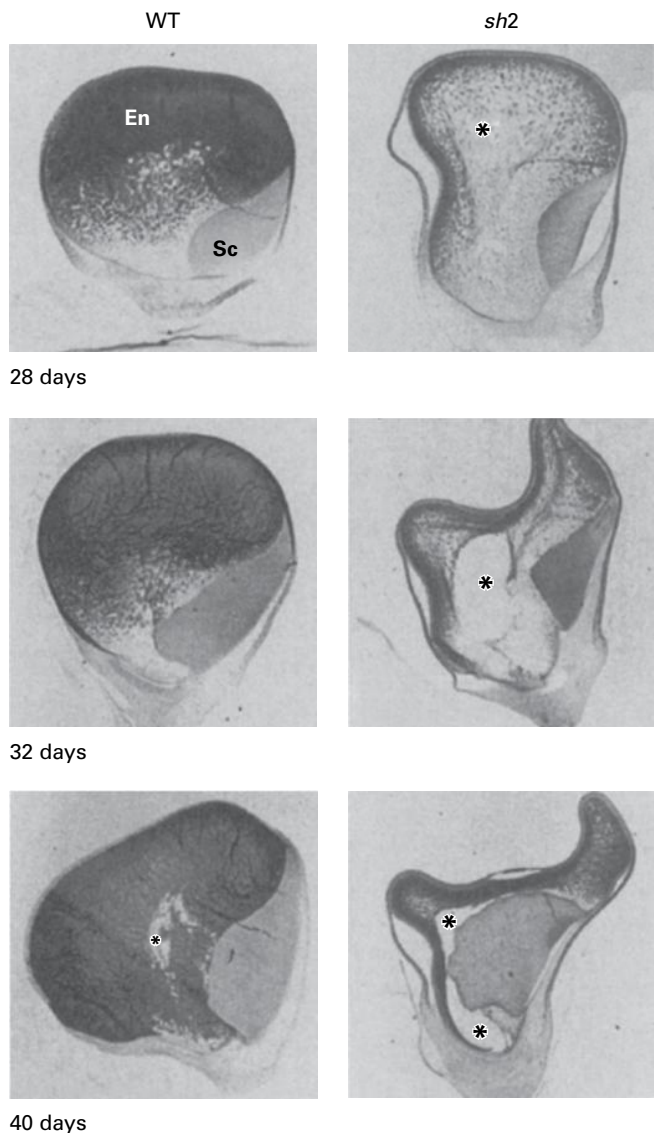

FIGURE 20.6 Endosperm (En) development in wild-type and shrunken2 (*sh2*) maize genotypes. The *sh2* mutant undergoes premature degradation of the starchy endosperm to yield cavities (*). Shown are kernels of wild type (WT) and *sh2* mutant plants at 28 days, 32 days, and 40 days after pollination. The starch is stained with iodine-potassium iodide. Sc, scutellum/embryo. Source: (A–F) Young et al. (1997). *Plant Physiol.* 115:737–751.

20.2.1 During cereal seed development, the contents of starchy endosperm cells undergoing PCD are preserved

Mutations have been identified in maize in which the normal pattern of endosperm development and endosperm cell death is altered. The *shrunkened2* (*sh2*) mutation results in premature death of starchy endosperm cells and degradation of their walls and contents (Fig. 20.6). Laddering of DNA occurs during PCD of *sh2* starchy endosperm cells. Furthermore, unlike

normal starchy endosperm cells, those of *sh2* mutants become autolyzed, which causes endosperm to deform and produces aberrant, shrunken kernels.

An interesting aspect of cell death in starchy endosperm of maize concerns the role of ethylene, a hormone frequently associated with senescence (see Section 20.11.2). Ethylene production is much higher in kernels of *sh2* mutants relative to wild type, and treatment of developing wild-type kernels with ethylene brings about an increase in cell death and production of aberrant kernels (Fig. 20.7). Additional evidence that ethylene might be an important player in regulating PCD in maize kernels comes from experiments with ethylene biosynthesis inhibitor aminoeth-

oxyvinylglycine (AVG). AVG reduced the extent of DNA fragmentation in *sh2* starchy endosperm cells and decreased the size of the central cavity formed in aberrant kernels (see asterisks in Fig. 20.6).

20.2.2 Gibberellic acid and abscisic acid are important regulators of cell death in cereal aleurone

Unlike cells of the starchy endosperm, aleurone cells remain alive until germination and endosperm mobilization are complete, whereupon they undergo autolysis and die (see Fig. 20.8). **Gibberellic acid (GA)** and **abscisic acid (ABA)** tightly regulate this process. Whereas GA stimulates onset of PCD in aleurone layers of barley (*Hordeum vulgare*) and wheat (*Triticum aestivum*), ABA postpones PCD (Fig. 20.9). The effects of ABA on cell death in barley aleurone are dramatic. ABA-treated aleurone protoplasts can be kept alive for more than 6 months, whereas GA treatment of protoplasts brings about death of most cells in 5–8 days.

The **protein storage vacuoles (PSVs)** of aleurone cells become acidic, lytic compartments within the first few hours following GA treatment. Aleurone cells contain PSVs that have a luminal pH of around 7, but after 3–4 hours of GA treatment the lumen reaches a pH of 5.5. The vacuoles of GA-treated cells also accumulate a spectrum of acid hydrolases, including several aspartic and cysteine proteases, as well as nuclease activities. Vacuoles in ABA-treated cells that do not undergo PCD lack these enzyme activities and maintain a pH near neutrality. The function of PSVs in GA-treated aleurone cells resembles that of vacuoles in senescing photosynthetic cells (see Section 20.7.1). The vacuoles of both kinds of tissue contain similar lytic enzymes and, in contrast to the PCD process in tracheary elements for example (see Section 20.3.2), they retain an intact tonoplast throughout the period of macromolecule breakdown and export. During GA-induced PCD, aleurone DNA is not degraded by laddering but instead is cleaved directly into small fragments that are not resolvable by electrophoresis (Fig. 20.10) or TUNEL.

FIGURE 20.7 Ethylene can cause kernel deformation in wild-type maize kernels. Shown are a control kernel of wild-type maize (A) and an ethylene-treated kernel (B) 32 days after pollination. The arrow points to dead cells in the scutellum. The starch is stained with iodine-potassium iodide. En, endosperm; Sc, scutellum/embryo. Source: (A, B) Young et al. (1997). *Plant Physiol.* 115:737–751.

FIGURE 20.8 PCD in the cereal aleurone is accompanied by an autolytic process during which there is extensive vacuolation of the cytoplasm without rupture of membranes or the formation of autophagic vacuoles. In the barley (*Hordeum vulgare*) aleurone cell (left) small protein storage vacuoles (PSV) lose their stored protein and fuse to form one large central vacuole (right). Membrane integrity is maintained until death ensues. Source: P. Bethke & R. Jones, University of California, Berkeley; previously unpublished.

FIGURE 20.9 Gibberellic acid (GA) promotes PCD and abscisic acid (ABA) delays PCD in barley aleurone cells. Aleurone cells were incubated in a medium containing 5 μM GA or 25 μM ABA; cell death was monitored by counting the number of live cells.

20.2.3 In cereal aleurone, cyclic GMP and nitric oxide may participate in the signaling pathway that leads to PCD

The signal transduction cascade leading to GA-induced synthesis and secretion of hydrolases has been extensively studied and is known to include cytosolic free Ca^{2+} , cytosolic pH, cyclic GMP, and calmodulin (CaM) as well as protein kinases and protein phosphatases. In contrast, much less is known about the signaling components that promote GA-induced death in cereal aleurone cells. Evidence in favor of an important role for protein phosphorylation comes from experiments in which aleurone cells have been treated with inhibitors and synthetic substrates. Blocking a cGMP-linked GA-signaling pathway reduces expression and secretion of α -amylase and prevents GA-induced increases in nuclease activities, DNA degradation, and cell death. This makes cGMP a likely candidate for the GA signal transduction pathway that leads to cell death in aleurone cells.

Recently nitric oxide (NO) has become recognized as a significant player in PCD processes in plants. NO donors such as sodium nitroprusside delay GA-induced cell death in barley aleurone, and NO scavengers accelerate the process. Aleurone tissue is able to make NO nonenzymatically from nitrite. The mechanism by which cells perceive NO and how this relates to signaling pathways for aleurone PCD are not clear. NO is known to react with heme-containing proteins, such as guanylyl cyclase, which is activated by NO to generate cGMP. NO also nitrosylates proteins containing exposed thiol groups, causing reversible conformational changes. NO is a potent antioxidant too. Any or all of these properties may turn out to be critical in the regulation of PCD in aleurone and other tissues.

20.3 Cell death during the development of secretory bodies, defensive structures and organ shapes

During embryogenesis in animals, structures are often formed by cell migrations (gastrulation). Generation of morphological and anatomical structures by gastrulation-type cell movement is not possible in plants because plant cells are locked in place by their rigid walls. Instead, plants typically

rely on localized cell death to regulate volume-to-surface-area ratios and develop spaces for transport and secretion.

Botanists use the term **lysigeny** to refer to the disintegration of cells that occurs when new structures are differentiated in this way. Lysigeny, with or without cell separation (**schizogeny**), is responsible for the differentiation of secretory ducts, cavities, and canals in many species. Cell and cytoplasm elimination processes similar to lysigeny and schizogeny in outcome are widely deployed by plants to sculpt external and internal structures into well-adapted configurations necessary for efficient function and survival. A developmental PCD process, with similarities to lysigeny, that is universal among higher plants is formation of the thick-walled cells lacking protoplasm that are essential components of vascular and supportive tissues. Examples of the sculptural roles of PCD in morphology and anatomy are discussed in subsequent sections.

20.3.1 Localized cell death during the differentiation of secretory structures occurs by lysigeny and schizogeny

Oil glands on the surfaces of citrus fruit develop because a group of subepidermal cells undergoes **schizolysigeny**, a combination of lysigenous and schizogenous PCD, forming a cavity that fills with essential oil (Fig. 20.11). Mucilaginous canals found in the bud scales of *Tilia cordata* (small-leaf linden, small-leaf lime) arise exclusively by lysigenous cell death, whereas air spaces in *Avicennia marina* (mangrove) leaves are schizolysigenous in origin. The resinous secretory ducts in the phloem of plants of the sumac family (Anacardiaceae) develop schizogenously and are the source of urushiol, the severe allergen in the sap of poison oak and poison ivy (*Toxicodendron* spp.).

Many trichomes, thorns or spines on the surfaces of leaves and stems are dead at maturity. Extreme examples of this are seen in cacti, in which green stems functionally replace leaves, and leaves are reduced to spines. Localized cell death during foliar development is also responsible for indentations and

FIGURE 20.11 Formation of an oil gland in citrus peel occurs by a combination of lysigeny, the death and dissolution of the protoplasm and cell wall, and schizogeny, wall separation to produce an intercellular space. The resulting cavity becomes filled with essential oils secreted from cells surrounding the cavity.

holes found in leaves of some species of the families Araceae and Aponogetonaceae (Box 20.1).

The extent to which lysigeny, autophagy and the other kinds of autolytic PCD process have common mechanisms of regulation and biochemical execution has not been established by systematic comparative studies.

20.3.2 PCD during tracheary element formation is studied in vitro using cultured *Zinnia elegans* mesophyll cells

Xylogenesis (wood formation) is a type of developmentally regulated PCD initiated during embryogenesis and continued throughout the life of the plant. Xylem typically contains tracheary elements (TEs), the vessel elements and tracheids of the water-conducting system (Fig. 20.12). During the final stages of differentiation, TEs undergo secondary cell wall thickening, followed by autolysis of protoplasm and cell death. All that remains of the cell in its final differentiated form is the cell wall with its characteristic secondary thickenings. Connected end to end, these hollow tubes form the vessels through which water is conducted.

Differentiation of TEs normally takes place from procambium and cambium but the process can be reproduced in vitro using cultured zinnia (*Zinnia elegans*) mesophyll cells, isolated from intact leaves. When isolated cells are incubated in a culture medium containing an auxin and cytokinin as many as 40–60% dedifferentiate and then re-differentiate into TEs in the absence of cell division (Fig. 20.13). Differentiating TEs develop secondary cell wall thickenings characteristic of those found during differentiation in vivo. Shortly after the secondary wall thickenings become visible, the tonoplast ruptures. This may be the committed step to death, as it is followed by breakdown of the remaining organelles and ultimately the loss of cell contents. Breakdown of protoplasm is paralleled by an increase in activity of degradative enzymes including DNases, RNases, and proteases.

In vitro induction of TE differentiation provides an ideal system for studying the development of cells in which programmed death is essential for final form and function. A large population of cells can be induced to undergo the process synchronously, allowing biochemical and molecular analyses of the events that accompany differentiation. This differs from most in vivo systems, where only a few cells differentiate at once, and those are embedded within other tissues.

20.3.3 Events during in vitro formation of zinnia tracheary elements comprise three stages

In the zinnia in vitro system, the process of TE formation occurs in 4 days and has been divided into three distinct stages—(1) dedifferentiation, (2) restriction of developmental

BOX
20.1

How PCD can modify leaf morphology

A freshwater plant popular with aquarists, the lace plant (*Aponogeton madagascariensis*, Aponogetonaceae) undergoes an unusual form of leaf sculpting that creates a delicate latticework. Starting early in leaf development, regions of cells experience PCD so that perforations form as the lamina expands. As in the case during differentiation of tracheary elements, the tonoplast membranes of lace plant cells rupture early in the PCD process, releasing the vacuolar contents. In contrast, the nuclei retain their integrity until late in the process, and although the genomic DNA becomes fragmented, it does not exhibit the laddering pattern seen in apoptosis. In addition to the cell contents, the walls of dying cells are also degraded during PCD, with cellulases acting early in the development of perforations and pectinases active throughout the whole period of lace plant leaf development. Later, the walls of living cells surrounding the perforations become modified by deposition of suberin (see Chapter 24), which may prevent the further spread of PCD and protect the cells from invasion by microbes.

Of the other plants that use PCD to create holes and indentations in their leaves, the best known is the Swiss cheese plant, *Monstera deliciosa* (Araceae). Unlike the lace plant, in *Monstera* the targeted leaf cells do not undergo cell wall degradation. Early in development, the leaf blade forms distinctive perforations as discrete patches of cells die. These initially minute perforations increase by about 10,000-fold in area as the leaf expands. The occurrence of PCD over a short period of time rather than throughout leaf development results in a relatively small number of holes or interruptions to the leaf surface.

In contrast to the lysigeny-like origin of holes in the leaves of *Aponogeton madagascariensis* and *Monstera*

deliciosa, the dissected, fan-like leaves of palms arise by cell separation (schizogeny). Corrugations (plications) are formed through intercalary growth, followed by dissection of the initially simple leaf blade through an abscission-like process of leaflet separation. Phylogenetic analyses of the diversity of mechanisms employed during development of perforated and dissected foliage indicate that recruitment of cell death and cell separation programs for sculpting leaves has occurred independently several times during plant evolution.

potential, and (3) TE-specific development. The expression patterns of many genes change as these stages progress (Fig. 20.14). Genes expressed during dedifferentiation (stage 1) include those involved in wound responses in plants, such as the protease inhibitor genes *ZePI-1* and *ZePI-2*, the pathogenesis-related gene *ZePR*, and those involved in protein synthesis, such as ribosomal protein (RP) and elongation factor (EF) genes. Different transcripts for genes involved in phenylpropanoid metabolism (see Chapter 24 and Section 20.6.3) are present at various stages, with phenylalanine ammonia lyase (PAL) and cinnamic acid 4-hydroxylase (C4H) expressed in both stages 1 and 3

and cinnamyl alcohol dehydrogenase (CAD) accumulating in stages 2 and 3. Tubulin (*Tub*) genes are expressed during all three stages. Onset of stage 2, during which the cultured cells commit to TE formation, is characterized by the appearance of tracheary element differentiation-related (TED) transcripts.

Secondary cell wall thickenings are laid down during stage 3 of zinnia cell culture. Immunocytochemistry has shown that arabinogalactan- and extensin-like proteins as well as novel glycoproteins accumulate in the TE cell wall. After secondary walls have been laid down, the protoplast degenerates. Electron microscopy indicates that autolysis of cell contents is

FIGURE 20.12 TE in the primary xylem of castor bean (*Ricinus communis*) showing annular (A) and double helical (B) thickenings in the cell walls of vessel elements.

brought about when the tonoplast ruptures and releases lytic vacuolar enzymes into the cytosol.

Genes encoding lytic enzymes (e.g., proteases and nucleases) are expressed during late stage 2 and early stage 3. Genes for cysteine proteases and an S1-type nuclease (ZEN1) have been cloned, and biochemical evidence confirms localization of these gene products in differentiating TE. Transient suppression of *Zen1* expression has shown ZEN1 to be the key nuclease in degradation of nuclear DNA. In addition to cysteine proteases, at least three serine proteases are found in zinnia TE. One of the serine proteases may be a secreted enzyme that is involved in regulating TE differentiation. There is evidence for a regulatory role for cysteine proteases and the proteasome (see Chapter 10) in initiating the death program. For example, when inhibitors of cysteine protease are added to zinnia cells before the start of secondary wall thickening, further TE differentiation is blocked. Inhibitors of proteasome activity also lead to arrest of TE formation. However, no specific protease has so far been shown to be indispensable for TE PCD. It appears that lignification continues following PCD, using precursors provided by adjacent cells.

G Isolated mesophyll cells

H Differentiated tracheary elements

FIGURE 20.13 The redifferentiation of cultured zinnia mesophyll cells into TE involves PCD. (A) A cultured mesophyll cell with its complement of cellular organelles. After induction by modification of the hormone content of the culture medium, the cell dedifferentiates (B), then differentiates to form sequentially a TE precursor cell (C), an immature TE with characteristic secondary cell wall thickenings (D), a maturing TE, in which lysis of the vacuole is followed by total degradation of the cellular contents (E), and finally a mature, dead, empty TE (F). (G) Cultured mesophyll cells, under normal light microscopy, in which small, green chloroplasts can be seen at the outer periphery of the cytoplasm. (H) Mature TE generated from a cultured mesophyll cell. This empty cell is stained with fluoroglucinol, which fluoresces in the presence of lignin and highlights the banded secondary cell wall. CaM, calmodulin.

Source: (G, H) A. Groover, University of North Carolina, Chapel Hill; previously unpublished.

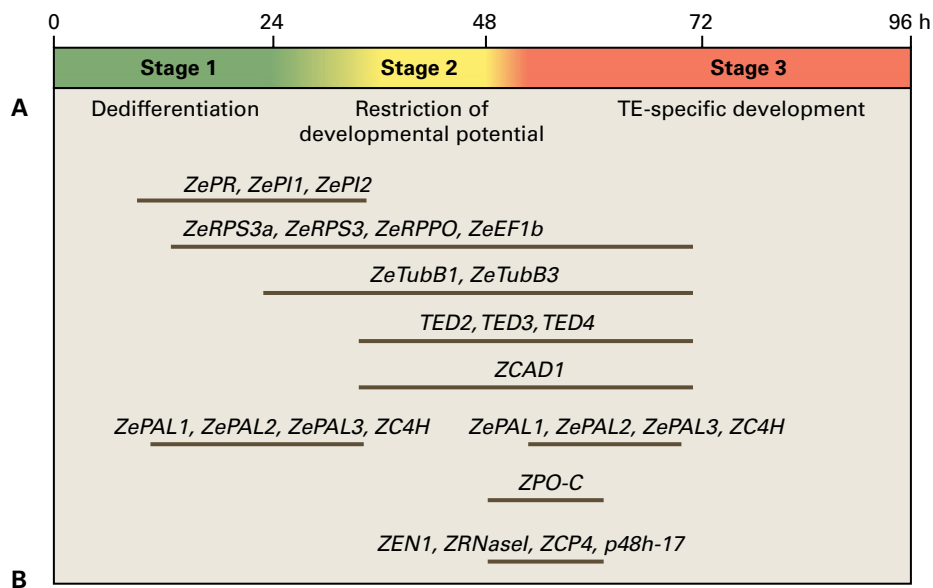

FIGURE 20.14 Stages of gene expression during zinnia mesophyll redifferentiation. TE differentiation has been divided into three stages totaling about 96 hours. The identities of most of the genes expressed during these stages are discussed in Section 20.3.3. Among the genes not named in the text are ZPO-C (a peroxidase gene), ZRNaseI, and ZCP4 and p48h-17 (possible cysteine proteases).

20.3.4 In addition to auxin and cytokinin, Ca^{2+} and proteases appear to promote PCD in zinnia TE

PCD in zinnia lacks the hallmark cellular events associated with apoptosis. Rupture of the tonoplast is accompanied by changes in the organization of cellular organelles and cell wall (Fig. 20.15). Lignification of the cell wall occurs after the tonoplast breaks, and the plasma membrane remains intact until almost all recognizable organelles have disappeared. This form of PCD may be particularly suited to the disposal of all cellular materials required to provide a clear pathway for water movement in the TE.

Auxins and cytokinins are required for zinnia TE differentiation, but other putative signaling molecules also play important roles in this process. Ca^{2+} and CaM have been shown to be likely players in signaling pathways leading to TE differentiation. For example, removal of Ca^{2+} from culture medium reduced TE formation from 50% to less than 10%, and Ca^{2+} channel blockers are effective in inhibiting TE differentiation when applied at any time during the first 48 hours of culture. Differentiation of TE can also be blocked by applying CaM antagonists to the culture medium. Ca^{2+} may be an important player in the cell death stages of TE formation as Ca^{2+} channel blockers can prevent cell death in differentiating TEs. There is also compelling evidence linking other molecules (NO, for example) to the initiation of cell death in zinnia TEs.

A secreted serine protease that accumulates in the incubation medium of cultured zinnia has also been shown to have an effect on PCD of TEs. Several types of experiments have shown that this serine protease may play a role in PCD of cultured zinnia cells. First, addition of soybean (*Glycine max*)

trypsin inhibitor to TE culture media inhibited cell death and arrested TE differentiation. The soybean inhibitor also inhibited the activity of a 40-kDa serine protease that accumulated in the medium coincident with cell death. Second, proteolytic enzymes such as trypsin or papain dramatically accelerate cell death of TEs when added to culture media. Effects of added trypsin on TE PCD can be reversed by lowering the Ca^{2+} concentration of the incubation medium or by adding Ca^{2+} channel blockers. These data were interpreted as showing the involvement of Ca^{2+} in protease-mediated PCD during TE formation.

20.3.5 TE formation has also been studied in *Arabidopsis* and *Populus*

Cell death in TEs has been analyzed in model systems in addition to zinnia. *Arabidopsis* has been used to study gene expression patterns during TE differentiation in vivo and to identify mutants affected in TE PCD. Several *Arabidopsis* homologs to zinnia TE-specific genes have been identified. Functional evidence for roles of such genes in TE PCD has been provided only for a paralogous pair of vacuolar cysteine proteases, XYLEM CYSTEINE PROTEASE1 (XCP1) and XCP2, and for an S1-type ZINNIA ENDONUCLEASE1 (ZEN1). ZEN1 was shown to promote nuclear DNA degradation in the zinnia tracheary elements in vitro, while a detailed immunolabeling analysis showed that XCP1 and XCP2 participate in clearing of TE cell contents. Studies in *Arabidopsis* have also addressed whether TE PCD is controlled as an independent process or is an inevitable fate following deposition of secondary cell walls. Transgenic *Arabidopsis* plants overexpressing *NAC SECONDARY WALL THICKENING*

FIGURE 20.15 Structural changes in the organelles of differentiating zinnia TE. The sequence of organelar changes is shown in relation to the status of the tonoplast and plasma membrane.

PROMOTING FACTOR1, 2 and 3 (*NST1-3*) display ectopic deposition of secondary cell wall thickenings in parenchyma cells without concomitant cell death. Conversely, *gapped xylem* (*gpx*) mutant plants display PCD without apparent secondary cell wall formation, demonstrating that secondary cell wall formation and PCD can be independent of each other.

The large size of tree trunks enables separation of discrete cell layers by tangential sectioning, and the availability of extensive genomics resources for the model genus *Populus* allows patterns of gene expression to be localized by transcriptional profiling. Figure 20.16 shows a micrograph of a section of the woody tissue of hybrid aspen (*Populus tremula* × *tremuloides*) in which the age-gradient of xylem at increasing distance from the cambium represents stages in cell death. Expression of cell death-related genes across the gradient is represented by a **heat-map** (a matrix in which intensity of expression is color-coded). Among the genes highly expressed are homologs of *Arabidopsis* genes encoding XCP2, VPE isoforms α and γ , and METACASPASE9 (*AtMC9*), all of which

are implicated in control of TE PCD or other PCD processes in plants. It is notable that xylem fibers of hybrid aspen undergo a cell death program differing significantly from that of TEs. PCD in xylem fibers proceeds slowly, involving gradual degradation of cytoplasmic contents. Upregulation of several autophagy-related genes in fibers, but not in TEs, suggests that cytoplasmic lysis in fibers is an autophagic process (Fig. 20.16).

20.4 PCD during reproductive development

As Figure 20.17 illustrates, PCD occurs throughout reproductive development, a topic discussed in detail in Chapter 19. This section focuses on the role of PCD in floral organ and gamete formation, pollination, and early embryo development.

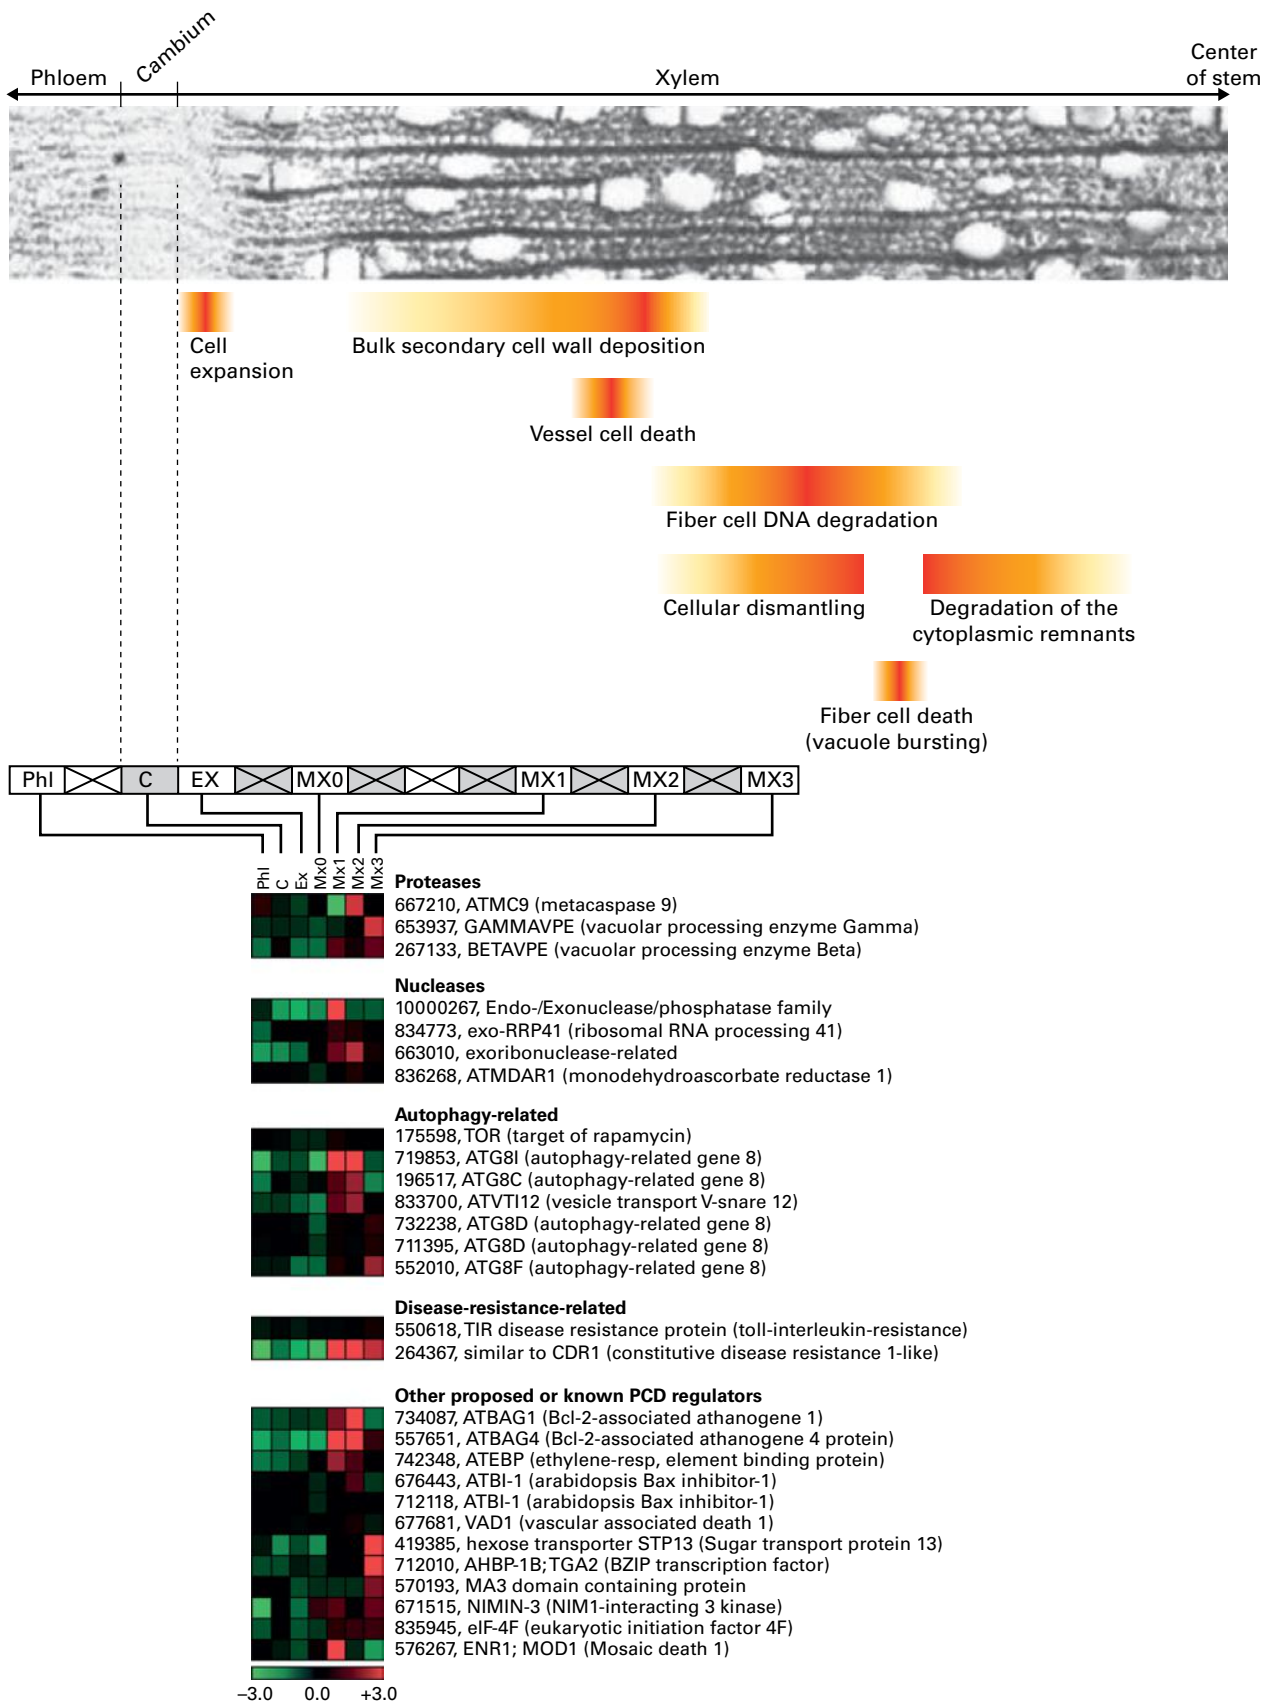

FIGURE 20.16 Gene expression during xylem development in the woody tissues of hybrid aspen (*Populus tremula* × *tremuloides*) stem. Samples were collected from the trunks of *Populus* trees by cryosectioning 50- μ m sections in the tangential plane. The lower part of the figure is a heat map representation of expression levels for *Populus* genes that show statistically significant upregulation during the late stages of xylem development and are homologous to known regulators of cell death or autophagy-related genes in *Arabidopsis*; the annotation given for each *Populus* gene corresponds to the name of the most similar *Arabidopsis* gene. Expression values are derived from a microarray analysis and are shown as relative values in \log_2 scale.

20.4.1 Selective death of male or female floral parts occurs during development of unisexual flowers

Flower development is radically affected by PCD of selected cells or groups of cells. In most plants that have unisexual flowers, the developing flower initially contains primordia for both male and female organs. At early stages, male and female flowers are indistinguishable. During flower formation, at a developmental stage that varies with plant species, either male or female parts cease growing and are eliminated via a cell death program. For example, in maize the male inflorescence (tassel, Fig. 20.18A) is spatially separate from the female inflorescence (ear). Young flowers in the tassel contain primordia for both stamens and gynoecium, but as the flowers develop, gynoecial cells stop growing and dividing, and organelles, including the nucleus, break down. In *tasselseed 2* mutants, however, arrest and degeneration of gynoecia do not occur, and female flowers are produced in tassels (Fig. 20.18B). Thus, *TASSELSEED 2* (*TS2*) is required for death of developing female organs in tassels. *TS2* is expressed in gynoecial cells in tassels just before the start of gynoecial degeneration. *TS2* encodes a product with similarity to hydroxysteroid dehydrogenases, raising the possibility that it may regulate cell death by generating a steroid-like molecule that acts as a signal in the cell death pathway. *TS2* is also expressed in pistils of female spikelets, but primary pistils do not undergo *tasselseed*-mediated cell death because its action is suppressed by another gene, *SILKLESS 1* (*SK1*). *TS2* and *SK1* are among a group of genes that control the sexual

identity of maize flowers by selectively promoting or inhibiting cell death in different tissues (Fig. 20.18C).

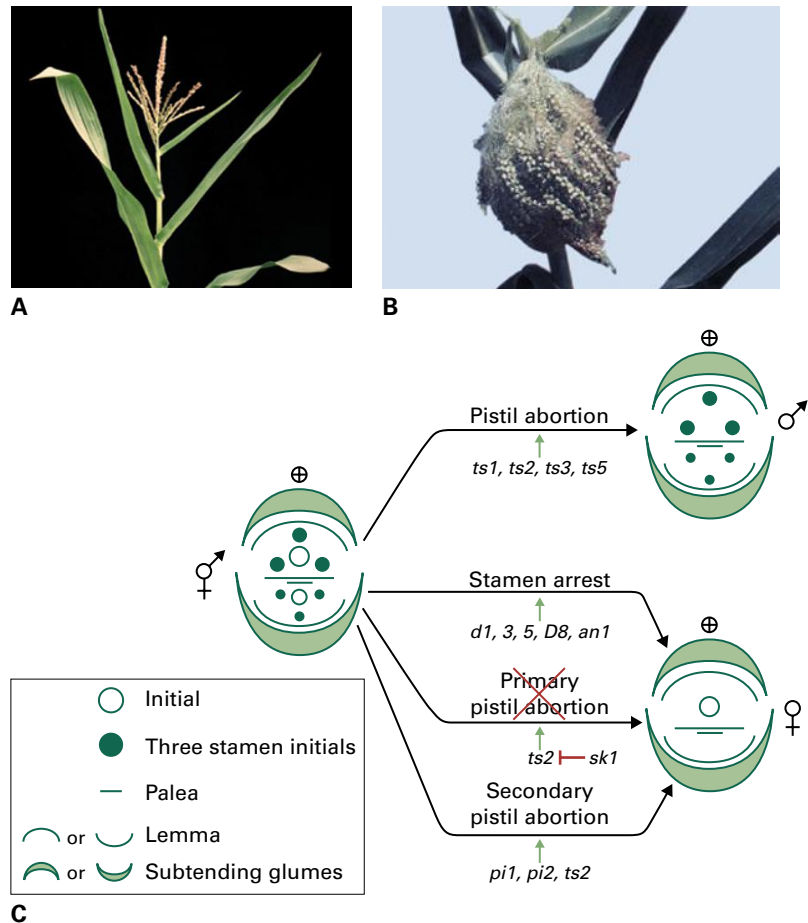

20.4.2 Cell death is an essential part of gametogenesis

Haploid tissues are also influenced by cell death programs. During megagametogenesis in angiosperms, three of four megaspores formed after meiosis of the megaspore mother cell undergo PCD, leaving one megaspore that gives rise to the egg and other components of the embryo sac.

In microsporogenesis, the tapetum that surrounds the microsporocytes dies and disintegrates. Cell shrinkage, condensation of chromatin, swelling of the ER, and the persistence of mitochondria has been observed. Towards the end of the unicellular stage of pollen development, DNA laddering occurs, and the nuclei of tapetal cells and tissues of the anther wall become TUNEL-positive. Release of cytochrome *c* from mitochondria, a characteristic of animal apoptosis, has been also reported. Blocking death of *Arabidopsis* tapetal cells by expressing early in microsporogenesis a transgene that encodes a suppressor of apoptosis results in pollen abortion. Development of viable pollen is also prevented if the tapetum undergoes PCD too early in microsporogenesis. This is a possible explanation for cytoplasmic male sterility (CMS), a phenotype in which pollen abortion is determined by the mitochondrial genome. Many kinds of CMS can be corrected by nuclear restorer genes, reflecting the importance of crosstalk between mitochondria and nucleus in microsporogenesis. One way in which plant

FIGURE 20.18 The inflorescences of maize contain flowers that are initially bisexual, but PCD results in the death of male or female tissues to give rise to a female inflorescence (ear) or male inflorescence (tassel, A), respectively. In the tasselseed2 (*ts2*) mutant (B), female tissues in the tassel do not undergo PCD, and the resulting tassel flowers are mostly pistillate. (C) Maize floral diagrams showing an immature spikelet (left) with two perfect (bisexual) floral meristems, each with a central pistil initial, three stamen initials, a palea, lemma, and subtending glumes. The transition to paired staminate spikelets in the tassel (top right) and to solitary pistillate spikelets in the ear (bottom right) is depicted. Secondary pistils also abort in ear florets (indicated by asterisk). The tasselseed (*ts*) genes are required for pistil abortion in the tassel and in the secondary ear florets. The silkless1 (*sk1*) gene protects primary ear pistils from tasselseed-mediated cell death. Stamen arrest in ear spikelets and in *ts2* mutant tassel spikelets requires dwarf (*d*) and anther ear 1 (*an1*) genes; pistillate (*pi*) genes are required for E2 pistil abortion.

Source: (A) Neuffer et al. (1997). Mutants of Maize. Cold Spring Harbor Laboratory Press; (B) L. Jesaitis, University of California, Berkeley; previously unpublished. (C) Kim et al. (2007). Genetics 177: 2547–2551.

mitochondria contribute to CMS is by releasing cytochrome *c*. We may conclude that the onset of PCD in tapetum is signaled through a relatively narrow developmental window at around the tetrad stage of microsporogenesis and is an example of timely and selective cell death as an essential event in normal differentiation.

20.4.3 Cell death during incompatibility reactions prevents self-pollination

Many plant species employ a self-incompatibility strategy to ensure outcrossing. In *Papaver rhoeas*, the field poppy, the pistil self-incompatibility locus encodes low-molecular-weight S proteins that trigger a Ca^{2+} -dependent signaling network in incompatible pollen. The consequence is a rapid arrest of pollen tube growth, depolymerization of actin, and activation of a MAP kinase cascade. These events in turn promote PCD during which cytochrome *c* leaks into the cytosol, DNA is fragmented, and metacaspases are activated.

Following fertilization in most angiosperms, the first mitotic division of the zygote gives rise to two cells. One produces the embryo. The other develops into the suspensor, which may undergo a few rounds of mitosis but eventually

undergoes PCD. DNA laddering has been observed in maize kernels during degeneration of the suspensor and differentiation of the scutellum, coleoptile, and root cap.

20.5 Senescence and PCD in the terminal development of leaves and other lateral organs

Senescence and subsequent death are the terminal phases of development in all plant organs, including leaves, stems, roots, and flowers. During senescence, plants dispose of unneeded cells and tissues while simultaneously reclaiming valuable resources, especially nitrogen and phosphorus. Senescence generally follows organ maturity and occurs without growth or morphogenesis. It can be dramatically influenced by environmental and endogenous (e.g., hormonal) perturbations. Sometimes senescence is rapid: the petals of *Ipomoea tricolor* senesce after the flower has been open for only one day (Fig. 20.19). In other cases, senescence is not initiated for months or even years. For example *Pinus longaeva*

FIGURE 20.19 Senescence in the *Ipomoea tricolor* corolla is very rapid. Flowers begin to open at around 05:00 to 06:00 hours (stage t_0) and remain open until 1300 to 1400 (t_8) the same day. At that time, the corolla begins to curl and the flower changes color from blue to purple (t_{12}). Curling continues during the day until reaching the final stage (t_{14}), where the corolla has completely curled inward. Source: Shibuya et al. (2009). *Plant Physiology* 149:816–824.

FIGURE 20.20 Leaves of the extraordinary South African desert plant *Welwitschia mirabilis* can live for decades or even centuries. Source: <http://www.biologie.uni-hamburg.de/b-online/earle/welwitschiaceae.htm>.

(bristlecone pine) leaves reportedly have a lifespan of 45 years, and the large strap-like leaf of the desert plant *Welwitschia mirabilis* (Fig. 20.20) has been estimated to survive for up to 1,000 years or more.

We do not know how various cellular senescence programs are integrated during the development and life history of organs or whole plants. There may be a “die now” signal constantly present to which a cell, tissue or organ becomes competent to respond at a time dictated by its individual developmental program. Alternatively, there may be cell-specific die-now stimuli that invoke senescence or death programs in their targets. The phenotypes of some genetic variants, including certain “stay-greens” (see Section 20.5.3) and disease-lesion mimics (see Section 20.10.3), appear to reflect mutations in genes regulating the timing or location of normal senescence and PCD. Analyzing these genes gives

important insights into how selective cell death is deployed in plant differentiation. Sections 20.5 through 20.8 discuss senescence in detail.

20.5.1 Senescing cells undergo internal reorganization and are metabolically active

During senescence, new metabolic pathways are activated and others turned off. A scheme outlining likely steps in the pathway leading to leaf senescence is shown in Figure 20.21. In this scheme, signal transduction cascades linked to various triggers such as hormonal or environmental stimuli lead to an initiation phase involving the activation and inactivation of many genes and the transition to a phase of controlled redifferentiation of cell structures and remobilizing of materials. Finally a termination phase ensues, in which many features of generalized PCD can be recognized. The integrity of organellar membranes and compartmentation of biochemical pathways are preserved until late in the terminal phase.

Leaf and fruit senescence are characterized by dramatic changes in major organelles:

- Chloroplasts of leaf mesophyll cells and green immature fruits respectively redifferentiate into gerontoplasts and chromoplasts (Fig. 20.22).
- As discussed in Section 20.2.2, protein storage vacuoles of germinating (i.e., senescing) aleurone cells form a large central vacuole that maintains the integrity of the tonoplast (see Fig. 20.8); this also occurs in eudicot endosperm and storage cotyledons.
- Oil bodies (**oleosomes**) of cotyledons and endosperm are lost during senescence, and lipid metabolism in these storage tissues is associated with a specialized type of peroxisome (originally referred to as **glyoxysome**), which plays

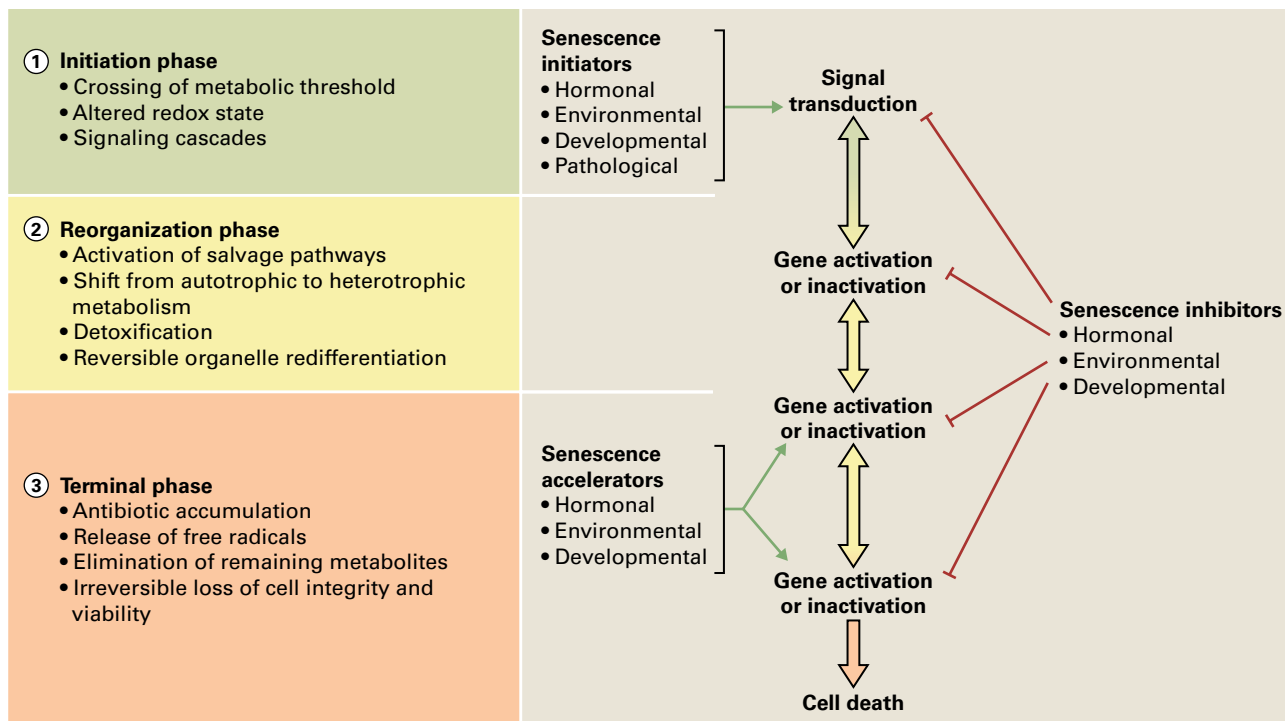

FIGURE 20.21 A proposed scheme showing steps in the process of leaf senescence from the initiating signal to cell death.

FIGURE 20.22 During senescence, chloroplasts in leaves are converted to yellow gerontoplasts, while the chloroplasts of green fruit redifferentiate into yellow, orange, or red chromoplasts during ripening.

an important role in gluconeogenesis (see Section 20.8.1, Chapter 1, and Chapter 8).

- Likewise, the peroxisomes of senescing photosynthetic tissues in many species become specialized for gluconeogenesis (see Fig. 8.65).

These changes in cellular compartmentation distinguish differentiation from deterioration and emphasize that senescence is a programmed process and not a form of necrosis.

Ultrastructural changes in senescing leaf cells are accompanied by biochemical conversions, notably degradation of chlorophyll and storage proteins accompanied by reconfiguration of primary and secondary metabolism. Much of the biochemical activity in a senescing plant cell is directed towards salvage and redistribution of metabolites and structural materials, particularly reserves of nitrogen and phosphorus.

However, other physiological imperatives also influence senescence. Declining photosynthesis means that energy demands of remobilization and other processes are met from heterotrophic sources, a trend associated with modifications to respiratory and oxidative metabolism. Further changes can involve secondary metabolites, which may influence interactions with both pests and beneficial organisms.

Because fertilized flowers would compete with those that have yet to attract pollinators, floral parts tend to have shorter lifespans than leaves (particularly post-pollination), and senescence in these organs is usually irreversible and comparatively insensitive to abiotic environmental influences. As in leaves, senescence of floral parts involves macromolecule breakdown, nutrient salvage and modification of organelle structure and function. Differential PCD occurs either by lysigeny or by an apoptosis-like route.

20.5.2 Applying the tools and resources of plant genomics gives new insights into the nature and control of senescence

DNA microarrays and other high-throughput techniques for gene-expression profiling have generated a wealth of information on gene expression during senescence. The general picture that has emerged is that there is no universal senescence gene expression pattern to be found. Although the overall patterns of gene expression during senescence seem to be similar in most plants, different senescence-inducing treatments in a single species yield unique gene expression profiles. However, entry into senescence is always accompanied by a massive shift in gene expression: numerous genes highly expressed in nonsenescent leaves are turned off, while others—including more than 800 described so far in *Arabidopsis*—are turned on. Many of the genes upregulated in senescence have putative roles in degradation of cellular components. The nomenclature of these genes varies from species to species, including *See* (Senescence Enhanced Expression) from maize, *LSC* (Leaf Senescence Clone) from *Brassica napus*, *SAG* (Senescence-Associated Gene) from *Arabidopsis*, *SENU* (Senescence Upregulated) from tomato (*Solanum lycopersicum*), and *PAUL* (*Populus Autumn Leaf*) from *Populus tremula*. Here we will use *SAGs* as a general designation for genes that are upregulated during senescence. Table 20.2 is a representative list of *SAGs*, compiled from studies of a range of species.

A variety of expression patterns have been observed for *SAGs* (Fig. 20.23). Some are expressed early in senescence, others late. Some appear in natural senescence of attached tissue but not in detached tissue. Gene expression profiles during senescence partially overlap with expression patterns induced by treatment with salicylic acid (SA), jasmonic acid, or ethylene, but distinguishing between primary and secondary events is not a straightforward task, and no clear pattern has emerged that fits a simple model for regulation of gene expression during senescence. Microarray studies can, however, provide much information concerning the classes of genes induced during senescence, including those responding differentially to particular treatments or mutations. Although increased mRNA abundance does not necessarily result in increased protein abundance, it is likely that in most cases higher expression of genes encoding enzymes in a given pathway indicates an increased flux through that pathway. For example, many genes coding for proteases are induced during senescence (Table 20.2). Other *SAGs* encode enzymes involved in remobilization of proteins and amino acids, lipid catabolism, β -oxidation of fatty acids, and gluconeogenesis. Numerous genes encoding metallothioneins (see Chapter 16), perhaps involved with protection against oxidative damage or with ion storage and transport, are likewise highly expressed during senescence. Antifungal proteins, pathogenesis-related (PR) proteins and chitinases (see Chapter 21) are also encoded by *SAGs* in a number of species (Table 20.2). The multitude of factors influencing leaf senescence is illustrated by the

characterization of *ore* mutants of *Arabidopsis*. Mutations in genes encoding a plastid ribosomal protein, a cytokinin receptor, and an F-box protein, among others, are linked to delayed senescence in *ore* mutant plants.

Nuclear genes encoding photosynthetic proteins are by and large turned off as leaves enter into senescence (see Fig. 20.21), and indirect evidence suggests that gene expression in plastids is massively suppressed. Not surprisingly, several genes relating to synthesis of photosynthetic pigments (chlorophylls and carotenoids) are also downregulated, while some flavonoid biosynthesis genes may be induced.

Genes encoding transcription factors show large alterations in mRNA abundance during senescence, and overexpression or downregulation of many of these have resulted in senescence phenotypes. However, causal relationships have been hard to elucidate, as all processes that influence the growth rate or wellbeing of a leaf can potentially delay or accelerate senescence. Nevertheless, *Arabidopsis WRKY53* (see Sections 20.8.2 and 20.11.3) and *AtNAP* are promising candidates. *WRKY53* interacts with more than 60 genes of various kinds, including genes for other transcription factors and for *SAG12*, a vacuolar cysteine protease in the aleurain family that is a recognized marker for senescence in *Arabidopsis*.

Similarities and contrasts between leaf and petal cell senescence are apparent in the complement of genes expressed in the two organs. Transcriptome analysis in *Arabidopsis* indicates that senescing leaves and petals have about 25–30% of expressed genes in common, possibly reflecting the evolutionary origin of petals as modified leaves. A systematic comparison of leaf and petal senescence in wallflower (*Erysimum linifolium*) (Fig. 20.24) identified upregulation in both tissues of remobilization-related genes, such as that encoding an aleurain-like cysteine protease similar to *SAG12*. By contrast, expression of chitinase and glutathione S-transferase defense genes remained constant or fell with age in leaves, whereas they were strongly activated in petals. This suggests that defenses against pathological infection are enhanced during senescence of floral tissues to safeguard healthy development and dispersal of seeds.

20.5.3 Mutant and variant senescence genes have been mapped to specific genomic locations, and some have been isolated by positional cloning

Genetic investigation of senescence has a long history: cotyledon color in peas (*Pisum sativum*) was studied by Gregor Mendel, the father of modern genetics. Plants homozygous for the recessive allele *i* are deficient in chlorophyll degradation (see Section 20.6.1), which results in green cotyledons and delayed yellowing of leaves during senescence. Mendel's gene for cotyledon senescence was recently isolated using a combination of gene mapping, comparative genomics, and functional analysis (Fig. 20.25).

*Classes 1 through 10 correspond to the expression patterns indicated in Fig. 20.23.

[†]Indicates type of enzyme or any other situations where induced expression of the gene has been detected. PR, pathogenesis related; ACC, 1-aminocyclopropane-1-carboxylic acid; MIP, major intrinsic protein.

The mutant gene *stay-green* (*y*), which confers unlimited foliar greenness in the pasture grass *Festuca pratensis* (Fig. 20.25A), was identified by conventional Mendelian analysis. Chlorophyll metabolism in the *F. pratensis* mutant shows similar biochemical abnormalities to Mendel's green cotyledon line. Grasses of the genera *Festuca* and *Lolium* readily form interspecific hybrids, and recombination between their genomes occurs at high rates. The stay-green locus *y* was introgressed from *F. pratensis* into *Lolium perenne* (perennial ryegrass; Fig. 20.25A), where it could be located in the genome by genetic mapping using *Festuca*-specific molecular markers. *L. perenne* is an agriculturally significant temperate pasture

species for which a good genetic linkage map has been established, and comparative studies have shown that much of the *L. perenne* map is co-linear with that of the model monocot, rice (*Oryza sativa*). By using common molecular markers, it is possible to “read across” from a region of the *L. perenne* map to the corresponding map location in rice. When this was done for the map position of the introgressed stay-green gene (on the short arm of *L. perenne* chromosome 5), it identified a region of rice chromosome 9 (Fig. 20.25B) where several research groups had previously located a quantitative trait locus (QTL) governing yellowing in rice leaf senescence. It seemed likely that the *F. pratensis* and rice loci represented the same gene.

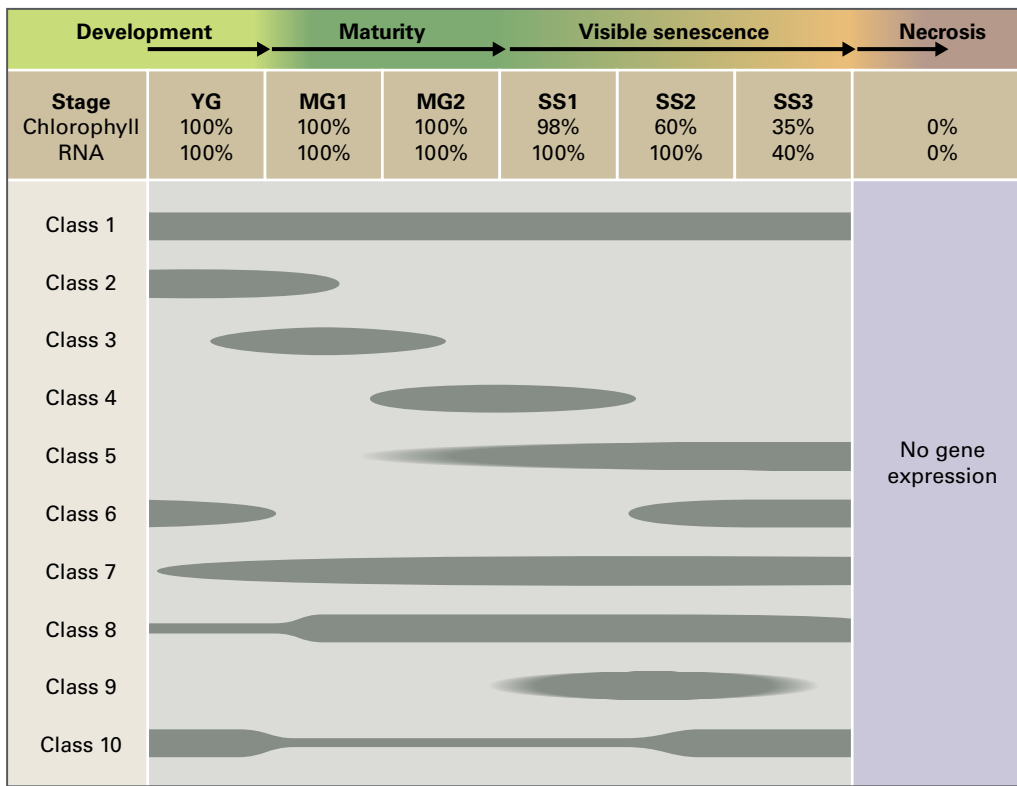

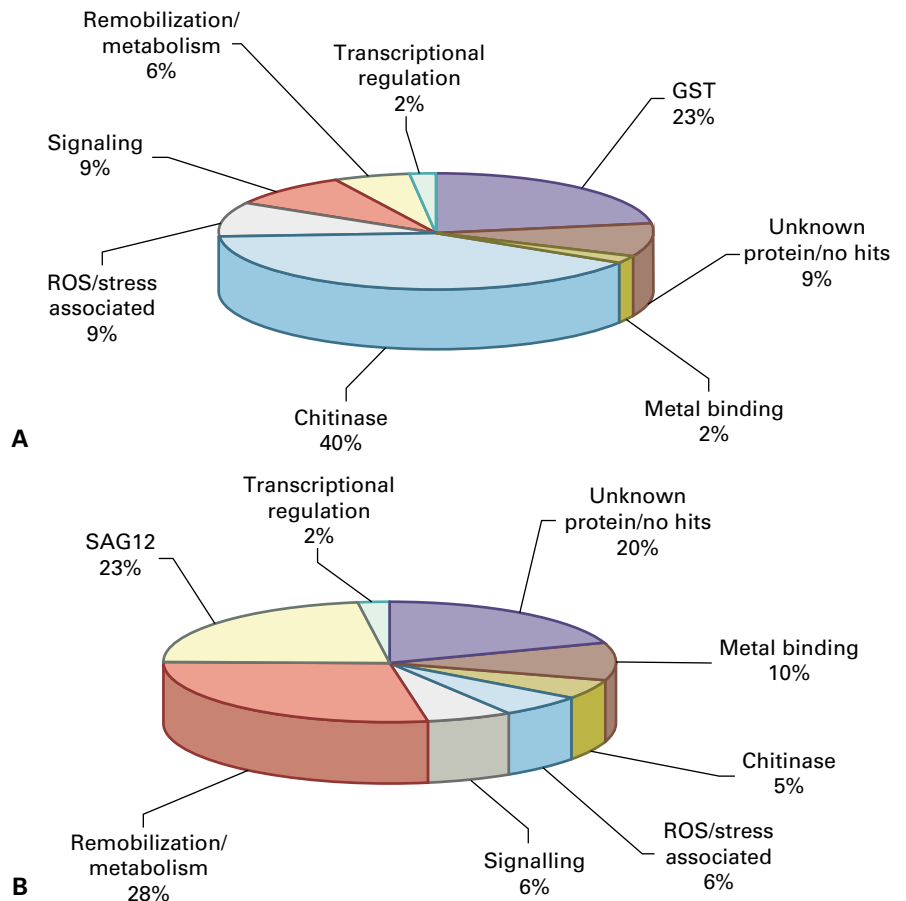

FIGURE 20.23 Stages in *Brassica napus* leaf senescence. SAGs are divided into 10 classes according to their temporal patterns of expression (see Table 20.2). Concentrations of chlorophyll and RNA are quantified as percentages of the concentrations of chlorophyll and RNA present in a mature, expanded leaf. YG, fully expanded leaf; MG1, leaves from flowering plants; MG2, leaves from plants with developing siliques; SS1, SS2, and SS3, visibly senescing leaves.

FIGURE 20.24 Microarray analysis was used to assess expression of genes in senescing leaves and petals in wallflower (*Erysimum linifolium*). (B) Groups of genes upregulated in both senescing petals and leaves. Source: Price et al. (2008). *Plant Physiol.* 147:1898–1912.

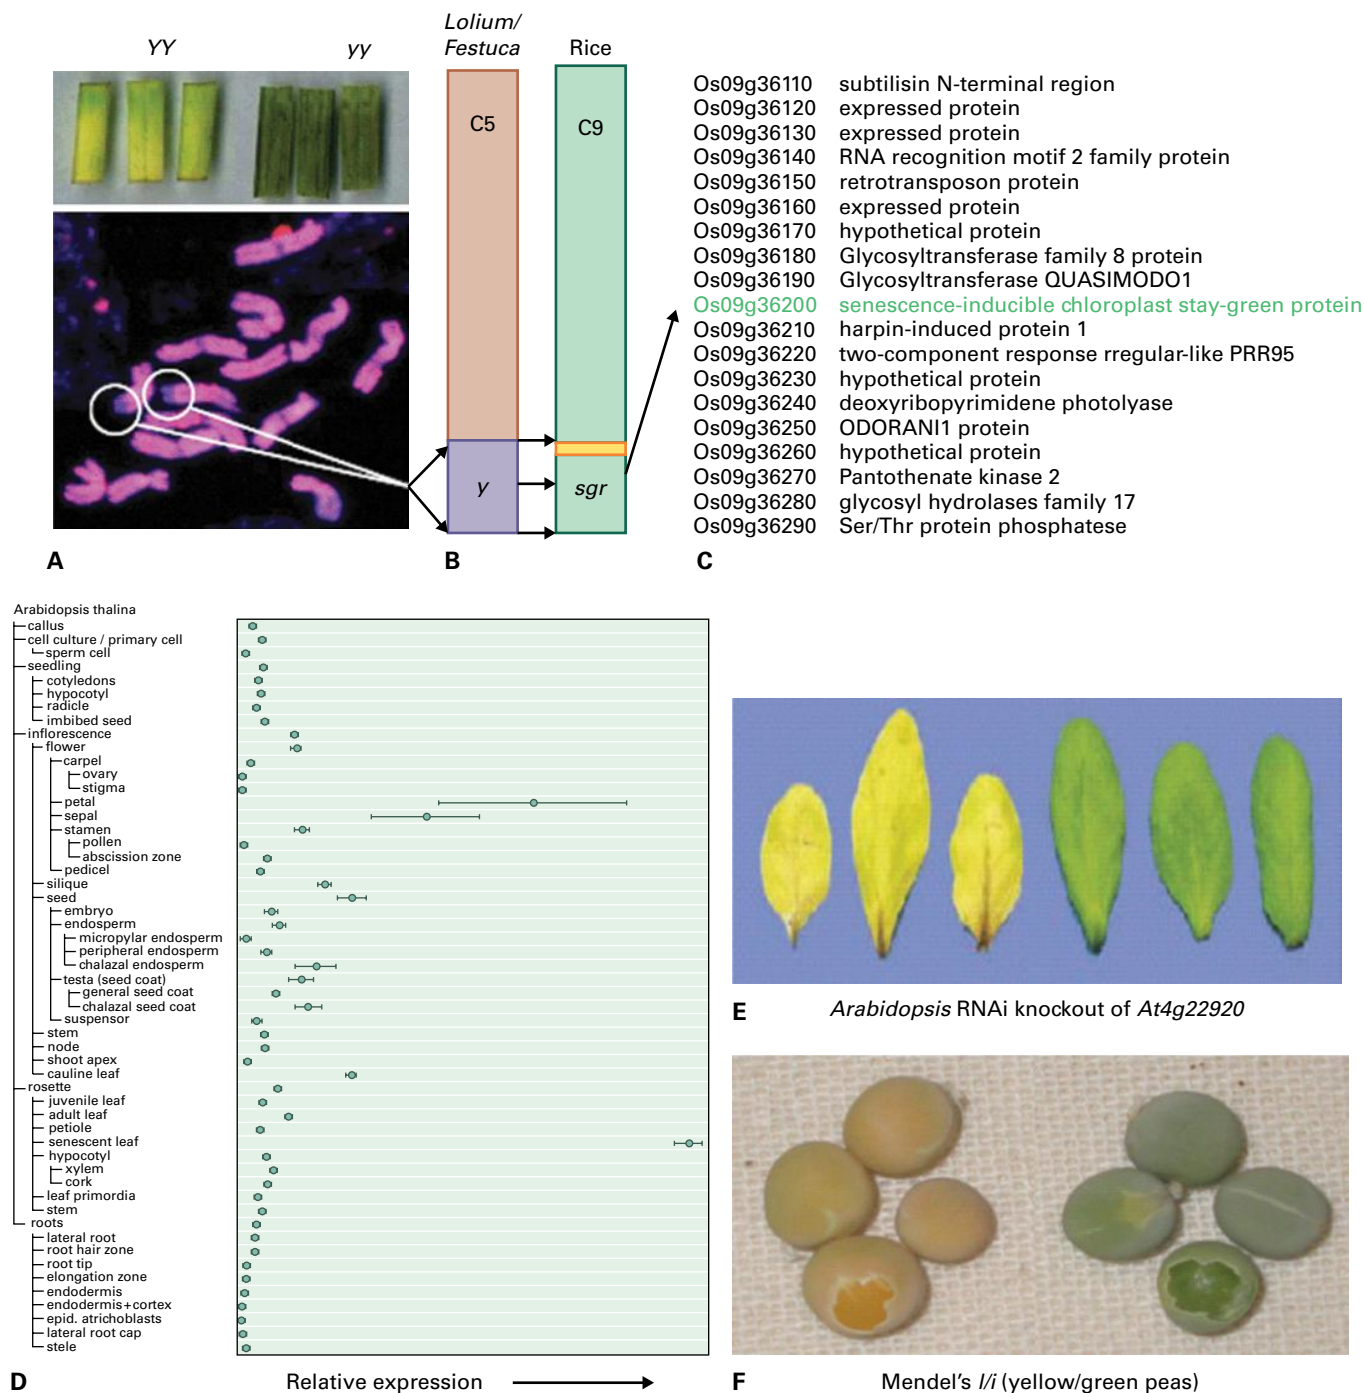

FIGURE 20.25 Isolation of a senescence gene by map-based cloning. (A) The recessive stay-green mutation (*y*) introgressed from *F. pratensis* into *L. perenne* is located in a terminal segment of each of a pair of *L. perenne* chromosomes. (B) Molecular mapping places the *Y* locus in a sector of *Lolium/Festuca* chromosome 5 syntenic with a region of rice chromosome 9, corresponding to *sgr*, a major QTL for rice leaf senescence. (C) The number of candidate genes is narrowed down to about 30 on a single rice BAC. (D) One sequence, Os09g36200, is homologous with *Arabidopsis* At4g22920, which shows very clearly the expected senescence-associated expression pattern. (E) The phenotype of an RNAi knockout of At4g22920 in *Arabidopsis* is identical to that of the *F. pratensis* phenotype. (F) Allelic variation in *SGR* is responsible for the phenotypes of Mendel's green and yellow pea cotyledons.

Source: Jones et al. (2009). *New Phytol.* 183:935–966.

Bacterial artificial chromosome (BAC) libraries of the rice genome are available in which each individual genomic clone has been related to a specific region of the rice genetic map. By reading across from the map position of

the stay-green locus to the rice physical map based on BAC alignments, the gene was narrowed down to a relatively small number of candidates on a few BACs. Further fine mapping in *Lolium-Festuca* introgression lines finally

focused on a single BAC carrying fewer than 20 genes (Fig. 20.25C).

Researchers now turned to *Arabidopsis*, in which sophisticated genomics tools allow putative genes to be rapidly evaluated and characterized. The expression profiles of *Arabidopsis* versions of each of the candidates on the rice BAC were examined, and one stood out as being strongly upregulated in leaf senescence (Fig. 20.25D). Expression of this gene (of unknown function at the time) was targeted for suppression in *Arabidopsis* using the RNA interference technique, and the resulting plants exhibited a stay-green phenotype identical to that of the original *F. pratensis* mutant (Fig. 20.25E). Finally, a combination of mapping and gene characterization showed that this gene, now called *SGR* (*Stay-GREEN*) is responsible for the green/yellow cotyledon trait observed by Mendel in pea (Fig. 20.25F). *SGR* has a highly conserved structure and has been identified not only in angiosperms but also in mosses, unicellular green algae, and prokaryotic cyanobacteria. *SGR* functions in the disassembly of thylakoid photosystem complexes, making chlorophyll and protein available to their respective degradation pathways.

The technique of positional cloning within a QTL has also identified an agriculturally important regulatory senescence gene in cereal species. Wild emmer (*Triticum turgidum* ssp. *dicoccoides*) is an ancestor of durum (pasta) wheat, *T. turgidum* ssp. *durum*. Inbred lines of durum wheat in which chromosome 6 was substituted with emmer chromosome 6 have higher grain protein content (GPC) than nonrecombinant durum wheat. This is associated with more rapid leaf senescence and mobilization of foliar nitrogen in emmer. Molecular mapping narrowed down the region of chromosome 6 responsible for high GPC to a single QTL and finally to a single gene encoding a transcription factor with close sequence similarity to the *Arabidopsis* protein NO APICAL MERISTEM (*NAM*). The *Triticum* spp. gene was designated *NAM-B1*. The *NAM-B1* alleles of durum wheat and hexaploid bread wheat (*T. aestivum* ssp. *aestivum*) are nonfunctional as a consequence of sequence changes that became fixed during cereal domestication. The effect of the *NAM-B1* emmer allele on senescence and GPC in durum wheat is partially moderated by redundancy at two other *NAM* loci in the genome. When transcript levels of all *NAMs* were reduced in hexaploid wheat by applying the RNA interference technique, leaf senescence was delayed by a remarkable 24 days and GPC reduced by 5.8%. Grain of delayed senescence lines was also deficient in Zn and Fe (30% and 24% respectively). This study identifies a critical role for *NAM* genes in regulating cereal leaf senescence and determining the partitioning of nitrogen and minerals between the grain and crop residue.

20.5.4 Delayed senescence has agricultural implications

A survey of stay-green genetic variants, in which senescence has been visibly modified, reveals two broad classes of SAGs. Members of the first group, exemplified by *SGR*, encode enzymes or effectors of the metabolic pathways activated in

senescence. *NAM-B1* is an example of genes in the second class, which regulate initiation of senescence programs or their rate of progress. SAGs in both classes have considerable agronomic importance. For example, the record yield of grain maize, achieved in 1985 on a farm in Illinois, is almost 24 t ha⁻¹. The factors contributing to this extraordinary productivity (over 70% of theoretical maximum) are complex, but it is significant that the variety used was FS854, a stay-green line. In the semi-arid tropics, stay-green is a vital character in the struggle to feed populations living under harsh economic and environmental circumstances. *Sorghum* spp. and *Pennisetum* spp. (millet) lines exhibiting the stay-green phenotype often show enhancement of other desirable characters such as disease and insect resistance, wide environmental adaptiveness, appropriate time to maturity, good tillering, reasonably good grain yield, juiciness, palatability, and digestibility.

Stay-green would seem to be such a desirable trait that it is reasonable to ask why it does not occur in all plants. One group of plants—evergreen shrubs and trees—have adopted this strategy as a fitness attribute for the particular ecological niches they occupy, often related to need for low rates of internal nitrogen recycling in nutrient-poor environments. We have seen that nonfunctional alleles of the *NAM* family confer extended greenness on the durum and bread wheat compared with their wild relatives. Protection of such crop species from consequent competitive and environmental pressures is largely achieved through agricultural practices including control of weeds and pests, water availability and fertilizer supply. Otherwise it seems that stay-greens pay a fitness penalty and are poor survivors in most ecosystems.

Plant breeding has traditionally brought about crop improvement incrementally by empirically selecting more favorable alleles associated with genetic loci specifying agronomically significant traits. A detailed understanding of the molecular basis of plant senescence combined with high-precision tools for mapping and modifying specific genes can make breeding increasingly efficient and targeted.

20.6 Pigment metabolism in senescence

Color change is a characteristic symptom of senescence, ripening, and programmed death in plants. Studying the genetic and biochemical regulation of pigment metabolism gives insights into the mechanisms and adaptive significance of senescence processes. Visible loss of green over time is the clearest symptom of senescence in leaves (Fig. 20.26). Color changes during foliar senescence are directly related to regulation of nutrient mobilization and resorption from leaf cells, often under conditions of biotic and abiotic stress. The colors of flowers and ripe fruits are invitations to pollinating and seed-dispersing animals, respectively. Some pathways of pigment metabolism, such as chlorophyll breakdown and anthocyanin synthesis,

FIGURE 20.26 Senescence in *Arabidopsis thaliana*. (A) Development of *Arabidopsis* plants is shown at various times after germination. Photographs show plants at 14, 21, 37, and 53 days after germination (left to right). Note the yellowing of shoots of the 53-day-old plant. (B) Age-related changes in rosette leaves of *Arabidopsis* 7, 9, and 11 days after leaf expansion had ceased. Note the progressive yellowing of leaves, beginning farthest from the major veins. Source: (A, B) Bleecker & Patterson (1997). *Plant Cell* 9:1169–1179.

are specifically turned on during senescence. In other cases existing pigments are unmasked or their light-absorption properties are altered as a result of chemical modification.

20.6.1 Chlorophyll is degraded by way of a complex enzymatic pathway involving several subcellular compartments

Figure 20.27 illustrates chlorophyll catabolism. The first step is release of chlorophylls from their association with pigment-binding proteins in the thylakoid membrane, a reaction in which SGR plays a critical role (Fig. 20.27 reaction 1). The Mg of chlorophyll *a* is removed, resulting in the production of pheophytin *a* (Fig. 20.27 reaction 3). It is not clear whether the loss of Mg is catalyzed by an enzyme or a low molecular weight chelating substance. Pheophytin *a* is hydrolyzed by the enzyme pheophytinase to yield pheophorbide *a* (Fig. 20.27 reaction 4). The other product of pheophytinase action is phytol, which usually accumulates in the **plastoglobules** (lipid droplets) of gerontoplasts (see Fig. 20.22), largely in the form of esters. Chlorophyll *b* must be converted to chlorophyll *a* before it can be metabolized by the breakdown pathway. The enzyme responsible, chlorophyll *b* reductase (Fig. 20.27 reaction 2), is activated during senescence. Both pheophytin and pheophorbide retain an intact tetrapyrrole ring structure and are olive-green in color.

FIGURE 20.27 The pathway and subcellular organization of chlorophyll breakdown during senescence. Enzymes and activities are identified as follows: 1, SGR; 2, Chlorophyll *b* reductase; 3, Dechelation reaction; 4, Pheophytinase; 5, Pheophorbide *a* oxygenase; 6, RCC reductase; 7, ATP-dependent catabolite transporter; 8, ABC transporter. Source: Thomas (2010). McGraw Hill 2010 Yearbook of Science and Technology, pp. 211–214.

The ring of pheophorbide is opened to generate a colorless straight-chain tetrapyrrole. Two enzymes are responsible, the first of which is pheophorbide *a* oxygenase (PaO; Fig. 20.27 reaction 5). The PaO reaction requires O_2 and involves Fe, which operates in a redox cycle driven by reduced ferredoxin. PaO uses pheophorbide *a* but not pheophorbide *b* as a substrate. The PaO reaction generates a red chlorophyll catabolite (RCC) that does not normally accumulate in plants but is immediately metabolized further by RCC reductase

(Fig. 20.27 reaction 6). This enzyme catalyzes the ferredoxin-dependent reduction of a double bond in the pyrrole system of RCC to produce an almost colorless tetrapyrrole with a strong blue fluorescence (primary fluorescent chlorophyll catabolite, or pFCC).

RCC reductase converts pheophorbide *a* to one of two possible epimers of pFCC, differing in stereochemistry around carbon atom 1. Substituting valine for a phenylalanine in the RCC reductase active site changes the product of enzymic reaction from pFCC-1 to pFCC-2. The role of RCC reductase in chlorophyll catabolism has been confirmed by genetically engineering the RCC reductase gene in *Arabidopsis*, a pFCC-1 forming species. Changing the active site resulted in the accumulation of terminal catabolites with the alternative stereochemistry.

Studies of the subcellular location and interactions of the enzymes of chlorophyll catabolism have established that they form a complex associated with the thylakoid membrane. SGR is thought to stabilise the complex and mediate in its docking with thylakoidal chlorophyll-proteins. Integrity of the complex is necessary to avoid leakage of phototoxic chlorophyll catabolites. In SGR knockout mutants, the complex fails to assemble and chlorophyll remains undegraded.

FCC is exported from the gerontoplast to the cytosol by an ATP-dependent transporter located in the plastid envelope (Fig. 20.27 reaction 7) and enters the vacuole through ABC transporters in the tonoplast (Fig. 20.27 reaction 8; see Chapter 3). En route to the vacuole, pFCC is hydroxylated and may be conjugated—malonyl and β -glucosyl derivatives have been identified—or otherwise modified. The end-products of these modifications are a range of nonfluorescent chlorophyll catabolites (NCCs) that vary greatly in number and type depending on the species. Once in the acidic environment of the vacuole, NCCs may undergo nonenzymic tautomerization and further alterations. All carbon and nitrogen in the chlorophyll molecule ends up in vacuoles: there is no evidence for transport out of the cell, which means that dismantled chlorophyll is simply abandoned when the senescing cell progresses into the death phase. This is the price the plant pays for getting access to the large reserves of mobilizable nitrogen tied up in the proteins of thylakoid membrane pigment complexes.

20.6.2 During senescence carotenoid pigments and their derivatives are unmasked, and in some cases their production can be upregulated

In leaves of some species chlorophyll loss is accompanied by decreases in carotenoids, but foliage of deciduous trees and many other plants develops striking colors before being shed. Fruits also become brightly colored during ripening. In such cases, the loss of chlorophyll reveals underlying carotenoids, which provide a yellow or orange background against which new pigments accumulate.

New carotenoids are synthesized by the terpenoid pathway (see Fig. 17.19). Geranylgeranyl diphosphate (GGPP) synthase

makes the basic C_{20} unit from which all carotenoids are constructed. Phytoene synthase condenses two molecules of GGPP into the C_{40} carotenoid phytoene, and phytoene desaturase (PDS) activity leads to the formation of lycopene, the red pigment of tomato, bell pepper (*Capsicum*), and similar fruits. The activities of GGPP synthase and PDS increase markedly during ripening of pepper. Carotenoids may be further metabolized to so-called apocarotenoids, compounds with important roles in diverse biological processes including synthesis of vitamins, production of volatile attractants, antifungal defenses, and regulation of development and senescence. For example, production of the apocarotenoid hormone ABA is generally upregulated during senescence (see Section 20.11.5). Apocarotenoids are products of the activities of carotenoid cleavage oxygenases. CCD8 is a cleavage dioxygenase that operates in a reaction sequence leading to the production of 13-apo- β -carotenone (C_{18}) and a C_9 product. It is currently unresolved whether either product functions as the biologically active inhibitor of branching or its precursor. The CCD8 gene is strongly expressed in tissues undergoing developmental cell death such as xylem, cork, and senescing leaves. Mutants with loss of CCD8 function show delayed senescence as well as increased branching.

The carotenoids synthesized in plastids of ripening fruit concentrate in structures variously described as fibrils, crystals, or globules, which become increasingly numerous as chloroplasts redifferentiate into chromoplasts or gerontoplasts. Specific proteins called **fibrillins** are associated with the carotenoid bodies of ripening fruit tissues. Fibrillins have also been detected on the surface of plastoglobules of gerontoplasts. Fibrillin genes are strongly expressed in fruits, floral parts, and senescing leaves. Plastoglobule-like lipid bodies occur throughout the plant and bacterial kingdoms, and fibrillin gene homologs are correspondingly widely distributed. Fibrillin proteins function in lipid storage, in transporting newly synthesized or modified carotenoids, and in stabilizing plastid structure in fruits, leaves, and other colored organs.

20.6.3 Senescence can also alter phenylpropanoid metabolism

Other pigments and secondary compounds that accumulate in senescing and ripening tissues are products of phenylpropanoid metabolism. Many of the striking pigments of autumnal foliage are red and purple anthocyanins and yellow flavanoids, water-soluble phenylpropanoid derivatives that accumulate in vacuoles. This diverse group of phytochemicals also includes phenolics, tannins, flavonoids, and lignins (see Chapter 24). Phenylpropanoid pathways are complex, branched metabolic sequences with several control points (Fig. 20.28). Wounding, ethylene treatment, exposure to ozone, and other stimuli that invoke senescence- or PCD-like pathological responses also commonly increase the rate and pattern of phenolic product synthesis. Among the important compounds derived from phenylpropanoid metabolism is SA, a significant factor in the regulation of disease resistance and associated PCD events (see Section 20.11.3 and Chapters 17 and 21).

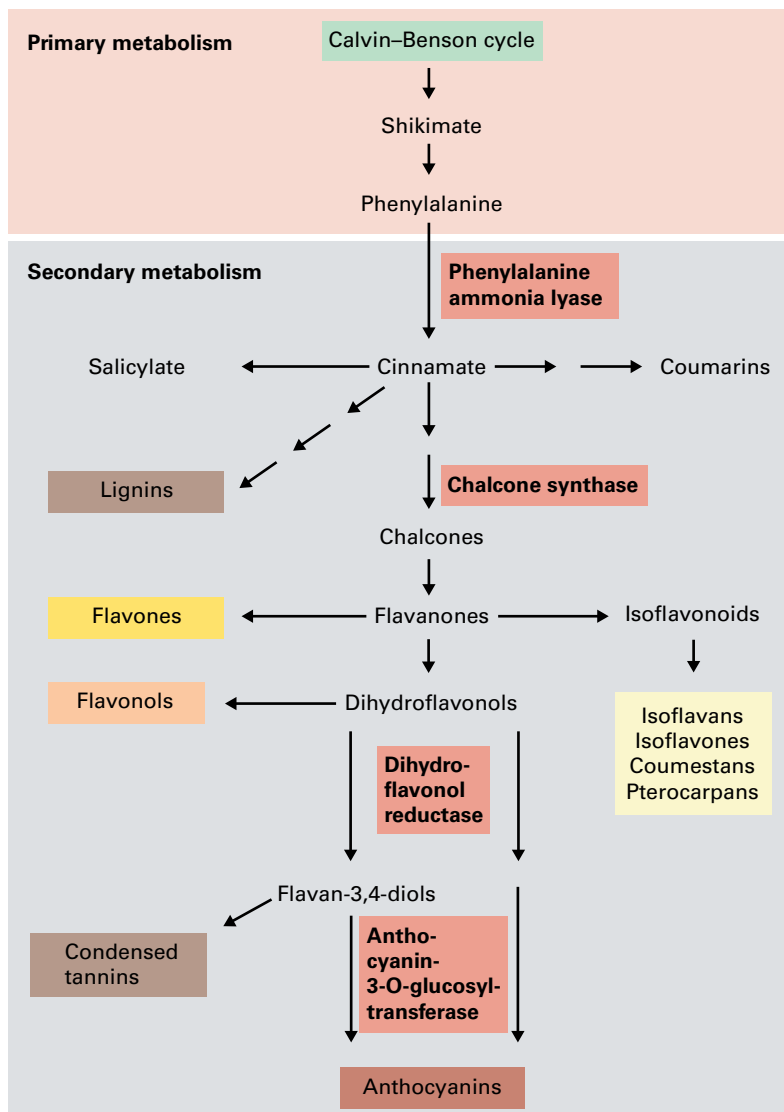

FIGURE 20.28 Phenylpropanoid metabolism. Phenylalanine, a product of the shikimate pathway (see Chapter 7), enters secondary metabolism by way of the reaction catalyzed by phenylalanine ammonia lyase. Among the phenylpropanoid end products important in senescence and PCD are salicylate, which is implicated in PCD-like resistance to pathogen infection (see Chapters 17 and 21); lignins and tannins, which accumulate as tissues age (see Chapter 24); isoflavonoid phytoalexins, which have antipathogen properties (see Chapters 21 and 24); and anthocyanins (see Chapter 24), which are responsible for some of the vibrant pigments of ripening fruits and senescing leaves. Anthocyanin production depends on dihydroflavonol-4-reductase, a developmentally regulated enzyme that is active during the ripening of strawberry fruit.

Anthocyanins are of adaptive value to plants both in stress responses and in signaling to beneficial or predatory animals, and there is an extensive literature on the significance of the range of possible anthocyanin functions in senescing leaves. By contrast with carotenoids, which are highly hydrophobic and confined to the lipophilic environment of plastid membranes and plastoglobules, anthocyanins and other flavonoids are water-soluble and accumulate in vacuoles. The behavior of the two classes of pigment during senescence is indicative of the state of their respective organelle compartments. Anthocyanins and proanthocyanins account for the colors of some ripe fruits, such as strawberry (*Fragaria* spp.). Expression of the branch-point enzyme dihydroflavonol reductase (DFR, Fig. 20.28) varies during strawberry fruit development. DFR is active in early development as condensed tannins accumulate, is subsequently downregulated, and then comes on again strongly as fruit color develops.

The anthocyanin responsible for the red color of autumn leaves is commonly cyanidin-3-glucoside. The final step in its synthesis is catalyzed by anthocyanidin-3-O-glucosyltransferase. Its gene is strongly upregulated in senescence. C1,

a transcriptional regulator of genes in the anthocyanin pathway, is expressed more strongly as leaves age and floral parts develop. C1 is also upregulated during developmental cell death in xylem and cork. Unlike carotenoids, which are ubiquitous in plants, animals, and bacteria, anthocyanins are restricted to conifers and angiosperms, and their participation in programs for senescence and cell death has evolved relatively recently.

20.7 Macromolecule breakdown and salvage of nutrients in senescence

Light and CO₂ are not usually limiting for plant growth, but in many ecological and agricultural situations water and nutrients, particularly nitrogen and phosphorus, are. Plants are generally economical with nitrogen and phosphorus, recycling these and other macro- and micronutrients from

FIGURE 20.29 Confocal images through the mesophyll of a senescing *Arabidopsis* leaf. The transgenic plant expresses a SAG12-GFP fusion protein which co-localizes with neutral red dye, indicating that SAG12 is targeted to the vacuole. Bar = 10 μ m.

Source: Otegui et al. (2005). *Plant J.* 41: 831–844.

older organs or from developing tissues undergoing PCD, like xylem. Much of the nitrogen and phosphorus of mature cells is tied up in proteins and nucleic acids and must be released from these macromolecules by activating specific metabolic pathways. A major function of the genetic programs for senescence and cell death is to regulate the efficient salvage of nitrogen and phosphorus and ensure their transfer to growing or storage tissues.

20.7.1 The expression of many protease genes is upregulated during senescence

In green cells, most protein is located in chloroplasts, so these organelles are the source of most organic nitrogen salvaged from senescing tissues. The most abundant proteins are Rubisco, located in the soluble stroma phase of the chloroplast, and the chlorophyll-binding light-harvesting proteins (LHCP) of the thylakoid membranes. Many studies have demonstrated that the progress of leaf senescence, measured as yellowing or as declining rates of photosynthesis, is broadly in step with decreasing amounts of these and other plastid proteins. Despite the scale of the process and the relative ease with which the substrates can be analyzed by sensitive methods such as immunoblotting, knowledge about the location, regulation, and enzymology of plastid protein breakdown during senescence is incomplete.

Among the many proteolytic activities present in plastids, ATP-dependent proteases of the Clp class are promising candidates for a key role in plastid proteolysis during senescence. At least 15 different Clps have been identified in plastids, the genes for two of which (Clp3 and ClpD) are strongly upregulated during senescence. Another class of proteases, the FtsH group, is also of interest, since genes encoding FtsH7 and FtsH8, two of the nine different enzymes of this class, are also highly expressed in senescing leaves. Whether any or all of these proteases play a part in the net loss of Rubisco and other plastid proteins during senescence and ripening remains an unanswered question.

Export of proteins from plastids for degradation elsewhere has been considered as a possible mechanism, and

vacuoles would be an obvious destination. Most researchers agree that proteolysis, especially the critical first stages, occurs within the plastid, but the application of new microscopy techniques is disclosing a more complex picture of vesicle traffic within senescing cells that may explain how proteases and substrates get together. By tagging the vacuolar protease SAG12 with green fluorescent protein, it can be located within the cell by confocal microscopy (Fig. 20.29). Fluorescence of the tagged protein is coincident with signal from a vacuole-specific dye revealing the presence of lytic vesicles in the cytosol.

SAG12 is one of a number of cysteine endopeptidases specifically expressed during leaf senescence in many species. These enzymes have none of the structural motifs characteristic of proteins imported into the plastid. Indeed, many are clearly targeted to the ER or vacuole (see Chapter 4) and are closely related to proteases expressed during seed germination (see Chapter 19). For example, SEE1, a cysteine protease from senescing maize leaves, is similar in structure to the aleurains and oryzains of germinating barley and rice respectively (Fig. 20.30). There are at least 15 members of the family of aleurain-like cysteine endopeptidases in *Arabidopsis*. Association of cysteine proteases with plant senescence has a suggestive parallel with involvement of caspases in apoptosis. However the two types of protease have very different structures and enzymic properties and are only distantly related. One feature that aleurain-type endopeptidases do share with caspases is post-translational activation. In general these proteins are synthesized as pre-pro enzymes. The newly synthesized protein has a 10–26 amino acid signal peptide (pre-domain) that directs it into the lumen of the ER. It also has a 38–150 amino acid pro-domain that blocks the enzyme's active site and facilitates correct protein folding. Activation of the enzyme requires removal of the pre-pro extensions by proteolysis.

The major cleavage-activated proteases of plants are vacuolar processing enzymes, asparagine-specific cysteine endopeptidases of the legumain class. VPEs have been identified as active participants in a wide range of senescence and PCD processes. Like aleurains, VPEs are synthesized in an inactive pre-pro form. Activation takes place in the vacuole and involves the autocatalytic removal of N- and C-terminal peptides. SEE2 is a maize legumain, the gene for which is activated during leaf

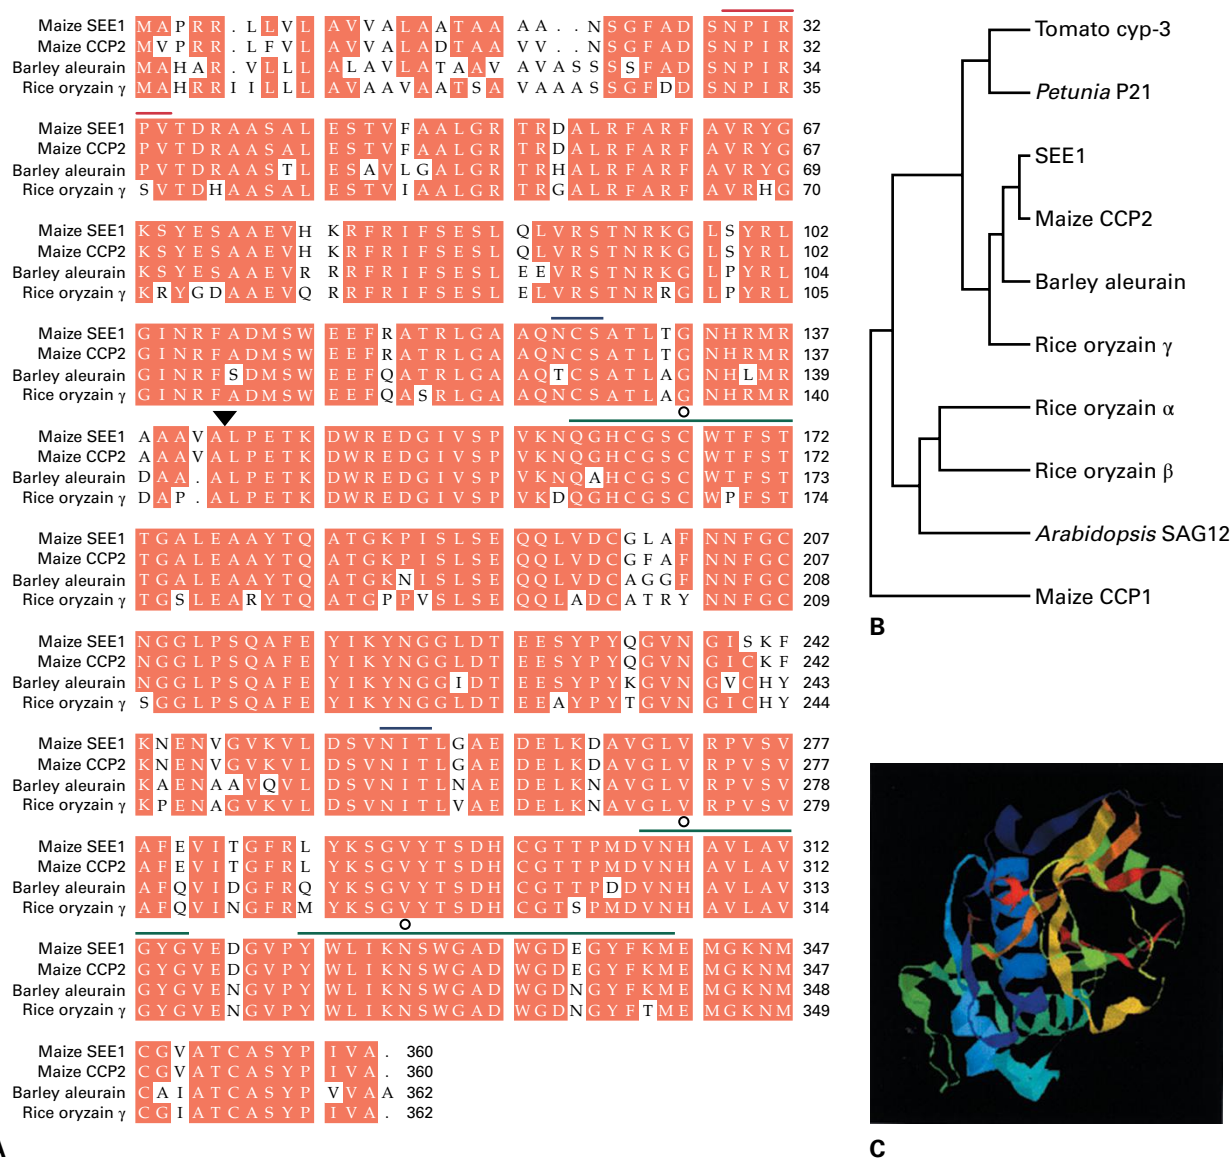

FIGURE 20.30 Comparison of the foliar senescence-associated protease SEE1 from maize with other cysteine endopeptidases. (A) The amino acid sequence inferred from See1 cDNA aligned with the sequences of other proteases from the same family. Conserved structural features include a putative vacuole sorting motif (residues 29 through 34; red line), potential glycosylation sites (125 through 127, 256 through 258; blue lines), and the probable cleavage point that removes the prodomain (between 142 and 143; arrowhead). Open circles indicate the cysteine-histidine-asparagine triad of the active site, and the green lines identify the surrounding conserved regions. (B) Dendrogram locating SEE1 in the same subfamily as the cereal germination proteases aleurain and oryzain. Note that SAG12 of *Arabidopsis* is comparatively distantly related to SEE1. (C). The degree of conservation of cysteine protease structural motifs in SEE1 allows a three-dimensional model to be devised.

senescence. Preventing expression of the *SEE2* gene by transposon mutagenesis has a range of morphological and physiological effects, including delaying senescence (Fig. 20.31). This is evidence that legumain-dependent proteolytic cascades may have both direct and indirect influence on developmental senescence in whole plants and their parts.

As in leaf cells, aleurain-like proteases and VPEs of the legumain family (possibly with a metacaspase function) are upregulated during petal senescence. Vesicles containing a cysteine protease have been observed in senescent daylily (*Hemerocallis* spp.) petals. It is thought that they release their contents into the cytosol, initiating rapid protein degradation. Loss of tonoplast integrity and leakage of water, electrolytes,

and hydrolases from vacuoles results in wilting, further degradation of macromolecules, and final loss of petal cell viability.

20.7.2 Plastid rRNA is an important source of phosphorus remobilized during senescence, but how nucleases access this substrate is not known

In many ways, nucleic acid degradation and its control in senescence resemble protein mobilization. Genes encoding catabolic enzymes are activated, hydrolytic activities increase,

FIGURE 20.31 Expression of SEE2, a VPE-type proteinase, in relation to leaf senescence in maize. (A) SEE2 protein detected by immunoblotting increases during leaf yellowing. B

and amounts of their presumed *in vivo* substrates decline correspondingly. However, locations of known enzymes do not correspond to principal sites of degradation. Quantitatively the largest nucleic acid fraction contributing to phosphorus remobilization is the RNA of plastid ribosomes. Ribonuclease (RNase) cleavage rapidly breaks RNA down to low-molecular-weight products with little accumulation of large intermediate fragments. Some RNases, particularly those associated with self-incompatibility (see Chapter 19), are extracellular in location, but others have ER and/or vacuole targeting motifs (see Chapter 4). BFN1 (BiFunctional Nuclease 1) is an *Arabidopsis* RNase that is strongly expressed in senescing leaves and also petals and stamens. It is highly similar to ZEN1, a nuclease associated with PCD during tracheary element development (see Fig. 20.14) and DSA6, a nuclease from ephemeral flowers of the daylily. Transcriptional regulation of BFN1 has been analyzed by fusing its promoter to a reporter gene and transforming the construct into *Arabidopsis* and tomato. The promoter was observed to be active in senescent leaves and floral organs; differentiating xylem; the abscission zones of leaves, flowers, and fruit; at anthesis; and during seed development. This is consistent with a function for BFN1 in senescence and PCD throughout the plant and the life-cycle.

20.7.3 The products of macromolecule breakdown are further metabolized before export from senescing cells

The proportions of different amino acids present in the phloem connecting senescent leaves with young developing tissues are quite divergent from the amino acid profile of total leaf protein. Although there is evidence that amino acids can be modified during transport, extensive metabolism of the

products of proteolysis occurs before they are loaded into the phloem.

Typically the amides glutamine and asparagine are prominent among the organic nitrogen exports derived from breakdown of protein during leaf senescence (Fig. 20.32). Assimilatory and catabolic formation of glutamine occurs by addition of a second amino group to pre-existing glutamate. The enzyme responsible is glutamine synthetase, which catalyses the ATP-dependent reaction between glutamate and ammonium (NH_4^+). The other major amide, asparagine, is made by transamidation from glutamine to aspartate. In senescence a major source of NH_4^+ for amide synthesis is thought to be deamination promoted by glutamate dehydrogenase. Deaminases may also release NH_4^+ from other amino acids. Glutamate is a key intermediate in amide formation, acting as both NH_4^+ donor and acceptor. Plant tissues contain a range of transaminases that catalyze reactions between particular amino acids and α -ketoglutarate to produce glutamate and potentially respirable α -keto acids (see Section 20.8.1 and Chapter 14).

Proteins are major sources of remobilizable sulfur as well as nitrogen. Organic sulfur is translocated mainly as homoglutathione. Growth under low nitrogen supply promotes both nitrogen and sulfur remobilization from senescing leaves, but sulfur insufficiency has a much less pronounced effect on sulfur redistribution. This suggests that the internal sulfur cycle is regulated via protein nitrogen cycling (see Chapter 16).

Much of the organic phosphorus in leaves is in the form of nucleic acids. A fundamental chemical difference between phosphorus and nitrogen in organic combination within cells is that the former does not bond directly to carbon but instead exists as ester-linked phosphate. Phosphate esters have high negative free energies of hydrolysis. Phosphatases are ubiquitous and especially active during senescence. Conditions during senescence are thus both energetically and enzymically favorable for the release of phosphate from organic molecules. Phosphate is the form in which phosphorus is readily moved

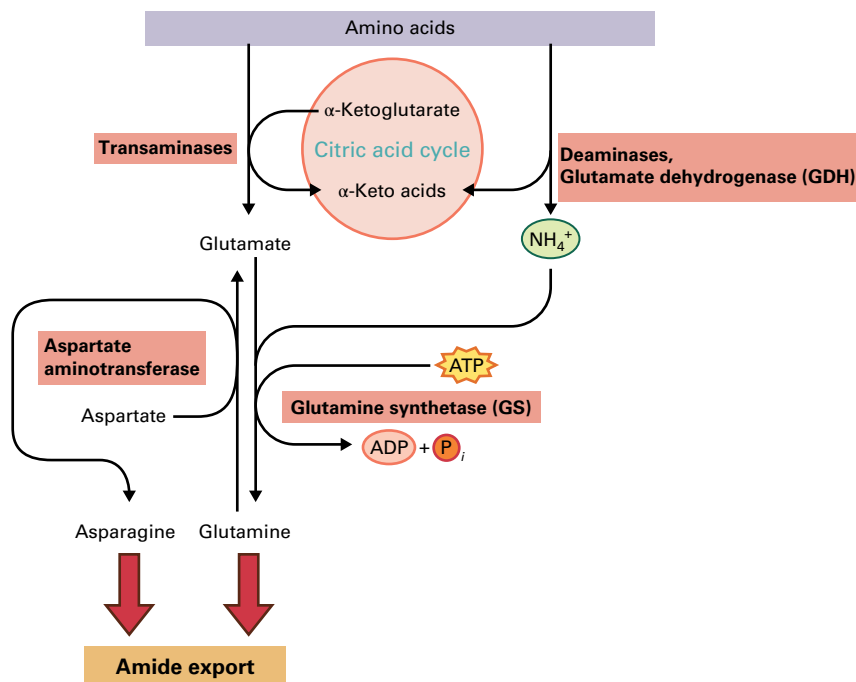

FIGURE 20.32 Glutamate has a central role in the interconversions undergone by amino acid products of proteolysis. Ammonium, the product of deaminases and of glutamate dehydrogenase, reacts with glutamate to make glutamine in a reaction catalyzed by glutamine synthetase. Glutamine and asparagine are major mobile forms of remobilized protein nitrogen.

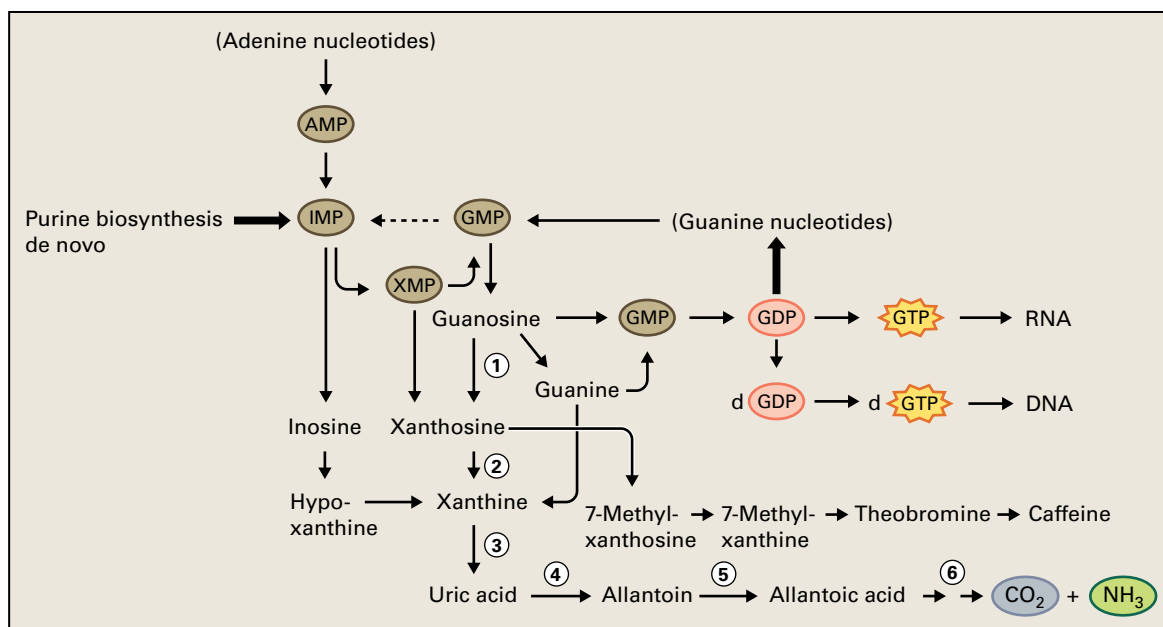

FIGURE 20.33 Possible pathway for guanosine metabolism in plants. During senescence, guanosine and other nucleotides are broken down to yield CO₂ and NH₃. Among the enzymes that participate in guanosine catabolism are (1) guanosine deaminase, (2) nucleosidase, (3) xanthine dehydrogenase, (4) uricase, (5) allantoinase, and (6) allantoicase.

around in the phloem. Nucleoside products of nuclease and phosphatase action are cleaved into sugars, purines and pyrimidines. Pathways leading to the catabolism of guanosine are shown in Figure 20.33. Expression of genes for xanthine oxidase-dehydrogenase, uricase, and allantoinase (glyoxysomal enzymes in the pathway that catabolizes adenine and guanine to ammonia and CO₂) is strongly activated in senescing leaves. Transcripts of the gene for allantoinase in *Arabidopsis* are also abundant in cells of xylem and cork tissues, indicating a role for this enzyme in terminal PCD processes.

20.7.4 Macromolecule salvage is regulated by substrate availability as well as the abundance of recycling enzymes

Making or activating new proteolytic activities is one way in which net protein breakdown can be initiated and sustained in senescence. Alternatively, or additionally, the degradative enzymes may already be present in pre-senescent tissues, but their substrates may have to undergo a change in structure or

subcellular location to become available for hydrolysis. How senescing cells retain structural and functional integrity of critical enzymes in a cellular environment where proteolysis and other lytic processes predominate is only beginning to be understood.

There are several ways in which differential stability may be ensured. One is to allow enzymes to be more or less equally exposed to degradation but to activate expression of selective genes so that some are continuously replenished. Another mechanism is compartmentation. Although their organelles undergo structural changes, the cells of senescing tissues retain a high degree of internal organization and compartmentation until late in PCD. Chlorophyll degradation illustrates the way in which controlled traffic between organelles is necessary for the orderly progress of senescence. The pathway includes highly localized actions in the thylakoid membranes, stroma, plastid envelope, cytosol, tonoplast, and vacuolar sap. It may seem strange to consider chlorophyll as a toxin, but free chlorophyll is a potent photosensitizer capable of killing any cell that accumulates it. To gain access to a major source of salvageable amino acids in the pigment–protein complexes of the chloroplast, it is necessary to remove chlorophyll and rapidly metabolize it by the general route used for dangerous compounds.

Compartmentation of enzyme isoforms can influence their stability. For example, plastids, mitochondria, peroxisomes, and cytosol each contain different isoforms of aspartate aminotransferase. During leaf senescence, total activities of aminotransferases and glutamine synthetase decline, but cytosolic isoforms remain unaffected or even increase in activity. Loss during senescence of plastid isoforms of several of the enzymes of primary carbon and nitrogen metabolism strongly suggests that proteolysis is compartmentalized. In addition, the plastid isoforms of some enzymes, for example, alanine aminotransferase, are intrinsically less resistant to proteolytic attack than the cytosolic forms. Thus the mechanisms that direct senescence programs include biochemical regulation as well as control of gene expression.

Experiments carried out on the lability of isolated enzymes indicate how the presence and absence of substrates, cofactors, and allosteric effectors may influence the integrity of protein structure and function within senescing cells. If an enzyme (e.g., the cytosolic form of glutamine synthetase) has its catalytic and allosteric sites occupied by the appropriate balance of metabolic effectors and substrates, it can be comparatively resistant to attack by proteases (Fig. 20.34). This implies that if an enzyme is gainfully employed in an active metabolic pathway, it is less likely to be proteolyzed than if it is operating below capacity. Thus if energy supply for photosynthesis declines and flux through the Calvin–Benson cycle decreases, as happens in senescence, one can see how enzymes of the cycle might be preferentially degraded compared with, for example, amino-acid-metabolizing enzymes that are fully occupied in processing the products of protein breakdown.

The notion that a cofactor can control degradation of a particular protein through its influence on conformational

FIGURE 20.34 Senescence may be associated with increasing susceptibility of proteins to breakdown. Two possible mechanisms are illustrated. In one case (left side of figure), occupation of binding sites by cofactors (e.g., enzyme substrates) or allosteric effectors locks the protein into a conformation resistant to proteolysis, so that the equilibrium between resistant and susceptible protein conformations is determined by the abundance of these ligands. In the other case (right side), the protein is marked for degradation by the addition of a tag such as ubiquitin and is thereby made available for proteolysis. Both the ubiquitin system and the influence of chlorophyll on the stability of some chloroplast proteins are discussed in Chapter 10.

state explains other aspects of senescence. For example, the chlorophyll–protein complexes of thylakoid membranes are highly resistant to attack by proteases, but without pigments present in the correct stoichiometric ratios, chlorophyll-binding proteins cannot fold properly and are susceptible to proteolytic attack. Thus removal of chlorophyll by degradation via PaO is necessary before proteins of the thylakoid complexes can be broken down in senescence. Mutants that lack PaO activity (see Fig. 20.25) not only retain chlorophyll but also have much reduced breakdown of pigment-binding thylakoid proteins.

Another way in which proteolysis may be activated is by structural modification of an intrinsically stable protein substrate (Fig. 20.34). For example, Rubisco is actively broken down following exposure to reactive oxygen species. The ubiquitin system (which regulates protein lifespans in a wide range of cell processes, see Chapter 10) is another mechanism for activation followed by proteolysis that has been suggested to play a part in PCD. Genes encoding polyubiquitin; ubiquitin extension protein; activating, conjugating, and ligase enzymes of the ubiquitin cycle; and components of the proteasome have been cloned from a variety of plant sources. Some of these genes have been isolated from senescing tissues, and mRNAs for polyubiquitin and conjugating enzyme are abundant in senescing tobacco (*Nicotiana tabacum*) leaves. Experiments with promoter–reporter gene fusions indicate that the polyubiquitin promoter is more active in senescent than young leaves. Biochemical evidence for a specific role of the ubiquitin system in protein remobilization during senescence is meager, but a function for the pathway in stress responses is well established. It may be that the ubiquitin system is not a causative agent in senescence, but rather is upregulated in response to the stress-like conditions that develop during PCD.

20.8 Energy and oxidative metabolism during senescence

Senescence is an active process and requires a supply of energy to power metabolic and transport activities. Photosynthesis supplies the needs of early events in the senescence program, but respiration becomes increasingly

significant as light interception and CO₂ fixation decline. The reactive oxygen species (ROS) that are generated during plant metabolism can damage and even kill cells; ROS often increase in abundance with tissue age. Specific enzyme systems and gene regulation mechanisms control, and are controlled by, the redox status of the cell. The loss of viability in the final stages of PCD is often the result of unconstrained oxidation and propagation of ROS and free radical cascades.

20.8.1 Senescence both modifies and is influenced by the state of energy metabolism in plastids, peroxisomes, and mitochondria

The rate of photosynthesis in leaves and other green tissues such as pericarp declines during senescence. Estimates of gas exchange show that photosynthetic capacity diminishes roughly in parallel with other indices such as chlorophyll or protein content. The precise nature of the rate-determining metabolic step that accounts for falling photosynthetic capacity is probably different in different species and under different developmental or environmental conditions. Often, declining efficiency of photosystem II (measured by chlorophyll fluorescence) is the limitation. In other circumstances the capacity of the cytochrome *b_f* electron transport complex or the CO₂-fixation activity of Rubisco may set the pace for falling rates of photosynthesis as leaves senesce. The time of onset and rate of decrease in photosynthetic capacity are important senescence parameters that place a limit on the net contribution of assimilate the leaf makes to whole-plant carbon economy (Fig. 20.35). For this reason, delaying

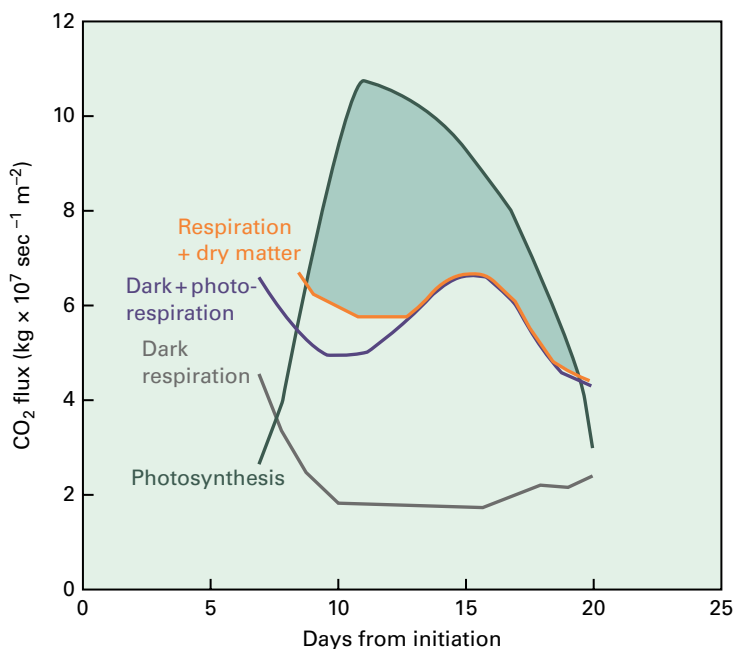

FIGURE 20.35 Over the life of a *Phaseolus vulgaris* leaf, the carbon it assimilates through photosynthesis can be respired, converted into leaf material (dry matter), or exported to support growth elsewhere in the plant. Leaf senescence, which begins about 10 days following leaf initiation, sets a limit on the leaf's carbon export capacity.

FIGURE 20.36 Gluconeogenesis in senescing leaf cells. The glyoxylate cycle is activated in peroxisomes during senescence and allows the carbon (acetyl-CoA) from lipolysis and β -oxidation to be routed around the two CO_2 -liberating steps of the citric acid cycle. Malate synthase and isocitrate lyase are the key activities in this sequence. The carbon salvaged from lipid can then be converted into transportable sucrose by the reversible steps of glycolysis, provided the irreversible pyruvate kinase reaction can be bypassed. This may be achieved by converting an organic acid to a glycolytic intermediate upstream from pyruvate [e.g., decarboxylation of oxaloacetate to phosphoenolpyruvate (PEP) by PEP carboxykinase]. Another type of pyruvate kinase bypass involves using an alternative route from pyruvate to PEP, such as the reaction catalyzed by pyruvate, orthophosphate dikinase, the gene for which is activated during maize leaf senescence.

senescence is often an agricultural objective to ensure high productivity (see Section 20.5.4).

During leaf senescence, particularly in crop species that have been bred for highly efficient transfer of fixed carbon from vegetative tissues to grain, the conversion of lipid to sugar via gluconeogenesis is activated (Fig. 20.36). The key feature of gluconeogenesis is a bypass through which acetyl-CoA from the β -oxidation of fatty acids is diverted from the two CO_2 -generating reactions of the citric acid cycle and is instead converted to organic acids. The glyoxylate bypass is characterized by two distinctive enzymes, isocitrate lyase and malate synthase, which become activated as senescence proceeds. Malate, oxaloacetate, and pyruvate are readily interconverted and represent entry points for carbon into the glycolytic pathway. Reversing the reactions of glycolysis leads to hexose and subsequently sucrose synthesis. There is, however, one essentially irreversible step in glycolysis, namely pyruvate kinase, which converts phosphoenolpyruvate (PEP) to pyruvate. If gluconeogenesis is an important pathway in mobilizing leaf reserves, one or more of the enzymes that bypass the pyruvate kinase reaction would be expected to be active, or even induced, during senescence. PEP carboxykinase, which catalyzes the formation of PEP from oxaloacetate, is thought to be the bypass enzyme active during oilseed germination, but generally declines in activity and protein abundance with leaf age. Another candidate for the bypass role in gluconeogenesis is pyruvate orthophosphate dikinase. The mRNA encoding this enzyme has been observed to be more abundant in senescing than pre-senescent maize leaves. There is also evidence of a further role for pyruvate orthophosphate dikinase in amino acid metabolism and export during senescence.

Activation of gluconeogenesis in leaf senescence is associated with functional transformation of peroxisomes. The transition has been studied in detail in cucumber (*Cucumis sativus*) cotyledons. Here the enzyme complement of peroxisomes responsible for lipid mobilization during seed germination is replaced by that of the photorespiratory organelles as cotyledon cells become photosynthetic, and subsequently reverts to a gluconeogenesis profile during cotyledon senescence. Elegant immunomicroscopy established that the glyoxylate cycle marker enzymes malate synthase and isocitrate lyase and the peroxisome marker glycolate oxidase coexist in the same particle during the changeover from one function to the other. Consistent with the reworking of protein complement within the organelle is the observation of specific endo- and exopeptidases, some of which are particularly active in senescence.

Senescence is an energy-demanding process and respiratory poisons such as the uncoupling agent dinitrophenol are very effective at halting its progress. Among the many ATP-consuming reactions that become active in senescence are chlorophyll catabolism; amide synthesis, transport and loading activities; reversal of glycolysis in gluconeogenesis; and de novo protein synthesis. Declining photosynthesis and continued active export of sugars combine to make senescing tissues increasingly carbon starved, so new sources of respirable energy are required to meet metabolic and transport demands.

Amino acids derived from proteolysis are an important source of carbon skeletons (see Section 20.7.3). One hypothesis for why amides are the most common form of organic nitrogen transported out of senescing tissues is that carbon starvation favors a carbon skeleton carrying two amino moieties (such as asparagine or glutamine) rather than just one (see Chapter 7 or 16).

In tomatoes, peaches (*Prunus persica*), and many other fruits, ripening is associated with the **climacteric**, a characteristic burst of respiration. The reason for a respiratory climacteric in such species is still poorly understood. All other aspects of ripening in nonclimacteric fruit such as citrus, strawberry, or grape, proceed in the absence of the respiratory climacteric. The respiratory climacteric is closely followed by the more or less total conversion of starch into sucrose. In unripe banana (*Musa* spp.), for example, starch accounts for about 20% of the fresh weight; up to 5% of carbohydrate is lost as respiratory CO_2 during sucrose accumulation. Glycolytic flux and mitochondrial respiration are enhanced and generate ATP for the conversion of starch to sucrose and carbon skeletons needed for transamination reactions and other metabolic processes in fruit tissue.

The respiratory climacteric is usually associated with an increase in ethylene production, which is itself an ATP-demanding process. Ethylene in turn exerts autocatalytic control over its own biosynthesis and acts as a transcriptional regulator of metabolism, including respiration, during senescence and ripening (see Section 20.11.2).

20.8.2 Senescence is sensitive to cellular redox conditions

Oxidative metabolism is a central feature of senescence at the cellular level. Some signaling pathways that regulate senescence may include redox-sensing components. For example, the expression of genes encoding fibrillins (see Section 20.6.2) is sensitive to oxygen. Induction of fibrillin biosynthesis by drought, wounding, or ABA involves a signaling pathway in which hydrogen peroxide (H_2O_2), or the superoxide anion ($\text{O}_2^{\cdot-}$) from which it is generated, is a key component. H_2O_2 is a product of normal enzymic reactions in peroxisomes, glyoxysomes, chloroplasts, and other cell compartments. Defenses against accumulation of H_2O_2 and $\text{O}_2^{\cdot-}$ include catalase (CAT), superoxide dismutase (SOD), and the antioxidant ascorbate, which with a second antioxidant, glutathione, participates in a cycle driven by ascorbate peroxidase (APX), monodehydroascorbate reductase, dehydroascorbate reductase and glutathione reductase (Fig. 20.37; see also Chapter 22). The activities of peroxisomal CAT2 and cytosolic APX1 decrease during bolting of *Arabidopsis*, before any measurable loss of chlorophyll. Levels of H_2O_2 increase at this time, then begin to fall as the stress-inducible CAT3 isoform is activated and APX1 activity restored. Finally, H_2O_2 increases as senescence proceeds to completion. These observations suggest a simple model of the control of ROS during senescence based on the timing and

FIGURE 20.37 The ascorbate–glutathione redox cycle in senescence. Ascorbate is regenerated from oxidized forms by a cycle catalyzed by ascorbate peroxidase (APX), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), and glutathione reductase (GR). Superoxide dismutase (SOD) is one of the enzymatic defenses against the buildup of reactive oxygen species. In mature leaves, photosynthetic electron transfer generates NADPH, which donates electrons to ascorbate by way of reduced glutathione (GSH). In senescing leaves, NADPH production decreases, resulting in increased ratios of oxidized glutathione (GSSG) to GSH and of dehydroascorbate to ascorbate. These relatively subtle changes can result in substantial changes in cellular redox conditions and signal new patterns of gene expression. PSI, Photosystem I; *, nonenzymatic reaction.

interaction of CAT and APX activities (Fig. 20.38). The shifting balance between ROS production and ROS removal and the resulting shifts in cellular redox state alter gene expression. In this context, the redifferentiation of peroxisomes into glyoxysomes could be of special significance in senescence, since the transition is clearly associated with an altered profile of superoxide-producing and antioxidant enzymes.

The transcription factor WRKY53 (see Section 20.5.2) participates in a complex signaling network by which redox status regulates senescence. WRKY53 is induced by H_2O_2 and autoregulates its own synthesis by feedback inhibition. The many senescence-related genes with which WRKY53 interacts include *CAT1*, *2*, and *3* and *NPR1* (*Non-expressor of Pathogenesis Related genes 1*), a redox-sensitive, stress-activated transcriptional cofactor that participates in transduction of SA signaling during both senescence and plant defense responses. SA and jasmonic acid, whose roles in senescence are discussed in Section 20.11, control WRKY53 functions in senescence and resistance to pathogens via the regulatory protein ESR (*Epithiospecifying Senescence Regulator*). Thus WRKY53 is a critical node in a complex signaling network by which redox status regulates senescence.

It should be emphasized that ROS are considered here to act as part of a subtle signaling mechanism in coherent, viable

FIGURE 20.38 A peak in H_2O_2 production occurs during bolting of *Arabidopsis*. The diagram illustrates a possible model to explain this peak. *CAT2* is downregulated, leading to an increased H_2O_2 level that may inactivate *APX1*. Declining *APX1* activity allows further increases in H_2O_2 that ultimately induce *CAT3* expression and activity, which removes H_2O_2 and thereby restores *APX1* activity.

cells. In excess they are capable of rapidly destroying the cell through the propagation of free radical cascades, and such a process certainly leads to death in some pathological conditions (see Chapters 21 and 22). But this kind of unregulated, catastrophic mechanism is likely to contribute only to the most terminal phase of normal senescence.

20.9 Environmental influences on senescence and cell death I: Abiotic interactions

Seasonal or otherwise, predictable environmental cues can trigger senescence as part of an adaptive strategy, as is observed in trees that respond to declining day length through mass leaf senescence in the autumn. Senescence is also a tactic deployed when an unpredictable stress is experienced, such as aerenchyma development as a response to oxygen limitation. The relationship between environmental stimuli and senescence can be complex. For instance drought invokes premature foliar senescence in many species, but water limitation during senescence will slow development of yellowing and other symptoms. Frequently the speed and severity of a developing

stress overruns the capacity of tissues to invoke and execute the comparatively slow senescence program, with the result that cells divert more or less directly to the more rapid PCD pathways characteristic of physiological or pathological events such as the hypersensitive response (see Section 20.10).

20.9.1 Plant adaptation and acclimation often requires senescence to be cued by environmental factors

At latitudes away from the tropics, change in day length over the course of the year is a reliable reference that permits plants that can sense it to prepare for seasonal stresses. Foliar senescence is a prominent developmental event in flora of these regions. Proper timing of leaf senescence is critical for a plant, and can be described in general terms as a trade-off between the carbon and nitrogen demands of the plant, since the loss of photosynthetic carbon acquisition that results from degradation of leaf photosynthetic pigments and proteins is balanced by recovery of nitrogen and other nutrients from senescing leaves. This can most easily be illustrated by the highly coordinated autumnal senescence that deciduous trees undergo in temperate regions. In aspen (*Populus tremula*) (Fig. 20.39), initiation of autumn senescence is strictly controlled by photoperiod. A particular aspen tree will always

FIGURE 20.39 Autumn senescence in an aspen tree, observed from September 7 to October 1 in Umeå, Sweden. The highly synchronized physiologies of a given individual's leaves makes aspen a convenient model for studies of senescence in free-growing tree species. The timing of the onset of senescence is set by day length, whereas the rate of senescence once initiated is largely determined by temperature.

Source: Bhalerao et al. (2003). *Plant Physiol.* 131:430–442.

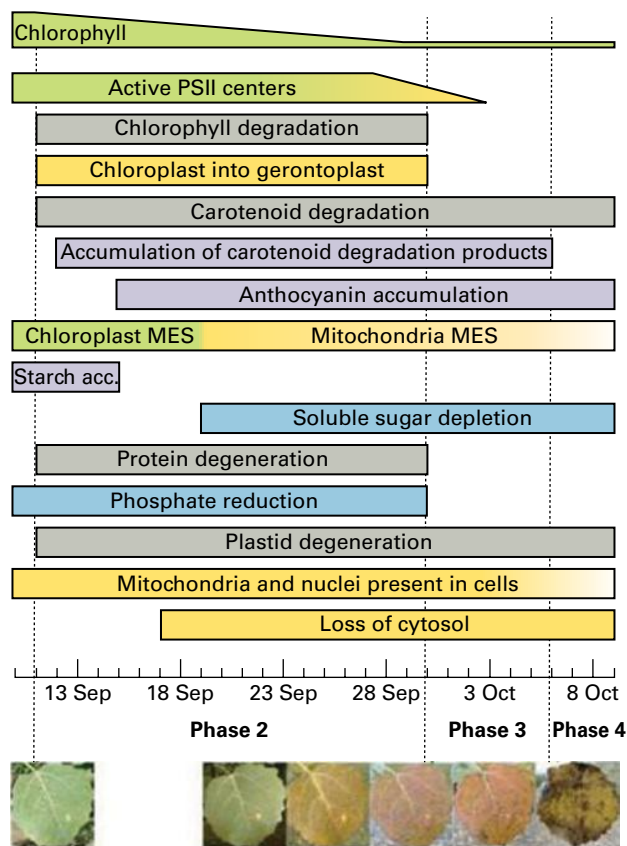

FIGURE 20.40 A timetable detailing cellular events during autumnal senescence in aspen. Four phases are identified, based on physiological, biochemical and microscopical analyses. The pre-senescent Phase 1 is followed by Phase 2, during which chloroplasts are converted to gerontoplasts, major pigmentation changes occur, N and P are mobilized and sugars metabolized. During Phase 2 the major energy source (MES) switches from chloroplasts to mitochondria. By Phase 3 less than 5% of original chlorophyll remains, cell contents are severely depleted but metabolism continues and viability is sustained in some cells. Phase 4 is the stage at which cell death is complete and few structures are recognizable within residual cell walls.

Source: Keskitalo et al. (2005). *Plant Physiol.* 139:1635–1648.

start autumn senescence at more or less the same date every year without any obvious influence of temperature. Many stresses, such as attack by pathogenic fungi or herbivorous insects, can induce localized leaf senescence prematurely, but when autumn senescence is triggered, the whole crown starts to senesce in a coordinated fashion, according to a predictable timetable of cellular events (Fig. 20.40).

Initiation of senescence is set by day length, but once the process is underway, changes in autumn coloration are controlled by temperature. The rate of chlorophyll degradation is enhanced by low temperature, probably via increased photooxidative stress, so that the time from initiation of senescence until leaves start to yellow (when about two-thirds of the chlorophyll has been degraded; see Fig. 20.40) can differ by 1 to 2 weeks, depending on severity of the decrease in temperature. Anthocyanin production is also stimulated by

low temperature. The combined effects of decreased chlorophyll and increased anthocyanin levels make autumn splendor more pronounced in years when the critical weeks represented by Phase 2 (Fig. 20.40) are colder. There is often a very large natural variation between trees of the same species: two aspens growing in the same stand can differ in timing of senescence by three weeks. Photoperiodic control of initiation of senescence is beneficial for trees growing at high latitudes. In these forests, nitrogen availability is typically a limiting factor for growth, and many trees sacrifice weeks of potential photosynthetic carbon gain in order to ensure that sudden frost will not kill leaf cells before remobilization has occurred, leading to losses of large amount of nitrogen and other nutrients in falling leaves. Since these climates are often characterized by rapid and unpredictable temperature changes in autumn, photoperiodic cues predict the approach of winter better than temperature. In addition, daily change in photoperiod is much greater at higher latitudes, allowing for a precise setting of the calendar. There is growing evidence for the importance of phytochrome (see Chapter 18) in day length perception and autumnal responses in *Populus tremula*, but how the signal to trigger senescence is transduced from photoreceptors is not known. Transcription factors have an important regulatory role integrating autumnal senescence with growth, flowering, and dormancy. For example, constitutive expression in transgenic poplar of a MADS homeotic gene known to induce early flowering in birch (*Betula pendula*) and apple (*Malus x domestica*) resulted in delayed bud dormancy and senescence and retention of photosynthetic activity, chlorophyll, and proteins in leaves under winter conditions. It should be noted that apple, pear (*Pyrus* spp.), and some other woody members of the family Rosaceae are unusual in being temperate deciduous winter-dormant trees that are photoperiod insensitive. It appears that chilling is the major triggering factor for the autumn syndrome in these species.

20.9.2 When environmental challenges exceed the plant's adaptive capacities, senescence becomes a stress response

As sessile organisms, plants cannot escape environmental stresses such as drought or flooding. Senescence is one of the responses employed by plants to deal with suboptimal environmental conditions, and senescence-related genes are frequently identified amongst those upregulated in response to abiotic stresses (see Chapter 22). For example, patterns of tissue senescence and death are responsive to temperature and CO_2 , and the changes induced in plant tissues by ultraviolet radiation include enhanced expression of genes associated with senescence.

The development of **aerenchyma** in plant roots subject to flooding illustrates how plants deploy PCD in response to stressful environmental conditions. During aerenchyma formation in most species, cells are removed from mature roots

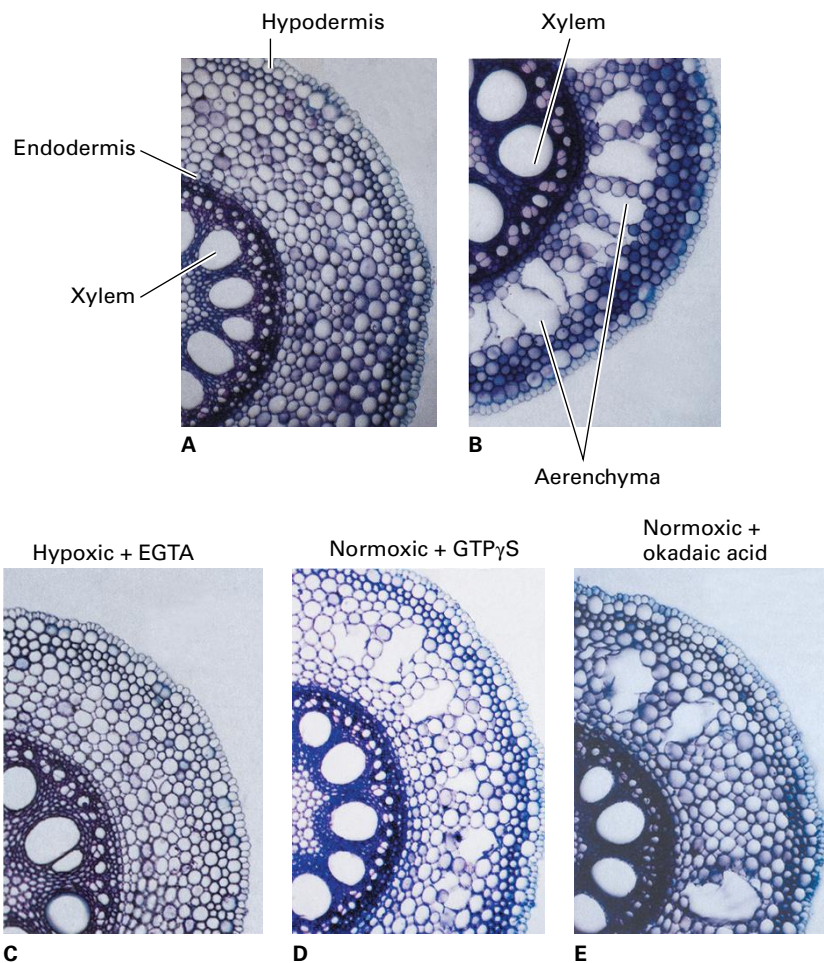

FIGURE 20.41 Aerenchyma formation in maize roots in response to hypoxia. Roots were grown under aerobic (A) and hypoxic (B) conditions. Under low-oxygen conditions, cortical cells between the endodermis and hypodermis undergo lysis to form air spaces that are continuous throughout the root, allowing submerged roots to access atmospheric gases obtained by above-ground tissues. Aerenchyma formation is influenced by agonists and antagonists of signal transduction pathways. The Ca^{2+} chelator EGTA prevents aerenchyma in maize roots under hypoxic conditions (C), whereas the G-protein activator $\text{GTP}\gamma\text{S}$ (D) and the protein phosphatase inhibitor okadaic acid (E) induce aerenchyma formation under aerobic conditions. Source: (A–E) He et al. (1996). *Plant Physiol.* 112:463–472.

by lysis, creating channels through which air can diffuse from shoot to root (Fig. 20.41A,B). In a few species, aerenchyma is schizogenous in origin; air spaces are formed by cell separation but no cells are lost. Because of the adverse effects of flooding and poor aeration on yield, much research on aerenchyma has been carried out on crop species, particularly rice and maize. More recently the important processes of root responses to hypoxia have been replicated in the model plant *Arabidopsis*, allowing the application of genomics to analysis of aerenchyma development.

The formation of aerenchyma in roots of plants that are not adapted to wetland conditions is triggered by oxygen deficiency. Aerenchyma formation has been extensively studied in maize roots in response to oxygen-limiting conditions as well as other environmental stresses, including the depletion of nitrogen and phosphorus. Aerenchyma results from PCD of a specific group of root cortical cells located between the endodermis and hypodermis. This response to hypoxia or anoxia can be rapid and results in removal of whole cortical cells including cell walls (Fig. 20.41A,B).

Concentrations of ethylene and its precursor 1-aminocyclopropane-1-carboxylic acid (ACC) are elevated in roots grown under low oxygen. There is strong evidence that ethylene regulates aerenchyma formation. Inhibitors of ethylene synthesis, such as aminoethoxyvinylglycine (AVG), or of

ethylene action, such as silver ions, can prevent formation of aerenchyma under oxygen-limiting conditions. Conversely, exogenous ethylene can bring about aerenchyma formation under aerobic conditions.

Microarray profiling of transcript abundance during low-oxygen-induced aerenchyma formation in *Arabidopsis* roots reveals significant alterations in expression of genes involved in glycolysis and fermentation pathways, ethylene synthesis and perception, calcium signaling, nitrogen utilization, trehalose metabolism, and alkaloid synthesis. Among the activities induced in maize roots by low oxygen or ethylene treatment are several cell-wall-modifying enzymes, including cellulase. The large increase in cellulase activity in hypoxic (4% O_2) conditions compared with the normoxic (21% O_2) control is strongly correlated with levels of ACC synthase, a key enzyme in ethylene biosynthesis (Fig. 20.42).

Cytosolic Ca^{2+} is part of a signal transduction pathway linking both anoxia and ethylene to PCD in maize cells. Under anoxic conditions, removing Ca^{2+} from the medium surrounding roots by using the Ca^{2+} chelator EGTA prevents aerenchyma formation (see Fig. 20.41C) and inhibits the rise in cellulase activity. Use of specific inhibitors has shown that G-proteins, protein kinases and protein phosphatases are also likely to be involved in regulating aerenchyma formation in response to both oxygen and ethylene in maize roots. $\text{GTP}\gamma\text{S}$,

which locks G-proteins into the active state, and okadaic acid, which inhibits protein phosphatase activity, each promote the formation of cellulase and aerenchyma in roots under aerobic

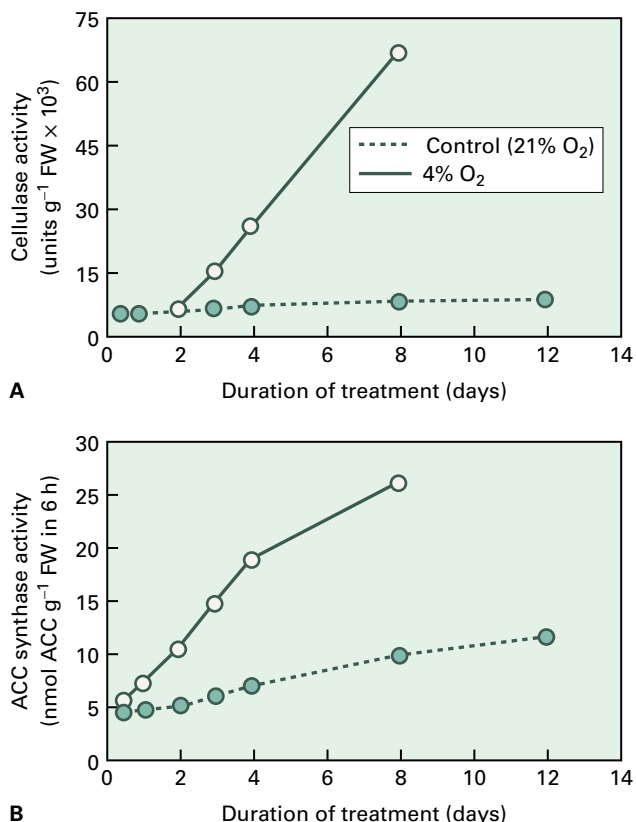

FIGURE 20.42 Increases in the activities of cellulase (A) and of a rate-limiting enzyme in ethylene biosynthesis, ACC synthase (B), accompany aerenchyma formation in hypoxic maize roots. Both enzymes increase with the duration of hypoxia.

conditions (see Fig. 20.41D,E). On the other hand, an inhibitor of protein kinase activity prevents formation of aerenchyma in roots under hypoxia. Taken together, these data implicate cytosolic Ca²⁺ and CaM in a signaling cascade that could activate protein kinase and protein phosphatase activities to promote modification of proteins involved in PCD. In maize roots incubated under low oxygen conditions, or treated with ethylene, TUNEL-positive nuclei develop in the cortex within hours, whereas there is little or no staining in normoxic controls (Fig. 20.43). This suggests that fragmentation of DNA is a factor in the mechanism of PCD in aerenchyma formation.

20.10 Environmental influences on senescence and cell death II: PCD responses to pathogen attack

Plants are continuously under attack from armies of microorganisms and pests such as insects. To survive they have evolved highly efficient defenses that, unlike the immune responses of humans and other animals, are mostly confined to the site of attempted invasion. Defense is often associated with cell death. Conversely, some pathogens actively induce cell death or senescence-like symptoms to promote disease development. Different strategies are employed by different pathogens, and it is prudent not to overgeneralize from observations made in a single species or from a small number of plant–pathogen interactions.

FIGURE 20.43 TUNEL staining (see Fig. 20.4, Section 20.1.1) in maize root transverse sections. (Top row, from left to right) The cortex of roots grown under normoxic (21% O₂) conditions reveals no DNA fragmentation (green fluorescence), but roots subjected to hypoxia (3% O₂) or treated with exogenous ethylene (1 μL L⁻¹ C₂H₄) stain positive for fragmented DNA. (Bottom row) Root sections stained with the DNA-binding agent propidium iodide (red fluorescence) are included for comparison. The scale bar is 250 μm. Source: Gunawardena et al. (2001) *Planta* 212:205–214.

20.10.1 Cell death is a common response to attack by pathogens

Plant cell death has perhaps been most intensively studied within the context of interaction with pathogens. In plants, cell death linked to resistance is known as the **hypersensitive response** (HR), a phrase coined following a microscopic examination of rust interactions with cereal species, cells of which were described as responding hypersensitively. HR has been linked with the organism's attempts at confining and neutralizing the threat of infection. Even after many years of study, however, it is unclear whether HR is required for, or is a consequence of, resistance.

The size of the area affected by HR may vary but it is always associated with the pathogen at the site of attempted infection. The phenotype of HR can be greatly influenced by the infection strategy of the pathogen. Tobacco Mosaic Virus (TMV) moves rapidly between infected cells so that when HR forms in resistant genotypes, large areas (about 0.5 cm diameter) of cell death are seen (Fig. 20.44A). In other cases, HR occurs as a necrotic fleck. A single pathogen can elicit flecks of different sizes on two distinct plant genotypes (Fig. 20.44B). Necrotic flecks and single cell HR (Fig. 20.44C) are usually elicited by fungal or bacterial pathogens. Although varying in phenotype, HR has some common features. Cell death in HR is often rapid, in many cases being complete within a day of first infection. Microscopic examination of cells undergoing PCD frequently reveals cytoplasmic clumping and vesiculation (Fig. 20.44D), and ultimately HR cell walls become reinforced with a variety of phenolic compounds so that they fluoresce under UV light (Fig. 20.44E). Early work using metabolic and protein synthesis inhibitors quickly showed that HR was dependent on the plant's biochemistry and therefore represented an example of PCD.

It is thought that in HR a common death mechanism (or small number of mechanisms) is triggered by multiple stimuli (e.g., different species of pathogen). Following pathogen attack, the genetic program associated with the HR is likely to involve three types of genes: (i) genes that respond to triggers that initiate death; (ii) genes involved in limiting the extent of death and that may suppress PCD in the absence of infection; and (iii) genes that integrate the death mechanism with other plant defenses. Identifying genes of each class has been a major objective for molecular plant pathologists.

Many genes involved in initiating HR have been studied for many years and are well-characterized. These genes were named **resistance (R) genes** by plant breeders who found them to be important sources of crop resistance against pathogens. Groundbreaking work in the 1940s demonstrated that initiation of the HR required the interaction of a single resistance gene product with a single product encoded by the pathogen, called an **avirulence (avr gene)**. *R-avr* interactions can be considered as triggers of PCD; they are discussed in detail in Chapter 21. Beyond *R* genes, plant molecular biologists have sought to elucidate HR mechanisms by (i) seeking parallels with better characterized mammalian forms of PCD;

(ii) generating and screening mutant lines that exhibit alterations in cell death; and (iii) investigating the roles of ROS and reactive nitrogen species that are generated on a large scale during HR. Each approach has made major contributions to our knowledge of HR.

20.10.2 Mechanisms of HR PCD have similarities with, but significant differences from, both autophagy and apoptosis

As researchers have compared HR with other forms of PCD in animals and plants, they have identified aspects of autophagy that are linked to HR, as well as some similarities between HR and apoptosis. Recent molecular breakthroughs have shown that autophagy (see Section 20.1.2) plays complex roles in HR. When the effects of suppressing *ATG* genes were assessed in *Nicotiana benthamiana*, reduced expression of *ATG6* (also known as *Beclin1*) resulted in a spreading HR following challenge with either TMV or bacterial pathogens (Fig. 20.45). *ATG6* is involved in the nucleation stage of vesicle formation, and consistent with this, suppression of the PI3-K-containing vacuolar sorting complex also leads to spreading cell death. Such observations suggest that autophagy is important in confining the extent of HR cell death.

Additional results show that VPEs (see Section 20.7.1), thought to be terminal components in autophagic body processing (see Fig. 20.5), play an active role in the cell death process. As with many forms of HR, the response induced by TMV in tobacco can be suppressed by the application of mammalian caspase inhibitors (Fig. 20.46A). However, VPE inhibitors but not general cysteine (E-64) or serine protease inhibitors (PMSF; phenylmethanesulphonyl fluoride) can also inhibit HR. In a major advance, suppression of VPE gene expression in *N. benthamiana* was shown to abolish HR (Fig. 20.46B–E), measurable caspase-like activity, and DNA laddering. Furthermore, an *Arabidopsis* γ VPE knockout mutant exhibited a significant reduction in cell death and caspase activity when challenged with an HR-eliciting bacterial pathogen. Such data suggest that VPEs are the source of HR-associated caspase-like activity and implicate vacuolar processing as a key feature of the HR cell death mechanism. The *in vivo* targets of VPE activity remain to be defined but are likely to be key triggers in the cell death process.

20.10.3 Cell death mutants are powerful tools for dissecting plant responses to pathogens

Basic to the concept of PCD is that the program is primarily genetic, so a common experimental approach is to search for mutants that display altered forms of death. Mutants that exhibit the abolition or reduction of cell death in situations where it would be expected are likely to be altered in genes

FIGURE 20.44 Cell death during the HR. (A) HR elicited by tobacco mosaic virus (TMV) on resistant tobacco at 4 days after infection. Bar = 1cm. (B) HR-flecks on *Brachypodium distachyon* ecotypes ABR5 and ABR2 at 3 days following inoculation with the rice blast pathogen *Magnaporthe grisea* strain Guy-11. A dying *B. distachyon* ABR5 cell attacked by *M. grisea* Guy11 is shown, either (C) dyed with the vital stain trypan blue (infecting fungus arrowed) or (D) unstained to highlight disruption of cytoplasmic structure. Bars = 10 mm. (E) Increased autofluorescence in and around a HR exhibited by a single barley cell at 48 h following attack by the powdery mildew fungus *Blumeria graminis* (arrowed). Bars = 10 mm.

whose products are components of the killing process. Alternatively, mutants that display unexpected cell death are probably altered in genes that normally suppress cell death (Fig. 20.47).

Spontaneous cell death lesions have often been noted in crop species, such as maize where there are some 32 examples known. One is lethal leaf spot 1 (*lls1*), which exhibits developmental and light-dependent cell death. Cloning and characterization of *lls1* shows that it encodes pheophorbide *a* oxygenase, a protein involved in cleaving the chlorophyll catabolite, pheophorbide (see Section 20.6.1). Damaging singlet oxygen may be generated when the intact tetrapyrrole ring of pheophorbide is excited by light. The *lls1* mutant accumulates pheophorbide because of the blockage at PaO, leading to cell damage and spontaneous light-induced lesions.

Some spontaneous lesion mutations are of great practical importance. In rice, spontaneous cell death was first associated with the Sekiguchi lesion (*sl*) mutant. The mutation underlying the *sl* phenotype has not been determined but this has not prevented its exploitation in agriculture, as it confers resistance against the devastating disease rice blast, caused by the fungus, *Magnaporthe grisea*. The *mlo* mutation of barley can lead to a tendency to form necrotic flecking on plants but it is widely used in spring barley cultivars as it confers long-lasting field resistance against powdery mildew.

It is, however, in *Arabidopsis thaliana* that the greatest efforts have been made to generate and characterize cell death mutants (Table 20.3). These are classified as either reduced cell death (RCD) or spontaneous death (SD) mutants. There are relatively few RCD mutants that exhibit greatly compromised cell death. Other RCD mutants have been isolated, but these are not listed in Table 20.3 as they have been linked either to an altered *R* gene or to situations where components immediately downstream of the *R* gene are abolished, such as *ndr1*, *pad4* and *eds1* (see Chapter 21). Such mutants still undergo non-HR forms of cell death, however, suggesting that only the triggering of the death program, rather than the program itself, is compromised.

Some SD mutants have likewise been linked to (presumably malfunctioning) *R* genes. For example, the *Rp1* gene in maize encodes resistance to the rust fungus *Puccinia sorghi*. Several alleles linked to a SD phenotype map to the *Rp1* locus. Further evidence for rogue *R* genes initiating cell death was found following a comprehensive crossing program involving large numbers of wild ecotypes of *Arabidopsis thaliana*. About 2% of these intraspecific crosses displayed a SD phenotype, and in at least one case the phenotype was linked to a disease resistance gene homolog interacting with a specific allele at a second locus.

Of the RCD mutants in which the killing components of the cell death program may be compromised, the *defense-no-death* (*dnd1*, *dnd2*) class (Table 20.3) are the best characterized. These are mutated in cyclic nucleotide gated channels located in the plasma membrane. These heterotrimeric ion channels facilitate cation fluxes of Ca^{2+} , K^+ , or Na^+ . The *dnd* class of mutants also exhibit highly activated defense responses but recent genetic analyses have indicated that

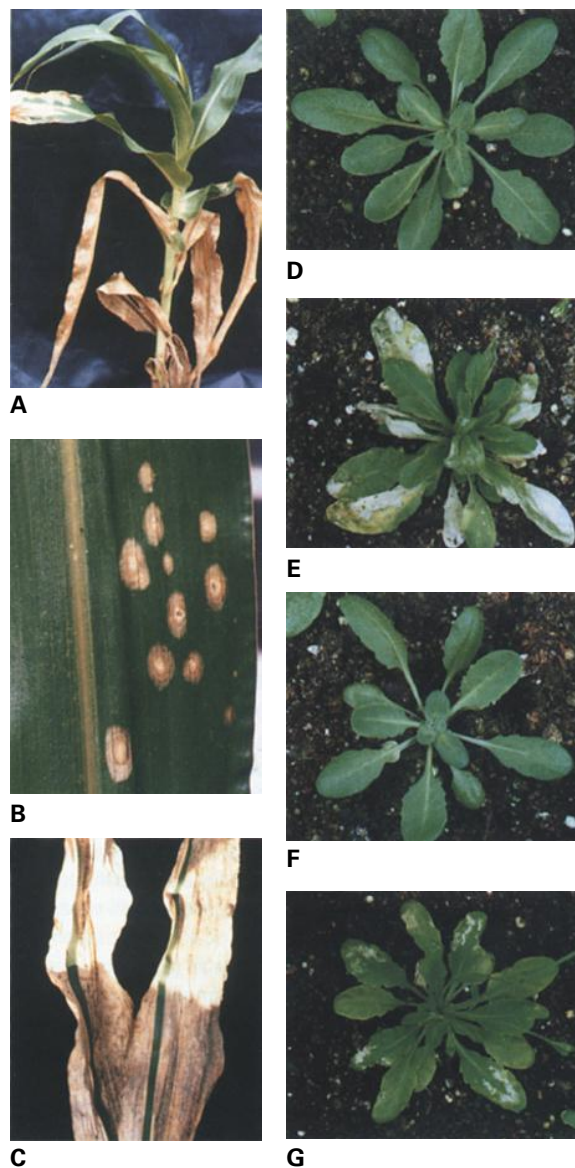

FIGURE 20.47 Lesion-mimic mutants spontaneously develop areas of dead tissue, indicating a misregulation of the functions that control cell death. Lesion mimics have been identified in a wide range of plants, including maize (e.g., *lls1*, left panels) and *Arabidopsis* (e.g., *lsd* mutants, right panels). (A) Expression of the *lls1* phenotype is developmentally regulated. Older leaves on the lower part of the plant are more severely affected, while younger leaves at the top are much less lesioned. (B) *lls1* lesions can be triggered by mechanical wounding, such as pinpricks. *lls1* is a propagation type of lesion mimic, which means that, once initiated, the lesion continues to spread across the leaf. The amount of cell death seen on this leaf exceeds that directly caused by the mechanical damage. (C) Revertant sectors remain green in this *lls1* plant, showing that *Lls1* function is cell-autonomous. (D) *lsd1-1*, a conditional lesion-mimicking mutant, remains healthy when grown under permissive conditions. (E) When shifted to nonpermissive conditions, *lsd1-1* develops areas of dead tissue. Like *lls1*, *lsd1* is a propagation type of lesion-mimicking mutant; the tissue death spreads out from the point of initiation until the whole leaf is dead. The mutant *lsd3* is also conditional, as shown under permissive (F) and nonpermissive (G) conditions. *lsd3* is an initiation type of lesion mimic, which means the lesions are determinate in size; once formed, they do not enlarge.

	<i>vad1</i>		Gram domain-containing protein			+			+

these are not the cause of the failure to initiate cell death. Within the context of a HR, ion fluxes are crucial early events. Biochemical analyses have shown that the first indication of HR is the initiation of a H^+/K^+ exchange across the plasma membrane leading to alkalinization of the leaf apoplast. The importance of H^+/K^+ exchange to initiation of cell death was shown when expression of a bacterial proton pump, *bO*, in transgenic plants initiated cell death. Ca^{2+} fluxes across the plasma membrane and from the ER and organelles into the cytoplasm represent a complex but important initiatory cell death pathway. Application of a range of Ca^{2+} inhibitors, coupled with imaging of Ca^{2+} in transgenic plant lines, has shown that cell death can be suppressed if Ca^{2+} fluxes are perturbed. One key effect of Ca^{2+} fluxes is to initiate the generation of ROS that can be directly toxic as well as having signaling roles.

SD mutants have also been called lesion-mimic mutants on the assumption that plants are acting as though under attack by pathogens to produce lesions analogous to the HR. Although this may be the case, cell death may also arise through loss of homeostatic function. In this context, it is relevant that HR is unaltered in many SD mutants. The SD category can be subdivided into mutants in which necrotic flecking does not spread and mutants that exhibit runaway cell death. Clearly, the former class could be altered in factors that suppress initiation of cell death (initiation class) while the latter could also be perturbed in factors that normally confine HR to the site of infection (propagative class). Unfortunately, molecular characterization of SD has revealed rather a diverse set of mutated loci that currently cannot be easily consolidated into a common mechanism (Table 20.3). Greater insights may be afforded from a consideration of defense signaling pathways that are active in each genotype. Mutants of the initiation class often display activation of SA, jasmonate, or ethylene-mediated signaling pathways, all of which are associated with HR. Activation of one or more of these pathways could be a key initiatory event. *vascular associated death1* (*vad1*) of *Arabidopsis* (Table 20.3) is a possible example of a propagative SD mutant, in which necrosis develops from the leaf veins. The *vad1* mutation has been mapped to a membrane-associated protein that is also induced during HR, and may represent a link between developmental and pathogen-induced cell death.

SD mutants of the *acd* class (Table 20.3) are characterized by their *accelerated cell death* phenotype. The observation that a lipid, possibly ceramide, kinase is altered in *acd5* SD could be a mechanistic clue. In mammalian apoptosis, the accumulation of the sphingolipid ceramide is an important initiatory event that acts, in part, by perturbing mitochondrial function. In contrast, phosphorylated sphingolipids have anti-apoptotic roles so that a mutation in a lipid kinase protein could lead to a deficiency of phosphoceramides resulting in cell death. The identification of a sphingolipid transfer protein as a propagative class SD mutant (*acd11*) underlines the importance of this class of lipids in plant cell death. However, it should be noted that HR in the *acd5* mutant is apparently normal.

A well-characterized propagative cell death mutant in *Arabidopsis* is *lesions simulating disease 1* (*lsd1*; Fig. 20.48). Mutant plants exhibit a sensitized HR that is initiated at lower levels of inoculation with a wide variety of pathogens. The LSD1 protein is a Zn-finger protein that acts as a transcriptional activator and is known to regulate the expression of Cu/Zn superoxide dismutase and *CAT* genes; hence abolition of LSD1 function increases levels of ROS. LSD1 also physically interacts with LSD-ONE-LIKE 1 (LOL1) protein, which promotes cell death via an unknown mechanism. In line with a role for LOL1 in HR PCD, overexpression of *LOL1* in transgenic plants augments HR.

Also within the propagation class of mutants are *acd1* and *acd2* (Fig. 20.48), which are mutated in genes encoding two enzymes involved in the breakdown of chlorophyll catabolites (see Section 20.6.1). *acd1* is the *Arabidopsis* equivalent of maize *lls1*, being mutated in PaO, while the next enzyme in the catalytic pathway, RCC reductase, is perturbed in *acd2*. Both mutants resemble maize *lls1* in accumulating free photosensitizing tetrapyrroles in the chloroplast stroma, leading to production of harmful singlet oxygen in light. Similarly, abnormal overproduction of free tetrapyrroles, such as occurs in the SD mutant *flu* (*fluorescent*), leads to cell death. In this case, singlet oxygen cell death requires the participation of at least two nuclear proteins, EXECUTER 1 and 2, the products of RCD class genes (Table 20.3). The mechanism through which either EXECUTER protein acts is unknown.

20.10.4 ROS are triggers and participants in the HR death program

An early response to HR-eliciting pathogens is the generation of reactive oxygen species (ROS), consisting mainly of superoxide ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2) and the hydroxyl radical (HO^{\cdot}). Each species can act as an oxidant, causing significant damage to macromolecules and thus affecting cell viability. Unsurprisingly, the **oxidative burst**, a surge in ROS production that often occurs within hours of infection, has been implicated as initiating HR and cell death. Central to establishing this theory was the observation that cell cultures or intact plant tissue respond to exposure to $O_2^{\cdot-}$ or H_2O_2 by initiating an HR-like cell death. Further, the application of the ROS scavenging enzymes CAT or SOD could suppress HR. However, even after many years of investigating, the relative importance of either $O_2^{\cdot-}$ or H_2O_2 to initiation of HR remains debatable.

A series of ROS-generating complexes has been implicated as contributing to the oxidative burst; their relative importance and roles are still debated by plant scientists (Fig. 20.49). Most often ROS generation has been linked to an NADPH oxidase complex, which exhibits homology to membrane-associated components of NADPH oxidases in human neutrophils. This complex uses NADPH as an electron donor to generate $O_2^{\cdot-}$. Some mutants in NADPH oxidase genes in *Arabidopsis* (e.g., respiratory burst oxidase homolog, *Atrboh*;

FIGURE 20.48 HR and lesion mimic mutants of *Arabidopsis*. Lesion-mimic mutants spontaneously develop areas of dead tissue, indicating a misregulation of the functions that control cell death. Cell death in lesion mimics resembles that in the HR, and yields genetic insights into the regulation of the latter. (A) A HR initiated in *Arabidopsis* at 48 hours following infiltration with *Pseudomonas syringae* pv. tomato DC3000 avrRpm1. (B) Spontaneous cell death in *lsd1-1*, which has been shown to influence the expression of antioxidant and cell death-promoting genes and to interact with metacaspase proteins which can either promote (*AtMC1*) or suppress cell death (*AtMC2*). (C) *acd1* is a lesion in the gene encoding PaO (see Section 20.6.1). In *acd1* pheophorbide builds up, which initiates cell death through the generation of singlet oxygen 1O_2 . (D) RCC is reduced to form primary fluorescent chl catabolite (pFCC) by red chlorophyll catabolite reductase encoded by *ACD2*. *acd2* null mutants exhibit cell death phenotypes through the accumulation of RCC and the generation of 1O_2 .

Table 20.3) have apparently reduced HR. Equally, however, such investigations have revealed ROS to have roles in cellular signaling not associated with cell death.

In neutrophils, the main role of NADPH oxidases is to increase the internal pH of hydrolytic vesicles called phagosomes within which invading pathogens have been phagocytosed. Similarly, the NADPH oxidase in plants may initiate the oxidative burst by changing the chemical environment to favor the activity of another demonstrated source of ROS, high-pH activated peroxidase. Other sources of ROS are the organelles: disruption of electron transport in mitochondria and/or chloroplast leads to the generation of ROS.

There are many mechanisms through which ROS could initiate cell death. One that has received much attention is lipid peroxidation. In this process hydrophilic moieties are introduced into lipid bilayers, leading to their disruption and the leakage of cytoplasmic contents. Indeed, increased electrolyte leakage is a widely used early marker for HR. Additionally, several of the breakdown products of bilayer phospholipid-derived products exhibit plant cell toxicity. There are a number of reports of significant lipid peroxidation during HR but there is considerable debate whether this occurs through oxidative

damage or the activity of lipoxygenase (see Section 20.11.4). For example, suppression of lipoxygenase gene expression in *N. benthamiana* resulted in reduced cell death following challenge with *Phytophthora parasitica* var. *Nicotianae*.

In considering mechanisms by which ROS kill cells, the contribution of NO cannot be ignored. As well as an emerging role in various senescence and cell death processes in plants (see Sections 20.2.3 and 20.11.2), NO has now an established role in HR and may act in concert with ROS in cell death. NO may also act to suppress cell death, with these very different modes of action being dependent on the concentration of NO. A range of approaches has been used to measure NO production and has shown increased production to coincide with the oxidative burst, consistent with its supposedly supportive role in lipid peroxidation. Besides such correlative evidence, addition of NO scavengers or mammalian inhibitors of nitric oxide synthase (NOS) suppresses HR cell death in range of plant–pathogen interactions. Genetic evidence for a role for NO in HR was provided through the expression of a nitric oxide dioxygenase (NOD) in transgenic *Arabidopsis*. NOD catalyses the dioxygenation of NO to nitrate, and in NOD-expressing transgenic lines

FIGURE 20.49 Model postulating the relationship between pathogen attack and the production of ROS. Pathogen-derived elicitors interact with a receptor to initiate extracellular generation of ROS. Pathways to ROS generation are indicated. The receptor can activate NADH-dependent cell wall peroxidase, which reduces molecular oxygen (O_2) to superoxide ($O_2^{\bullet-}$) via an as yet poorly defined mechanism. Alternatively, the receptor may activate a heterotrimeric G-protein to initiate an influx of Ca^{2+} , which in turn stimulates protein kinase activity to turn on an NAD(P)H oxidase. Using NAD(P)H as a reductant, the NADPH oxidase generates $O_2^{\bullet-}$. $O_2^{\bullet-}$ can contribute towards killing the pathogen or else, in a low pH environment, forms H_2O_2 . H_2O_2 can also aid in killing the pathogen or may be used as a cofactor in oxidative crosslinking of cell wall proteins, thereby restricting pathogen penetration of the host. H_2O_2 , particularly if further reduced to form hydroxyl ($\bullet OH$) radicals, will initiate membrane lipid peroxidation. This could be a step inducing the formation of the defense hormone, jasmonic acid. Equally, H_2O_2 can migrate through the membrane to act as an oxidative signal regulating defense gene expression.

HR elicited by a bacterial pathogen showed reduced NO production and, crucially, delayed cell death. One important outstanding question is the mechanism through which NO is generated. Although mammalian NOS inhibitors can suppress NO production no plant NOS has been isolated. The NADPH-dependent reduction of nitrite by nitrate reductase is a likely alternative mechanism but nonenzymatic reduction of nitrite is also a potential source of NO (see Section 20.2.3).

20.10.5 Some plant pathogens cause necrosis of the host plant tissue

HR is not the only form of cell death associated with pathogenic challenge. In the case of attack by necrotrophic pathogens, which feed on dead tissue, host cell death and maceration is intrinsic to their pathogenic mechanisms. One such necrotrophic pathogen is the causal agent of grey mold, *Botrytis cinerea*, which is highly virulent on soft fruits (Fig. 20.50A) and a major source of reduced soft fruit yields. *B. cinerea* attacks not only the fruit but also the leaves of plants (Fig. 20.50B).

It may be surprising that necrotrophic pathogens induce PCD given that cell death in HR is often a mechanism to limit

the spread of pathogens. It is clear, however, that initiation of HR actually aids *B. cinerea* pathogenesis. Indeed, microscopic examination shows that cells infected with *B. cinerea* exhibit cytoplasmic vesiculation and coagulation, a feature of HR (compare Fig. 20.44D with Fig. 20.50C). In necrotrophic attack, cell death is initiated not through recognition of an avirulence gene product, but through the action of a pathogen-derived toxin or enzyme. *B. cinerea* produces a series of botrydial and botcinolide toxins that, when applied to plants, cause chlorosis and light-dependent death. However, more important for *B. cinerea* are enzymes that degrade the cuticle. These serve two functions: to aid in host penetration and to induce the host to generate an oxidative burst elicited through cell wall fragments. Hence, the pathogen tricks the host into killing itself. However, *B. cinerea* must still withstand effects of ROS generation. Here it is likely that SOD plays a role, as knockouts in the *BcSOD1* gene exhibit reduced virulence. As cells start to die, a cocktail of pectolytic enzymes produced by the fungus helps macerate host tissue via non-PCD necrotic mechanisms as well as by supplying further PCD elicitors.

In other necrotrophic pathogens, toxins play a much more active role in initiating host cell death. A particularly well-characterized toxin, victorin, is produced by *Cochliobolus victoriae*. *C. victoriae* is the cause of Victoria blight in oats

FIGURE 20.50 Infection of plants with *Botrytis cinerea*. (A) Strawberry fruits at 7 days and (B) *Arabidopsis* leaves at 3 days following inoculation with *Botrytis cinerea*. Bar = 1cm. (C) Trypan blue vital staining of an infected *Arabidopsis* epidermal cell at 24 hours following infection. Bar = 50 mm. Source: Photographs from L. Mur's own work, taken by T. Pugh.

(*Avena sativa*), and its pathogenicity is absolutely dependent on the production of victorin. Victorin is a host-selective toxin in that it requires interaction with an oat *Vb* allele. Application of victorin alone to *Vb* oats is an effective inducer of chlorosis and ultimately cell death and has become a well-characterized model for PCD (Fig. 20.51). Initial studies established that victorin binds to and inhibits the 100-kDa protein of glycine decarboxylase (GDC), an enzyme of photorespiration (see Chapter 14). Victorin also initiates proteolytic cleavage of Rubisco by an unidentified protease, making a return to normal carbon fixation impossible and encouraging the initiation of senescence. More exhaustive analyses have demonstrated that victorin induces many features classically associated with PCD, including DNA fragmentation and the initiation of PTP formation within mitochondria. PTP formation allows the entry of victorin to inhibit GDC as well as dissipating the mitochondrial membrane potential leading to a collapse in ATP generation. Crucially, the use of inhibitors has established that a key trigger for these victorin effects is the activation of host Ca^{2+} and ethylene signaling. Taken together,

victorin appears to trigger host PCD in a manner that also includes facets of a senescence program. The next section considers further interplay between senescence and pathogenesis-related PCD in terms of the role of plant hormones.

20.11 Plant hormones in senescence and defense-related PCD

It is notable that initiation of a senescence-like chlorosis response is a feature common to many plant diseases. In the well-characterized bacterial pathogen *Pseudomonas syringae* pathovar (*P.s. pv.*) *tomato*, which can attack *Arabidopsis*, chlorosis is dependent on the toxin coronatine. Coronatine acts by exactly mimicking the action of jasmonates, which, although having a role in defense, can also contribute to initiation of chlorosis. Related bacterial phytopathogenic species provide

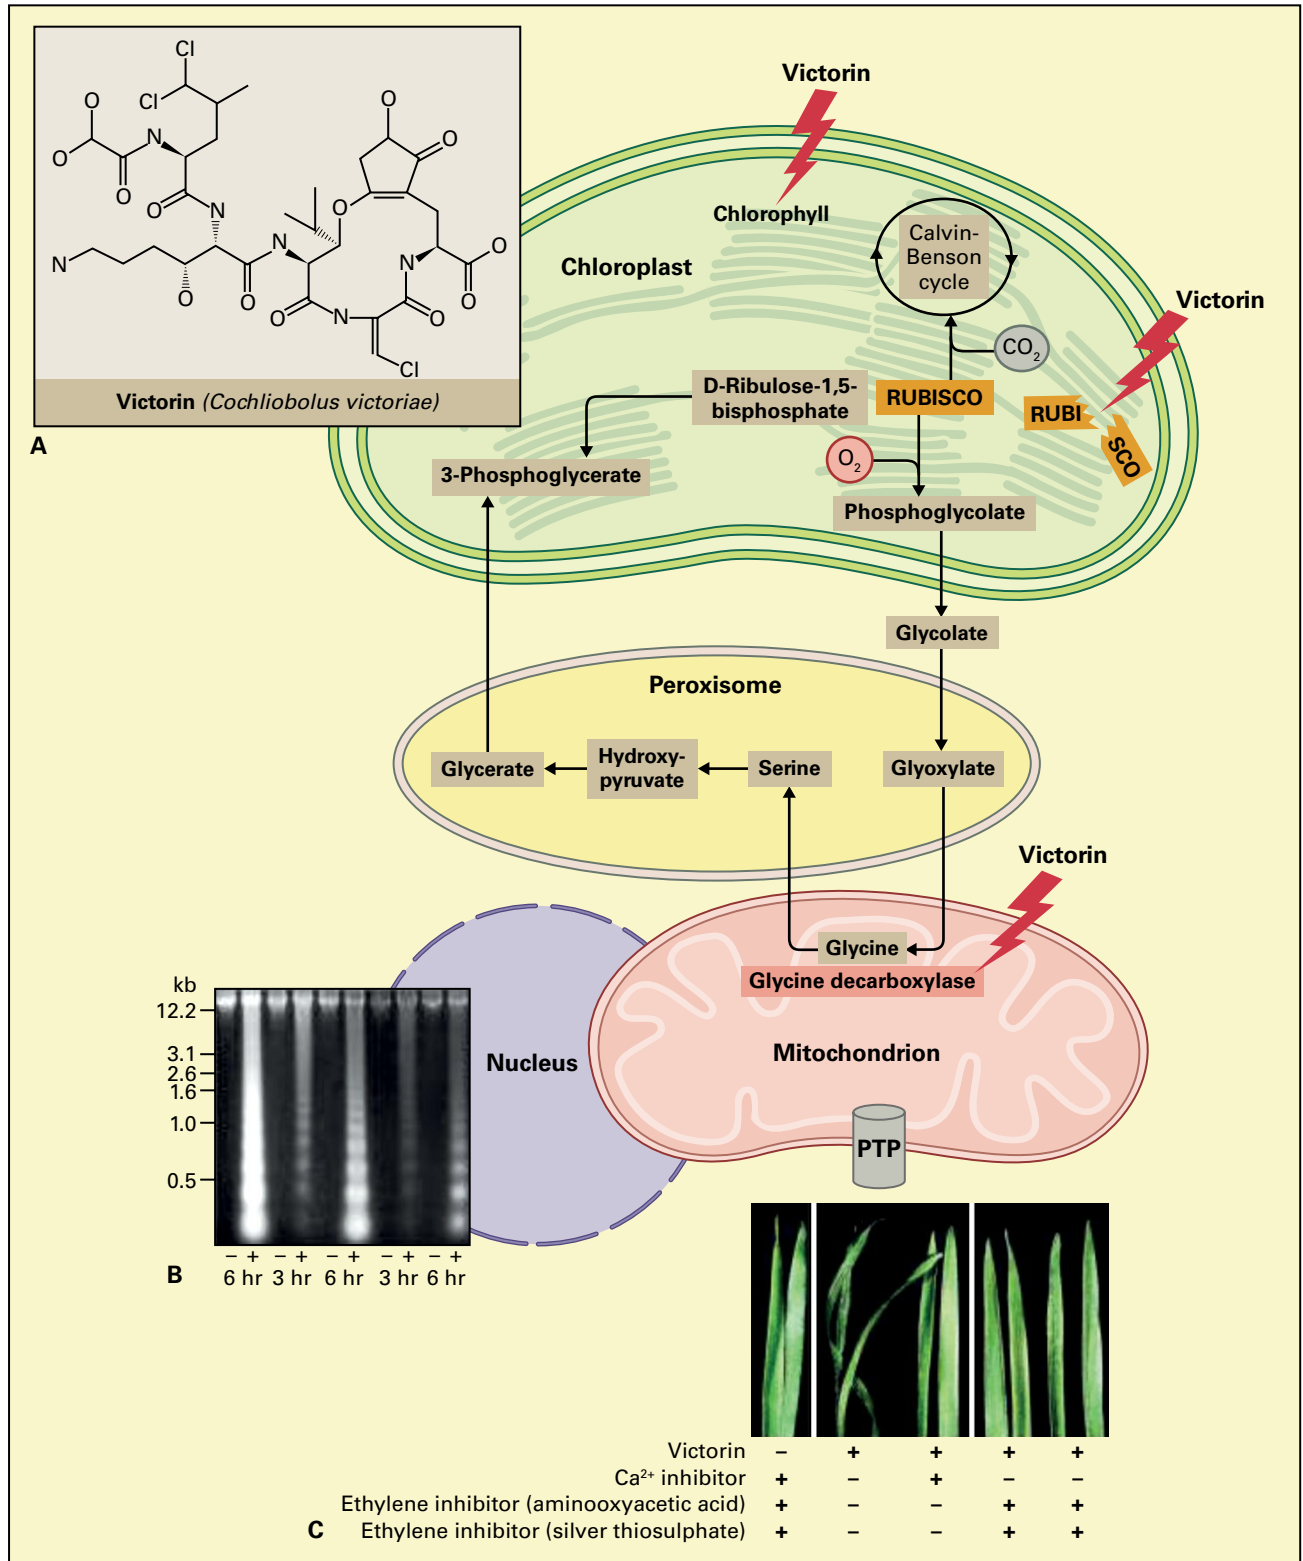

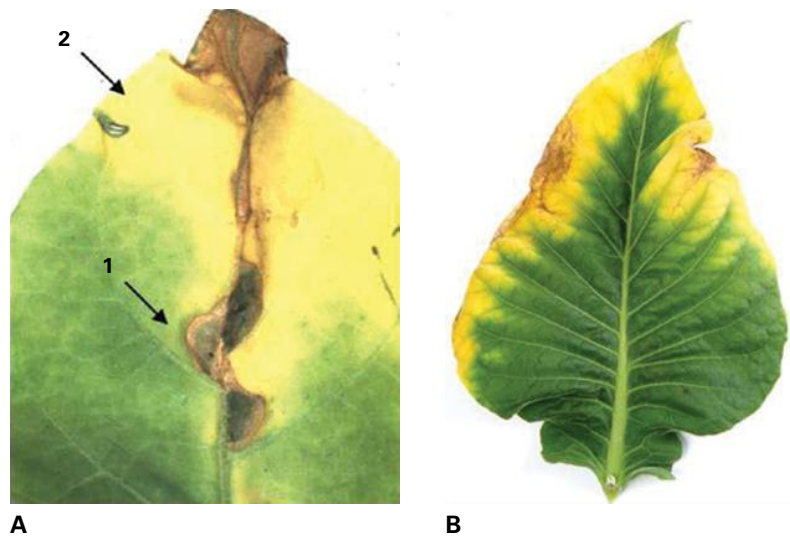

FIGURE 20.51 Mechanism of victorin-induced PCD. The toxin victorin (A) is produced by the oat fungal pathogen *Cochliobolus victoriae*. (B) Treatment with victorin will cleave RUBISCO, initiate proteolytic chlorophyll catabolism and disrupt photorespiration by inhibiting glycine decarboxylase. Mitochondria are perturbed through the initiation of PTPs, leading to a dissipation of proton motive force. Within the nucleus, victorin initiates DNA laddering. (C) Victorin-initiated PCD can be suppressed by calcium and ethylene inhibitors. Source: Navarre & Wolpert (1999). *Plant Cell* 11:237–249.

FIGURE 20.52 Wildfire disease and senescence in tobacco. (A) Wildfire disease symptom at seven days after infection caused by *Pseudomonas syringae pathovar tabaci*. The original site of infection, by this stage a necrotic area, is shown (arrowed 1). Note the spreading necrosis proceeding along the central vein, and large area of chlorosis (2). (B) A senescent tobacco leaf also displaying necrotic and chlorotic symptoms.

other examples of toxins. In *Phaseolus vulgaris* pathogen *P. s. pv. phaseolicola*, chlorosis is elicited through the action of a tetrapeptide toxin, phaseolotoxin. This acts by inhibiting carbamoyltransferase within the ornithine cycle to block arginine biosynthesis. With the wildfire pathogen of tobacco, *P. s. pv. tabaci*, chlorosis is initiated by tab-toxin, a dipeptide that inhibits glutamine synthase resulting in a buildup of ammonia that disrupts photosynthesis and destroys thylakoid membranes. If wildfire symptoms on tobacco are compared with senescence in the same species, phenotypic similarities are immediately apparent (Fig. 20.52). Hence, current thinking suggests that pathogenic attack establishes a new sink within plants so that infected plant cells become a source of photoassimilates. Upon infection, there is a rapid reduction in photosynthetic electron flow but an increase in the production of hexose sugars, possibly arising from the mobilization of starch. There are also increases in cell wall invertase activities, which could supply sugars to pathogens located in the apoplast.

Equally, it is counterintuitive that, during the senescence phase of their life cycles, plants would offer a feast to potential invaders when resources should be allocated elsewhere, for example in seed filling. This may explain why bona fide senescence in plants is often associated with the initiation of plant defense, and why certain hormones to which senescence has been shown to be responsive, for example, jasmonates or salicylates, are also well-established mediators of resistance against pathogens. Here we discuss the roles of the major classes of plant growth regulators in senescence, PCD and pathogenesis.

20.11.1 Cytokinins act as senescence antagonists

Cytokinins appear to play a major role in regulating senescence by inhibiting the senescence process. Two lines of evidence initially suggested that cytokinins might function in blocking senescence. First, levels of endogenous cytokinins

FIGURE 20.53 Green islands in leaf of *Prunus*, caused by infection with the necrotrophic fungus *Cercospora*. Original photograph by John L. Stoddart and Howard Thomas.

decrease in most senescing tissues. Second, exogenous application of cytokinins can cause a delay in senescence in most tissues. The effect of cytokinins varies with the age and type of tissue treated as well as from species to species. The ability of cytokinins to delay senescence has been exploited by some plant pathogens that infect leaves. Increased cytokinin levels in a zone surrounding the infection site causes delayed senescence in this tissue, producing “green islands,” areas of green tissue in a background of senescing, yellowing leaf (Fig. 20.53). It is not clear whether the pathogen generates cytokinin directly or induces the plant to produce it.

Molecular techniques have been used to examine the role of cytokinins at various stages of plant development, including senescence. The *ipt* gene from *Agrobacterium tumefaciens* encodes the enzyme isopentenyltransferase, which catalyzes a limiting step in cytokinin biosynthesis (see Chapter 17). This bacterial gene has been used to generate transgenic plants that overproduce cytokinins. The *ipt* gene has been fused to a variety of promoters to enhance tissue-specific expression and produce localized areas with high concentrations of cytokinins. In all cases, delayed senescence was seen in the parts of the plant that had highest cytokinin levels. Elevated levels of cytokinin caused by the overexpression of the transgene led to other phenotypic

FIGURE 20.54 Autoregulated expression of a cytokinin biosynthesis gene in tobacco results in delayed leaf senescence in the transgenic plant (right) in comparison with the wild-type plant (left). The *Agrobacterium tumefaciens* gene encoding isopentenyltransferase (*ipt1*), an enzyme that catalyzes the synthesis of cytokinin, was fused to the promoter of *SAG12*, a gene specifically expressed in senescing tissue. Expression of this fusion gene in transgenic tobacco is induced when a leaf begins to senesce. The resulting increase in cytokinin content blocks leaf senescence.

Source: Gan & Amasino (1997). *Plant Physiol.* 113:313–319.

abnormalities as well, making it difficult to determine if the delay in senescence was due directly to high cytokinin levels or to some secondary effect. When plants containing the *ipt* gene fused to a heat shock promoter were given a heat treatment to induce transgene expression delayed leaf senescence correlated with elevated levels of cytokinins. These results are somewhat complicated by the fact that the heat treatment required to induce expression via the heat shock promoter is in itself a form of stress that may affect the senescence program.

In an elegant refinement of these experiments, *ipt* was fused to the promoter of *SAG12*, a gene specifically expressed in senescing *Arabidopsis* leaf tissue. Tobacco (*Nicotiana tabacum*) plants transformed with the *SAG12* promoter-*ipt* fusion produce cytokinin in an autoregulated fashion (Fig. 20.54). As tissue starts to senesce, the transgene is induced, and cytokinins are produced. Cytokinins inhibit senescence, which in turn decreases expression of the transgene. Cytokinin is produced only in senescing tissue, and only in the amount needed to block senescence. Plants expressing *SAG12-ipt* have no significant morphological differences from the untransformed plants but do show a significant delay in leaf senescence, with older leaves retaining photosynthetic activity longer than leaves of control plants lacking the transgene (Fig. 20.54). These experiments have been repeated in many plant species, including food crops, and demonstrate that production of cytokinins in leaves can result in delayed senescence. One consequence of longer photosynthetic life span of leaves on these plants is a concurrent increase in the number of seeds produced. Remarkable improvements in drought tolerance have also been observed. The practical implications for agriculture are obvious.

One possible explanation for the senescence-delaying effects of cytokinin is their enhancement of sink activity. Tissues with the highest cytokinin levels are the strongest metabolic sinks, thus the majority of nutrients are directed to them. Cytokinins are normally produced in roots and

transported to leaves. One hypothesis to explain leaf senescence post-flowering suggests that, in many plants, cytokinins from the root are redirected into the developing seed instead of into leaves. The seed, therefore, becomes a stronger sink and nutrients are diverted from leaves into seeds, triggering leaf senescence. Extracellular invertase, which is associated with apoplastic phloem unloading, is of particular significance for source–sink interactions in cytokinin function. Inhibiting extracellular invertase also results in the inhibition of cytokinin-mediated delay of leaf senescence.

Recent work has identified an important role for a cytokinin receptor, the histidine kinase *AHK3*, in controlling the response of leaf senescence and other developmental processes to cytokinin. A loss-of-function mutant of *AHK3* in *Arabidopsis* is alone among the known cytokinin receptors in conferring reduced sensitivity of leaf senescence to applied cytokinin, but the timing of natural leaf senescence is not affected. On the other hand, the gain-of-function *AHK3 Arabidopsis* mutant *ore12-1* (see Section 20.5.2) shows delayed leaf senescence. The action of *AHK3* is mediated by phosphorylation of *ARR2* (*Arabidopsis Response Regulator 2*), which is essential for determining leaf longevity.

Cytokinin may influence the course of senescence by repressing the expression of key *SAGs*. Among a group of genes observed to be upregulated when *Petunia hybrida* callus cultures are transferred to low-cytokinin medium is a gene encoding a cysteine protease and one encoding a peroxidase. Expression of these two genes is strongly enhanced in senescing leaves. Upregulation of the protease gene *See1* in maize and *Lolium multiflorum* has also been shown to be suppressed by cytokinin treatment. It seems likely, therefore, that cytokinins act at two levels: at a distance by promoting differentiation and strong sink activity, and locally in senescing cells by mediating the launch of the senescence program.

The dual action of cytokinins is seen most dramatically in regreening (Fig. 20.55). At flowering the lowest, oldest leaves of a mature plant of *Nicotiana rustica* are almost completely yellow. If the shoot is cut off just above the lowest node and the plant kept in dim light, leaves will gradually regain their green color. This process is greatly accelerated if the leaf is treated with cytokinin solution. During regreening, expression of *SAGs* is suppressed, genes for plastid assembly are turned on, gerontoplasts of the yellow leaf redifferentiate into chloroplasts and photosynthetic activity returns. Not only is this a demonstration of the potency of cytokinin as an anti-senescence factor, it shows that leaf senescence is potentially reversible to an advanced stage and thus fundamentally distinct from other PCD processes.

20.11.2 Ethylene acts primarily as a promoter of senescence

Among the known plant hormones, ethylene is typically the strongest promoter of senescence. Treatment with exogenous ethylene can induce senescence of leaves and flowers and

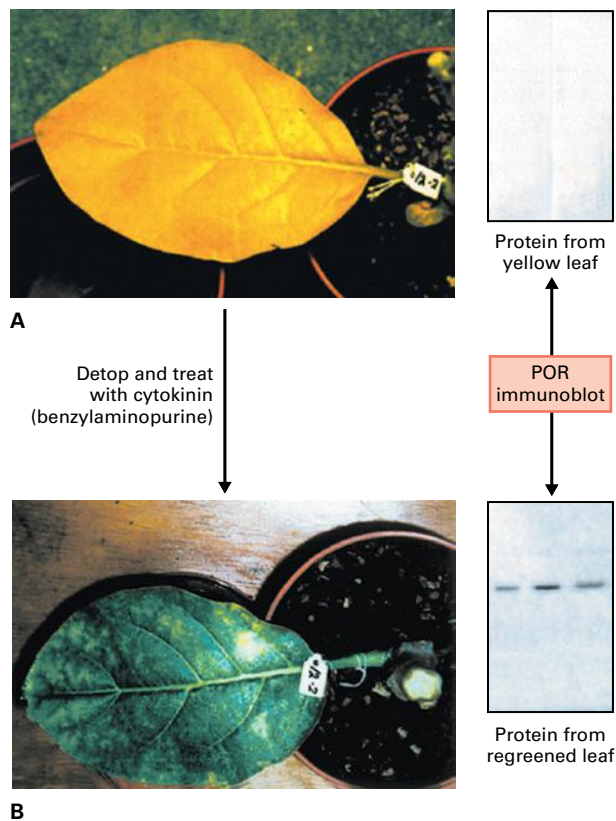

FIGURE 20.55 Regreening in tobacco. Nothing illustrates the fundamental distinction between senescence and many other kinds of PCD better than reversibility. (A) The most basal (oldest) leaf on a flowering *Nicotiana rustica* shoot has lost nearly all measurable chlorophyll. However, the leaf can recover full greenness (B) if the stem is removed at the node, particularly if the leaf is treated with the synthetic cytokinin benzylaminopurine. Even terminally senescent tobacco leaf cells can redifferentiate their gerontoplasts into functional chloroplasts. Proteins characteristic of chloroplast assembly in very young cells—such as the chlorophyll synthesis enzyme protochlorophyllide oxidoreductase—are re-expressed.

Source: Bleeker, University of Wisconsin, Madison; previously unpublished.

ripening of fruits in many, but not all, plants. For example, treatment of *Arabidopsis* leaves with ethylene causes changes that parallel those seen in naturally senescing leaves (Fig. 20.56). Leaves begin to yellow, and there is a corresponding decrease in expression of photosynthesis-related genes along with an increase in expression of SAGs. Furthermore, endogenous ethylene levels correlate with leaf senescence. As leaves get older, or are induced to senesce by dark treatment, they produce more ethylene.

For many plants, pollination triggers floral senescence. Ethylene production in *Petunia hybrida* can be detected within 20 minutes of pollination, preceding penetration of the stigma by the pollen tube (Fig. 20.57). Thus, the recognition of pollen by stigma may be sufficient to induce ethylene production. In contrast, there are also cases in which normal flower senescence is essentially insensitive to ethylene. Lilies of the genus *Alstroemeria*, widely used as cut flowers, are among the best-known examples of ethylene-insensitive floral senescence.

Because of its economic importance, much of the work on ethylene regulation of senescence has been done in the context of fruit ripening. During normal development of climacteric fruit such as tomato there is a developmentally regulated burst of respiration and ethylene production, followed by an increase in the expression of specific genes encoding enzymes such as polygalacturonidase that contribute to the softened-tissue phenotype associated with ripening. Linked to this are changes in fruit color and flavor that characterize ripening. The effectiveness of exogenous ethylene as a ripening agent has been known for over a century, and controlled exposure to ethylene is still a major factor in the successful marketing of many fruits. Further evidence for the critical role of ethylene in senescence comes from experiments designed to test whether ethylene perception is required for senescence. The *Arabidopsis etr1* mutant (see Fig. 20.56) and tomato *never ripe* (Fig. 20.58) are insensitive to ethylene due to mutations in an ethylene receptor protein. These plants show delayed leaf senescence and, in the case of tomato, normal senescence of floral organs is delayed as well. *never ripe* fruits do not fully ripen, giving the tomato mutant its name.

Experiments to reduce ethylene production in plants have provided more evidence for the role of ethylene in senescence. Chemical inhibitors of ethylene biosynthesis or action have been shown to inhibit fruit ripening and leaf senescence. Similar results have been obtained with plants engineered to produce reduced levels of ethylene. ACC synthase and ACC oxidase catalyze the last steps in ethylene biosynthesis in plants. Tomato plants expressing these genes in the antisense orientation exhibit greatly reduced ethylene levels. When these plants are grown in air, their fruit never completely ripen and leaf senescence is delayed, but they show normal senescence and ripening when treated with exogenous ethylene (Fig. 20.59).

FIGURE 20.57 Ethylene production by unpollinated control and pollinated *Petunia hybrida* flowers. Note the burst of ethylene synthesis that rapidly follows application of pollen.

It should be noted that the role of ethylene can be somewhat different in different organs, even within the same plant. In ethylene-insensitive mutants of *Arabidopsis* and tomato, leaf senescence is delayed, but leaves eventually senesce even in the absence of ethylene perception. However, fruits of ethylene-insensitive tomato mutants never fully ripen. Therefore, ethylene promotes but is not essential to senescence in leaves, whereas it is an absolute requirement for tomato ripening. Finally, ethylene does not act alone to promote senescence. Age-related factors not yet identified are also important in regulating senescence, and treatment of leaves, flowers and fruits with ethylene is effective in inducing the senescence program only if various organs have reached the appropriate developmental stage. In addition, tomato plants engineered to overproduce ethylene show no altered leaf senescence phenotype, again suggesting that ethylene alone is not sufficient to trigger senescence.

Ethylene effects on senescence are antagonized by NO. In unripe strawberry and avocado (*Persea americana*) NO levels are high and ethylene levels low, a condition which is reversed during ripening. Transgenic *Arabidopsis* expressing a NO-degrading dioxygenase (NOD) exhibit a senescence-like phenotype with associated increases in many senescence-associated and ethylene biosynthesis genes. If NOD plants were gassed with NO, the senescence phenotype was suppressed. A possible mechanism through which NO could suppress ethylene synthesis was revealed by a proteomic study focusing on protein S-nitrosylation, where NO is covalently attached to cysteine thiol groups. Among the S-nitrosylated proteins identified was S-adenosylmethionine (SAM) synthetase that forms part of the ethylene biosynthetic cycle. S-nitrosylated SAM synthetase exhibited suppressed enzyme activity and therefore, in presence of NO, ethylene production is likely to be reduced.

FIGURE 20.58 In wild-type tomato, treating the inflorescence with ethylene causes the flowers to senesce and abscise (A). An ethylene receptor mutant, never ripe, is insensitive to ethylene, so that treatment of a never ripe inflorescence does not trigger senescence and abscission (B). In untreated wild-type flowers, floral senescence follows pollination (C), whereas never ripe flowers do not senesce after pollination but instead remain intact, even as the fruits begin to develop (D). As the name implies, fruits of the never ripe mutant do not ripen, as illustrated by never ripe and wild-type tomato fruits of approximately the same age and grown under the same conditions (E). Thus, in tomato ethylene is a key signal in inducing floral senescence after pollination as well as fruit ripening.

Source: (A–E) Lanahan et al. (1994). *Plant Cell* 6:521–530.

FIGURE 20.59 Tomato fruits require both ethylene and unknown age-dependent factors for normal ripening. Fruits from wild-type control plants (left panel) maintained in air or in air supplemented with ethylene ripen at roughly the same time. Tomato plants expressing the ACC synthase gene in the antisense orientation (right panel) produce markedly less ethylene than do wild-type plants, and their fruits do not ripen when maintained in air but do ripen normally when kept in air with added ethylene. These results demonstrate two points. First, ethylene is necessary for tomato fruit ripening. In the plants that produce little ethylene, the fruit do not ripen unless they are treated with exogenous ethylene. Second, ethylene alone is insufficient to induce ripening. For example, ethylene does not induce ripening in fruits from wild-type plants that are less than 59 days old. Source: Theologis et al. (1993) *Dev. Genet.* 14:282–295.

20.11.3 Salicylic acid is a key component of signaling pathways in some forms of PCD

The hormone SA was first described as an important mobile signal in establishing systemic acquired resistance to pathogen attack within days of the initial hypersensitive response (HR; see Section 20.10). Subsequently it has become clear that SA may not be the most important systemic signal, but it has emerged as playing a major role in setting the kinetics of HR and also in conferring tolerance to heat stress and suppressing plant growth in response to chilling. The expression of many genes has been shown to be influenced by SA, including those encoding acidic forms of PR proteins and the class of small molecular weight heat shock proteins. The PR protein gene *PR1* has been particularly useful for mapping the SA signaling pathway. In particular, characterization of the non-PR expressing mutant *npr1-1* (see Section 20.8.2) has revealed a key transcriptional regulator of SA-mediated effects. Under nonstressed conditions *NPR1* exists in the cytoplasm in oligomeric form, but with oxidative stress *NPR1* monomers are liberated, aided by thioredoxins. *NPR1* monomers are targeted to the nucleus where they interact with activators of *PR1* gene expression. *NPR1* also binds to *WRKY53*, an important transcriptional regulator of senescence.

Interaction of SA with oxidative stress is essential for its action. Moreover SA acts to augment oxidative stress. Such potentiation of the oxidative burst by SA has been shown to occur during pathogen-elicited HR and responses to heat stress. In both cases the SA-ROS interaction is essential for full resistance/tolerance to be exhibited. The mechanism(s) of SA-augmented oxidative stress remain to be defined completely, but they include disruption of mitochondrial electron transport.

SA also has a role in leaf senescence. In a microarray experiment comparing senescence in wild-type *Arabidopsis* to that in *npr1* and in a transgenic line expressing *NahG* (a bacterial gene which degrades SA to catechol), expression of many SAGs, including *SAG12*, is suppressed (Fig. 20.60). Phenotypically, *NahG* transgenic plants and *npr1* mutants show delayed yellowing and reduced necrosis, indicating that SA acts mainly in the death phase of senescence.

20.11.4 Some evidence suggests roles for jasmonates in senescence

Jasmonates, a large group of signal molecules that includes jasmonic acid (JA) and related compounds (see Chapter 17), are derived from the acyl chains of membrane phospholipids. Lipoxygenase enzymes catalyze the dioxygenation of

FIGURE 20.60 cDNA microarrays illustrate the impact of salicylic acid (SA) on senescence-related gene expression in wild-type *Arabidopsis* and a transgenic line expressing the bacterial NahG gene, whose product degrades SA to catechol. cDNAs for senescence-enhanced and control genes were spotted onto glass slides and probed with first-strand cDNA made from RNA isolated from wild-type or NahG plants. Intensity of fluorescence correlates to levels of expression, with white the highest, followed by red, orange, yellow, green, turquoise, bright blue, and dark blue. Most genes are expressed at the same level in both plants, but some SAGs are suppressed in the NahG plants (see boxes).

Source: Buchanan-Wollaston et al. (2003) *Plant Biotechnol. J.* 1:3–22.

polyunsaturated fatty acids in lipids, leading to the formation of oxylipins, the group of biologically active derivatives to which jasmonates belong. Oxylipins in general, and jasmonates in particular, came to prominence when it was established that they play a central role in defenses against insects. There is growing evidence in favor of many developmental functions for oxylipins, including regulation of senescence. For example, suppression of phospholipase or acyl-hydrolase activity has been shown to delay senescence, and increases in lipoxygenase activity are characteristic of senescence. The role of jasmonates themselves in senescence is unclear. Levels of JA increase during senescence in detached *Arabidopsis* leaves, and senescence is perturbed in the JA-insensitive mutant *coi1*, which is altered in a key signaling component. On the other hand, normal developmental senescence is unaffected in *coi1*. Further work is required to clarify the role of jasmonates in senescence.

20.11.5 Additional hormones influence defense responses and senescence

ABA acts in most situations as a promoter of senescence. While leaf abscission is clearly related to senescence, and exogenous ABA can often cause yellowing in leaves, there is no consistent correlation between endogenous ABA levels and tissue senescence. During senescence there is generally an increase in expression of genes encoding enzymes of ABA biosynthesis, including 9-*cis*-epoxycarotenoid dioxygenase and aldehyde oxidase, and of the ABA-inducible receptor-like kinase gene *RPK1*.

Some of the possible links between ABA and senescence appear contradictory. ABA is reported to promote accumulation of H_2O_2 in leaf tissues, though it is not clear whether

this is a cause or effect of accelerated senescence. At the same time, ABA has also been observed to enhance gene expression and enzyme activity for SOD, APX, and CAT. Furthermore, ABA induction of senescence was suppressed in transgenic lines where the activity of phospholipase was reduced. This suggests that membrane perturbation, which may or may not depend on oxidative stress, is important for the action of ABA on senescence. A known interaction between ABA and ROS has been revealed in the tomato ABA mutant *sitiens*. In this mutant, compromised ABA signaling leads to increased H_2O_2 generation, cell death and resistance following attack by the necrotrophic pathogen *Botrytis cinerea*. This suggests a role for ABA in suppressing defense—including cell death—against pathogens. Similarly, in the case of *Pseudomonas syringae*, a bacterial virulence effector, *AvrPtoB*, is delivered into the cytoplasm and specifically activates ABA signaling, again to suppress defenses. In short, ABA effects are strongly context-specific. For example, the capacity of ABA to immortalize isolated aleurone cells (Section 20.2.2) suggests a function in regulating the balance between the maintenance of viability during senescence and the subsequent onset and execution of terminal PCD processes.

Other hormones have been shown to contribute to senescence. Gibberellins (GAs) usually retard senescence, but this is by no means a universal response. For example, in *Arabidopsis* GA has been noted to repress the effects of the anti-senescence hormone cytokinin. This may be mediated by the gene *SPINDLY* (*SPY*) because *spy* mutants, besides exhibiting a constitutive GA phenotype, do not respond to exogenously applied cytokinin by delaying senescence. In most cases, treatment with exogenous auxins delays senescence, but there are also species in which such treatments promote senescence. Attempts to correlate levels of endogenous auxin or GA with senescence have been inconclusive.

Summary

Mechanisms of senescence and cell death in plants share some features with PCD processes in other organisms, but the ways in which they are regulated, integrated into development and responsive to the environment are distinctive. The fate of most plant cells is sooner or later to undergo autolysis, following one of several possible routes. These routes include lysigeny (with or without schizogeny), autophagy, transdifferentiation, hypersensitive cell death, or necrosis. There are common factors between these different outcomes, for example, activation of macromolecular hydrolysis and oxidative metabolism, but also many nonoverlapping functions. These provide plants with versatile options for dealing with the challenges of a sedentary lifestyle.

Despite rapid advances in our understanding of plant PCD, many major unknowns remain. To what extent is the picture established for model species, notably *Arabidopsis*, applicable to plants in general (and crop species in particular)? How are cell death and senescence processes switched on at the molecular level?

What are the biochemical and regulatory mechanisms of nutrient recycling? To what extent are PCD, senescence, maturation, ripening, lifespan and ageing related and can understanding such relationships offer the prospect of controlling these critical biological processes? Among the new approaches that are being employed to answer these questions are the tools of Systems Biology, the study of micro-RNAs and epigenetics and the application of modeling techniques and phenology. The objectives of the next period of research effort will include breaking down PCD and senescence into subprocesses and quantifying their contributions to development, fitness, and productivity. This will involve physiological, biochemical, and “omics” analyses and comparative studies to establish read-across between plant models and other species. Ultimately the practical aim is to pinpoint the genes that will make a difference when manipulated, allowing development, longevity, fitness, and crop performance to be predicted and controlled.

Responses to Plant Pathogens

*Kim E. Hammond-Kosack
and Jonathan D. G. Jones*

Introduction

Plants must defend themselves continuously against attack from bacteria, viruses, viroids, fungi, oomycetes, protists, mycoplasmas, invertebrates, and even other plants. In vertebrate immune systems, specialized cells devoted to defense are rapidly mobilized to the infection site, where they either kill the invading organism or limit its spread. In contrast, plant cells have both preformed and inducible defenses, and these cell-autonomous plant defenses prevent most infections. Indeed, in wild plant populations, most plants are healthy most of the time; if disease does occur, it is usually restricted to only a few plants and affects only a small amount of tissue. Disease, the outcome of a successful infection, rarely kills a plant. Natural selection likely acts to curtail pathogen lethality; those pathogens that keep a host species alive longer may achieve more reproduction.

Interactions between plants and pathogenic organisms have been the subjects of intensive research for at least five main reasons. First, a detailed understanding of plant–pathogen interactions should provide sustainable solutions for the control of crop diseases. Crop monocultures are vulnerable to severe disease epidemics that can lower both crop yield and quality and diminish the safety of our food supply (Fig. 21.1 and Box 21.1). Disease control using agrochemicals increases energy consumption, environmental pollution, and the cost of production. Second, studies of plant–pathogen interactions can reveal signaling mechanisms by which plant cells cope with biotic stresses. For example, do defense signaling mechanisms triggered by

pathogen invasion differ from those provoked by wounding, low or high temperature, high salinity, desiccation, or water-logging? Third, studying plant–microbe interactions in general reveals how organisms from different kingdoms communicate with one another. What type of messages do they exchange, how and where do these exchanges occur, and how are appropriate responses on both sides activated? Fourth, understanding plant–pathogen interactions leading to disease can illuminate how other organisms co-exist within a plant without causing damage, and how symbiotic organisms establish beneficial interactions with plants. Fifth, host–parasite and host–symbiont interactions provide fascinating insights into evolution.

This chapter examines the molecular mechanisms by which plants defend themselves from attack by microbial and viral pathogens and invertebrate pests. It also covers how pathogenic organisms may have evolved and the strategies they use for invasion of plant tissue.

21.1 Pathogens, pests, and disease

Pathogens and pests have coevolved with plant hosts since long before the domestication of crop plants. A **plant pathogen** is any organism that completes a part or all of its life cycle inside the plant, often with detrimental effects. A **plant pest**, on the other hand, is a herbivorous insect, nematode, mammal, or bird that eats vegetative tissue, fruits, and seeds.

FIGURE 21.1 The floral tissues of hexaploid wheat (*Triticum aestivum*) severely infected with the ascomycete fungus *Fusarium graminearum* and other cereal-attacking *Fusarium* species. Referred to as *Fusarium* head blight, *Fusarium* ear blight, or head scab, this disease is a threat to global wheat crops. Wheat spike infections take place at crop anthesis if wet weather prevails, leading to premature bleaching and senescence of floral tissues (left). Infected wheat grains are small, shriveled, and show a pink coloration (lower right) compared to the plump grains recovered at harvest from a healthy wheat ear (upper right). Several mycotoxins produced by cereal-infecting *Fusarium* species are harmful to both human and animal consumers. Source: Beacham et al. (2009). *The Biologist* 56:98–105.

Three scenarios can explain the origin of pathogens. First, when plant ancestors emerged onto the land from the oceans, they may have brought parasites with them. Second, ocean-dwelling species, upon arrival on dry land, may have evolved from a free-living existence to a pathogenic lifestyle. Third, the arrival of the new land-dwelling species and the emergence of non-motile, plant-based communities may have provided new niches for existing pathogenic species to either switch or expand their host range. These evolutionary steps occurred many millions of years ago and resulted in a continuum of intimate associations between land plants and other species (Fig. 21.2).

The onset of agriculture approximately 10,000 years ago shifted the relationship between the few (<30) domesticated species and their pests and pathogens. During crop domestication, agricultural practices became more mechanized and intensive. The size, density, and genetic uniformity of crop populations expanded, as yields and product quality increased to meet rising human and domestic animal needs. Today, on the 10.5% of the planet's surface where crop agriculture is practiced, large areas are occupied by **monocultures** of millions of genetically identical crop plants. These monocultures favor the selection of genetic variants of pathogens and pests that can overcome the defense mechanisms of the host genotype. When a genetic variant arises that can overcome resistance, either through mutation, genetic recombination, or acquisition of new genetic information by **horizontal gene transfer** from another species, it can reproduce rapidly and cause massive crop losses.

21.2 An overview of immunity and defense

The interactions between organisms from different kingdoms can be represented as consisting of three phases, referred to as a “zig-zag-zig” scheme (Fig. 21.3A).

Most microorganisms carry molecules called pathogen- or microbe-associated molecular patterns (PAMP/MAMPs), which are often cell wall components that can be recognized by cell surface **pattern recognition receptors** (PRRs) in plants. This recognition by PRRs activates plant defenses, resulting in pattern (or PRR)-triggered immunity (PTI) (Fig. 21.3A,B). PTI in plant cells places selective pressures on potentially pathogenic species to produce proteins or other **effector** molecules, which interfere with and suppress these defense mechanisms or their activation (Fig. 21.3B). This is known as **effector-triggered susceptibility** (ETS). PTI selects also for P/MAMP variants that trigger less PTI.

Successful plant colonization mediated by specialist pathogen effector molecules places selective pressure on the plant population for recognition of these effector molecules and consequent activation of defense. These variant plants have alleles of **resistance (R) genes** that recognize either the effector molecules or the effects of these effectors on host proteins. This form of defense is known as **R gene-mediated defense**, or **effector-triggered immunity** (ETI; Fig. 21.3A,B). Defense mechanisms triggered during ETI are usually stronger than

Plant diseases have plagued agriculture throughout history

Throughout history, a number of plant diseases have plagued agriculture, some resulting in dramatic crop losses and devastating societal consequences.

Perhaps the most notorious of these was the Irish potato famine of the 1840s. The result of late blight disease (A), caused by the oomycete pathogen *Phytophthora infestans*, the famine reduced the population of Ireland from 8 to 5 million in just 3 years through starvation and emigration.

Black stem rust, which results from infection by the basidiomycete *Puccinia graminis* f. sp. *tritici* (B), caused the collapse of production of the North American wheat (*Triticum* spp.) crop in the 1950s. Through the development of new wheat varieties able to resist infection, this problem was alleviated. The disease has since returned in Africa, however, with the emergence of Ug99, a new and highly virulent strain that is not controlled by resistances in most wheat

varieties. Wheat productivity has decreased in all the African regions affected by Ug99. It is spreading across Africa and the Middle East and may soon reach the Punjab in India.

Global banana (*Musa* spp.) production is under threat from black Sigatoka disease, caused by the ascomycete fungus *Mycosphaerella fijiensis*. The disease leads to the premature ripening of fruit, which are then difficult to export and often causes yield losses of over 50%. It is a constant threat to banana productivity because a single highly susceptible variety called Cavendish, bred over 80 years ago, is now grown globally in monoculture.

In addition to mass food shortages, plant diseases have cultural impacts. In the 1870s, the rust *Hemileia vastatrix* decimated coffee (*Coffea* spp.) production of Sri Lanka and led to the adoption of tea as the caffeinated drink of choice in Britain.

A

B

Worldwide, 25 to 35% of crop yield is lost each year because of pests and pathogens, necessitating a USD 30 billion/year agrochemical industry. Diseases on the harvested grain, fruits, seeds, and roots may also cause blemishes that can severely reduce market value. Some pathogenic species attack plant material after harvest, during transport and storage and cause post-harvest losses.

(A) The rapid development of late blight disease in a potato crop caused by the oomycete pathogen *Phytophthora infestans*. Left top to bottom, development of a late blight epidemic in a Scottish potato field crop over a two-week period destroys plants in the entire field. Top right, multiple late blight lesions on a potato (*Solanum tuberosum*) leaf. When lesions are formed on the same leaf by the two different mating types A1 and A2, mating and oospore formation can occur. Bottom right, a close up of the white asexual sporangia and sporangiospores emerging from the lower leaf surface under high humidity around the margins of the leaf lesion.

(B) Black stem rust disease on wheat caused by the basidiomycete *Puccinia graminis f. sp. tritici*. Left, an

infected wheat (*Triticum aestivum*) tiller with pustules of urediniospores erupting onto the plant surface. The spores are subsequently dispersed either by the wind or during grain harvest (center). Wheat yield losses caused by black stem rust are often severe (50–70%), and individual fields can be destroyed. The fungus also develops teliospores on wheat plants that grow and following sexual mating produce a secondary spore, the basidiospore. Basidiospores infect an alternate host, the common barberry plant (*Berberis vulgaris*). On barberry leaves and stems a further spore stage, the aeciospore, is produced (right), and these wind-dispersed spores re-infect the wheat crop. Elimination of barberry from areas of wheat cultivation prevents sexual reproduction in the fungus and slows the evolution of new resistance-breaking strains.

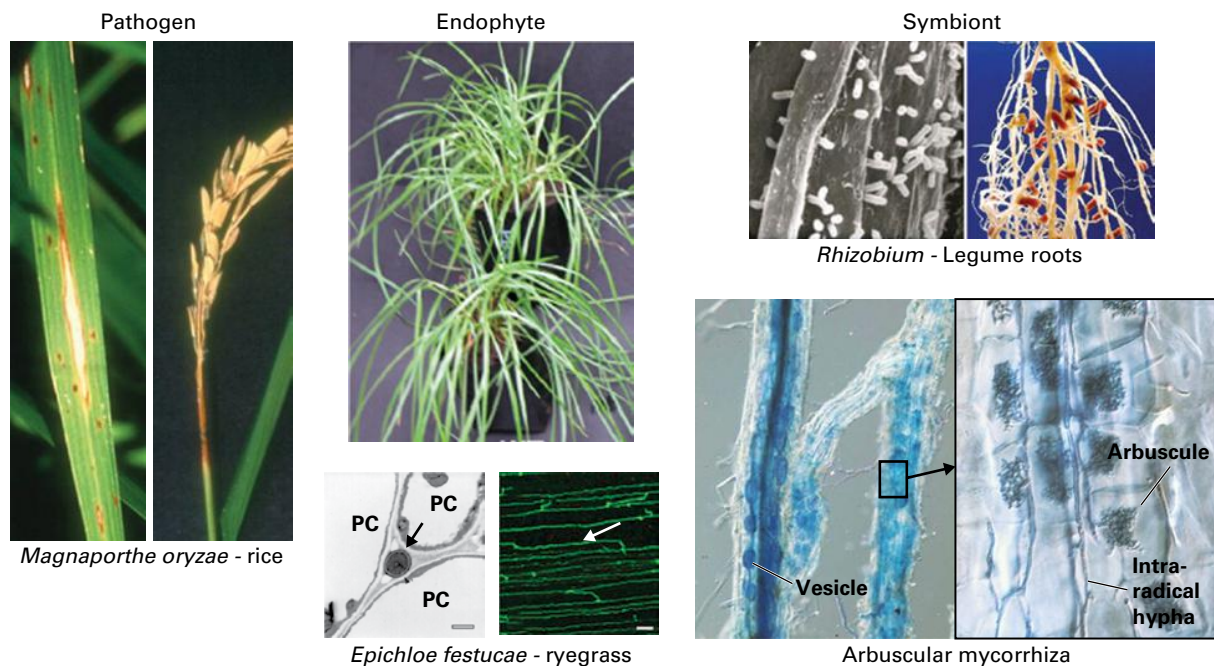

FIGURE 21.2 Pathogens, endophytes, and symbionts: the continuum of microbe–plant interactions. Numerous microbial species have evolved the ability to infect plants in order to grow, develop, and complete their life cycle, but the outcomes are diverse. Pathogens (left) enter and colonize plants in different ways, feed on plant cells, adversely alter plant metabolism, cause a range of detrimental disease symptoms, and lower yields. For example, the fungus *Magnaporthe oryzae* causes rice blast disease and is a serious threat to global rice production. In contrast, endophytes (center) enter and live within plants for at least part of their life without causing apparent disease. Some endophytic infections protect plants by improving tolerance to abiotic or biotic stresses, but others cause detrimental effects. For example, *Epichloe festucae* is an endophytic fungus that infects cool season grasses of the subfamily Pooideae. Infection causes no symptoms to the plant, but causes health problems for foraging farm animals and wild mammals because the fungal hyphae that grow between the plant cells (PC, see arrows in bottom panels) produce various toxic indole–diterpene metabolites. Symbionts (right) form intimate associations with plants that greatly benefit plant growth and development. Numerous species of *Rhizobium* bacteria, for example, infect roots of different legume species, induce nodule formation, and fix nitrogen for the plant. Endomycorrhizae are specialist fungi that infect plant roots and invade cells to form arbuscules. The plant and fungal plasma membranes surrounding the arbuscules contain special transporter proteins across which nutrients can be exchanged. Sugars move from the plant to the fungus as a carbon source for fungal growth, and minerals, especially phosphate, move from the fungus to the plant. Fungal hyphae extend from the infected root into the surrounding soil beyond the regions that can be exploited by root hairs. Arbuscular mycorrhiza associations benefit numerous plants, especially tree species, by acquiring phosphate from nutrient poor soils. (2006). *Plant Cell* 18:2807–2821. *Rhizobium* – Todar’s Online textbook of bacteriology, http://textbookofbacteriology.net/Impact_2.htm. Arbuscularmycorrhiza - Prof Martin Parniske.

FIGURE 21.3 The principles of plant immunity. (A) Zig-zag-zig plant defense response model, showing the amplitude of the defense response elicited by various stages of infection. P/MAMP, pathogen- or molecule-associated molecular patterns; PTI, pattern-triggered immunity; ETS, effector-triggered susceptibility; ETI, effector-triggered immunity; Avr-R, interaction of the recognized effector (avr gene) and the host resistance gene (the R gene); HR, hypersensitive cell death response. (B) The various cellular locations where pathogen–host communication occurs. Bacterial plant pathogens propagate in the extracellular spaces of plant tissues. Most fungal and oomycete pathogens also extend hyphae into this space, although many also form specialized feeding structures, haustoria, that penetrate host cell walls but not the plasma membrane. Other fungi extend invasive hyphae into plant cells, but again do not breach the host membrane. Molecules released from the pathogens into the extracellular spaces, such as lipopolysaccharides, flagellin, and chitin (pathogen- or molecule-associated molecular patterns, P/MAMPs) are recognized by cell surface pattern recognition receptors (PRRs) and elicit P/MAMP-triggered immunity (PTI). Many PRRs consist of an extracellular leucine-rich repeat (LRR) domain (mid-blue), and an intracellular protein kinase domain (red). Many PRRs interact with the related protein BRASSINOSTEROID INSENSITIVE 1-ASSOCIATED KINASE 1 (BAK1) to initiate the PTI signaling pathway. Bacterial pathogens deliver effector proteins into the host cell by a type-III secretion pilus, whereas fungi and oomycetes deliver effectors from haustoria or other intracellular structures by an unknown mechanism. These intracellular effectors often act to suppress PTI; however, many are recognized by intracellular nucleotide-binding (NB)-LRR receptors, which induce effector-triggered immunity (ETI). NB-LRR proteins consist of a carboxyl-terminal LRR domain (light blue), a central NB domain (orange crescent) that binds ATP or ADP, and an amino-terminal Toll, interleukin-1 receptor, resistance protein (TIR), or coiled-coil (CC), domain (purple oval).

FIGURE 21.4 The hypersensitive cell death response (HR) in resistant barley (*Hordeum vulgare*) epidermal cells to attack by germinating spores of the barley powdery mildew fungus (*Blumeria graminis* f. sp. hordei). (A) Image obtained by phase-contrast light microscopy showing the fungal spore and stained extracellular primary germ tube, the appressorial germ tube. (B) Whole cell autofluorescence of the same epidermal cells as seen under UV light excitation (wavelength 310 nm); only the single cell undergoing the HR exhibits autofluorescence.
Source: Gorg et al. (1993) *Plant J.* 3:857–866.

those triggered by PAMPs, often culminating in a programmed cell death referred to as the **hypersensitive response** (HR) (Fig. 21.4). Though R proteins are usually cytoplasmic receptors that recognize, directly or indirectly, cytoplasmic pathogen effectors, some R proteins are cell surface receptors that recognize apoplast effectors.

For historical reasons, many effector-encoding genes were first called **avirulence (Avr) genes**, because they are recognized by a cognate resistance gene. For example, the *Pseudomonas* AvrPto effector causes **avirulence** (lack of disease) on tomato (*Solanum lycopersicum*) lines that carry the corresponding *Pto* resistance gene.

A successful pathogen overcomes PTI and has effectors that evade R protein-mediated detection. PTI can either be evaded (or attenuated) by mutations that result in subtle changes in the P/MAMP, or suppressed using effectors. Successful pathogens that evade detection in turn impose selection for novel *R* gene variants that can recognize other pathogen effector molecules and then activate defense. In turn, an R protein that recognizes a widespread pathogen effector provides selection pressure on the pathogen for variants that can evade this new *R* gene-specified recognition. These molecular interactions result in **coevolution** between plants and pathogens.

Even during susceptibility, plant defenses are activated, though not enough to completely stop the pathogen. This is sometimes referred to as **basal defense**. Enhanced disease susceptibility (EDS) mutants are compromised in basal defense and are thus quantitatively more susceptible than wild-type plants. This basal defense activation is thought to be due to incomplete attenuation of PTI by the pathogen effector complement, and may also include some weak effector recognition and thus weak ETI.

Mammals have an innate immune system based primarily on PTI via cell surface TOLL-like receptors, and also can trigger defense via Nod-like receptors (NLRs) that resemble plant intracellular R proteins. They also carry an adaptive immune system involving somatic diversification in their antibody complement and circulating antibody-producing cells. Plants lack adaptive immunity and mobile cells, and rely entirely on cell-autonomous **innate immunity**.

Only a small proportion of plant–pathogen infections result in disease. This low rate of pathogen success may be the result of one or several of four main factors:

- the plant species attacked is unable to support the life-strategy requirements of the potential pathogen and so is considered a nonhost;
- the plant possesses preformed structural barriers or toxic compounds that confine infection to specialized pathogen species. Such preformed defenses can be important for disease resistance;
- on recognition of the attacking pathogen, defense mechanisms are induced and the invasion remains localized (Fig. 21.4);
- environmental conditions change, and the pathogen perishes before infection has reached the point at which it is no longer influenced by adverse external stresses.

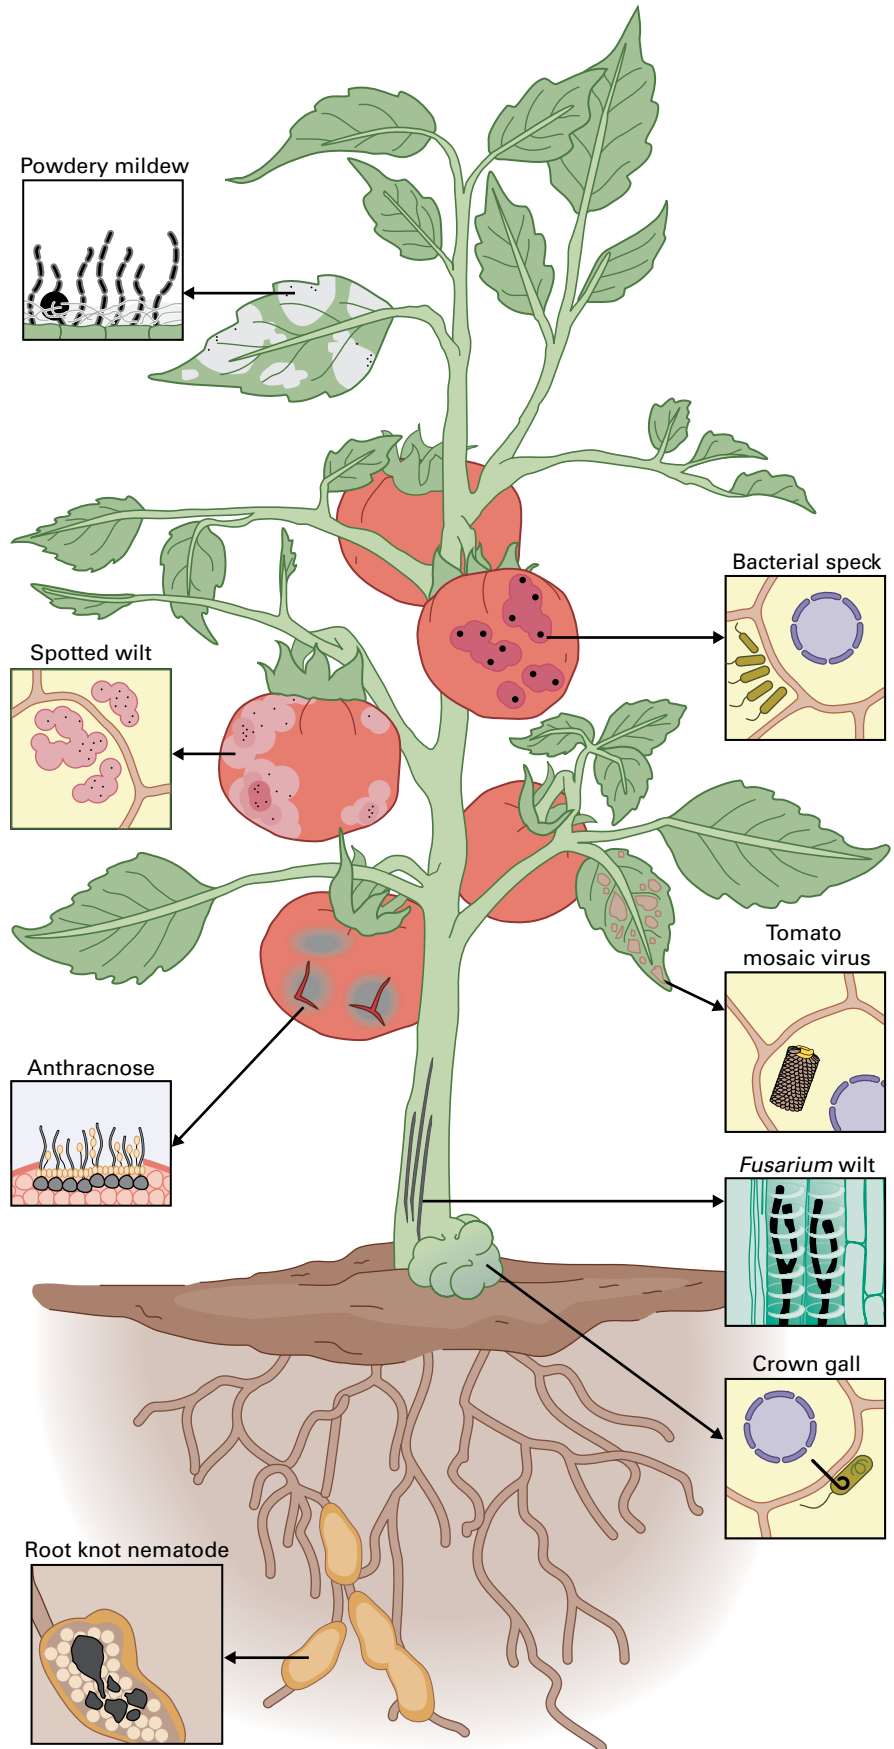

The first three interactions are said to be genetically **incompatible**, but only the third mechanism based on pathogen recognition depends exclusively on induction of defense responses to limit pathogen attack.

Induced defenses can appear rapidly (e.g., production of reactive oxygen species) or later (e.g., accumulation of antimicrobial compounds). Activation of defense in a leaf can trigger elevation of defenses in distal leaves via the movement of systemic signal molecules around the plant. The plant defense system must have enough discriminatory capacity to distinguish harmful plant pathogens from beneficial organisms such as *Rhizobium* bacteria (for legume species) and mycorrhizal fungal species (for almost all vascular plants).

21.3 How pathogens and pests cause disease

Successful pathogens must enter the host plant, grow long enough to obtain nutrients, suppress defenses, and then reproduce to continue their life cycle. Each phase requires different solutions to various problems.

FIGURE 21.5 Most microbes attack only a specific part of the plant and produce characteristic disease symptoms, such as a mosaic, necrosis, spotting, wilting, or enlarged roots. Tomato (*Solanum lycopersicum*) plants are attacked by more than 100 different pathogenic microorganisms. The diagram illustrates symptoms caused by bacteria (bacterial speck, spotted wilt, crown gall), fungi (Fusarium wilt, powdery mildew, anthracnose), viruses (tomato mosaic virus), and nematodes (root-knot nematode).

Pathogens have evolved various and specific ways to invade plants (Fig. 21.5). Some species penetrate surface layers directly using mechanical pressure or enzymatic attack, some pass through natural openings, such as stomata or lenticels, and others only enter through wounded tissue. Once inside the plant, one of three main attack strategies is deployed (Table 21.1): **necrotrophy**, where the plant cells are killed in advance of infection; **biotrophy**, where the plant cells remain alive throughout infection; and **hemibiotrophy**, where the pathogen initially keeps cells alive but at later stages of the infection, kills them.

This process of infection, colonization, and reproduction is known as **pathogenesis**. A pathogen strain that causes disease is termed **virulent**. Some of the biotrophic species can only exist in association with living plants and are termed **obligate biotrophs** (Fig. 21.6).

21.3.1 Virulent pathogens have unique survival-promoting characteristics

The success of plant pathogens can be attributed to various factors:

- a mode of pathogenesis that permits a high rate of reproduction (often with multiple cycles) during the main growing season;
- an efficient dispersal mechanism by wind, water (rain splash), or vector organisms, such as insects;
- A different type of reproduction (often sexual) toward the end of each growing season to produce a second type of structure (e.g., spore or propagule) that has long-term survival capacity (sometimes as long as 30 years);
- a high capacity to generate genetic diversity. Many pathogens have a haploid genome during the phase of greatest reproduction, which permits adaptive mutations to be immediately selected within the pathogen population. Subsequent sexual reproduction creates a novel pool of recombinant genotypes from which new epidemics can arise;
- monocultures of crop plants and well-adapted pathogen genotypes.

21.3.2 Oomycete and fungal pathogens use diverse pathogenesis strategies

Oomycetes are fungus-like organisms that belong to the *Chromalveolates*, along with brown algae and mammalian parasites, such as the malaria parasite *Plasmodium falciparum*. Both oomycetes and fungi can be biotrophic, necrotrophic, or hemibiotrophic plant pathogens; less than 2% of the $\approx 100,000$ known fungal species, however, colonize plants and cause disease.

Necrotrophic species that produce cell wall-degrading enzymes tend to attack a broad range of plant species. For example, the oomycete *Pythium* and fungus *Botrytis* each

attack over 1,000 plant species. Some necrotrophs produce host-selective toxins that are active in only a few plant species; such toxins have a specific mode of action, inactivating a single plant enzyme. For example, the **HC toxin** produced by the fungal pathogen *Cochliobolus carbonum* of maize (*Zea mays*) inhibits histone deacetylase activity (Fig. 21.7), which is involved in gene regulation (see Section 21.3.7 and Chapter 9). *Alternaria alternata* f. sp. *lycopersici* produces the AAL toxin, which activates a plant cell death program in tomato (*Solanum lycopersicum*) leaves. Two cereal-infecting fungi produce light-sensitive toxin proteins: ToxA is produced by both *Stagonospora nodorum* and *Pyrenophora tritici-repentis*, which cause glume blotch and tan spot disease, respectively, on wheat (*Triticum* spp.). Other fungi produce nonselective toxins. For example, *Fusicoccum amygdali* produces the toxin **fusicoccin**, which targets the plasma membrane H^+ -ATPase in many plant species (see Chapter 3), causing irreversible opening of stomata and plant wilting, followed by cell death and fungal colonization.

Sclerotinia sclerotiorum is a necrotrophic fungus that infects over 400 plant species. It secretes the phytotoxin **oxalic acid** to assist the early phases of the infection. Oxalic acid, by manipulating the redox status of invaded plant tissues, suppresses several early plant defenses, including the oxidative burst (see Section 21.5.3) and callose deposition. Once infection is established, however, this necrotroph then induces the generation of plant **reactive oxygen species** (ROS), which lead to death of host tissue and, ultimately, pathogen growth.

Biotrophic fungi keep host cells alive and usually exhibit specialization for plant species. For example, the obligate biotroph powdery mildew fungus (*Blumeria graminis*) occurs in genetically distinct forms called *formae specialis* ('forms of a species'; f. sp.) that infect either barley (*Hordeum vulgare*) or wheat (*Triticum* spp.), but not both. When biotrophic pathogens colonize, the metabolism and development of the plant are often dramatically altered. Metabolites are lost from the host to feed the pathogen, and there are alterations in the levels of **phytohormones** involved in plant growth and development. Effects can include delayed **senescence** of the infected tissues (Fig. 21.8) and stunting or other abnormal growth patterns, resulting in yield losses.

To efficiently utilize living plant cells as a food substrate, biotrophic fungi undergo three developmental changes (Fig. 21.9). First, they usually penetrate the rigid cell wall via the formation of a specialized infection structure on the plant surface called an **appressorium**. Then, the emerging penetration peg breaches the rigid plant cell wall and provides entry into the plant cell. Finally, a **haustorium** (Fig. 21.9B) forms upon entry into the plant cell. The haustorium develops behind an invagination of the plant plasma membrane, and each haustorium becomes encased in a host **extrahaustorial membrane** (EHM). This specialized feeding structure increases surface contact between the two organisms to maximize nutrient and water flow and favor pathogen growth. The origin and constitution of the EHM remains enigmatic. Studies involving *Arabidopsis thaliana* and powdery mildew infections have shown the EHM lacks numerous host plasma

TABLE 21.1 Strategies utilized by plant pathogens.

	Necrotrophy	Biotrophy	Hemibiotrophy
Attack strategy	Secreted cell wall-degrading enzymes, host toxins, or both	Intimate intracellular contact with plant cells	Initial biotrophic phase
Specific features of interaction	Plant tissue killed and then colonized by the pathogen; extensive tissue maceration	Plant cells remain alive throughout infection; minimal plant cell damage	Plant cells alive only in the initial stages of infection; extensive plant tissue damage at later stages
Host range	Broad	Narrow; often only a single species of plant is attacked	Intermediate
Examples	Rotting bacteria (e.g., <i>Erwinia</i> spp.); rotting fungi (e.g., <i>Botrytis cinerea</i>)	Fungal mildews and rusts; viruses and endoparasitic nematodes; <i>Pseudomonas</i> spp. bacteria	<i>Phytophthora infestans</i> (causal agent of potato late blight disease)

FIGURE 21.6 Scanning electron micrographs of a powdery mildew pustule on a barley or grape vine leaf. The two fungal species infecting are *Blumeria graminis* f. sp. *hordei* on barley (*Hordeum vulgare*, left) and *Uncinula necator* on grape vine (*Vitis* sp., right). The abundant asexual mildew spores are held high above the leaf surface in preparation for wind dispersal under dry conditions.

Source: J. Foundling, Syngenta Jealott's Hill; previously unpublished.

membrane proteins. This suggests that it originates from another membrane, such as the vacuole, from de novo assembly, or from the plasma membrane by a mechanism that excludes host proteins. Fungal rusts, powdery mildews, oomycete white rusts, and downy mildews all make haustorial associations with host plants.

Not all species require formation of an appressorium for penetration. A few biotrophic fungi (for example, the tomato leaf mold pathogen *Cladosporium fulvum*) enter through stomata and do not form haustoria. Instead, they grow within the intercellular air space (the **apoplast**), subsisting on leaked nutrients (Fig. 21.10).

Hemibiotrophic pathogens first use a biotrophic and then a necrotrophic mode of nutrition. The switch may be triggered by higher nutritional demands as pathogen biomass increases and asexual reproduction occurs. Some of the most devastating phytopathogenic species are hemibiotrophs. For example, the oomycete *Phytophthora infestans* causes late blight of potato (*Solanum tuberosum*, see Box 21.1). In this interaction, the switch from biotrophic to necrotrophic nutrition occurs

within a few days. In contrast, for other nonbiotrophic species, the symptomless phase is far longer. For example, the wheat-infecting fungus *Mycosphaerella graminicola* (*Zymoseptoria tritici*) infects leaves through open stomata, but only kills plant cells after a long intercellular growth phase; the fungal biomass subsequently increases and sporulation occurs (Fig. 21.11). For the related banana-infecting *Mycosphaerella fijiensis*, the symptomless infection phase is typically around 50 days before the black Sigatoka disease symptoms (see Box 21.1) first appear.

21.3.3 Bacterial pathogens of plants and animals use similar molecular virulence mechanisms

Phytopathogenic bacteria specialize in colonizing the apoplast to cause rots, spots, vascular wilts, cankers, and blights. Most are Gram-negative rod-shaped bacteria from the genera

FIGURE 21.7 Some necrotrophic fungi produce host-selective toxins. The maize pathogen *Cochliobolus carbonum* secretes HC toxin (1) and numerous nonspecific fungal elicitors that trigger plant defense responses. (2) HC toxin is hypothesized to enter the responding plant cells, where it inhibits histone deacetylase activity. Histone deacetylase is responsible for the reversible deacetylation of core histones (H3 and H4) assembled in the chromatin. Its inhibition is believed to interfere with transcription of maize defense genes to favor fungal growth and disease development. (3) Hm1-resistant maize plants produce an HC-toxin reductase (HCTR), which detoxifies HC toxin by reducing the carbonyl group of the side chain of L-Aeo (2-amino-9,10-epoxy-8-oxo-decanoic acid), an unusual epoxidated fatty amino acid.

Pseudomonas, *Agrobacterium*, *Xanthomonas*, *Dickeya*, and *Erwinia/Pectobacterium*. *Agrobacterium*-mediated plant transformation is described in Box 21.2.

Three features characterize bacteria–plant relationships. First, phytopathogenic bacteria rarely enter plants by direct penetration of the cell wall. During their parasitic life, most reside within the intercellular spaces of plant organs or in the xylem (Fig. 21.12), and many damage plant tissues by secreting toxins, extracellular polysaccharides (EPSs), or cell wall-degrading enzymes. Second, bacterial toxins contribute to the production of symptoms in certain plant species, but targeted mutagenesis has shown they are often nonessential for pathogenesis. Third, the secreted EPSs, which surround the growing bacterial colony, may aid bacterial virulence, for example, by saturating intercellular spaces with water or blocking the xylem to produce wilt symptoms, but are not required for pathogenesis.

Other potential roles for bacterial toxins and factors associated with disease are receiving renewed attention. Coronatine is a toxin effector produced by the bacterium *Pseudomonas syringae* to mimic the plant hormone jasmonic acid-isoleucine (see Section 21.8.5), and this assists bacterial infection. Coronatine is involved in causing stomata to open after closing in response to PAMPs, as well as in interfering with salicylic acid (SA)-mediated defense responses. Necrotrophic bacteria that deploy pectic enzymes from the outset of infection, such as *Erwinia*, have a broad host range

and cause extensive cell death and tissue maceration. The pectic enzymes cleave plant cell wall polymers either by hydrolysis (polygalacturonases) or through beta-eliminations (pectate or pectin lyases) (see Chapter 2).

Bacteria frequently deploy a “quorum-sensing” mechanism to facilitate successful colonization of plant tissue (Fig. 21.13). Virulence factors are usually not expressed until the bacterial population density is sufficient to ensure the plant cells are immediately overwhelmed by the attack. The soft rot pathogen *Erwinia carotovora* only produces cell wall-degrading enzymes when the bacterial population reaches a certain density in the host extracellular spaces. If these enzymes were produced at a low pathogen density, they might activate plant defenses (see Section 21.8.2) without the bacteria being present in sufficient numbers to resist them. Quorum sensing in *E. carotovora* is mediated by *N*-acylhomoserine lactones, small molecules released from the bacterial cells into the surrounding medium. The bacterial blight pathogen of rice (*Oryza sativa*), *Xanthomonas oryzae* pv. *oryzae*, secretes a highly conserved sulfated peptide called Ax21, which mediates quorum sensing by controlling *Xanthomonas* motility, biofilm formation, and virulence.

Some phytopathogenic bacteria depend on insects for entry into plants. These are mainly species that infect the phloem, xylem, and associated vascular tissues. During herbivore insect penetration and feeding, the mouthparts pick up

FIGURE 21.8 Biotrophic pathogens keep plant cells alive. Post infection, biotrophs can alter the levels of phytohormones to delay senescence of the infected tissue and aid nutrient acquisition. In and around pustules of the sporulating barley mildew fungus (*Blumeria graminis* f. sp. *hordei*) (top), delayed senescence causes the formation of “green islands” (lower left), which are evident as the leaves senesce and lose their chlorophyll content more slowly from the infected regions (lower right).

Source: P. Spanu, Imperial College; previously unpublished.

bacteria already within the tissue. These bacteria are then transmitted to a new vascular region on which the insect next feeds. For example, phytoplasmas are specialized bacteria that are obligate parasites of the phloem tissue. They are mainly spread by insects in the families Cicadellidae (leaf hoppers), Fulgoroidea (plant hoppers), and Psyllidae (jumping plant lice). The xylem-colonizing bacterium *Xylella fastidiosa* is transmitted by various species of *Homalodisca* in the family Cicadellidae.

During infection, most bacteria remain in extracellular spaces and use a specialized mechanism, the **type III secretion system** (T3SS), to deliver bacterial effector proteins into the plant cell. This mechanism is also used by many bacterial species that infect animals. The T3SS involves a protein

complex that spans both the inner and outer bacterial membranes and a pilus that projects through the plant cell wall and into the host cell (Fig. 21.14). The structural components of the T3SS are encoded by the clustered **hypersensitive response and pathogenicity cluster** (*hrp*) genes. Many different types of bacterial Avr effectors delivered by type III secretion have been identified to be enzymes such as phosphatases, proteases, phosphoserine lyases, or E3 ubiquitin ligases that attenuate host defense signaling.

21.3.4 Plant pathogenic viruses move by way of plasmodesmata and phloem

Over 40 families of DNA and RNA plant viruses exist, and most are single-strand (ss) positive-sense (+) RNA viruses (Fig. 21.15A). Symptoms of viral infection include tissue yellowing (chlorosis) or browning (necrosis), mosaics, and plant stunting. Plant viruses are biotrophs, and all species face the same three basic challenges: How to replicate in the initially infected cell, how to move into adjacent cells and the vascular system and thereby colonize the entire plant, and how to be transmitted to the next host plant.

Plant viruses have small genomes; most encode only three to 10 proteins. Each gene has one or more specific functions, as illustrated by the genome of tobacco mosaic virus (TMV) (Fig. 21.15B), which functions in replication, cell-to-cell movement, symptom development, and encapsidation. The initial major challenge was to identify the host genes required for viral replication and transmission.

When viruses enter plant cells following mechanical wounding or transmission by a vector, either viral translation or transcription followed by translation occurs to produce the proteins required for viral replication. Genome replication for ss (+) RNA viruses, ss negative-sense (–) RNA viruses, double-stranded (ds) RNA viruses, and plant pararetroviruses, such as CaMV containing partially dsDNA genomes, occurs in the cytoplasm and utilizes the virus DNA-encoded RNA-dependent RNA polymerases (RdRps). In contrast, genome amplification of ssDNA viruses, such as geminiviruses, occurs in the nucleus and involves hijacking components of host DNA replication.

The compartmentalization of viral genome replication means that replicated nucleoprotein complex or nascent genomes require transportation to the only site in the host cell where intracellular (symplastic) movement is permitted, the **plasmodesmata**. In contrast to animal viruses, there is no example of plant viruses crossing the plasma membrane of the infected plant cell. Plant virus movement proteins in association with various components of the host cell cytoskeleton, including actin filaments and microtubules, facilitate transport of nucleoprotein complexes and virus particles into adjacent cells via modified plasmodesmata.

Two mechanisms are deployed for viral movement. Tobamoviruses (ss (+) RNA genomes), such as TMV, transiently increase the size exclusion limit of plasmodesmata

FIGURE 21.9 Some biotrophic fungi invade host cells to extract nutrients. (A) The fungal haustorium facilitates transfer of nutrients from a living plant cell to the pathogen. The extracellular haustorial matrix contains products of both fungal and plant origin. (B) Haustoria of the biotrophic barley mildew fungus *Blumeria graminis f.sp. hordei* inside the epidermal cell of barley (*Hordeum vulgare*), stained with a lectin (wheatgerm agglutinin) bound to Alexa-288. Each multidigitate structure is surrounded by the periaustorial membrane of host origin. As with other mildews, this specialized membrane is continuous with the host plasma membrane, but has different biochemical properties. In mildews, the periaustorial membrane is thought to be where nutrients are absorbed and effectors are delivered. Source: (B) P. Spanu, Imperial College; previously unpublished.

FIGURE 21.10 Some biotrophic fungi invade their host leaf through stomata. (A) The leaf mold fungus *Cladosporium fulvum* infects through the lower surface of a tomato (*Solanum lycopersicum*) leaf, shown at 14 days after infection. This biotrophic pathogen is restricted to attacking only a few species of the genus *Solanum*. (B) The *C. fulvum* life cycle on tomato. Spores germinate on the leaf surface, hyphae grow across the surface until a stomatal opening is encountered, and hyphae enter the intercellular spaces of the leaf (left). Hyphae within the leaf grow through the intercellular spaces in the mesophyll cell layer (center). Approximately 14 days after infection, the sporulation structures (conidiophores) emerge through the stomatal openings (right). Source: (A) K.E. Hammond-Kosack, The Sainsbury Laboratory, Norwich, UK; previously unpublished.

FIGURE 21.11 Wheat leaf (*Triticum* sp.) infection caused by the hemibiotrophic fungus *Mycosphaerella graminicola* (*Zymoseptoria tritici*). This leaf blotch disease is particularly severe when cool, moist conditions prevail and can reduce wheat grain yields by as much as 30%. (A) Time course of symptom development. A representative leaf was inoculated with fungal sporidia within the region delimited by the arrows and then photographed at 24-hour intervals. For the first 8–9 days, the infection is symptomless; visible brown lesions rapidly appear by day 14 and fungal sporulation within pycnidia occurs within the lesion. (B) The infection process. (Left) Early symptomless colonization (<7 days post leaf inoculation, DPI) involves the release of plant defense-suppressing apoplastic effectors (red and blue triangles) from slow-growing intercellular hyphae (orange). (Right) After 7 days, leaf mesophyll cell death and the loss of membrane permeability allow nutrient release into the apoplast. Defense-suppressing effectors are “switched off”, although other potentially toxic effectors (blue diamonds) may be produced. Extensive hyphal growth and asexual sporulation (pycnidia and pycnidiospore formation) are now supported within leaf lesions. Under high humidity, the mature pycnidiospores ooze out onto the leaf surface via the open stomata.

BOX 21.2

Agrobacterium-mediated T-DNA transfer, a mechanism used in pathogenesis, is also a tool for plant transformation

Agrobacterium tumefaciens is a soil bacterium that is closely related to *Rhizobium*. It causes crown-gall disease in many dicotyledonous plant species (A). *Agrobacterium* genetically transforms plant cells with a DNA fragment called the **T-DNA** (transferred DNA). The process involves DNA transfer from the bacterium into the plant cell nucleus, where it stably integrates into the plant genome (B).

Gene expression from a wild-type T-DNA results in remarkable changes in plant cell metabolism. Plant growth hormones (auxins and cytokinins) are made, leading to neoplastic growth (tumor formation). Also, within gall tissue, various amino compounds called **opines** are synthesized, which the bacteria can use as their sole carbon and nitrogen source. *Agrobacterium* strains are classified based on the types of opine production they cause (e.g., octopine and nopaline).

Opine catabolism within bacterial cells requires specialized enzymes encoded by the *Agrobacterium* **tumor-inducing (Ti) plasmid**. Because neither the plant nor any other soil-dwelling microorganism can use opines, this provides a competitive advantage for *Agrobacterium* within the gall tissue.

Molecular genetic studies have been the key to elucidating *Agrobacterium*–plant cell interactions. The bacterium predominantly infects plants at a wound site where damaged plant cells synthesize and secrete unusual phenolic compounds that include **acetosyringone**. A set of chromosomal virulence (*chv*) genes located on the *Agrobacterium* chromosome are involved in bacterial chemotaxis toward and attachment to the wounded plant cells. However, open stomata can sometimes be used to circumvent the physical barrier of the plant cuticle.

The subsequent binding of the bacteria to specific plant cell wall components initiates a seven-step process involving the synthesis, transfer, targeting, and insertion of the *Agrobacterium* T-DNA into the plant genome, culminating in gall formation (B). This process is controlled by genes located on the 200-kB Ti plasmid of *Agrobacterium*, either within the T-DNA itself or within a 35-kB virulence (*vir*) region, which is composed of seven major loci (*VirA* to *VirG*). For step 2, the *VirA/VirG* transcriptional regulators that activate all the other *vir* genes, are two-component sensor/signaling systems (see Chapter 18) widely used by bacteria to regulate both environmental and developmental mediated responses. In step 5, the proteins that transport the T-complex from *Agrobacterium* into the plant cell cytoplasm are functionally similar to those involved in bacterial plasmid conjugation. The targeting of the T-complex into the plant

cell nucleus proceeds via an endogenous macromolecular transmission and targeting pathway, which appears to be analogous to that deployed by certain DNA plant viruses.

The ability of *Agrobacterium* T-DNA to integrate stably into a plant genome has led to its widespread exploitation as a vector for the genetic transformation of higher plant cells with **recombinant DNA** molecules. However, to regenerate plants with a normal appearance, the *Agrobacterium* genes specifying tumor formation had first to be eliminated. In addition, a technique called agroinfiltration is used routinely in several plant species to transiently express genes in leaf cells by infiltration into leaf panels of a high density of *Agrobacterium* cells containing defined recombinant DNA molecules.

FIGURE 21.13 Quorum sensing during growth of a pathogenic bacterium in the intercellular spaces of plant leaves. Bacteria enter the leaf through stomatal openings. (A) Early in leaf colonization, the bacterial population is sparse and only a low concentration of N-acylhomoserine lactone is present. (B) As the density of the bacterial population rises, elevated N-acylhomoserine lactone concentrations lead to expression of many different types of cell wall-degrading enzymes and other effector molecules. (C) These higher concentrations of bacteria, enzymes, and effectors result in the death of plant cells and the appearance of disease symptoms.

10-fold to permit trafficking of the large nucleoprotein complex. Genetic studies showed that interaction of the TMV 30-K movement protein with a cell wall pectin methyltransferase is required for TMV cell-to-cell movement and infection. In contrast, some dsDNA viruses, such as cauliflower mosaic virus (CaMV), orchestrate the formation of large tubular structures composed of movement proteins to facilitate the movement of encapsidated virus particles through enlarged plasmodesmata.

The second common feature of virus cell-to-cell movement is the involvement of the endoplasmic reticulum and membrane trafficking. Synaptotagmin proteins are calcium sensors that regulate synaptic vesicle exo- and endocytosis in animals and plants (see Chapter 4). In *Arabidopsis*, the synaptotagmin protein SYTA regulates endosome recycling as well as movement protein-mediated trafficking of plant virus genomes through plasmodesmata. The SYTA protein localizes to endosomes in plant cells and binds directly to the movement

FIGURE 21.14 Bacterial pathogens of plants and animals utilize similar secretion pathways during pathogenesis. One such system, the type III secretion system (T3SS), involves a protein complex that spans both the inner and outer bacterial membranes and a pilus that projects through the plant cell wall and into the host cell. The structural components of the T3SS are encoded by clustered *hrp* genes. Nine of the Hrp proteins of pathogenic plant bacteria are similar to components of the T3SS of animal pathogenic bacteria; consequently, members of this subset of Hrp genes are referred to as Hrc genes (hypersensitive response and conserved). Cytoplasmic R proteins activate plant defense responses only after corresponding Avr effectors have been delivered directly into the plant cytoplasm. Once Avr effectors are inside the plant cell, Hrp proteins are not needed for plant defense activation.

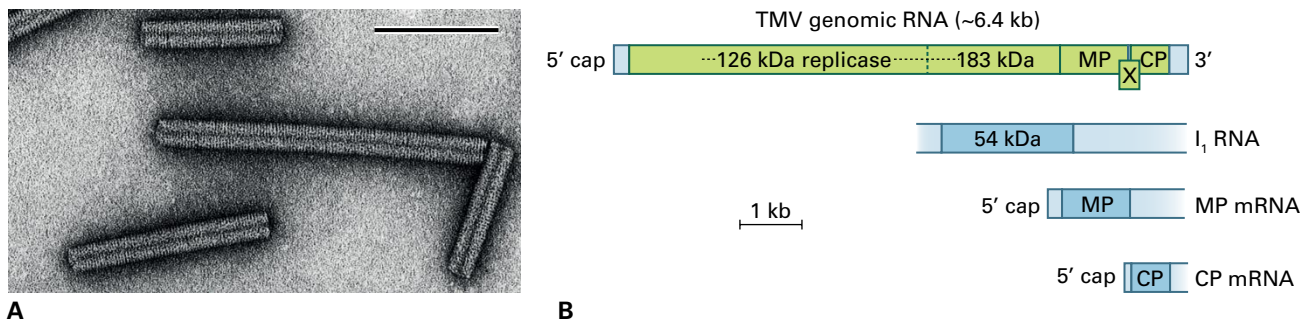

FIGURE 21.15 The encapsidated ssRNA virus, tobacco mosaic virus (TMV). (A) Transmission electron micrograph of TMV particles. Each rod is 18 nm in diameter. (B) TMV has a single-stranded positive sense RNA genome that is 6,395 nucleotides in length, with a cap at the 5' end and a tRNA-like secondary structure at the 3' end. The genome encodes at least four viral proteins, the open reading frames (ORFs) of which are represented by boxes. The 183-kDa replicase protein is synthesized by readthrough of a leaky termination codon at the end of the 126-kDa replicase protein ORF. The replicase proteins are translated from the genomic RNA. The movement protein (MP, 29 kDa), which facilitates the cell-to-cell movement of viral particles via plasmodesmata and into systemic tissue, and the coat protein (CP, 17 kDa) are translated from subgenomic RNAs. An additional subgenomic RNA (I_1) encoding a putative 54-kDa protein has been detected in TMV-infected tobacco leaves, but it is not known whether this is translated to produce a protein product during TMV infection. Source: (A) Franki et al. (1985) Atlas of Plant Viruses, Vol. 2, CRC Press, Boca Raton, FL, p. 138.

proteins of both cabbage leaf curl virus (CaLCuV-ssDNA genome) and tobacco mosaic virus (TMV-ssRNA genome) to facilitate cell-to-cell movement. These virus movement proteins transport their cargo to the plasmodesmata in readiness

for cell-to-cell spread via an endocytic recycling pathway (Fig. 21.16).

The processes controlling long-distance systemic transport of virus particles or viral nucleic acid within the phloem

FIGURE 21.16 The plasmodesmata protein *STYA* assists virus movement. (A) Endosome localization of the *SYTA*-GFP tagged protein in a leaf epidermal cell (top) or protoplast prepared from a leaf mesophyll cell (bottom). The *STYA* protein binds directly to the movement protein of both cabbage leaf curl virus (*CaLCuV*-ssDNA genome) and tobacco mosaic virus (*TMV*-ssRNA genome) and facilitates cell-to-cell movement. (B) Infection by the *CaLCuV* virus is slower in the *syta-1* mutant *Arabidopsis* plants (top), and the disease symptoms are less severe (bottom).

are probably distinct from those controlling movement between mesophyll cells. How viruses enter or leave the phloem is not well understood. Once inside the phloem, viruses can move at speeds of up to 1 cm/hour. Most viruses are transported in the phloem as either nucleoprotein complexes or virions, with contributions from host and virus proteins. The coat protein is necessary for this process to work efficiently for some viruses, for example TMV; for other viruses, however, it may not be involved. One challenge is to identify the host components in the phloem that interact with either the coat protein or virus particles to facilitate this rapid transport and subsequent re-entry of the virus into mesophyll cells once a new organ is reached. The interaction between the TMV 30-kDa movement protein and a specific host-encoded pectin methylesterase is one of the few mechanisms involved in vascular exit of the TMV virion or a coat protein–viral nucleic acid–protein complex into distal leaves. Some virus proteins contribute to the establishment and maintenance of systemic infection by suppressing RNA silencing-mediated degradation of viral RNA (see Section 21.9.2).

21.3.5 Some pathogenic nematodes modify the metabolism of root cells, inducing the plant to form specialized feeding structures

More than 20 genera of nematode cause plant diseases, and infections by these tiny roundworms (≈ 1 mm long) are nearly always confined to the plant root system. These root infections can dramatically alter plant metabolism and often result in substantial modifications to root architecture (Fig. 21.17).

All parasitic nematode species are obligate biotrophs, and all possess a hollow feeding stylet that can penetrate plant cell walls. Ectoparasitic nematodes feed exclusively at the root surface, whereas endoparasitic species invade root tissues and spend a large portion of their life cycle in intimate association with root cells. By far the most damaging nematodes are the two groups of sedentary endoparasitic species belonging to the family *Heteroderidae*: the **cyst nematodes** (genera *Heterodera* and *Globodera*) and the **root-knot nematodes**

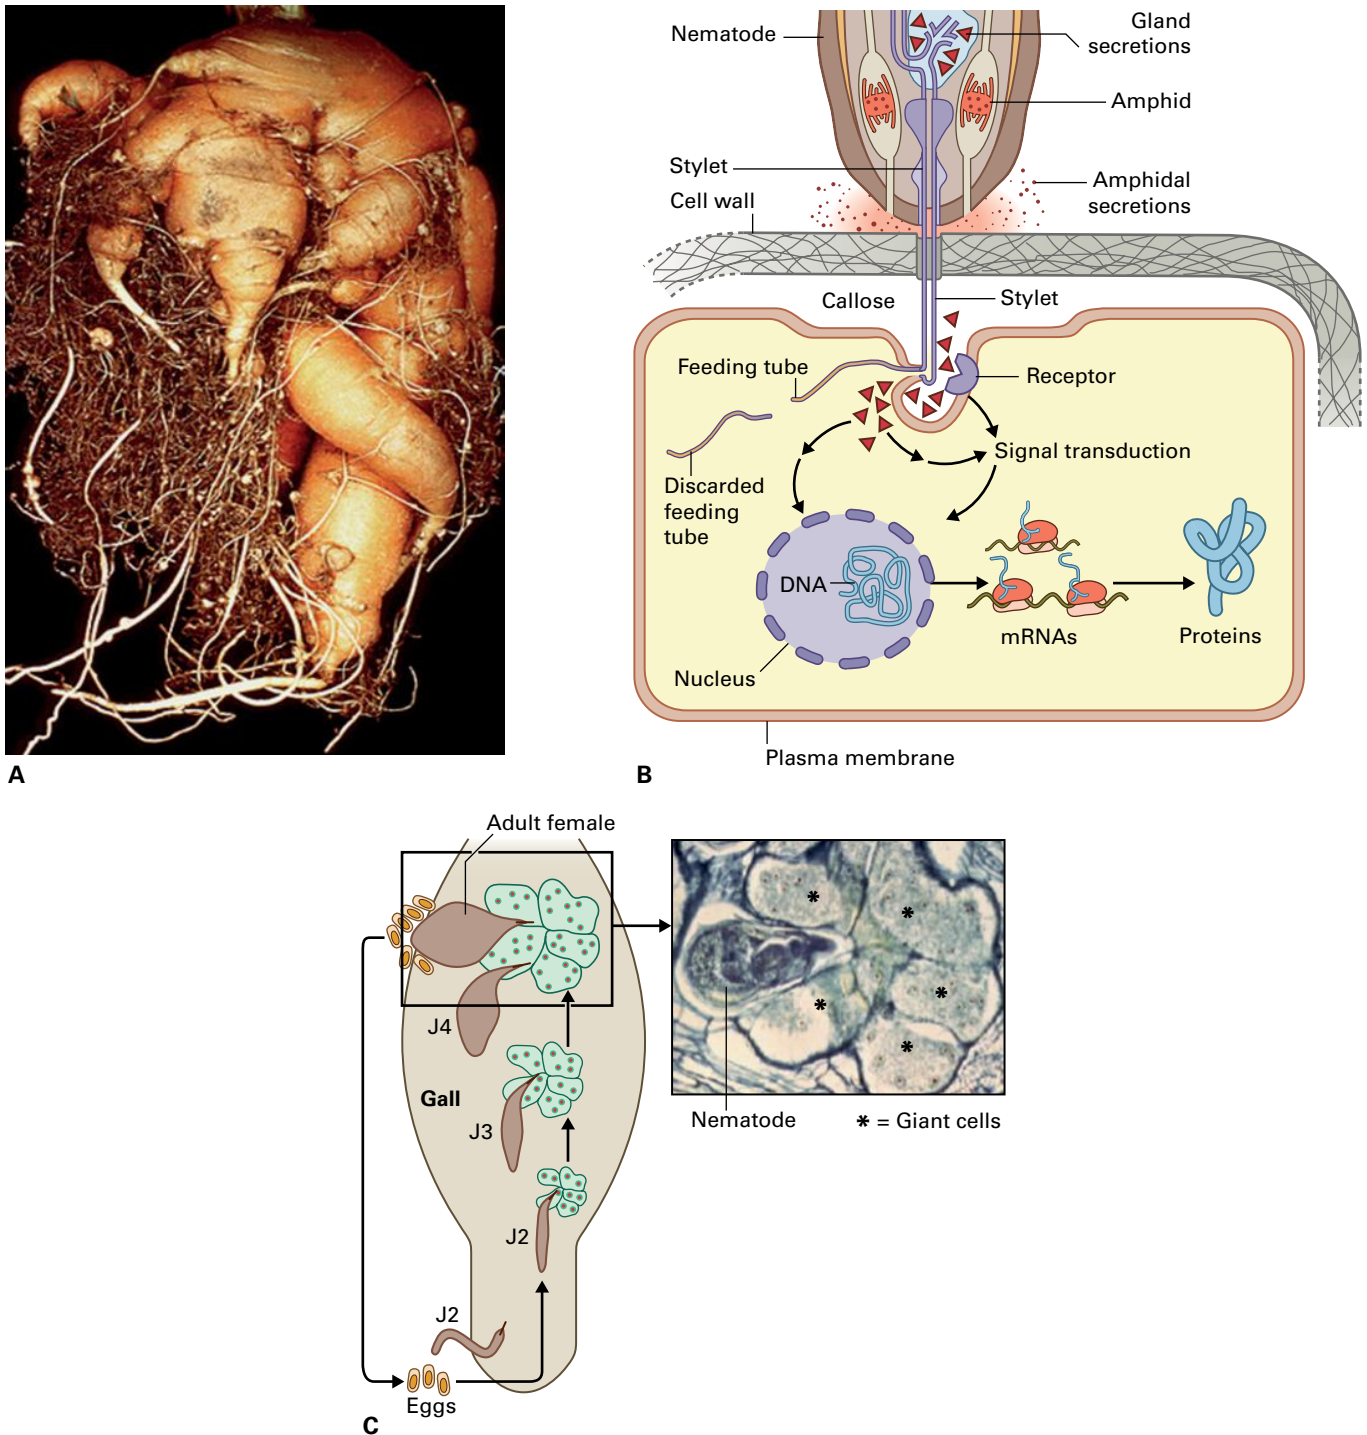

FIGURE 21.17 Plant root–endoparasitic nematode interaction. (A) The swollen and distorted appearance of a carrot (*Daucus carota*) root caused by infection of the root-knot nematode *Meloidogyne hapla*. (B) The nematode uses a stylet at the anterior to enter a plant cell and pump secretions from the amphid glands into the plant cell. Subsequently, inside the invaded plant cell a new feeding tube is synthesized, which the nematode uses to extract nutrients specifically from the modified cell cytoplasm. In each plant cell selected, hundreds of discarded feeding tubes can accumulate. (C) Life cycle of the root-knot nematode and a stained transverse tissue section showing the giant cells induced by the feeding sedentary nematode. Nematode eggs hatch in the vicinity of the root tip. The second-stage juvenile (J2) then migrates towards the root, enters it close to the tip, migrates towards the vascular tissue, selects a single xylem parenchyma cell, loses mobility, and commences feeding. The body of the feeding sedentary nematode swells (third stage juvenile—J3), and feeding induces plant cell mitosis uncoupled from cytokinesis and DNA endoreduplication. This results in abnormal cortical cell growth and the formation of large giant cells around the J3, fourth-stage juvenile (J4) and the adult nematode. The induced giant cells facilitate nutrient removal from the vascular tissue to enhance nematode growth and facilitate the formation of hundreds of mature eggs inside the body of the female nematode.

Source: (A) Hapla, APS website; (C) Mitchum et al. (2008). *Curr. Opin. Plant Biol.* 11:75–81.

(genera *Meloidogyne*). These nematodes spend 30–40 days feeding on highly modified xylem parenchyma cells, and they severely restrict plant growth and development.

The life cycle of the endoparasitic nematodes commences when dormant eggs perceive a chemical signal released by plant roots to induce the hatching of the juvenile nematode. For the potato (*Solanum tuberosum*) and soybean (*Glycine max*) cyst nematodes, the hatching factors are solanoclepin A and glycinoeclepin A, respectively. Motile second-stage juveniles penetrate roots and then migrate to the vascular tissue just behind the root tip. Once feeding is initiated, the nematode loses motility and becomes sedentary.

To commence feeding, the juvenile cyst nematodes push their stylets through the plant cell wall, but not the plasma membrane, and release glandular secretions into the selected cell(s) (Fig. 21.17B). Molecules in the secreted fluid induce rapid modifications to the cytoplasm of the plant cell, and the metabolic activity of the plant cell increases. In addition, the nematode triggers partial dissolution of cell walls, such that the symplastic connections of the modified cell to its neighbors become more extensive, until finally protoplast fusion occurs. Eventually, as many as 200 plant cells may be recruited by the nematode to form the **syncytial feeding structure**. In contrast, the feeding of root-knot nematode juveniles induces mitosis uncoupled from cytokinesis and DNA endoreplication (see Chapter 11). These result in abnormal cortical cell growth and the formation of a series of **giant cells** (Fig. 21.17C). In other respects, the morphology of the syncytial and giant cells is similar; both become closely associated with the phloem via transfer cell connections to ensure the entire plant is tapped for nutrients. In effect, the developing female root-knot and cyst nematode populations on the root system become powerful alternative sinks for sugars and so lower crop yields from infected plants.

Studies with mutant lines of *Arabidopsis thaliana* have revealed several plant proteins and metabolites required for nematode infection. The root-knot nematode must disrupt the plant cytoskeleton to establish a successful infection. By lowering the levels of a plant actin depolymerizing factor, the F-actin component in the cytoskeleton can be stabilized, thereby blocking giant cell maturation and reproduction of the nematode. For the beet cyst nematode, transport of auxin to the initial syncytium and the subsequent lateral redistribution of auxin are critical to ensure the radial expansion of the feeding site as the female nematode's size increases and egg maturation occurs.

One key issue in plant-sedentary nematode associations is the nature of the biochemical signals within the nematodes' glandular secretions that cause such dramatic changes in root cell architecture. Microscopic analysis has revealed a structure called a **feeding tube**, which is exclusively associated with the stylet. Unlike the stylet, the feeding tube is located within the plant cell cytoplasm (Fig. 21.17B). A new feeding tube is formed every time the nematode feeds; thus, by the time pathogenesis is complete, hundreds of feeding tubes

have been made in each giant or syncytial cell. Microinjection experiments using fluorescently labeled dextrans of different molecular weights determined the size exclusion limit for molecules passing through the feeding tube is between 20 and 40 kDa. This suggests the signals of the nematodes could be relatively small molecules. The identification of the bioactive gland secretion components is currently an area of intense research (see Section 21.3.7).

21.3.6 Feeding arthropods damage plants and facilitate colonization by viral, bacterial, and fungal pathogens

Diverse insect species feed, reproduce, and shelter on plants. Two main herbivorous insect categories are recognized: those that chew and those that suck sap (Fig. 21.18).

Chewing insects cause the more spectacular plant tissue damage. For example, Colorado potato beetles (Fig. 21.18A) and locust species may defoliate an entire crop within a few days. For other chewing species, the extent of damage frequently depends on the developmental stage of both the pest and the plant. The larva of the European corn borer attacks only the leaves of young maize (*Zea mays*) plants, but as both plant and pest mature, the insect becomes a devastating stalk borer. Other chewing insects feed exclusively on roots or seeds.

The sap-sucking insects, such as adult leafhoppers, aphids (Fig. 21.18B), thrips, and plant bugs, instead cause minimal direct tissue destruction. Via a specialized mouthpart, the stylet, the phloem sieve elements are located, penetrated, and the sap removed (Fig. 21.19). Heavy infestations of sap-sucking insects cause chronic shortages of photosynthates and lead to a severe reduction of plant growth.

Plant volatiles released at the site of insect feeding can act as both attractants and deterrents to further colonization by the same or other insect species. Detailed analysis of the changes to air composition in the vicinity of feeding insects, in combination with electrophysiological experiments to explore insect neural stimulations in response to specific plant volatiles, reveal the complexity of insect–plant communication events.

The largest group of plant volatiles is the terpenes, a diverse class of secondary metabolites that includes monoterpenes (C₁₀) and sesquiterpenes (C₁₅) (see Chapter 24). One plant-produced sesquiterpene, (E)- β -farnesene (EBF), has been considered a potential defense against aphids, since its emission by plants causes aphids to drop off the plant or depart from the feeding site. For many aphids, EBF is the principal constituent of the aphid alarm pheromone, and the constitutive production of EBF by plants could hold promise in the control of specific aphid pests. In certain cropping habitats (e.g., tropical rainforests) the insect pressure is so great that young plant leaves emerge with different spectral and volatile properties than the mature leaves and initially remain undetected.

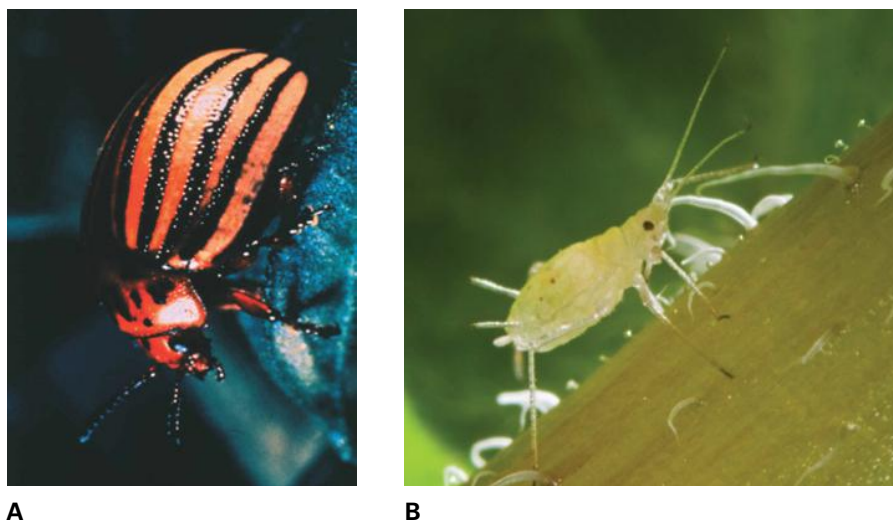

FIGURE 21.18 Chewing and sap-sucking insects.

(A) The stem- and leaf-chewing Colorado potato beetle (*Leptinotarsa decemlineata*). (B) Sap-sucking green peach-potato aphid (*Myzus persicae*). The green peach-potato aphids can transmit over 100 species of plant infecting viruses. Some of the most damaging diseases include potato leaf roll virus and potato virus Y to Solanaceae, beet western yellows and beet yellows viruses to Chenopodiaceae, lettuce mosaic virus to Compositae, cauliflower mosaic and turnip mosaic viruses to Cruciferae, and cucumber mosaic and watermelon mosaic viruses to Cucurbitaceae.

FIGURE 21.19 Insects can be vectors for the transmission of viruses into plant cells.

An aphid feeding stylet delivers viruses directly into the phloem sieve elements (SE). The virus particles then move by way of the translocation stream to other regions of the plant, where they can exit into the surrounding cells through the SE and the companion cells (CC), through the plasmodesmatal connections. BSC, bundle sheath cell; MC, mesophyll cell; EC, epidermal cell. The relative frequency of plasmodesmatal connections is indicated by the number of lines between cells.

Many insect pest species also transmit viruses. The sap-sucking species are effective virus vectors, delivering virus particles directly into the vascular tissue, thereby permitting their rapid dissemination throughout the plant. Some virus species can also replicate and persist inside insect vectors. During subsequent feeding, the insect thus infects almost every susceptible plant. Both the barley yellow dwarf virus and potato virus Y are transmitted persistently by the green peach aphid (*Myzus persicae*) (see Fig. 21.18B). Chewing insects rarely transmit viruses, but the tissue damage caused frequently permits attack by necrotrophic fungal and bacterial species (see Sections 21.3.2 and 21.3.3).

21.3.7 Pathogen effectors promote susceptibility by diverse mechanisms

The interactions between plants and fungi, oomycetes, bacteria, nematodes, viruses, and insects reveal the range of molecules that pathogens can synthesize in an effort to

gain nutrients from their host plants and, hence, reproduce to complete their life cycles. An **effector molecule** is made by a pathogen to enhance the pathogen's colonizing abilities.

Effector molecules are sometimes referred to as compatibility factors because interactions between plants and pathogens that result in disease are described as **compatible interactions**. In contrast, interactions that fail to result in disease formation are **incompatible**. Many effector molecules either singly or in specific combinations suppress host PTI or ETI (see Fig. 21.3). The isolation and characterization of effector molecules is of great interest, because nature has selected over millions of years molecules that target important host defense components. Different types of effectors are summarized in Table 21.2.

The plant cuticle and the cell walls represent significant barriers to colonization. To promote infection, many fungal and bacterial pathogens secrete enzymes, such as cutinases, cellulases, xylanases, pectinases, and polygalacturonases. Hydrolysis of the major components of the aerial surface of plants such as **cutin**, and those within the underlying plant

TABLE 21.2 Examples of plant pathogen effectors.

Pathogen class	Species	Effector name	Effector function
Virus	Tobacco mosaic virus (TMV)	P50	Viral replicase
Virus	Potato virus X	CP	Coat protein
Oomycete	<i>Hyaloperonospora arabidopsidis</i>	Atr1/Atr13	Contributes to pathogen virulence inside host cells by suppressing PTI
Oomycete	<i>Phytophthora infestans</i>	Avr3a	Interacts with and stabilizes the plant U-box E3 ligase CMPG1 protein, preventing INF1 triggered plant cell death during the biotrophic phase
Fungus	<i>Melampsora lini</i>	AvrL567	Haustorially expressed secreted protein translocated into plant cells; exact function in virulence unknown
Fungus	<i>Cladosporium fulvum</i>	Avr2	Inhibits multiple extracellular cysteine proteases, like Rcr3, required for ETI and basal defense
Bacterium	<i>Pseudomonas syringae</i> pv. <i>tomato</i>	AvrPto	Enhances bacterial growth and plant necrosis. Interferes with protein kinase function to suppress defenses
Bacterium	<i>Xanthomonas euvesicatoria</i>	AvrBs2	Protein containing a domain homologous to the <i>Escherichia coli</i> glycerolphosphodiesterase and the agrocinopine synthase of <i>Agrobacterium tumefaciens</i> . Required for bacterial virulence by an unknown mechanism
Bacterium	<i>Ralstonia solanacearum</i>	PopP2	PopP2 belongs to the YopJ-like family of effectors found in mammalian and plant pathogens. PopP2 has autoacetyl-transferase activity that targets a lysine residue well conserved in this effector family. Probably affects plant gene transcription to favor bacterial virulence
Root-knot nematode	<i>Meloidogyne incognita</i>	16D10	Interacts with tomato Scarecrow-like transcription factors which regulate root radial patterning. This secreted nematode peptide functions as a signaling molecule to interfere with root proliferation by targeting host transcription factors
Cyst nematode	<i>Heterodera schachtii</i>	CBP	Binds to and increases plant pectin methyl-esterase protein, thereby reducing the level of methyl-esterified pectin in cell walls. This subsequently facilitates the access of other cell-wall-modifying enzymes to cell wall polymers, which is required for syncytium formation and development
Aphid	<i>Acyrtosiphon pisum</i>	C002	Assists aphid feeding on phloem sap in sieve elements and thereby increases aphid survival rates

cell wall such as **cellulose**, **hemicelluloses**, and **pectin**, weakens these structures and facilitates pathogen entry. Most pathogens produce a diversity of **cell wall-degrading enzymes**.

Many plant pathogens also produce a range of toxins (see Section 21.3.3). Some chemicals are toxic to all plants, whereas

others are toxic to only one or a few plant species (**host-selective toxins**). Regardless of type, these toxins inhibit the action of specific plant proteins. For example, the fungus causing Northern leaf blight disease of maize, *Cochliobolus carbonum*, makes a host-selective toxin called HC toxin (see Fig. 21.7). Like many other fungal toxins, the HC toxin is a cyclic

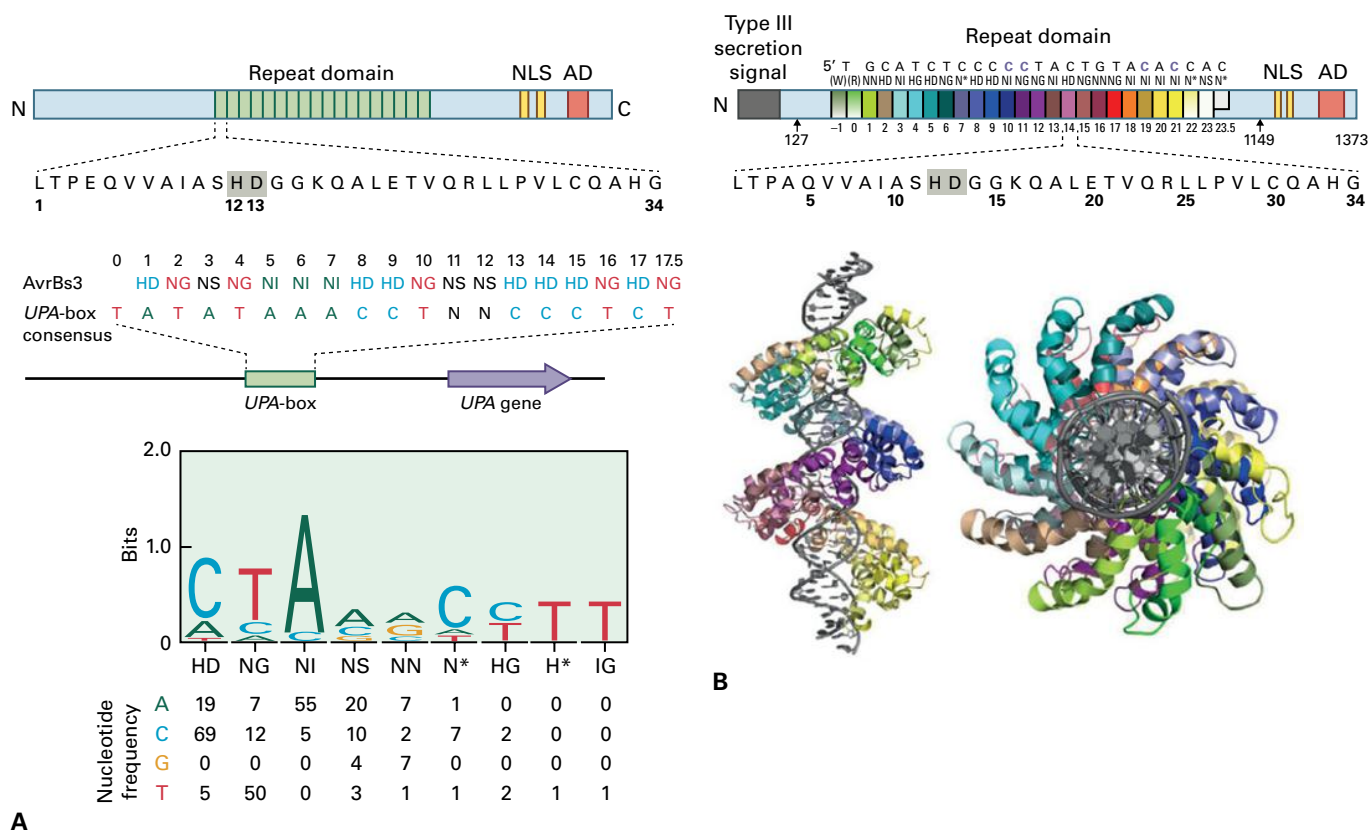

FIGURE 21.20 Transcription activator-like effectors (TALEs) are natural type III effector proteins that are secreted by numerous species of *Xanthomonas*. (A) TALEs have an elegant code linking the central domain of TALEs with their target DNA binding site. In the example illustrated, the AvrBs3 effector acts as a transcriptional activator in the plant cell nucleus, where it directly binds to DNA in the promoters of plant genes upregulated by AvrBs3 (UPA), via the tandem repeats. The repeats in the central domain differ from each other mainly in amino acid positions 12 and 13 (repeat variable di-residues, RVDs). Computational and functional analyses have revealed a strong correlation between unique pairs of RVDs and the corresponding nucleotide in the TALE-binding site. For example, the amino acid di-residue histidine-aspartic acid (HD) binds to cytosine (C), the di-residue asparagine-glycine (NG) binds to thymine (T), the di-residue asparagine-isoleucine (NI) binds to the nucleotide adenine (A), and the di-residue asparagine-asparagine (NN) binds to guanine (G), and to a lesser degree adenine (A). The UPA-box contains the nucleotide consensus sequence in the promoter region to which the AvrBs3 effector binds and UPA-gene denotes the induced target gene. (B) The crystal structure of the *Xanthomonas oryzae* effector PthXo1 bound to its DNA target in the promoter of the rice Os8N3 gene. The domain organization of PthXo1 shown in the upper panel has the 23.5 repeats color-coded to match those shown in the lower panel. The RVDs that recognize the nucleotide cytosine are shown in gray box. The lower panel shows the structure of the PthXo1 DNA-binding region in complex with its target site. Each repeat forms a left-handed, two-helix bundle that presents the unique RVD-containing loop to the DNA. The repeats self-associate to form a right-handed superhelix wrapped around the DNA major groove. The first RVD forms a stabilizing contact with the protein backbone, while the second makes a base-specific contact to the DNA sense strand. Two degenerate amino-terminal repeats also interact with the DNA.

peptide. It is synthesized continuously by two specific tetra-partite cyclic peptide synthetases (HTS1 and HTS2) and then exported outside the fungal cell. In maize (*Zea mays*) leaves, the HC toxin inhibits histone deacetylases to effect changes in host gene expression, presumably those genes involved in defense against *C. carbonum*. Mutant strains of *C. carbonum* that do not produce the HC toxin are **nonpathogenic** (do not cause disease). Maize genotypes that carry the *Hm1* gene, which encodes an enzyme that can metabolize and thereby detoxify HC toxin (see Fig. 21.7), are resistant to *C. carbonum*.

The related fungi *Stagonospora nodorum* and *Pyrenophora tritici-repentis* are necrotrophic pathogens of wheat (*Triticum*

aestivum) and cause the diseases *Stagonospora nodorum* blotch and tan spot, respectively. Numerous secreted proteinaceous host-specific toxins are produced by both pathogens. These toxins trigger severe necrosis and disease in wheat lines harboring the corresponding dominant sensitive alleles of the wheat gene. The *ToxA* gene encodes a 13-kDa polypeptide and was likely transferred from *S. nodorum* to *P. tritici-repentis*. In wheat leaves, the small ToxA protein is internalized within sensitive host cells, where it localizes to chloroplasts. ToxA stimulates host cell death in a light-dependent manner: it forms oligomers and interacts with plastocyanin, a component of the photosynthetic electron transport chain (see Chapter 12). Protein sequence and

structural studies on ToxA have revealed an arginine-glycine-aspartate solvent-exposed loop is required for internalization into wheat cells. The ToxA protein has structural similarity with effectors produced by other fungal pathogens (Table 21.2)

For plant pathogenic bacteria in the genus *Xanthomonas*, TAL (transcription activator-like) effectors (Fig. 21.20) contribute to disease formation or trigger defense by binding host DNA and activating effector-specific host genes. So far, these are the only type of bacterial effectors known to regulate host cell gene expression directly. Their discovery also led to the description of a new type of DNA-binding protein. TAL effectors are delivered into plant cells by T3SS, and once inside, they activate transcription of specific plant genes that enable pathogen spread. For example, PthXo1, a TAL effector of the rice pathogen *Xanthomonas oryzae*, activates expression of the rice gene *Os8N3*, allowing *Xanthomonas* to colonize rice plants. The rice *Os8N3* protein is also required for normal plant development, so the host gene cannot be inactivated or eliminated to avoid infection. Instead, there is strong selective pressure for the plant to accumulate *Os8N3* promoter mutations that prevent PthXo1 binding and, as a consequence, for the *Xanthomonas* bacteria to make compensatory changes in the TAL effector's DNA-binding specificity.

The specificity of DNA binding by each TAL effector and ability to adapt to host mutations depend on a variable number of typically 34 imperfect amino acid repeats in each TAL protein. The greatest polymorphism has been observed at positions 12 and 13 in each repeat, the repeat-variable diresidue (RVD) (Fig. 21.20A). Remarkably, the amino acid residues representing the RVDs of each TAL bacterial effector protein correspond to the nucleotides in the target site plant DNA. A “one-RVD-to-one nucleotide” relationship was identified, which can be imprecise. RVDs bind their cognate nucleotides through a unique structure of the protein when it interacts with the binding site in the DNA (Fig. 21.20B). The RVD code was initially deduced through molecular genetic analyses of the interaction between AvrBs3 (the TAL effector of a *Xanthomonas* pathogen of pepper (*Capsicum* sp.)) and its target DNA sequence in the promoter of the *Bs3* resistance gene. *Bs3* evolved as an allele of a gene that, when transcriptionally activated by a bacterial effector, elicits defense responses. The specificity of each *Xanthomonas* effector can be predicted from the protein sequence, and the target site in the promoter DNA of the host gene can be readily identified. Different DNA binding motifs can be added to a plant promoter, and these confer TAL effector-dependent expression of reporter genes in planta. Furthermore, TAL effectors can be designed to bind any DNA sequence (see Section 21.11).

Pathogenic strains of the bacterium *P. syringae* pv. *syringae* (*Pss*) cause disease on many different plants, including brown spot disease on bean (*Phaseolus vulgaris*). Some *Pss* strains secrete syringolin A (SylA), a peptide derivative synthesized by a mixed nonribosomal peptide synthetase/polyketide synthetase encoded by a gene cluster. The effector SylA is secreted by the bacteria into the host plant cells. Strains of

Pss engineered not to produce SylA are significantly reduced in virulence towards bean leaves (see Fig. 21.16). Once inside the cells, SylA irreversibly inhibits the proteasome (see Chapter 10).

Effectors often target host cell enzymes for inactivation. Three functions for different *C. fulvum* effectors have been defined, and each exhibits a different type and degree of sequence polymorphism (Table 21.3). The Avr2 effector inhibits tomato cysteine proteinases that are important components of plant defense. Effectors from *P. infestans* and from nematodes also inhibit this class of cysteine proteases. Avr4 inhibits plant chitinases, likely playing a crucial role at the growing hyphal tip. The Ecp6 effector contains a LysM domain, which specifically binds chitin fragments. However, unlike Avr4, Ecp6 does not inhibit plant chitinases. Instead, it functions by binding to chitin fragments, thus preventing this type of PAMP from being detected by plant cells and initiating PTI. Effectors from the rice blast fungus *Magnaporthe oryzae* and wheat blotch fungus *Mycosphaerella graminicola* also contain multiple LysM domains and bind chitin fragments to prevent PTI and assist the early biotrophic phase of the infection.

The rice blast fungus *Magnaporthe oryzae* invades rice by forming an appressorium (Fig. 21.21) in which enormous turgor pressure is created via hydrolysis of storage carbohydrate to glycerol. A septin ring assembles on the lower side of the appressorium to provide cortical rigidity and membrane curvature for the formation of a single penetration peg, which then enters the plant cell. However, unlike the powdery mildews, the penetrating *M. oryzae* hyphae do not form a haustorium to extract nutrients; instead, the hyphae invade successive living rice cells while enclosed in host-derived extra-invasive hyphal membrane. A structure called the **biotrophic interfacial complex** (BIC) accumulates fluorescently labeled effectors secreted by the invasive hyphae (Fig. 21.21). At the BIC complex, some of the accumulating *M. oryzae* effectors are translocated into the host cell cytoplasm. Other *M. oryzae* effectors do not accumulate at the BIC, but instead uniformly surround the invasive hyphae. The fungal effectors that reach the rice cytoplasm then move via plasmodesmata into uninvaded neighboring host cells, presumably preparing them before invasion.

Several effectors from the basidiomycete fungus *Melampsora lini*, which causes flax rust disease, have been identified and their crystal structures determined. They are small secreted proteins expressed exclusively in the fungal haustorium and then translocated into the host cells (Fig. 21.22A). The mechanism of AvrL567 and AvrM rust effector entry into plant cells is controversial and likely involves endocytosis (Fig. 21.22B). Residues located on the protein surface are important for recognition by the plant (see Section 21.7).

Another basidiomycete, the maize smut fungus *Ustilago maydis*, causes the formation of large tumors. During infection, *U. maydis* secretes several chorismate mutases, key enzymes of the shikimate pathway that catalyze the conversion of chorismate to prephenate, the precursor for tyrosine

TABLE 21.3 Features of some of the Avr and ECP proteins produced by the fungus *Cladosporium fulvum* and secreted into the apoplast during tomato leaf infection.

Protein	Extent/type of polymorphism	Main protein function	Role in the interaction
Avr2	Small deletions or insertions	Inhibition of plant cysteine proteases	Reduction in the effectiveness of one class of induced defense proteins
Avr4	Point mutations leading to amino-acid substitutions	Chitin-binding	Protection of fungal chitin from degradation by induced plant chitinases
Avr9	Whole gene deletions	A high-affinity Avr9 binding site (HABS) has been detected in resistant and susceptible tomato and non-host Solanaceous plants	Secreted cysteine-knot protein; unknown function
Ecp2	Point mutations leading to amino acid substitutions	Unknown function; gene sequences homologous to Ecp2 have been identified in over 100 other microbial species, including plant pathogens	Unknown function
Ecp6	Limited point mutations resulting in a total of five single-nucleotide polymorphisms (SNPs) and one amino-acid substitutions	Binding chitin fragments; functional homologs have been identified in other plant pathogens	Removal of chitin fragments detectable by plant chitin receptors; gene deletion leads to reduced virulence

and phenylalanine (see Chapter 7). The chorismate mutase Cmu1 secreted by *U. maydis* is required for plant colonization. The enzyme is taken up by plant cells, can spread to neighboring cells, and changes the metabolic status of these cells. The overall effect of Cmu1 and other secreted effectors produced by *U. maydis* is to reduce the accumulation of salicylic acids and therefore reduce the intensity of the defense response at the site of infection (see Section 21.8.2).

Effector properties of plant viral proteins and their ability to trigger disease resistance have now been clarified for many viruses and often the viral coat protein can elicit the resistance response, but the plant can evolve to recognize any viral protein. In contrast, identifying the effector molecules produced by parasitic nematodes of feeding aphids is difficult. The nematode-secreted peptide 16D10, which was first isolated from the soybean root-knot nematode *Meloidogyne incognita*, interacts with a plant regulatory protein, stimulates root growth, and binds *in planta* to two SCARECROW-like transcription factors (see Chapter 11). But how this peptide contributes to the infection process remains unclear.

21.3.8 Pathogens specialize to colonize different host tissues

Infection by each pathogen species tends to be restricted to specific plant organs and tissue types (see Fig. 21.5). The mechanisms underlying this organ and tissue specificity

have not been elucidated. Conceivably, only specific plant organs can fulfil the nutritional requirements of the pathogen. Alternatively, different effector molecules may need particular conditions to be fully functional, so that effector molecules can only aid the infection process in particular regions of the plant or at specific stages of plant development.

Some obligate biotrophs, such as the fungal rusts, infect taxonomically distinct plant species to complete different phases of their complex life cycle. For example, *Puccinia graminis* var. *tritici* infects wheat stems and leaves, but subsequently infects the leaves of a dicotyledonous plant species Barberry (*Berberis vulgaris*) to complete the life cycle (see Box 21.1). Successful infection of these **alternate hosts** might require a distinct suite of effector molecules. Importantly, asexual spores are produced during growth on grass leaves, but the sexual reproductive cycle is confined to the barberry.

The downy mildew pathogen *Hyaloperonospora arabidopsidis* and the white rust pathogen *Albugo laibachii* are obligate biotroph oomycete pathogens of *Arabidopsis*, and both elaborate haustoria in infected cells. Remarkably, infections by *A. laibachii* enhance host plant susceptibility to other pathogens to which the host is normally resistant, including recognized races of *H. arabidopsidis* (Fig. 21.23). After suppression of host defense by *Albugo* infection, genetically incompatible pathogens become able to infect and sporulate. Cell death mechanisms are also suppressed. The result is a mixture of different pathogenic species successfully infecting in close proximity

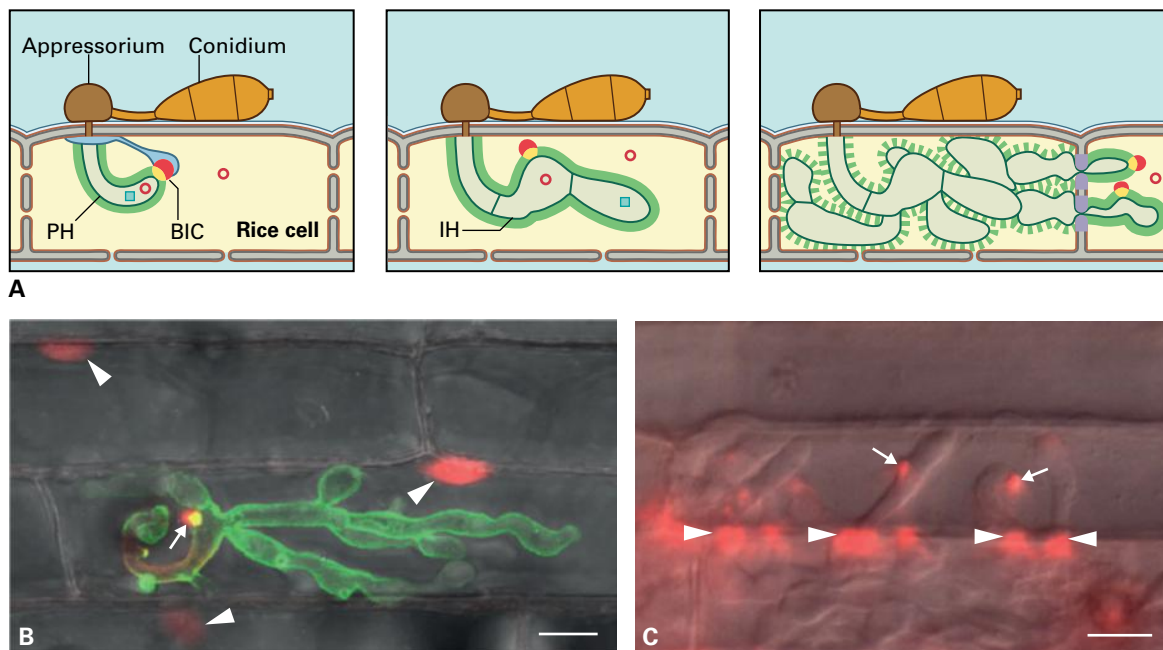

FIGURE 21.21 Formation of the biotrophic interfacial complex (BIC) complex during *Magnaporthe oryzae* infection of rice (*Oryza sativa*) leaves. The BIC is a plant-derived, membrane-rich structure that facilitates translocation of some effector proteins into the host cell cytoplasm. (A) Schematic representation of the post-penetration differentiation of a filamentous primary invasive hypha (PH) (left, ≈ 22 – 25 hours post inoculation, hpi) into a pseudohyphal-like bulbous invasive hypha (IH) (middle, ≈ 26 – 30 hpi.) in an invaded rice cell. This differentiation occurs for each new hypha invading a living neighbor cell (right, ≈ 36 – 40 hpi). Cytoplasmic effectors (open red circles) show preferential accumulation in the BIC, which is first located in front of the growing primary hyphal tips, and then remains behind beside the first-differentiated bulbous IH cell. Other apoplastic effectors (green squares) are secreted into and retained within the extra-invasive hyphal membrane compartment surrounding the PH (green solid line). (B) A confocal projection image shows an IH (at 30 hpi) expressing the BAS4 effector fused to the fluorescent reporter protein GFP and the effector protein PWL2 fused to a different fluorescent reporter protein mCherry (red, a brighter variant of mRFP) engineered with a C-terminal viral nuclear localization signal. The fluorescently labeled PWL2 (red) preferentially accumulated in the BIC (white arrow). The nuclear targeting of the cytoplasmic effector PWL2:mCherry (red color) facilitates visualization of effector translocation through the BIC and subsequent cell-to-cell spread in advance of hyphal colonization. The apoplastic effector BAS4:EGFP (green) remains localized to the outside of the invasive hyphae within the extra-invasive hyphal membrane. (C) IH expressing cytoplasmic effector BAS2:mRFP (red). The IH were imaged after growth into a second-invaded cell at 36 hpi. The BAS2:mRFP fusion protein accumulated in BICs (arrows) and at cell wall crossing points (arrowheads, purple in right panel in A).

to each other. Such mixed infections are common in nature, though due to their complexity, less commonly investigated.

21.3.9 Genome sequencing reveals the gene complements and virulence factor repertoires of plant pathogens

Pathogen genome sequencing enables definition of the complete repertoire of predicted genes for a plant pathogenic species. Comparison of the content and organization of each genome provides researchers with a wealth of information to better understand pathogen and pest biology. Genome information also provides clues to the range of inter- and extracellular molecules (proteins and metabolites) produced by pathogens that might be detected by plant cells to prevent infection of the different types of pathogens. The genomic era began for plant-infecting pathogens with the sequencing of plant viruses and viroids, then plant pathogenic bacteria, and recently a full range of plant pathogenic fungi, oomycetes, plant parasitic nematodes, and insect pests. The first pathogenic species to be fully sequenced in each kingdom is given in Table 21.4, along with some species where the sequenced genome has given insight into the mechanisms underlying pathogenicity and host range.

Since the late 2000s, low-cost next-generation sequencing (NGS) methods and new sequence assembly algorithms have made it possible to undertake whole genome sequencing of many different strains or isolates of the same pathogenic species. By comparing closely related genomes, the candidate effector gene sets that may be responsible for key biological differences can be pinpointed and then assessed for function. In many whole genome studies, the transcribed portion (transcriptome) of the pathogen genome expressed *in planta* was also characterized, in an attempt to identify the putative effector sequences and induced metabolic pathways. Today, the genome sequences of hundreds of pathogenic species are available, with the number of species with full genomic sequence information predicted to rise to several thousands in the near future.

What has this wealth of genomic sequencing revealed so far? Particularly striking is the discovery that the genomes of taxonomically closely related species often exhibit remarkable diversity in genome size and architecture (Fig. 21.24 and Table 21.5). Reciprocally, common genome features, such as the clustering of effector genes in specific regions of the genome, can be found in phylogenetically unrelated species. For example, within the genomes of many plant pathogenic bacteria resides a cluster of genes that encode the type 3 secretion system (T3SS) (Fig. 21.25). The genomes of plant pathogens often show similarities to their free-living relatives.

In summary, the availability of full genome sequences for hundreds of pathogenic species from a wide range of taxa is revealing the gene complements and virulence factor repertoires of plant pathogens.

21.4 Preformed defenses

Most healthy plants synthesize a range of secondary metabolites with antimicrobial properties (see Chapter 24). These compounds either exist in biologically active forms or are stored as inactive precursors and converted by host enzymes to active forms in response to pathogen attack or tissue damage. In general, these preformed inhibitors are sequestered in vacuoles or organelles in the outermost layers of plant cells. Therefore, the mode of pathogen attack influences the concentrations of inhibitors it encounters: Necrotrophs invariably cause the release of high levels of inhibitors, while haustoria-forming biotrophic fungi may never encounter them. Two well-characterized classes of preformed inhibitors are the saponins and the glucosinolates (see Chapter 24); a third class are the benzoxazinoid acetal D-glucosides.

Saponins are glycosylated triterpenoid compounds related to sterols. The chemical structure of the triterpenoid saponin **avenacin A1**, found in oat (*Avena sativa*) roots, is illustrated in Figure 21.26. The wheat root pathogen *Gaeumannomyces graminis* var. *tritici* is extremely sensitive to avenacins. As a consequence, the root-debilitating disease called “take all” caused by *G.g. tritici* occurs on wheat and barley, but never in

TABLE 21.4 The history of model species and plant pathogen genome sequencing.

Date	Species	Estimated gene number	Comments
1977	Bacteriophage ϕ X174	11	First replicating agent (virus) genome
1995	<i>Haemophilus influenzae</i>	1,740	First prokaryote (bacterial) genome
1996	<i>Saccharomyces cerevisiae</i>	6,000	First eukaryote (yeast) genome
1998	<i>Caenorhabditis elegans</i>	20,000	First invertebrate (nematode) genome
2000	<i>Drosophila melanogaster</i>	14,000	First insect genome
2000	<i>Arabidopsis thaliana</i>	25,500	First plant genome
2000	<i>Xylella fastidiosa</i>	2,900	First bacterial plant pathogen genome
2002	<i>Magnaporthe grisea</i>	11,100	First fungal plant pathogen genome
2002	<i>Oryza sativa</i>	37,500	Rice. First cereal crop. Draft sequences 2002, completed 2005
2003	<i>Pseudomonas syringae</i>	5,800	Model bacterial plant pathogen
2008	<i>Meloidogyne hapla</i>	14,200	First plant pathogenic nematode genome
2009	<i>Phytophthora infestans</i>	14,000	Potato blight pathogen – Oomycete genome
2010	<i>Acyrtosiphon pisum</i>	34,000	First aphid genome
2010 onwards	Parallel sequencing of multiple isolates per species		Predominantly use NGS approaches and the reference sequenced genome as the scaffold

oat (Fig. 21.26). *G.g. avenae* carries a saponin-detoxifying enzyme (avenacinase) that is required for pathogenesis on oats. Tomato plants produce tomatine, a compound that is closely related to avenacin. Only certain pathovars of the fungal pathogen *Septoria lycopersici* can cause disease on tomatoes, and these pathovars produce a glucosidase that can detoxify tomatine.

Glucosinolates are sulfur-containing glucosides produced by *Brassicaceae*, including *Arabidopsis thaliana*. Glucosinolates are divided into three classes, depending upon the nature of their side chains, which are derived from aliphatic, indolyl, or aralkyl α -amino acids (see Chapter 24). Defenses based on glucosinolates can be preformed or induced. Some glucosinolates become biologically active only in response to tissue damage via the activity of the enzyme myrosinase (a thioglucosidase) (Fig. 21.27). In healthy plant cells, subcellular compartmentalization separates myrosinase from the glucosinolate substrate, either in specialized myrosin cells in the phloem parenchyma or in stomatal cells. The unstable aglycone intermediate generated by myrosinase enzyme activity is converted into various products, including volatile isothiocyanates (mustard oils) (Fig. 21.27). Genetic variation exists for the glucosinolate profiles in oilseed rape plants (*Brassica*

napus). An elevated proportion of butenyl glucosinolates, via the elimination of the pentenyl type, decreases leaf tissue palatability to unspecialized *Brassicaceae* pests, such as rabbits, pigeons, and slugs, whereas it increases susceptibility to specialized insect pests, such as adult flea beetles (*Psylliodes chrysocephala*). Glucosinolates active against insects and necrotrophs are usually preformed, but some antimicrobial glucosinolates are induced (see Section 21.5.6).

The benzoxazinoid acetal D-glucosides are a class of nitrogen-containing compounds produced by maize, wheat, and rye (*Secale cereale*). Resistance to various insect species is strongly correlated with the presence of some of these compounds. For example, in maize, resistance to the European corn borer (*Ostrinia nubilalis*) is strongly correlated with the presence of DIBOA and DIMBOA (see Chapter 7). The biosynthetic pathway required for their production has been elucidated for maize (Fig. 21.28). In chloroplasts, indole is synthesized and then exported to the cytoplasm for metabolism by cytochrome P450 enzymes located in the endoplasmic reticulum. The benzoxazinoids formed are then glucosylated by the transfer of glucose from UDP-glucose, and the resulting glucosides are stored in the vacuole. These glucosides are non-toxic. Within maize chloroplasts, specific glucosidases cleave

TABLE 21.5 Key features of plant pathogen genomes.

Pathogen type/species	Genome features	Function
Gram-negative bacteria/ <i>Pseudomonas</i> , <i>Xanthomonas</i> , <i>Ralstonia</i> , <i>Erwinia</i> , <i>Pectobacterium</i>	Multiple genomic islands: clusters of genes coding for type III secreted effectors (T3SE)	T3SE are either species-specific or common to multiple species, and many contribute to the infection process
	Horizontal gene transfer between distantly related bacterial species	Acquiring new disease-causing abilities or expanded host ranges
Gram-positive bacteria/ <i>Leifsonia xyli</i> subsp. <i>xyli</i>	Large fraction of pseudogenes (13%) and genome shrinkage (i.e., loss of specific gene types)	Adaptation to a specific plant niche—for this species, the xylem
Obligate biotrophs/ <i>Blumeria formae speciales</i>	Large genomes (120–150 Mb) with a high proportion of repetitive DNA (65–75%); both lineage-specific expansion and contraction of specific gene families	Restricted gene set for nitrate assimilation and sulfate assimilation reflects the reliance on plant metabolism for pathogen nutrition
Hemibiotrophic and necrotrophic ascomycetes	Majority have genome sizes of 35–45 Mb; small to large gene families for CWDE and small secreted proteins (SSPs); many possess secondary metabolism gene clusters	Gene gain/loss or gene family expansion/reduction associated with particular infection lifestyles; many SSPs are species-specific and may assist infection of specific plant hosts
Biotrophic basidiomycete smut fungi/ <i>Ustilago maydis</i> and <i>Sporisorium reilianum</i>	Smaller genomes (≈19–21 Mb), small clusters of genes coding for secreted proteins, and a reduced set of genes encoding plant cell wall hydrolytic enzymes	To assist the long biotrophic lifestyle and tumor formation on the different host plants
Oomycetes/ <i>Phytophthora</i>	Large genomes (≈220–280 Mb) of the <i>Phytophthora</i> species; a proliferation of repetitive DNA and, in particular transposable elements (TEs); RXLR and Crinkler effector genes embedded within long stretches of repetitive DNA	Repetitive DNA frequently coincides with a breakdown in the overall macro and micro order of the genes (synteny) between closely related species; within these syntenic breakpoint regions, effector and other genes evolve at accelerated rates compared to genes residing elsewhere in the genome
Obligate biotrophic oomycetes/ <i>Albugo</i> and <i>Hyaloperonospora</i>	Smaller genomes (≈40–100 Mb), reduced set of genes encoding plant cell wall hydrolytic enzymes	Restricted gene sets reflect reliance on plant metabolism for pathogen nutrition
Root-knot nematodes/ <i>Meloidogyne</i>	<i>M. hapla</i> – 54 Mb, <i>M. incognata</i> – 86 Mb Large gene families for plant cell wall-degrading enzymes (PCWD), including cellulases, xylanases, arabinases, pectinases, and expansins; many genes acquired by horizontal gene transfer from soil bacteria or from plant hosts; many species-specific sequences in the predicted secretomes	Adaptation to a specific plant niche and specific plant taxa
Phloem-feeding specialist insect/pea aphid (<i>Acyrtosiphon pisum</i>)	Large genome (≈464 Mb); many expanded gene families include those involved in sugar transport; many of the genes encoding immune system components are absent	The reduced immune capabilities of aphids could facilitate the acquisition and maintenance of bacterial symbionts, which provide essential amino acids that are absent or rare in the sugar-rich phloem sap

FIGURE 21.24 Evolution and genome sizes of sequenced filamentous plant pathogen genomes. Filamentous eukaryotic plant pathogens belong to either the fungi or the stramenopiles (oomycetes). The representative phylogeny was generated using Interactive Tree Of Life (iTOL) with National Center for Biotechnology Information (NCBI) taxonomy identifiers (branch lengths are arbitrary). Isolate identifier, or the number of isolates sequenced, is indicated next to the species name. Pathogen lifestyles and major variations in gene families are indicated along the tree branches. The principal host plants and genome size, main insights gained from genome comparisons, are shown next to the tree branches. CWDE, cell wall-degrading enzyme; RXLR, arginine-any amino acid-leucine-arginine; SMB, secondary metabolites biosynthesis; SSP, small secreted protein.

the glucosides to release the free benzoxazinoids. The benzoxazinoid DIMBOA, which is toxic to insects, only accumulates when the plant cell is damaged and permits the mixing of the vascular and chloroplast contents.

21.5 Induced defense

As explained in Section 21.2, defense is induced either by recognition of relatively conserved P/MAMPs by cell-surface pattern recognition receptors (PRRs), resulting in P/MAMP- (or PRR-) triggered immunity (PTI), or by recognition of effectors (directly or indirectly) by intracellular NB-LRR receptors leading to effector-triggered immunity (ETI). The following section explains how the recognition process then triggers signaling pathways that lead to the induction of various defense mechanisms.

21.5.1 PTI is one mechanism of induced defense

Pathogen molecules that can trigger PTI are shared by many different pathogenic species because they have conserved functions, such as **chitin** and other **glucans** that are essential for rigid fungal cell wall formation, the protein **flagellin** of the flagellum that is required for bacterial movement, and elongation factor-Tu (EF-Tu) of bacterial ribosomes.

Specialized PRRs have been identified in plants that recognize distinct P/MAMPs (Fig. 21.29). In *Arabidopsis*, the flagellin-sensing FLS2 protein detects a 22 amino acid peptide (flg22) derived from the N-terminal fragment of flagellin; this part of the protein is highly conserved across bacterial species. The *Arabidopsis* EF-Tu receptor EFR protein perceives an acetylated N-terminal 18 amino acids (elf18) of elongation factor-Tu. FLS2 and EFR have a similar

FIGURE 21.25 Bacterial virulence gene islands. Schematic overview of the hypersensitive response and pathogenicity (*hrp*) regions from four different sequenced plant pathogenic bacteria. The *hrp* clusters of *Xanthomonas campestris* pv. *vesicatoria* strain 85–10, *Ralstonia solanacearum* strain GMI1000, *Erwinia carotovora* subsp. *atroseptica* strain SCRI1043, and *Pseudomonas syringae* pv. *tomato* strain DC3000 are shown. Red arrows indicate *hrc* (*hrp* conserved in plant and animal infecting bacteria) genes, blue arrows indicate *hrp* genes, green arrows indicate *hpa* (*hrp* associated) genes that contribute to, but are not essential for the pathogenic interaction with the plant, black arrows indicate type III effector genes, gray arrows indicate genes coding for proteins of unknown or other functions, and white arrows indicate genes encoding regulators of type three secretion system (T3SS) expression. Yellow boxes denote insertion sequences (IS) elements, acquired by horizontal gene transfer from other plant pathogenic bacteria. Arrows above the *Xanthomonas* sequence indicate the operon structure and the black dots highlight the HrpX-regulated genes which contain in their promoter region a plant-inducible promoter box (PIP box).

FIGURE 21.26 Avenacin A-1 is a preformed defense saponin produced in the roots of oat (*Avena sativa*) but not in wheat (*Triticum* spp.) or barley (*Hordeum vulgare*). The epidermal location of avenacin in healthy oat roots is revealed when root sections are viewed under UV fluorescence. The root-infecting take-all fungus *Gaeumannomyces graminis* var. *tritici* is extremely sensitive to avenacin A-1, whereas a closely related species, *G. g.* var. *avenae*, carries a saponin-detoxifying enzyme that removes the 1 → 2- and 1 → 4-linked terminal D -glucose (glu) sugar molecules, rendering the avenacin A-1 nontoxic. Source: Osbourn (1999). Fungal Genet. Biol. 26:163–168.

FIGURE 21.27 Some glucosinolates are preformed defense compounds. Glucosinolates contain two sulfur atoms, one forming the link between a central carbon atom and the sugar group, the other in a sulfite (SO_3^-) group. When plant tissue is damaged, hydrolysis of these stored, preformed glucosinolates leads to the formation and release of numerous bioactive toxic compounds. Wounding activates myrosinase enzyme activity and also causes cellular decompartmentalization, which brings the activated myrosinase enzyme into contact with the glucosinolate substrates. Myrosinase cleaves the sugar-sulfur bond to release the sugar. The resulting compound spontaneously decays to produce sulfate (SO_4^{2-}) and toxic isothiocyanates, nitriles and thiocyanates.

overall protein structure, and their activation triggers a rapid association with LRR kinase BAK1, which participates in subsequent signal initiation (Fig. 21.29).

Plant PRRs that recognize fungal chitin fragments (chitin oligomers) have been isolated from rice (*Oryza sativa*), wheat (*Triticum* sp.), and *Arabidopsis*. CEBiP (chitin elicitor binding protein) and CERK1 (chitin elicitor receptor kinase 1) both span the plasma membrane only once and possess extracellular domains that contain a different number of LysM motifs that bind chitin fragments. The CERK1 protein possesses an intracellular protein kinase domain that is involved in downstream signaling (Fig. 21.29; see also Fig. 21.41), whereas CEBiP does not. *Arabidopsis* CERK1 is also involved in recognition of bacterial peptidoglycan, a polysaccharide that carries a repeating *N*-acetylglucosamine unit.

The sequence of events activated during PTI is summarized in Figure 21.30. The microbial elicitor is recognized by a PRR in the plant plasma membrane. Recognition results in the rapid influx of calcium (Ca^{2+}) ions into the cell and production of ROS, such as superoxide anions ($\text{O}_2^{\cdot-}$) and hydrogen peroxide (H_2O_2). When ROS are produced at locally high concentrations, they have direct antimicrobial properties, while at lower concentrations ROS act as signaling molecules. These early events activate a signaling pathway that involves a series of specific protein kinases. BIK1 (and several related proteins) are receptor-like cytoplasmic protein kinases that are required for full FLS2 or EFR signaling, and they are targeted by some pathogen effectors (see Section 21.3).

21.5.2 Protein kinase signaling in plant defense involves MAPKs and CDPKs

Upon elicitation, at least two classes of protein kinases are activated: the **mitogen-activated protein kinases** (MAPKs; see Chapter 18) and **calcium-dependent protein kinases**

(CDPKs). The CDPK class of protein kinases is absent from mammals, whereas the MAP kinases participate in signaling in all eukaryotes. In response to PAMP recognition and the rapid influx of Ca^{2+} ions, there is post-translational and sequential activation of a MAPKK kinase (MAPKKK), a MAPK kinase (MKK), and four different MAP kinases, as well as simultaneous activation of CDPKs (Fig. 21.30).

The expression of some genes is also induced rapidly. These genes typically encode other signaling proteins, such as protein kinases and regulatory proteins, such as transcription factors, which increase signaling complexity and further enhance plant defense activation. Later-expressed genes often encode proteins responsible for targeting other proteins for degradation via the **proteasome** (see Chapter 10). Such degradation may promote defense via removal of negative regulators of defense, or enable the defense response program to be reset so that subsequent pathogen challenges can be recognized and responded to. Protein inactivation is often achieved by the addition of ubiquitin molecules to certain sites on the protein (ubiquitination), thereby marking it for proteasome degradation (see Chapter 10).

The MAP kinases MPK3, MPK4, and MPK6 have roles in defense. MPK3, MPK6, and MPK11 have been linked to PTI. MPK4 was originally reported as a negative regulator of plant immunity because the *mpk4* mutant has a severely dwarfed growth phenotype, accumulates high levels of SA, and constitutively expresses several defense related genes. The *P. syringae* HopA11 effector is a phosphothreonine lyase that irreversibly inactivates MPK3, MPK6, and MPK4, thereby preventing defense responses that would otherwise inhibit bacterial growth.

The best-studied *in vivo* substrate of MPK4 activity is MPK4 substrate 1 (MKS1). MKS1 forms a nuclear complex with MPK4 and the WRKY33 transcription factor (see Section 21.5.5). Following P/MAMP perception and MPK4 activation, phosphorylation of MKS1 leads to its exit from complexes with MPK4, thereby releasing the WRKY33 transcription factor, which is then available to bind to the cognate W box in the promoters of various target genes. For

FIGURE 21.28 Synthesis and storage of benzoxazinoid (Bx) secondary metabolites in grass species. The first step in Bx biosynthesis, the production of indole, occurs in the chloroplast by the conversion of indole-3-glycerol phosphate, an intermediate in the pathway to tryptophan synthesis, into indole. In maize (*Zea mays*), this reaction is catalyzed by either *BENZOXAZINELESS1* (Bx1) or *INDOLE GLYCEROL PHOSPHATE LYASE* (Igl). The Bx1 gene is under developmental control and is mainly responsible for Bx production, whereas the Igl gene is inducible by stress signals, such as wounding, herbivory, or jasmonates. In maize leaves, the indole is exported to the cytosol, where it undergoes reactions catalyzed by various Bx enzymes associated with the endoplasmic reticulum. In many grass species Bx biosynthesis is mostly under developmental control and leads to accumulation of inactive Bx-glucosides that are stored in the vacuole. In rye (*Secale cereale*) and wild barley (*Hordeum vulgare*), 2,4-dihydroxy-2H-1,4-benzoxazin-3(4H)-one (DIBOA) is the dominant Bx, whereas in wheat and maize, the methoxy derivative, 2,4-dihydroxy-7-methoxy-2H-1,4-benzoxazin-3(4H)-one (DIMBOA) is more prevalent. DIMBOA accumulates in the apoplast, whilst inactive DIMBOA glucoside is stored in the vacuole. With the exception of Bx9, which is on maize chromosome 1, all Bx genes are located in a small segment of maize chromosome 4, spanning a genetic distance of only 6 cM. Lines of maize with high levels of DIMBOA in their roots are less damaged by the larvae of the Western Corn rootworm (*Diabrotica virgifera virgifera*) than lines with lower DIMBOA levels. Source: Ahmad et al. (2011). *Plant Physiol.* 157(1):317–327.

example, WRKY33 induces transcription of *PHYTOALEXIN DEFICIENT3* (*PAD3*), which encodes the cytochrome P450 monooxygenase required for synthesis of the antimicrobial phytoalexin camalexin (see Section 21.5.6). MPK3 and MPK6

can also directly phosphorylate WRKY33. Therefore, both MPK4 and MPK3/MPK6-mediated signaling are involved in WRKY33-induced *PAD3* expression, indicating dual control of *PAD3* regulation in response to pathogen perception.

FIGURE 21.29 Plants activate defense via cell surface pattern-recognition receptors (PRRs) upon recognition of conserved pathogen molecules (P/MAMPs), resulting in pattern-triggered immunity (PTI). In *Arabidopsis*, the flagellin-sensing FLS2 protein detects an N-terminal fragment of flagellin (flg22) that is highly conserved in pathogenic bacterial species. A second *Arabidopsis* PRR, the EF-Tu receptor EFR perceives an acetylated N-terminal 18 amino acids (elf18) of bacterial elongation factor-Tu. FLS2 and EFR have a similar overall protein structure. Both span the plasma membrane only once and possess an extracellular leucine-rich repeat (LRR) domain that recognizes and binds the cognate PAMP, and both carry an intracellular protein kinase domain. Activation of FLS2 or EFR triggers a rapid association with a second LRR kinase, BAK1, which participates in subsequent signal initiation. A third *Arabidopsis* PRR, the chitin receptor CERK1 (chitin elicitor receptor kinase 1) contains extracellular domains that contain LysM motifs that bind chitin fragments. The CERK1 protein possesses an intracellular protein kinase domain that is involved in downstream defense signaling, and does not require BAK1 for signaling. Note that the cell wall is not shown for clarity.

21.5.3 Synthesis of reactive oxygen species (ROS) involves two mechanisms

The synthesis of ROS during the oxidative burst involves at least two separate mechanisms: NADPH oxidase and extracellular peroxidases.

The plasma membrane-spanning **NADPH oxidase** transfers an electron from NADPH within the cell across the plasma membrane and uses this to convert extracellular oxygen to the superoxide anion ($O_2^{\cdot -}$) (Fig. 21.31). The superoxide anions are then rapidly converted to hydrogen peroxide (H_2O_2), either spontaneously or through the action of **superoxide dismutase**. In *Arabidopsis*, NADPH oxidases are encoded by 10 respiratory burst oxidase homolog (*Atrboh*) genes. Two of the proteins, *AtrbohD* and *F*, are required for production of ROS in response to flg22 and during genetically incompatible host–pathogen interactions involving the oomycete *Hyaloperonospora arabidopsidis* and the bacterium *P. syringae*. Activation of NADPH oxidases involves the combined action of CDPKs and other protein kinases.

Two extracellular (apoplastic) peroxidase enzymes (PRX) are also sources of ROS production leading to the arrest of pathogen growth. *Arabidopsis* lines with diminished PRX33 and PRX34 expression have reduced ROS production and callose deposition in response to the P/MAMPs flg22 and elf18. The *prx33* mutant line is more susceptible to infection by a virulent strain of *P. syringae* than either the *AtrbohD* or *AtrbohF* mutant lines. The ROS generated by the extracellular peroxidases likely have role(s) as antimicrobial agents and in crosslinking specific polymers to the cell wall to improve rigidity.

21.5.4 Cell wall fortification is another induced defense response

Minute **papillae** often form directly beneath the attempted penetration site of biotrophic fungi (Fig. 21.32). These papillae are primarily composed of **callose** (a β -1,3 glucan polymer) and **lignin** (a highly complex phenolic polymer; see Chapter 2), and they are thought to block fungal penetration into plant cells. Induced callose deposition within plasmodesmata also likely blocks virus cell-to-cell movement.

Extracellular basic **hydroxyproline rich glycoproteins** (HRGPs) contribute to fortifying the cell wall in two ways. Preformed HRGPs crosslink rapidly to the wall matrix via the tyrosine in the repeated motif PPPPY that reacts with H_2O_2 . The later de novo HRGP synthesis initiates additional lignin polymerization to further reinforce cell walls (see Chapter 2). These localized reinforcements make the plant cell wall more refractory to microbial penetration and enzymatic degradation.

Another class of defense-related extracellular proteins are **polygalacturonase-inhibiting proteins** (PGIPs), which carry a leucine rich-repeat (LRR) motif (see Section 21.6.2). These inhibit a specific subclass of necrotrophic pathogen cell wall-degrading enzymes called polygalacturonases. PGIPs likely retard polygalacturonase function, which would result in elevated levels of **oligogalacturonides** with chain length of >8 units (sometimes referred to as damage-associated molecular patterns or DAMPs) that are detected by PRRs (Fig. 21.33). Thus, PGIPs prevent complete hydrolysis of pectin so that oligogalacturonides persist long enough to activate these PRRs.

21.5.5 WRKY transcription factors contribute to plant defense responses

WRKY proteins are a large class of WRKY domain-containing, sequence-specific, DNA-binding transcription factors found almost exclusively in plants. WRKY domains comprise an almost invariant WRKYGQK sequence followed by a zinc-finger motif. *Arabidopsis* contains over 70 WRKY proteins that have been classified into three main groups and various subgroups. More than 70% of the *Arabidopsis* WRKY gene family members are

FIGURE 21.30 Pattern-triggered immunity (PTI) and effector-triggered immunity (ETI) activation of early defenses. Following bacterial infection, detection of P/MAMPs by cell surface pattern-recognition receptors (PRRs) and detection of specific bacterial effectors delivered into the plant cell cytoplasm by resistance proteins (R) results in the rapid activation of numerous plant responses. These coordinated responses include alterations in ion fluxes at the plasma membrane, a local rise in cytoplasmic free calcium ion concentrations, the generation of various reactive oxygen (ROS) species at the cell surface, induction of cytoplasmic signaling cascades involving mitogen activated protein (MAP) kinases and calcium-dependent protein kinases (CDPKs), protein phosphorylation (P), induction of the expression of a first set of genes that encode regulatory and signaling proteins, and localized callose deposition to strengthen the cell wall. Collectively, these plant responses create a local environment that is unfavorable for bacterial growth and multiplication.

FIGURE 21.31 Production of various reactive oxygen species. (A) Three routes are depicted: conversion of oxygen to superoxide (O_2^-) by the plasma membrane NADPH oxidase, generation of hydrogen peroxide (H_2O_2) by an apoplasic peroxidase, and conversion of O_2^- to hydrogen peroxide by the intracellular enzyme superoxide dismutase. (B) Activity of the NADPH oxidase. Electrons from intracellular NADPH are donated to extracellular oxygen to form superoxide, via electron carrying FAD and heme groups in the membrane-spanning enzyme.

FIGURE 21.32 A mildew fungus spore germinates and, after a short distance of growth over the leaf surface, forms an appressorium (A) structure for attachment. Subsequently, a fungal penetration peg (PP) is produced that passes through the plant cuticle and epidermal cell wall. Papillae frequently form on the inner surface of the cell wall, directly beneath the invasion site, to prevent further ingress of hyphae. In some pathosystems, however, this localized reinforcement of the cell wall is thought to anchor an invading hypha by forming a tight seal between the neck of the haustorium and the plasma membrane of the epidermal cell invaded. A transmission electron microscope image of the point of penetration. PCW, plant cell wall; V, vacuole.

FIGURE 21.33 PG–PGIP model.

(1) Polygalacturonases (PG) secreted by the fungal hyphae interact with secreted polygalacturonase-inhibiting proteins (PGIP) in the plant cell wall. (2) PGs release from the plant cell wall various oligogalacturonides that interact with the plant receptor of oligogalacturonides (in *Arabidopsis*, the wall-associated kinase 1, or WAK1 receptor). (3) Transduction of the oligogalacturonide signal results in the expression of plant defense proteins, including PGIPs. (4) Chitinases, glucanases, and phytoalexins are secreted by the plant and (5) damage the fungal hyphae.

responsive to pathogen infection or salicylic acid treatment, and some WRKY genes are also induced by abiotic stress (see Chapter 22).

In *Arabidopsis*, WRKY proteins contribute to the regulation of a wide range of biological functions, including hormone signaling, growth, secondary metabolism, response to various abiotic stresses, seed germination, leaf senescence, and the synthesis of phytoalexin and other defenses against pathogens. Despite this functional diversity, almost all the analyzed WRKY proteins recognize and bind to the core W box sequence TTGACC/T in the promoter of the responsive plant genes. Different WRKY proteins interact with each other and with other plant proteins.

21.5.6 Phytoalexins are antimicrobial compounds that accumulate at sites of incompatible pathogen infection

Phytoalexins are low molecular weight, lipophilic antimicrobial compounds that accumulate rapidly at sites of incompatible pathogen infections. They are derived from primary metabolites that are used for novel biosynthetic pathways. For example, phenylalanine is a substrate for the synthesis of various flavonoid and isoflavanoid phytoalexins via **phenylalanine ammonia lyase (PAL)**, which controls a key branch point in the phenylpropanoid biosynthetic pathway (see

FIGURE 21.34 Structures of a selection of phytoalexins.

Chapter 24). Other phytoalexins, for example, capsidiol and rishitin, accumulate rapidly in tobacco (*Nicotiana tabacum*) and potato (*Solanum tuberosum*) in response to pathogen attack.

Different plants make chemically distinct phytoalexins (Fig. 21.34), and the synthesis of most phytoalexins involves the activities of many biosynthetic enzymes, requiring highly coordinated signal transduction and regulation of gene expression. Coordination is likely achieved via a common DNA sequence element within the promoters of genes that encode enzymes of phytoalexin synthesis. In the case of flavonoid biosynthesis in parsley (*Petroselinum* sp.), this appears to involve an H-box (CCTACC(N)7CT) and a G-box (CACGTG).

Definitive genetic and biochemical proof of the role of phytoalexins in disease resistance has come from mutants that are deficient in phytoalexin production. The phytoalexin deficient (*pad*) mutants of *Arabidopsis* fail to synthesize a UV-fluorescent compound camalexin. The *pad3* mutant, which lacks the cytP450 required for camalexin biosynthesis, is more susceptible to the necrotroph *Alternaria brassicicola*, but has an unaltered response to other pathogens, such as the bacterium *P. syringae*.

In *Arabidopsis*, PTI induces production of indole glucosinolates, which provide broad-spectrum control of fungal pathogens. PTI and fungal pathogen entry into epidermal tissue induces several specific cytochrome P450 enzymes, and this leads to accumulation of the indole glucosinolate 4-methoxyindol-3-ylmethylglucosinolate (4M13G). *Arabidopsis* PEN2 encodes a peroxisome-associated myrosinase and is induced upon infection and by P/MAMPs (see Section 21.4). The atypical PEN2 myrosinase then converts the indole glucosinolate 4M13G into toxic compounds that are exported

from the plant cell via the ABC transporter encoded by PEN3 to the sites of fungal infection (Fig. 21.35).

21.5.7 Salicylic acid biosynthesis is required for local defense signaling

Salicylic acid (SA) is a phenolic compound (see Chapter 24) that accumulates to high levels as both free and glucoside conjugates in the vicinity of incompatible infection sites. SA is derived from the phenylpropanoid pathway, and numerous roles for them in plant defense have been proposed (Fig. 21.36).

The requirement for SA in some incompatible pathogen interactions has been demonstrated using transgenic plants that constitutively express a bacterial *nahG* gene. This gene encodes the enzyme salicylate hydroxylase, which converts SA to catechol and thus dramatically reduces SA levels. Reduced SA accumulation in the *nahG*-expressing plants correlates with a weakening of several *R*-gene-mediated resistance phenotypes, for example *N*-mediated resistance to TMV, and also abolishes the induction of various defense genes. SA-mediated defenses are especially important in conferring resistance to pathogens that are either obligate biotrophs or have an initial phase of biotrophic colonization.

Two distinct biosynthetic pathways to SA have been identified in both *Arabidopsis* and tobacco (*Nicotiana tabacum*): the isochorismate (IC) and the phenylalanine ammonia-lyase (PAL) pathway (Fig. 21.37). Both originate from chorismate, the end product of the shikimate pathway (see Chapter 7). *Arabidopsis* appears to synthesize SA primarily

FIGURE 21.35 An inducible tryptophan-derived indole glucosinolate pathway in plant cells mediates broad-spectrum antifungal defense. The CYP81F2 gene encodes a P450 monooxygenase that is essential for the pathogen-induced accumulation of 4-methoxyindol-3-ylmethylglucosinolate (4MI3G), which in turn is activated by the atypical PEN2 myrosinase (a type of β -thioglucoside glucohydrolase) for antifungal defense. This pathway is active in living cells and enables the recruitment of indole glucosinolates into PAMP-triggered immunity (PTI). Other tryptophan-derived metabolites are involved in *Arabidopsis* defense against powdery mildews, including the phytoalexin camalexin. Components critical for termination of pre- and post-invasive fungal growth are highlighted with blue and orange frames, respectively. The matching structure fragments of the isothiocyanate-glutathione adduct and some of the Brassicaceae phytoalexins are highlighted in red. GSH, glutathione; I3G, indol-3-ylmethylglucosinolate; I3A, indol-3-ylmethylamine; PEN2, penetration 2 gene; γ -ECS, gamma-glutamylcysteine synthetase; PAD3, phytoalexin deficient 3 gene; RA, raphanusamic acid; 4MI3A, 4-methoxyindol-3-ylmethylamine.

A

B

FIGURE 21.37 Biosynthesis of salicylic acid (SA) in plants. (A) SA in Arabidopsis is predominantly produced from isochorismate. Isotope feeding experiments suggest that other plants synthesize SA from cinnamate produced by PAL. The importance of the enzymes phenylalanine ammonia lyase (PAL) and isochorismate synthase (ICS) in SA accumulation has been demonstrated in experiments using mutants, gene silencing, and chemical inhibition. EDS5, ENHANCED DISEASE SENSITIVITY 5, a MATE transporter of unknown function. via isochorismate in the chloroplast, whereas in tobacco, SA biosynthesis may occur primarily via benzoic acid in the cytosol. In some plant species, such as rice (*Oryza sativa*) and poplar (*Populus* sp.), SA synthesis is not dramatically induced by pathogen infection; instead, the SA and SA-derived compounds are present at high levels in uninfected plants already, typically higher than those levels found in pathogen-induced *Arabidopsis* leaves. *Arabidopsis* salicylate-deficient mutations *sid1* and *sid2* cannot make SA and show enhanced disease

susceptibility. *SID1* encodes a MATE transporter and *SID2* encodes isochorismate synthase. These genes are weakly induced during PTI but strongly during ETI.

During the local response, SA has been proposed to act synergistically in a signal amplification loop with ROS to drive the local HR at the point of initial pathogen infection. Low doses of both exogenous H_2O_2 and pathogen facilitate SA accumulation, leading to enhanced local ROS production. Also, SA accumulation can inhibit heme-containing ROS scavenging

systems, such as catalases and ascorbate peroxidases, thereby increasing overall ROS levels following pathogen recognition.

21.5.8 Some pathogen infections activate jasmonic acid (JA) and ethylene biosynthesis and signaling

The biosynthesis of **jasmonic acid** (JA) and ethylene (see Fig. 21.36) are described in detail in Chapter 17. In response to P/MAMPs, JA and ethylene biosynthesis is initiated. Ethylene is produced by *Arabidopsis* within 10 minutes in response to flg22, while JA levels rise more slowly. The subsequent signaling processes are complex because they reflect the balance of processes initiated by SA, JA, and ethylene. The output of the combination of these signaling molecules is different from the sum of each alone, owing to extensive crosstalk between the various signaling processes (see Section 21.8.5). Additional functions of both signaling molecules are described in Chapters 17 and 18.

21.5.9 Many defenses activated in PTI are also activated in ETI

PTI leads to cell wall fortification and the induction of genes that encode antimicrobial proteins or enzymes in pathways leading to the synthesis of antimicrobial compounds and ROS induction. Many of the responses are shared with ETI (see Section 21.6), although how the activation of these mechanisms converges after PTI and ETI is not understood. ETI is usually stronger than PTI (see Fig. 21.3A and Fig. 21.4) and often culminates in the hypersensitive response (HR). These induced defense responses result in the creation of unfavorable conditions for pathogen growth and reproduction, while at the same time the responding cells detoxify and impair the spread of harmful enzymes and toxins produced by the pathogen.

21.6 Effector-triggered immunity, a second level of induced defense

Plant breeders rely on genetic variation for disease resistance in their selection of superior crop varieties. Such genetic variation, however, usually maps to genes that are not specifically involved in PTI. This section reviews how analysis of such variation led to the discovery of receptors that recognize pathogen effectors.

21.6.1 Plants show extensive and heritable variation for disease resistance

Variation in disease susceptibility in the wild is widespread. Following the rediscovery of Mendel's work, plant breeders in the early 1900s recognized that resistance to plant pathogens

was often inherited as a single dominant or semi-dominant trait. Cereal plant pathologists working in the 1910s to 1930s realized that pathogen populations could shift from season to season and between regions, as new wheat, barley, and oat varieties were locally introduced. Therefore, pathologists began to propagate different strains of pathogens in pure form and found that not all races could grow on the same host variety.

Research in the 1930s and 1940s on the interaction between flax and the flax rust fungus *Melampsori lini* clarified the inheritance of plant resistance and pathogen virulence, resulting in the **gene-for-gene model** (Fig. 21.38). This model predicts that plant resistance only occurs when a plant has a **dominant resistance** (*R*) **gene** and the pathogen expresses the complementary **dominant recognized effector** (*Ree*), previously referred to as an avirulence (*Avr*) gene. The model holds true for most biotrophic and many hemibiotrophic plant–pathogen interactions. Within the model shown in Figure 21.3A, the pathogen *Avr* genes encode effectors that are recognized by the products of *R* genes.

Virulence of pathogens that deploy host-selective toxins for successful pathogenesis involves a different mechanism. In this case, virulence is dominant when the pathogen produces a functional toxin or enzyme to cause disease (see Fig. 21.7). Plant resistance is then a recessive trait when the toxin target has been lost or altered. For example, in wheat the interaction between the *Tsn1* gene product and the *ToxA* gene product of the fungus *Stagonospora nodorum* (see Section 21.3.8) causes disease in wheat genotypes possessing a functional copy of the *Tsn1* gene. In contrast, the maize *Hm1* gene, which encodes a reductase that can detoxify the *C. carbonum* HC toxin (see Fig. 21.7), confers resistance as a dominant trait.

Disease-tolerant plants restrict symptom development even though they are heavily infected, but they can still be an important source of pathogen spores that can infect fully susceptible plants.

Following the realization that disease resistance can be heritable, 20th century plant breeders developed breeding programs to identify resistant germplasm in wild relatives of crop plants and then introgress (breed) the corresponding resistance (*R*) genes into elite cultivars. The discovery that plants have centers of origin, where the greatest genetic diversity for both the plant and its pathogens resides, greatly assisted the collection of novel germplasm for breeding. Considerable early success was achieved in disease control using such resistant cultivars. Within a few years of an *R* gene being introduced into commercial production, however, pathogen races often evolved to overcome the *R* gene, and severe disease epidemics frequently recurred. This **boom and bust cycle** has a simple underlying molecular explanation (Fig. 21.39). Some *R* genes have, however, given excellent disease control for over 25 years in large-scale commercial production. For example, the tomato *Cf-9* gene-mediated resistance to the fungus *Cladosporium fulvum* has remained effective since the early 1980s. The various molecular and biochemical explanations underlying these **durable resistances**

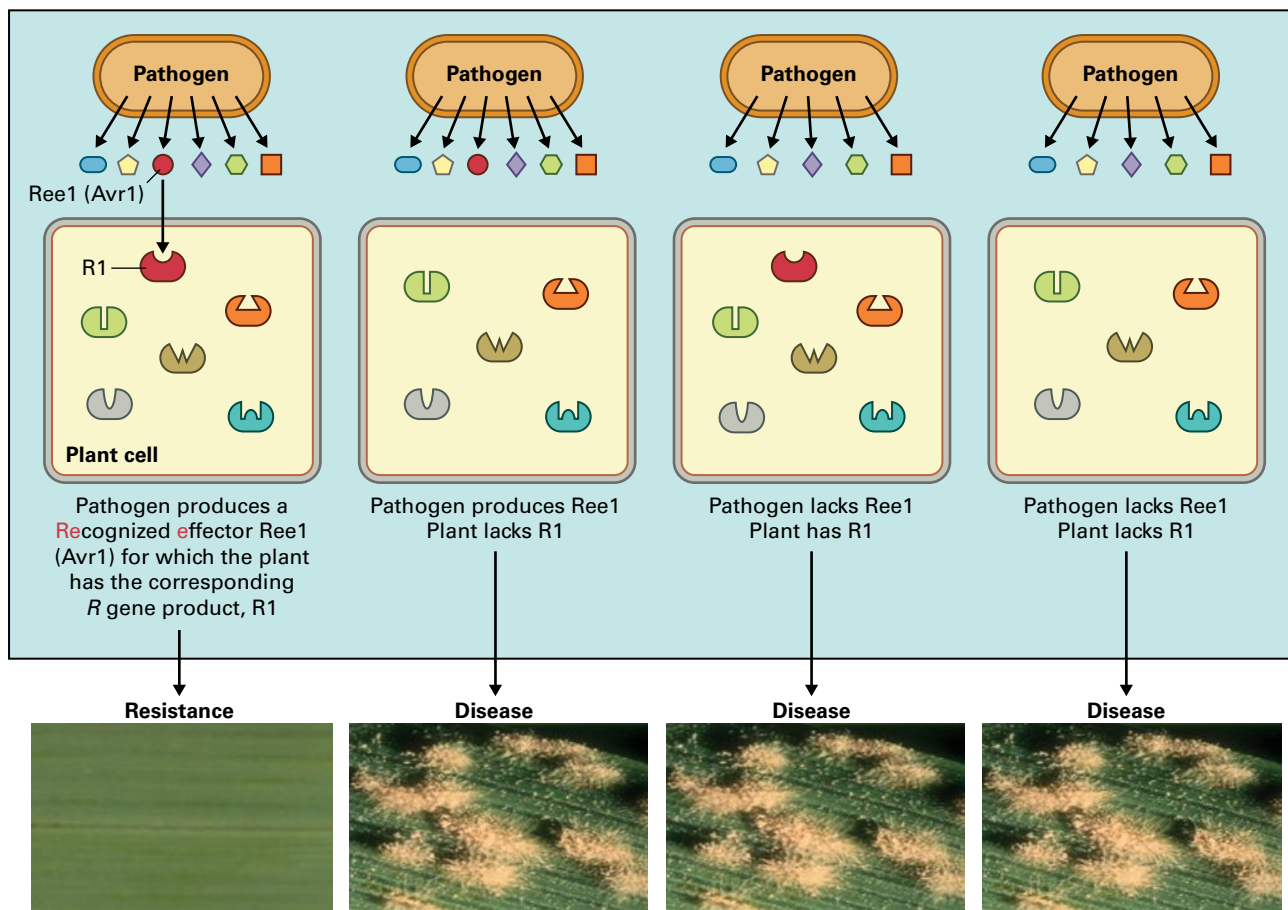

FIGURE 21.38 The gene-for-gene model. The four strains of a pathogen (top) each produce a distinct repertoire of effector molecules. Two of the four carry the *avr1* gene and so produce the effector molecule Avr1 (red). The four genotypes of the host each have a repertoire of R genes, and two of the four have the R1 gene, which encodes the R1 protein that enables the plants to recognize the pathogen Avr1 effector. Therefore Avr1 can also be called the recognized effector (Ree1). A plant is resistant to the pathogen only when a pathogen carrying the *avr1* gene infects a plant carrying the R1 gene, thus triggering R gene-mediated defense mechanisms (left). In all other cases, the plant is unable to recognize the pathogen and thus is susceptible to infection and disease. The photographs show resistant and susceptible outcomes following inoculation of barley leaves (*Hordeum vulgare*) with the barley mildew fungus (*Blumeria graminis* f. sp. *hordei*).

are of great interest. Because many R genes are not durable, agrochemical control of disease is widespread.

21.6.2 Plant disease resistance proteins share common motifs

The majority of predicted R proteins that mediate **race-specific resistance** and trigger ETI (see Fig. 21.3A) have diagnostic structural motifs (Table 21.6). This suggests the different R protein classes use a limited range of biochemical mechanisms to fulfill two basic functions: first, they directly or indirectly recognize the presence of the effector, and second, following recognition, they activate downstream signaling leading to rapid induction of various defense responses. During normal plant growth and development, most R genes conferring race-specific resistance are constitutively expressed at low levels. Likewise, R protein levels are low in healthy plants.

The common structural motifs found in R proteins conferring race-specific resistance are illustrated in Figure 21.40. A nearly ubiquitous feature is the reiterated LRR motif, which contains several leucine or other hydrophobic amino acids at regular intervals over a stretch of 23 or 24 amino acids (Fig. 21.41). This part of the repeat forms a structure within the protein called a **parallel β -sheet**. Within this structure, the hydrophobic leucine sequence is in the interior of the protein, and the other residues are exposed to the solvent, where they form a surface capable of interacting with other proteins. Different interacting surfaces can be generated via single amino acid changes, and this permits the evolution of specific interactions (Fig. 21.41B).

LRR motifs mediate protein–protein and receptor–ligand interactions in many organisms, and in plant R proteins they likely participate in effector perception. This LRR motif also predominates in the extracellular domain of several P/MAMP receptors, for example FLS2 (see Fig. 21.29) and in some downstream components of the activated defense response, for example, the polygalacturonase-inhibiting proteins

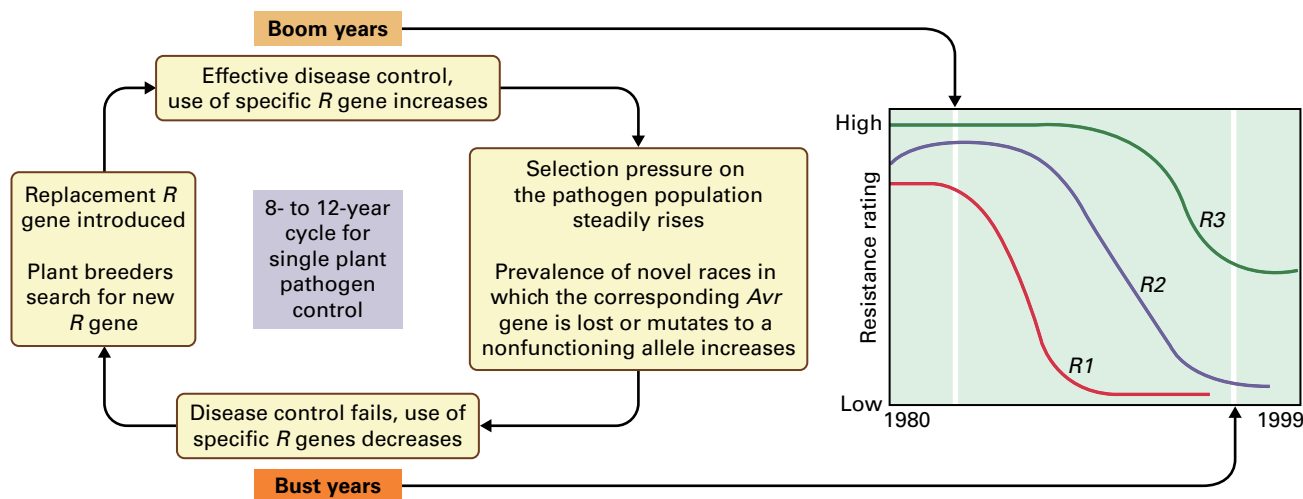

FIGURE 21.39 The boom and bust cycle. Plant breeders often achieve initial success in disease control through breeding new disease resistant cultivars. However, within a few years of the introduction of an R gene into commercial production, the gene may cease to protect the crop from disease, and severe epidemics occur (left). This boom and bust cycle of disease resistance results because effective disease control (the boom years) occurs only when the pathogen population consists entirely of races that express the corresponding functional Avr gene (i.e., the recognized effector gene). Once an avr mutant race of the pathogen appears, disease control fails (the bust years). Introgression of another R gene allele typically initiates another boom and bust cycle, as illustrated by the disease rating curves for R2 and R3 (right). The cyclic nature of the disease control achieved with many R gene alleles sustains demand for agrochemicals to provide an alternative solution.

TABLE 21.6 Diagnostic structural domains and motifs in the intracellular immune receptors.

Protein domain or motif	Feature(s)	Function(s) in plant defense
CC domain	Coiled-coil structure—a repeated heptad sequence with interspersed hydrophobic amino acid residues	Protein–protein interactions and protein dimerization; CC domain of barley MLA10 interacts with WRKY1/2 transcription factor
TIR domain	Sequence similarity to the cytoplasmic domain of the Toll and IL-IR proteins	Avr-dependent TIR–TIR interactions required for tobacco N protein oligomerization
NB-ARC domain	Nucleotide binding domain shared by APAF1, certain R proteins and CED-4. Contains a P-loop NTPase fold, an ARC1 motif, which consists of four-helix bundles, and an ARC2 motif that adopts a winged-helix fold	Binds and hydrolyzes ATP, a molecular switch that performs reversible intra- and intermolecular protein phosphorylation and autophosphorylation
LRR domain	Intracellular or extracellular; concatenated repeats of 23 or 24 amino acids in length; inner beta-sheet surface with buried leucines and solvent-exposed x residues in LxxLxL	Protein–protein interactions; controls direct or indirect recognition of specific pathogen races. Interactions between LRR and NB-ARC domain contribute to recognition specificity
Serine-threonine kinase domain	Intracellular	Protein phosphorylation and autophosphorylation

(PGIPs, see Section 21.5.4). LRR protein kinases are also important in other aspects of plant growth and development: The *Arabidopsis* LRR-kinase protein CLAVATA 1 is required for maintenance of the shoot apical meristem and recognizes the peptide CLAVATA 3 (see Chapter 11), and BRI1 is required for brassinosteroid perception (see Chapter 18).

The majority of intracellular LRR-containing R proteins possess a nucleotide-binding site (NB). The NB is part of a larger NB-ARC domain that is shared between R proteins

and the human apoptotic protease-activating factor 1 (APAF1) and the *Caenorhabditis elegans* cell death protein CED-4. Many conserved motifs can be recognized in the NB-ARC domain (Fig. 21.42), including the NB motif (which forms a P-loop NTPase fold), the ARC1 motif (which consists of four-helix bundles), and the ARC2 motif (which adopts a winged-helix fold). A nucleotide-binding pocket forms at the interface of these three motifs, where the most conserved motifs in the NB-ARC domain occur.

FIGURE 21.40 Schematic diagram illustrating several plant resistance proteins and other LRR-containing proteins (left). Structurally related proteins that are involved in various aspects of plant development, as well as other eukaryotic proteins that coordinate development and the induction of the immune response in animals, are included for comparison (right). The predicted protein domains and motifs include: CC, coiled-coil domain; TIR, Toll, Interleukin 1 receptor, Resistance protein-like motif; NB, nucleotide binding site; LRR, leucine-rich repeat, WRKY, a motif characteristic of some plant transcription factors and domain 1 that lack significant homology to known proteins. The plant R proteins depicted from left to right are Arabidopsis RRS1 and RPS4 resistance to *Pseudomonas syringae* strains expressing AvrRps4, tobacco N resistance to tobacco mosaic virus, L6 flax rust resistance 6; Mla10 resistance to *Blumeria graminis* f.sp. hordei expressing AvrA10, Arabidopsis RPM1 resistance to *Pseudomonas syringae* pv. maculicola expressing AvrRpm1 or AvrB; pepper Bs2 resistance to *Xanthomonas euvesicatoria* strains expressing AvrBs2; tomato Cf-2, Cf-4, Cf-5 and Cf-9 for resistance to *Cladosporium fulvum* races expressing, respectively, Avr2, Avr4 Avr5 and Avr9; tomato Pto resistance to strains of *Pseudomonas bacteria* expressing AvrPto, Arabidopsis PBS1 a serine/threonine protein kinase required by the NB-LRR R protein RPS5 for resistance against strains of *Pseudomonas bacteria* expressing AvrPphB; rice Xa21 resistance to *Xanthomonas oryzae* pv. *oryzae* and Arabidopsis RPW8 resistance to several powdery mildew species, including *Golovinomyces orontii*.

The activity of these multidomain R proteins depends on their ability to bind and hydrolyze nucleotide triphosphates; mutations that alter key residues within the binding pocket abolish or derepress R protein function. The activation of R proteins is tightly regulated because they frequently trigger cell death. This balance between R protein autoinhibition and activation seems to be achieved by intramolecular interactions between the various domains. It is likely that the ATP-bound form activates defense, and recognized effectors may stabilize this ATP-bound form.

The N-termini of NB-LRR proteins are structurally diverse. Some possess a domain similar to the cytoplasmic signaling domain of the *Drosophila* Toll and mammalian interleukin-1 receptor (IL-1R) proteins, and these are called TIR domains (see Fig. 21.40). Interestingly, these animal proteins are crucial to innate immunity. The non-TIR-NB-LRR

R proteins are often referred to as CC-NB-LRRs or CNLs, because many possess a coiled coil region (CC) between the N-terminus and the NB domain. CC domains are implicated in protein homo- and heterodimerization (see Table 21.6). Interestingly, the TIR-NB-LRR class is absent from the genomes of cereal species and from the Lamiales. Evolutionary studies suggest CNLs are likely the more ancient subclass of R gene. Structural studies suggest both CC and TIR domains are capable of homo- or heterodimerization.

Some R proteins that recognize apoplastic effectors are receptor-like proteins (RLPs) that have an extracellular LRR domain, a single transmembrane domain, and a short cytoplasmic tail that lacks a C-terminal protein kinase domain (see Fig. 21.40). For example, the tomato Cf genes confer race-specific resistance against the extracellular colonizing fungus *Cladosporium fulvum*. Cf-9 confers resistance to

FIGURE 21.41 Structure of leucine-rich repeat (LRR) containing proteins. (A) LRRs of cytoplasmic and extracytoplasmic plant *R* proteins, which contain leucine or other hydrophobic amino acids at regular intervals over a 23 or 24 amino acid length, respectively. The boxed area indicates the leucine residues within the β -strands/ β -turn structure which are predicted to project into the hydrophobic core of the protein while the side chains of the flanking x amino acids are exposed to solvent. *R* gene sequence comparisons indicate the x amino acids in the $xxLxLxx$ region are hypervariable and have ratios of nonsynonymous to synonymous substitutions significantly greater than one. There is a selective advantage when a protein possesses a high amino acid diversity in this region, which in some cases has evolved to detect variation in interacting ligand molecules including pathogen-derived effectors. (B) Two plant LRR proteins forming a defense immunity complex in which both LRR proteins interact with the P/MAMP flg22. The LRR-rich ectodomains mediate flg22-induced heterodimerization of the immunity receptors FLS2 and BAK1. The overall structure of the FLS2LRR-BAK1LRR immunity complex with the P/MAMP flg22 (red) shows that flg22 is positioned between LRR3 and LRR16 in the FLS2 protein (indicated by blue numbers). BAK1 recognizes the C-terminal side of the FLS2-bound flg22. N, N terminus; C, C terminus.

FIGURE 21.42 Model for NB-LRR protein activation. In the absence of a pathogen, an NB-LRR protein resides in its resting (ADP) state, in which the LRR stabilizes the closed conformation. The recognition platform for the AVR protein (triangle) is provided by the C-terminal part of the LRR together with the TIR/CC domain and the latter could be bound to an interactor (referred to as the guardee or decoy, G/D). Perception of the AVR (directly or via the G/D) changes the interaction surface between the N-terminal part of the LRR and the ARC2 subdomain, thereby releasing the auto-inhibition conferred by the LRR. Subsequently, nucleotide exchange triggers a conformational change, altering the interactions of the NB-ARC domain with the CC and LRR domains (induced state). In the activated state the NB subdomain is accessible to interaction with downstream signaling partners. Hydrolysis of ATP returns the NB-LRR protein to its resting state.

races of *C. fulvum* carrying *Avr9*, while *Cf-4* confers recognition of *C. fulvum* races carrying *Avr4*. The proteins encoded by *Cf-9* and *Cf-4* are closely related (90% identical), and small differences in their LRRs specify whether *Avr9* or *Avr4* is recognized.

21.6.3 Allelic variation occurs at some *R* gene loci

To overcome individual *R* gene alleles, plant pathogens can mutate their recognized effector genes to a form that is not detected; natural selection then favors these novel virulent races (see Fig. 21.39). Therefore, plants must evolve novel *R* protein variants to detect either the modified *Avr* determinant or another pathogen component (see Fig. 21.3A). The most informative clue as to the evolution of this diversity is the genomic organization of *R* genes.

Genetic and molecular analysis of various *R* loci revealed the existence of two main types of *R* locus (Fig. 21.43). First, many *R* genes are members of multigene families arranged in clustered arrays to form **complex loci**. Sometimes these loci extend genetically over several centimorgans and contain numerous *R* gene alleles. Examples include the maize *Rp1*

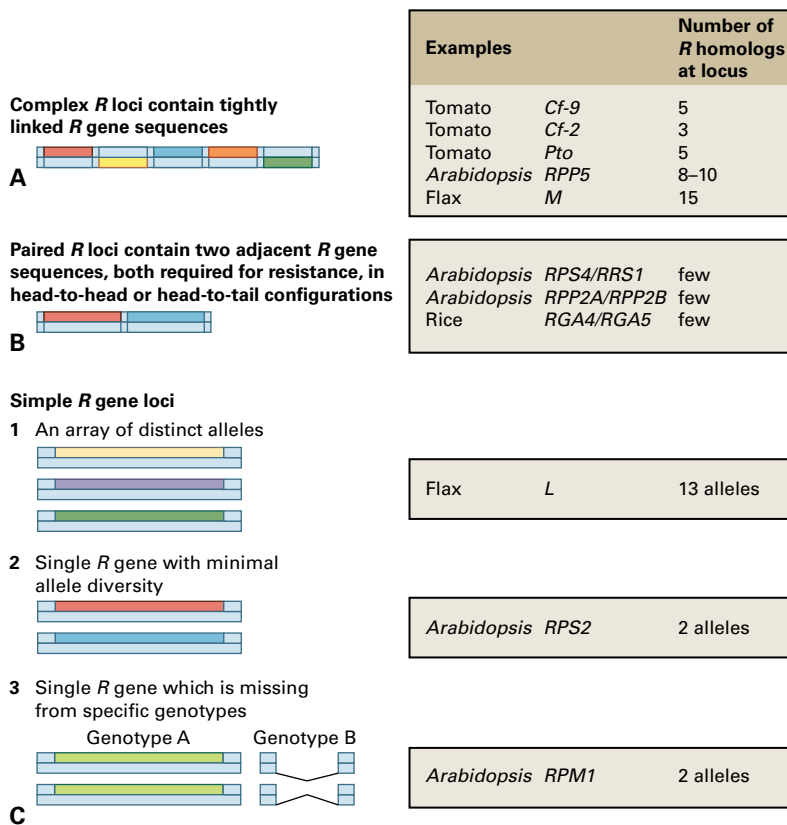

FIGURE 21.43 Main types of plant resistance (*R*) locus organization: (A) complex *R* loci, (B) paired *R* loci and (C) various simple *R* loci.

rust resistance locus, the flax *M* rust resistance locus, and the potato *R2* and *R3a* loci for *P. infestans* resistance. Some alleles may confer resistance to several different fungal species, as is the case for the maize *Rp1* locus. Some complex loci, such as *Xa21* in rice, do not exhibit alleles other than for presence and absence of the *R* gene. The tomato *Pto* gene is linked to five other *Pto* homologs at the *Pto* locus, but only two haplotypes have been characterized physically and genetically. At the tomato *Cf-9* locus, three haplotypes have been described in *Cf9*, *Cf4*, or near-isogenic *Cf0* tomato, carrying 5, 5, or 1 *Cf-9* homologous genes (Fig. 21.40), several of which individually confer *Cf*-resistance gene function. A second type of *R* locus consists of a single copy gene at a **simple locus**, which can also exhibit an array of distinct alleles, as at the flax *L* locus (Fig. 21.43). Alternatively, simple *R* loci can carry *R* gene sequences that either exhibit no allelic diversity, or simply vary for the presence or absence of the functional gene.

How then do novel *R* protein variants arise from complex and simple *R* loci? For complex loci, the linked and homologous *R* gene sequences provide the DNA homology for recombination events leading to the evolution of novel specificity through mispairing, intra- and intergenic recombination, and gene duplication, as shown in Figure 21.44. However, there is no evidence to suggest that plants evolved a special mechanism to generate novelty at *R* loci. For *R* genes at simple loci with an array of distinct alleles, in addition to spontaneous mutations, unequal intragenic recombination or slipped alignment during replication, facilitated by direct DNA repeats within the LRR coding sequence, may generate *R* gene

allelic diversity. For solitary *R* genes, the possibilities to generate novelty are more limited, but can still enable substantial allelic diversity, as found in flax *L6*.

21.6.4 Recognition of pathogen effectors is direct or indirect

Each *R* gene product is envisaged to have two functions: recognition of the corresponding effector and activation of downstream signaling pathways to activate defense. How does recognition occur?

The most simple scenario is one in which *R* proteins directly recognize the corresponding Avr protein. For example, all flax rust *R* genes cloned to date encode intracellular TIR-NB-LRR proteins, and several of these bind the cognate Avr effectors. Following effector detection, a hypersensitive response at the haustorial formation site prevents further infection. Eleven allele variants at the flax *L* locus confer different recognition specificities, mostly specified by the sequence coding for the LRR domain. Domain swap experiments involving different *L* alleles have confirmed that the LRR domain is important for determining R-Avr recognition specificity. The most variable amino acids in the different L proteins lie in the concave β -sheet surface (see Fig. 21.41) and, therefore, could participate in R-Avr interactions. By altering specific surface-exposed amino acid residues, these rust Avr effector proteins escape recognition, rendering the

FIGURE 21.44 New R alleles can be generated by several different mechanisms, but the likelihood of their occurrence depends on whether the plant species is maintained as an outbreeding (cross-pollinating) population (A,B) or an inbreeding (self-pollinating) population (C,D,E). The evolution of resistance in plants appears to occur primarily at the single-gene level so that novel specificities that arise by intergenic recombination between similar genes (C) are rare. The variant R alleles eventually selected encode proteins with increased effectiveness or confer a novel recognition capacity. RT, RU, RV, RW, RX, RY, and RZ represent different recombination products.

plant susceptible. Similarly, the polymorphic barley mildew A (MLA) R locus encodes allelic receptors of the CC-NB-LRR type. MLA alleles share >90% sequence identity, but each recognizes a different race of powdery mildew. The recognition specificity of distinct MLA alleles is conferred by their LRR domains.

Only a few of the first-discovered R proteins directly bind the cognate effector. Many R proteins recognize the effects of pathogen effectors on host proteins (Fig. 21.45) rather than the effectors directly. As described in Section 21.2.4, plants respond to pathogens by activating PTI, and in turn, some pathogens can overcome these defenses by producing effector molecules to modify or suppress host responses. Each R protein might act as a guard of a host component (the “guardee”). When the pathogen effector molecule modifies this component, the modification is recognized by the R protein and ETI is activated.

This guard hypothesis predicts that multiple pathogen effector proteins may interact with a common host target that can be guarded by more than one R protein. The CC-NB-LRR R proteins RPS2 and RPM1 recognize AvrRpt2, or AvrRpm1 and AvrB, respectively. The *Arabidopsis* RIN4 protein is targeted by these three effectors, which are delivered into plant cells via the bacterial type III secretion system (Fig. 21.46). RIN4 is a 211 amino acid plasma membrane-associated protein, which interacts with the nonrace-specific disease resistance 1 protein NDR1 that triggers SA production. The AvrB and AvrRpm1 proteins cause phosphorylation of RIN4, whereas the AvrRpt2 protein is a protease that degrades it. *Arabidopsis* plants that carry the *RPM1* gene are

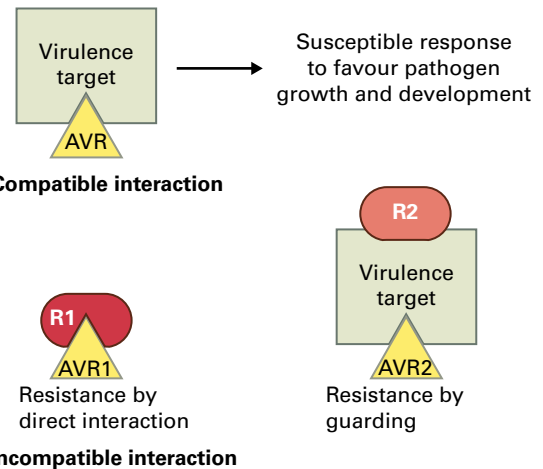

FIGURE 21.45 Guarding of pathogen virulence targets by plant R proteins. (A) A virulence target exists in a susceptible host plant. Upon pathogen infection, the Avr effector binds to its cognate virulence target, resulting in modifications to the target. These modifications lead to pathogen virulence and host susceptibility, thereby generating a compatible interaction. (B) Incompatible interactions conferred by a resistant host plant can arise in two ways. (Left) The R1 protein directly recognizes the Avr1 effector itself. An example of this type of interaction occurs between rice blast Avr-Pita and rice Pi-ta. (Right) The R2 protein is a guard protein, recognizing the modified plant virulence target caused by the earlier binding of the Avr2 effector. An example of this type of interaction occurs between AvrB/AvrRpm1 (Avr), RIN4 (the virulence target) and RPM1 (R2). Direct recognition by R1 may be circumvented by alterations of the Avr1 effector without modifying its virulence function. By contrast, recognition mediated by the guarding R2 protein cannot be circumvented by alterations of the Avr2 effector without affecting its virulence function.

FIGURE 21.46 Direct and indirect recognition of pathogen effectors triggers plant defenses. (A) *Pto* is a tomato serine/threonine protein kinase that requires the NB-LRR protein *Prf*. The two proteins form a molecular complex in which *Prf* guards *Pto*. *Pto* is the target of two unrelated *P. syringae* effectors, *AvrPto* and *AvrPtoB*, delivered into the cell by the type III secretion system (T3SS; brown and green syringe). Each effector contributes to pathogen virulence. (B) Arabidopsis *RPM1* is a peripheral plasma membrane NB-LRR protein. It is activated by either the *AvrRpm1* or the *AvrB* effector proteins. *AvrRpm1* enhances the virulence of some *P. syringae* strains on Arabidopsis as does *AvrB* on soybeans. *AvrRpm1* and *AvrB* are modified by eukaryote-specific acylation once delivered into the cell by the T3SS and are thus targeted to the plasma membrane. The biochemical functions of *AvrRpm1* and *AvrB* are unknown, although they target *RIN4*, which becomes phosphorylated (+P), and activate *RPM1*. In the absence of *RPM1*, *AvrRpm1* and *AvrB* presumably act on *RIN4* and other targets to contribute to virulence. Light blue unlabeled ovals in this and subsequent panels represent unknown proteins. (C) *RPS2* is a plasma membrane NB-LRR protein. It is activated by the *AvrRpt2* cysteine protease type III effector from *P. syringae*. *AvrRpt2* is a third effector that targets *RIN4*. Cleavage of *RIN4* by *AvrRpt2* leads to *RPS2*-mediated ETI. In the absence of *RPS2*, *AvrRpt2* presumably cleaves *RIN4* and other targets as part of its virulence function. (D) The transmembrane R protein *Cf-2* guards the extracellular cysteine protease *Rcr3*. *Cf-2* recognizes the *C. fulvum* extracellular effector *Avr2*, which encodes a cysteine protease inhibitor. *Avr2* binds and inhibits the tomato *Rcr3* cysteine protease. Mutations in *Rcr3* result in the loss of *Cf-2*-dependent recognition of *Avr2*. Hence, *Cf-2* seems to monitor the state of *Rcr3* and activates defense if *Rcr3* is inhibited by *Avr2*. Remarkably, a nematode effector also targets *Rcr3* and triggers *Cf-2*-dependent resistance. Note that in D the plant cell wall is not shown for clarity.

resistant to infection by *P. syringae* strains carrying the *avrRpm1* or *avrB* genes, because *RPM1* recognizes phosphorylated *RIN4*. *RPM1* then activates a signaling pathway that leads to defense activation. Similarly, *Arabidopsis* plants that carry *RPS2* are resistant to infection by *P. syringae* carrying *avrRpt2*. *RPS2* is normally found in a complex with *RIN4*, and degradation of *RIN4* by the *AvrRpt2* protease releases *RPS2*, rendering the R protein capable of activating a defense response. Thus, the guarding of *RIN4* by at least two different

R proteins assures continuous monitoring of the *RIN4* protein status.

The tomato *Mi-1.2* protein also belongs to the CC-NB-LRR class of R proteins, but is extended at the C-terminus with a Solanaceae-specific domain. Remarkably, *Mi-1.2* confers resistance to the root-knot nematode *Meloidogyne incognita*, the potato aphid *Macrosiphium euphorbiae*, the sweet potato white fly *Bemisia tabaci*, and the tomato psyllids insect *Bactericerca cockerelli*. These diverse resistances conferred by

FIGURE 21.47 The NONRACE-SPECIFIC DISEASE RESISTANCE 1 protein (NDR1) and the ENHANCED DISEASE SENSITIVITY 1 protein (EDS1) mediate, respectively, the defense signaling abilities of CC-NB-LRR and TIR-NB-LRR disease resistance proteins. (Left) NDR1 spans the plasma membrane and interacts with the RIN4 protein that resides in the cytoplasm in close proximity to the plasma membrane. RIN4 is targeted by three bacterial effectors delivered into plant cells via the type III secretion system. The guarding of RIN4 by at least two different R proteins (RPM1 and RPS2) assures continuous monitoring of the RIN4 protein status. RPM1 or RPS2 then activate a signaling pathway that leads to defense activation. (Right) EDS1 is required for resistance mediated by the TIR-NB-LRR class of R proteins (RPS4 and RRS1) as well as basal defense against many virulent pathogens. EDS1 is a lipase-like protein that always functions in association with either of two other lipase-like proteins, PAD4 or SAG101. Both the cytoplasmic and nuclear pools of EDS1 are required to activate defense signaling. At least two bacterial effectors interact with the WRKY domain of the RRS1 protein. Both RRS1 and RPS4 cooperate to activate plant defenses. Although the NDR1 and EDS1 proteins function in two different signaling pathways, these must later converge, because all these resistances require the induction of salicylic acid synthesis.

one R gene might be due to each invertebrate targeting a shared guarder that is guarded by Mi-1.2.

The Prf protein (a NB-LRR protein) from tomato (*Solanum lycopersicum*) may recognize the direct interaction between Pto and AvrPto. The Pto protein kinase confers resistance in tomato to strains of *Pseudomonas* bacteria that express AvrPto. Bacteria deliver AvrPto protein into the plant cell cytoplasm via a T3SS (see Section 21.3.3). When AvrPto interacts with the Pto kinase, both proteins are directed to the plasma membrane via an N-terminal myristoylation site. The direct interaction between the Pto and AvrPto proteins is recognized by Prf, which then activates various downstream defense responses (Fig. 21.46A). The discovery of the direct Pto–AvrPto interaction was important because cytoplasmically localized protein kinases were previously unknown to function as receptors in any organism and the same domain in the Pto kinase confers both recognition and signaling capacity. Another example of R protein guarding is provided by the tomato Cf-2 protein. Originally identified as mediating resistance to specific races of the fungus *C. fulvum* expressing the effector Avr2 (Table 21.3), Cf-2 also confers resistance to the cyst nematode *Globodera rostochiensis*. Cf-2 enables the

plant to recognize binding of the Avr2 proteinase inhibitor (PI) of *C. fulvum* to the plant apoplastic protease Rcr3 (Fig. 21.46D), which then triggers defense responses. The presence of Cf-2 also senses binding of the venom allergen-like effector protein Gr-VAP1 of *G. rostochiensis* to the Rcr3 protease. In the absence of Cf-2, variants of Rcr3 encoded by specific alleles increase susceptibility of tomato plants to *G. rostochiensis*, revealing a key role for Rcr3 as a virulence target for this cyst nematode species. Some alleles of Rcr3 trigger Cf-2-dependent defense, even in the absence of Avr2, suggesting that selection must constrain guarder alleles to avoid inadvertent R protein-dependent defense activation.

The TIR-NB-LRR class of R proteins can confer resistance to biotrophic fungi, bacteria, and viruses. How might they signal? The presence of the conserved TIR domain has raised the possibility that immune responses in plants, mammals, and invertebrates utilize an ancient, conserved mechanism, or arose via convergent evolution (see Fig. 21.40). Intriguingly, the protein kinases PELLE and IRAK that function downstream of the *Drosophila* Toll and human IL-1R receptors, respectively, show strong homology to the PTO resistance protein (Fig. 21.46, see also Fig. 21.40).

FIGURE 21.48 A proposed model for NB-LRR (NLR) protein maturation by the HSP90-SGT1-RAR1 ternary complex. The three proteins are HEAT SHOCK PROTEIN 90 (HSP90, brown), SUPPRESSOR OF THE G2 ALLELE OF SKP1 (SGT1, purple), and REQUIRED FOR MLA12 RESISTANCE 1 (RAR1, blue). This model shows HSP90 as the central protein of the cycle that involves the following interacting domains: the N-terminal domain of HSP90 containing the ATP-binding site (yellow half-circle), the TPR, SGS and CS domains of SGT1, and cysteine- and histidine-rich domain 1 and 2 (CH1 and CH2) of RAR1. In this model, interactions occur sequentially in a clockwise direction. Upon ATP binding, the lid segments of the HSP90 dimer form a closed conformation to create an active ATPase enzymatic site with the key arginine in the catalytic (green triangle). When the RAR1 CH1 domain binds to one of the ATP-loaded HSP90 lids this prevents the formation of the lid-closed conformation. Binding of the RAR1-CH1-domain then facilitates the interaction of the RAR1 CH2-domain with the other HSP90 lid of the dimer. The bound RAR1 CH-domains promote the formation of the HSP90 complex with SGT1 and an immature NLR protein (orange). The stable HSP90-RAR1-SGT1-NLR ternary complex then triggers the hydrolysis of ATP by the catalytic Arg to facilitate the intramolecular reorganization of the NLR protein. After release of the ADP, the RAR1-SGT1-NLR complex dissociates from HSP90 and releases the mature NLR protein (red).

21.6.5 Other plant proteins are required for R protein action

Mutagenesis of resistant plant lines carrying an *R* gene followed by screening for disease-sensitive mutants has revealed other plant genes required for disease resistance.

In *Arabidopsis*, mutations in the *EDS1* (*ENHANCED DISEASE SENSITIVITY 1*) gene eliminate race-specific resistance mediated by the TIR-NB-LRR class of R proteins, and also reduce basal defenses against many virulent pathogens. *EDS1* is required for many (but not all) *RPP* gene-mediated resistances to various races of the downy mildew oomycete (*Hyaloperonospora arabidopsidis*), and for *RPS4*- and *RRS1*-mediated resistance to *P. syringae* carrying *AvrRps4*. *EDS1* is a member of a family of proteins that carry an atypical lipase motif, and has been located to both the nuclear and cytoplasmic compartments. *EDS1* likely functions as a heterodimer with either of two related proteins *PAD4* and *SAG101*. *PAD4* mutants are also more disease-susceptible. Although mutations in *EDS1* and *NDR1* (see section 21.6.4)

compromise function of TIR-NB-LRR and CC-NB-LRR signaling, both proteins are required for SA production, indicating that the signal transduction pathways involving these proteins later converge (Fig. 21.47 and see Section 21.8.4).

In barley and *Arabidopsis*, mutations in either *RAR1* (required for *Mla*-mediated resistance 1) or *SGT1* (suppressor of the G2 allele of *skp1*) result in susceptibility to powdery mildew fungi or downy mildew, respectively, even when the plant genotypes carry functional copies of various race-specific *R* genes and the fungal races express the correct cognate *Avr* effector. These two proteins, in conjunction with HSP90 (heat shock protein 90) (Fig. 21.48), are required for resistance mediated by multiple R proteins recognizing viral, bacterial, oomycete, or fungal pathogens.

RAR1 contains two highly conserved zinc-binding domains called CHORD-I and CHORD-II (cysteine- and histidine-rich domain). The CHORD-I domain binds to the molecular chaperone HSP90. Both *RAR1* and HSP90 stabilize certain NB-LRR proteins and thereby ensure the R proteins can assume a conformation that is competent to receive

pathogen signals. Both RAR1 and HSP90 bind to SGT1 (Fig. 21.48), which is required for the function of R proteins of the TIR-NB-LRR class, the CC-NB-LRR class, the eLRR class, and RPW8. SGT1 contains three distinct domains: a tetratricopeptide repeat domain (TPR), the CS motif (present in CHP and SGT1 proteins), and the SGS motif (an SGT1-specific sequence). The CS motif of SGT1 is sufficient to bind to the ATPase domain of HSP90 as well as interact with the CHORD-II domain of RAR1.

The structure of the HSP90–SGT1–RAR1 complex has been elucidated, and a dynamic model for the interaction of the three components proposed (Fig. 21.48). Overall, this HSP90–SGT1–RAR1 chaperoning complex is proposed to maintain the steady state levels of different R proteins and ensure that R proteins are correctly folded and maintained in a recognition-competent state in the appropriate cellular compartment. It may be required for the conformational changes involved in resistance activation. Misfolded R proteins can inappropriately activate defense and therefore must be immediately inactivated and degraded. This chaperon complex is structurally and functionally conserved in other eukaryotes.

Some NB-LRR proteins require other NB-LRR proteins to function. The *N REQUIRED GENE 1* (*NRG1*) is required for function of the tobacco TIR-NB-LRR protein N, which confers resistance against TMV through recognition of the TMV p50 protein. *NRG1* is a CC-NB-LRR type R protein. Similarly, the TIR-NB-LRR protein RPS4 also requires the TIR-NB-LRR-WRKY protein RRS1 for its function (and vice versa) (see Section 21.5.5). In some CC-NB-LRRs, the CC domain resembles that present in the atypical *Arabidopsis* R protein RPW8 (see Section 21.6.3). This is referred to as the CC_R domain. CC_R-NB-LRR-encoding genes are present in most plants; examples include the *Nicotiana benthamiana* *NRG1* protein and the *Arabidopsis* activated disease resistance gene 1 (*ADR1*) protein. CC_R domains are sufficient for the induction of defense responses, and this activity is SGT1-independent. Both CC_R domain genes are unique to genomes that carry TIR-NB-LRR genes, suggesting CC_R domain proteins may be required for signaling by TIR-NB-LRR R proteins.

21.6.6 Many R genes can function in heterologous plant species

Most R gene sequences confer resistance when introduced into a susceptible genotype of the original host or a closely related species. For example, the tobacco N gene is active in tomato, where it restricts TMV infections to localized necrotic lesions, as it does in tobacco. Thus, Avr-dependent R protein signaling cascades are conserved between related plant species.

Pto, Cf-9, and Bs2 from Solanaceous plants do not confer recognition of their corresponding effectors in *Arabidopsis*. However, barley Mla can confer function in *Arabidopsis*, and *Arabidopsis* RPS4 and RRS1 can function in Solanaceae. Overexpression of some R genes in heterologous plants results

in necrotic symptoms in the absence of pathogen attack, or plants with altered development.

These data highlight how finely tuned the relationship is between R proteins and signaling partners in their native species. The evolution of R gene sequences is most likely constrained not only by selection for pathogen recognition, but also for functional interactions with guarder proteins, and for avoidance of recognition of related endogenous plant proteins that control plant development.

21.7 Other sources of genetic variation for resistance

21.7.1 A few plant R proteins are unique

A few R genes provide broad-spectrum resistance to multiple pathogenic species, and functional homologs of these R genes have not been reported in other plants. Potentially each R protein could provide a plant species-specific function, but it is more likely that the corresponding R gene needs to be formally identified in other plant species.

RPW8.2 from *Arabidopsis* confers broad-spectrum resistance to several powdery mildew species, including *Golovinomyces orontii*. RPW8 proteins feature an N-terminal transmembrane domain and one or more coiled-coil (CC_R) domains (homologous to the *ADR1*/*NRG1* subclass of CC-NB-LRR proteins), and they lack an LRR domain.

The wheat *Lr34* gene provides durable adult plant resistance to the basidiomycetes *Puccinia triticina* and *P. striiformis*, which respectively cause leaf rust and stripe rust, and to the ascomycete powdery mildew species *Blumeria graminis* f. sp. *tritici*. Through plant breeding, the *Lr34* gene is now present in most wheat cultivars globally. The *Lr34* gene sequence encodes a putative adenosine triphosphate binding cassette (ABC) transporter that may translocate toxic compounds stored in plant cells (possibly in the vacuole) to the point of fungal ingress, arresting growth.

Two major quantitative loci, *rhg1* and *Rhg4*, control root infections in soybean (*Glycine max*) crops caused by the cyst nematode *Heterodera glycines*. Roots of plants carrying the *Rhg* genes are penetrated by infective juvenile nematodes, but the feeding nematodes die before reaching adult stages (see Section 21.1.5). The *Rhg4* locus encodes a serine hydroxymethyltransferase, an enzyme that is ubiquitous in nature and structurally conserved across kingdoms. It is responsible for interconversion of serine and glycine and essential for one-carbon metabolism. Transcriptional and metabolic profiling studies indicate the syncytial feeding cells support a demand for folate one-carbon metabolism. Nematodes, like other animals, acquire folate from their diet; therefore, impaired folate production at induced feeding site may lead to a nutritional deficiency that starves the nematode.

21.7.2 Insensitivity to host-selective toxic proteinaceous effectors and metabolites is important in plant defense against necrotrophs

Two closely related necrotrophic fungal pathogens, *Stagnospora nodorum* and *Pyrenophora tritici-repentis*, produce host-selective toxins that induce susceptibility only in wheat genotypes that harbor the corresponding toxin sensitivity gene *Tsn1*. The Tsn1 protein has several R protein-like features, including serine-threonine kinase, NB, and LRR domains, which are required for ToxA sensitivity and disease susceptibility. Wheat genotypes that are insensitive to ToxA lack the entire gene sequence, and Tsn1 does not seem to directly bind the ToxA effector. These findings suggest that necrotrophic pathogens may subvert the resistance mechanisms acquired by plants to combat other pathogen types by making molecules that provoke cell death, and have also evolved ways to thrive in environments that would be detrimental to biotrophic pathogens.

21.7.3 Recessively inherited resistance genes provide resistance against bacteria, fungi, and viruses in cereal and noncereal species

Recessively inherited resistance is rarely reported to control either bacterial or fungal infections. However, this mode of inheritance is more frequently encountered in the successful control of plant viruses. Some of the different types of recessive resistance (*r*) genes and how they function are described below and in Table 21.7.

Resistance to some bacteria involves sequence variation in proteins targeted by virulence effectors. In rice, nine of the 30 documented resistance genes against the bacterial blight pathogen *Xanthomonas oryzae* pv. *oryzae* are recessively inherited. The *xa13* gene occurs as a series of natural alleles of *Os-8N3*, whose expression is induced by strains of *Xanthomonas oryzae* pv. *oryzae* carrying the gene *pthXo1*, which encodes the transcription activator-like (TAL) effector PthXo1 described in Section 21.3.8. The *xa13* alleles are unresponsive to PthXo1, and plants with *xa13* are resistant to strains of the pathogen that rely solely on PthXo1 as the essential effector for virulence. *Os-8N3* encodes a member of the NODULIN3 gene family of SWEET proteins that transport sugar.

Recessive (*mlo*) alleles of the *Mlo* locus in barley, *Arabidopsis*, tomato, and pea confer broad spectrum resistance to various powdery mildew species. The deduced MLO ≈60-kDa gene product is predicted to be anchored in the plasma membrane by a conserved seven membrane-spanning-domain protein. Two *mlo* mutant alleles are deployed commercially to reduce the risk of mildew infection in barley (*Hordeum vulgare*).

Recessively inherited resistance against viruses often confers non-HR immunity, as opposed to an HR-associated defense. Virus genomes are small and code for just a few functional proteins (see Section 21.3.4; see Chapter 10). To complete their life cycle, viruses rely on host plant proteins involved in DNA replication, transcription, and translation. Therefore, recessive antiviral resistance genes are frequently mutant alleles of genes that encode plant host proteins required at specific steps in the virus life cycle. For example, mutations in the eukaryotic translation initiation factor 4E (eIF4E) or its isoforms eIF(iso)4E occur in many cereal and noncereal plant species, where they confer resistance primarily against RNA viruses belonging to the *Potyviridae* family (Fig. 21.49). These viruses encode VPg, a small protein that is attached to the 5' end of the viral RNA genome. VPg is a likely functional equivalent of the eukaryotic mRNA cap structure, which is important for translation initiation and recruitment of ribosomes via interaction with eIF4E or eIF(iso)4E (see Chapter 10). Both the potyviral VPg protein and the eIF4E/eIF(iso)4E proteins are multifunctional and are involved in processes other than initiation of protein synthesis. The exact purpose of the VPg–eIF4E interaction has still to be discovered; however, specific mutations in the host *eIF4E* gene lead to a failure of the potyvirus to complete their life cycle (i.e., translation, replication, or cell-to-cell trafficking), which results in resistance without HR formation.

21.8 Local and systemic defense signaling

Within minutes of pathogen, insect, or nematode attack, plant defense responses are activated locally, and within hours, defense responses are elaborated in tissues distant from the invasion site and even in neighboring plants. Remarkably, the type of induced systemic response is determined by the identity of the initial attacking organism. As shown in Figure 21.50, induced systemic responses to fungi, bacteria, and viruses are distinct from those to insects. Nematodes appear to induce a mixture of the two. The adaptive significance to plants of orchestrating systemic responses is enormous. They ensure that distant plant tissues can deal more effectively with subsequent attackers.

21.8.1 Plants activate systemic responses to pathogens

Fungi, bacteria, and viruses systemically activate a defense response known as **systemic acquired resistance** (SAR). For SAR to occur, the initial infection must result in formation of necrotic lesions, either as part of the HR or as a symptom of disease. SAR is induced strongly by ETI and weakly by PTI, and during SAR, a specific subset of pathogenesis-related (PR) genes (described later) is activated in the plant tissues distant to the initial pathogen infection site. SAR activation

TABLE 21.7 *Recessively inherited resistance genes.*

Gene	Plant	Pathogen(s)	Infection type/organ/ cell layer attacked	Protein type	Proposed/known protein function	Race specific?
<i>edr1</i>	<i>Arabidopsis</i>	Enhanced resistance to <i>Pseudomonas syringae</i> , <i>Hyaloperonospora arabidopsidis</i> , powdery mildew <i>Golovinomyces cichoracearum</i> , but enhanced susceptibility to <i>Colletotrichum higginsianum</i> and the necrotrophic <i>Alternaria brassicicola</i>	Various extracellular and intracellular lifestyles on leaves	A Raf-like mitogen-activated protein kinase kinase kinase (MAPKKK)	Mutation creating a premature stop codon eliminates the kinase domain. Proposed to be a negative regulator of plant defense	No
<i>eIF4E</i> or its isoforms <i>eIF(iso)4E</i>	Multiple cereal and noncereal species	RNA viruses mostly belonging to the <i>Potyviridae</i> family	Systemic intracellular infections throughout the plant	Eukaryotic translation initiation factor. Multifunctional and involved in processes other than the initiation of protein synthesis	Mutations result in abolition of interaction with the viral Vpg protein attached to 5' end of the viral RNA genome. As a result, virus fails to hijack various host processes to complete its life cycle	Mostly yes
<i>mlo</i>	Barley (<i>Hordeum vulgare</i>), <i>Arabidopsis</i> and tomato	Various powdery mildew fungal species	Obligate biotroph/multiple organs/epidermal specific	Plant-specific seven transmembrane helices protein	Negative regulator of plant defense and/or PCD	No
<i>RRS1-R</i>	<i>Arabidopsis</i>	Bacterial blight pathogen <i>Ralstonia solanacearum</i>	Extracellular/multiple organs/all tissue layers	TIR-NB-ARC-LRR-WRKY	Upon physical interaction with bacterial effector Pop2, RRS1 cooperates with another TIR-NB-LRR protein RPS4 to activate defense	Yes
<i>xa5</i>	Rice (<i>Oryza sativa</i>)	Bacterial blight pathogen <i>Xanthomonas oryzae</i> pv. <i>oryzae</i>	Extracellular/multiple organs/all tissue layers	Subunit of the general transcription factor TFIIA required by RNA polymerase II	The mutant xa5 protein, which has only two residue changes, retains its basic transcription factor function and may possess enhanced ability to interact with the bacterial effector Avrxa5	Yes
<i>xa13</i> (<i>Os-8N3</i>)	Rice	Bacterial blight pathogen <i>Xanthomonas oryzae</i> pv. <i>oryzae</i>	Extracellular/multiple organs/all tissue layers	A member of the NODULIN3 gene family of SWEET proteins that transport sugar	<i>xa13</i> alleles are unresponsive to the TAL effector PthXo1	Yes

FIGURE 21.49 *R* proteins and defense activation. Recessive resistance to potyviruses is conferred by mutant alleles of a eukaryotic translation initiation factor 4E (eIF4E). Initiation of translation in plants (and other eukaryotes) uses a multi-protein complex consisting of initiation factors 3, 4A, 4B, 4E, 4G, poly(A)-binding proteins (PABPs), 40S ribosomal subunit and several other minor components. An interaction between the mRNA cap structure (m⁷GpppG) and eIF4E is required for efficient translation. Potyviruses produce a small protein called VPg, which is covalently attached to the 5'-end of their RNA genomes and is likely to play a role similar to the mRNA cap structure during translation initiation (left). Some naturally occurring structural variants of eIF4E confer resistance to potyviruses in many plant species, probably because of their inability to bind potyviral VPg and recruit potyviral RNA into the translation initiation complex (right).

also leads to a significant reduction in disease symptoms after subsequent infection by many different pathogen species. For example in tobacco, *N*-gene mediated resistance against TMV protects the plant against later infection by most, but not all, tobacco pathogens, including an identical TMV strain. SAR can convert normally genetically compatible plant–pathogen interactions into incompatible ones. Therefore, by understanding how SAR works, it may be possible to engineer broad-spectrum disease control into crops (see Section 21.10).

A requirement for SA in SAR activation was demonstrated by expression of the bacterial NahG SA hydroxylase in tobacco and *Arabidopsis* plants. These plants do not accumulate free SA and are incapable of activating SAR. So is SA the translocated signal?

In vivo ¹⁴C-SA labeling studies revealed that, following TMV infection on N tobacco, as much as 70% of the SA increase in uninfected tissue results from its translocation from the infected leaves; a series of grafting experiments between wild-type and NahG plants, however, indicated that SA is only needed in the distal plant organs for SAR to be induced (Fig. 21.51). Therefore, SA is probably not the mobile signal in tobacco. Grafting experiments using tobacco showed that SA methyltransferase activity, which converts SA into methylsalicylic acid (MeSA), is required in the tissue that generates the mobile signal. Conversely, MeSA esterase activity, which converts MeSA back to SA is required for signal perception in the distal tissues. However, in *Arabidopsis*, SA is required for SAR, whereas MeSA is dispensable for SAR. Thus, MeSA may have a signaling role for SAR induction in tobacco, but not in all plant species.

SA induces or potentiates many plant defense responses and induces a set of pathogenesis-related (PR) proteins. Seventeen families of PR proteins have been classified (Table 21.8), and the same types of PR protein families occur in most plant species. Transcripts of PR genes accumulate within minutes to hours of pathogen attack and PTI or ETI activation, and they are also induced in compatible interactions, but much more weakly and slowly. Induction of PR proteins distal to the initial site of infection frequently occurs. Several PR proteins are also induced as plants start to flower or experience abiotic stress.

Some PR proteins function as chitinases and glucanases, degrading fungal cell wall structural polysaccharides and impairing fungal growth. SA regulates the transcriptional activation of many PR genes. Also, ethylene and SA can act synergistically, enhancing PR gene expression even further. Other PR defense proteins, such as lipoxygenase, may contribute to defense by generating secondary signal molecules, such as jasmonic acid (JA) and lipid peroxides, and by producing an array of toxic volatile and nonvolatile secondary metabolites with antimicrobial activity.

Various synthetic chemicals induce SAR. Two of the most potent are 2,6-dichloroisonicotinic acid (INA) and benzo(1,2,3) thiodiazole-7-carbothionic acid S-methyl ester (BTH). Both compounds act as SA mimics and activate SAR when applied to NahG plants.

To understand the molecular and biochemical basis of SAR, mutagenesis screens using *Arabidopsis* revealed the SAR-deficient mutant *dir1-1* (defective in induced resistance). The *dir1-1* mutant plants can activate defenses locally,

FIGURE 21.50 Systemic responses to plant pathogens. (A) Viruses, fungi, and bacteria activate systemically a subset of defense responses in a phenomenon known as systemic acquired resistance (SAR), in which local necrosis formation at the initial site of pathogen invasion triggers both a local increase in salicylic acid (SA) and formation of a phloem-mobile signal. Subsequently, in distal plant tissue, SA concentrations increase and volatile methyl-SA (MeSA) is released. Together, these signals induce synthesis of various pathogen-related proteins in non-invaded parts of the plant. (B) In contrast, attack by chewing insects or mechanical wounding activates a different protective response, the systemic PI/wound response, wherein initial tissue damage causes a transient increase in the synthesis of ethylene and jasmonic acid (JA). Volatile methyl jasmonate (MeJA) and another phloem-mobile signal called systemin then activate the systemic responses, which include the accumulation of proteinase inhibitors (PIs) and other systemic wound response proteins (SWRPs). Root-attacking nematodes appear to induce a mixture of both the SAR and systemic PI/wound responses. (C) Induced systemic resistance (ISR) caused by soil-inhabiting nonpathogenic rhizobacteria colonizing plant roots. ISR requires both JA- and ethylene-mediated signaling to induce protective defense responses in the distant leaf tissue. This form of defense does not involve accumulation of pathogenesis-related (PR) proteins or require SA.

indicating DIR1 is only required for the systemic responses. DIR1 is predicted to encode an apoplastic lipid-transfer protein, and this protein was detected in the vascular exudates of wild-type plants after localized pathogen inoculation. Therefore, the DIR1 protein has a role in either the generation

of the systemic signal or transport of another lipid-based signal to distal tissues.

A mutant impaired in the biosynthesis of glycerol 3-phosphate (G3P) also fails to activate SAR. The SAR response can be rescued by the addition of either G3P or vascular exudates from

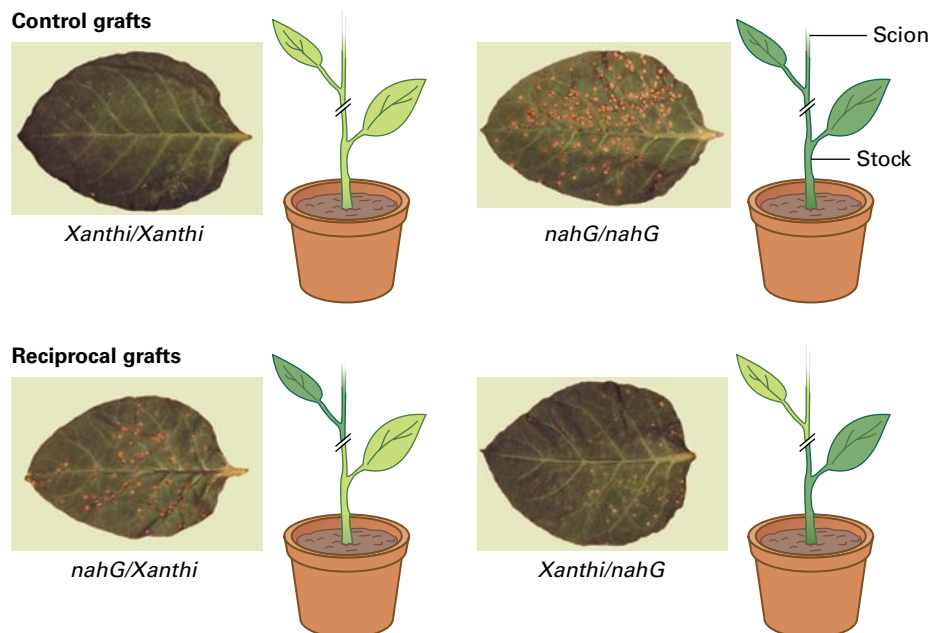

FIGURE 21.51 Grafting experiments demonstrate that salicylic acid (SA) is unlikely the phloem-mobile signal that activates SAR. An absolute requirement for SA in systemic acquired resistance (SAR) was demonstrated using transgenic tobacco (*Nicotiana tabacum*) and *Arabidopsis* expressing the bacterial *nahG* gene, in which the NahG SA hydroxylase degrades SA to catechol, CO_2 , and water. These plants did not accumulate free SA and were incapable of activating SAR. Then a series of grafting experiments between wild-type and transgenic *nahG*-expressing plants revealed that, to induce SAR, SA only needed to be present in the distal plant organs. Reciprocal and control grafts were generated using two types of tobacco plants, which expressed either the *N* resistance gene alone (cultivar Xanthi) or the *N* gene in combination with the *nahG* transgene to remove inducible SA (*nahG*). The four types of grafted plants were inoculated with TMV on the lower rootstock leaves; 7 days later, the same TMV isolate was inoculated onto the upper scion leaves. The photographs show the infection types on the scion leaves five days after the second TMV inoculation. The *nahG* scions grafted onto the Xanthi rootstocks (*nahG*/Xanthi) were unable to mount an SAR response. In contrast, Xanthi scions grafted onto *nahG* rootstocks (Xanthi/*nahG*) demonstrated SAR responses similar to those of the control Xanthi/Xanthi grafts not expressing the *nahG* transgene. The *nahG*/*nahG* grafts lacking SA were unable to mount an SAR response. Source: (Photos) Vernooij et al. (1994). *Plant Cell* 6:959–965.

induced wild-type plants to the distal tissues. Thus, G3P may also be a signaling molecule in SAR that requires DIR1. In addition, analysis of vascular exudates revealed azelaic acid as a mobile signal capable of inducing SAR. Application of azelaic acid leads to induction of the *AZI1* (*AZELAIC ACID-INDUCED 1*) gene, which is predicted to encode a secreted lipid-transfer protein. Reciprocal application of vascular exudates from wild-type and *azi1* mutant plants show that *AZI1* is involved in the production or translocation of a mobile signal. Together, these studies reveal that multiple mobile signals are transported through the vasculature to systemic, uninfected parts of the plant, where they induce the accumulation of SA, a signal molecule for SAR. These mobile signals in *Arabidopsis* and their roles and potential interplay are depicted in Figure 21.52.

21.8.2 NPR1, NPR3, and NPR4 mediate SA induction of *PR* genes

A key protein in SAR is NPR1 (NONEXPRESSOR OF PATHOGENESIS-RELATED GENES 1) (Fig. 21.53). *Arabidopsis npr1* mutant plants fail to induce *PR* genes upon

treatment with chemical inducers, such as SA and INA, and are compromised in SAR. The *npr1* mutant does, however, show a stronger HR and greater SA accumulation in response to genetically incompatible pathogens, whereas NPR1 overexpressing *Arabidopsis* lines exhibit a weaker HR. Therefore NPR1 is a positive regulator of SAR but a negative regulator of effector triggered HR (ETI). NPR1 encodes an ankyrin repeat protein that positively regulates SA signaling and is a member of a small gene family that includes NPR3 and NPR4 (see later). Similar ankyrin repeats are found in numerous eukaryotic proteins involved in protein–protein interactions.

In healthy plant cells, NPR1 is retained in an oligomeric form in the cytoplasm by intermolecular disulfide bridges, and S-nitrosylation by nitric oxide (NO) facilitates NPR1 oligomerization. The NO moiety becomes covalently attached to the thiol side chain of cysteine, resulting in protein S-nitrosylation (NPR1 oligomer). Upon pathogen infection, thioredoxins also located in the cytoplasm counteract the S-nitrosylation of NPR, leading to monomer release and migration of this transcription cofactor to the nucleus (NPR1 monomer). SA affects cellular redox state and NPR1 nuclear translocation. Once inside the nucleus, NPR1 binds to TGA (TGACG-motif binding) transcription factors, enhancing

TABLE 21.8 Recognized families of pathogenesis-related proteins.

Family	Type member	Properties
PR-1	Tobacco PR-1a	Unknown
PR-2	Tobacco PR-2	β -1,3-glucanase
PR-3	Tobacco P, Q	Chitinase type I,II,IV,V,VI,VII
PR-4	Tobacco 'R'	Chitinase type I,II
PR-5	Tobacco S	Thaumatococcus-like
PR-6	Tomato Inhibitor I	Proteinase-inhibitor
PR-7	Tomato P ₆₉	Endoproteinase
PR-8	Cucumber chitinase	Chitinase type III
PR-9	Tobacco "lignin-forming peroxidase"	Peroxidase
PR-10	Parsley "PRI"	Ribonuclease-like
PR-11	Tobacco "class V" chitinase	Chitinase type I
PR-12	Radish Rs-AFP3	Defensin
PR-13	<i>Arabidopsis</i> THI2.1	Thionin
PR-14	Barley LTP4	Lipid-transfer protein
PR-15	Barley OxOa (germin)	Oxalate oxidase
PR-16	Barley OxOLP	Oxalate-oxidase-like
PR-17	Tobacco PRp27	Unknown

their binding to SA-responsive promoters. This then leads rapidly to the transcriptional activation of a wide repertoire of defense responses and pathogen resistance.

The NPR1 protein carries a Broad-complex, Tramtrack, and Bric-a-brac BTB domain, also found in various proteins that make E3 ligase complexes with CULLIN3 (see Chapter 10). In addition, once within the nucleus NPR1 is phosphorylated on two serine residues, and this facilitates the interaction between NPR1 and CULLIN to enhance NPR1 degradation. NPR1 protein turnover (degradation) by the 26S proteasome is required for full induction of the NPR1-induced genes, the mechanism of which is still under investigation. It is hypothesized that NPR1 turnover facilitates the "refreshment" of the transcription initiation complex. NPR1 is responsible for heightening defense responses in SAR-induced plants during subsequent pathogen attacks.

Two receptors for SA have been identified in *Arabidopsis*: the low-affinity NPR3 protein and the high-affinity NPR4 protein. At the site of infection, NPR1 must be degraded in

the nucleus via interaction with NPR3 to allow PCD and ETI to occur. In a healthy plant, if NPR1 enters the nucleus, it is degraded by NPR4, whose interaction with NPR1 does not require SA. At a distance from the site of infection, NPR4 functions in conjunction with NPR1 and promotes defense gene induction without host cell death. In *npr3npr4* double mutant plants, local NPR1 levels remain high and no SAR occurs.

Both NPR3 and NPR4 proteins have two functions, as SA receptors and as adaptor proteins that link the NPR1 protein to CULLIN3. Upon binding SA, NPR3 promotes the NPR1–NPR3 interaction, whereas NPR4 disrupts the NPR1–NPR4 interaction. At the high SA concentrations typically induced locally at the sites of initial pathogen infection, the low-affinity NPR3 receptor mediates degradation of the cell death suppressor NPR1, thereby permitting activation of ETI and cell death to occur. In contrast, at the lower SA concentrations typically found in distal tissues, SA is unable to bind to NPR3, and cell death is blocked. In these distal tissues, SA instead binds to the high-affinity

FIGURE 21.52 Systemic activation of plant defense responses. Several proteins and metabolites with various functions are required to establish and maintain the systemic acquired resistance (SAR) response. DIR1 and AZI1 are predicted to be apoplastic lipid-transfer proteins that have a role in either generation of the systemic signal or transport of various systemic signals to distal tissues. The metabolites glycerol 3-phosphate (G3P) and azelaic acid are two systemically mobile signals that accumulate in vascular exudates in activated plants. When the mobile signals reach the systemic tissues, accumulation of salicylic acid (SA) occurs and induces or potentiates many plant defense responses, including the induction of a set of pathogenesis-related (PR) proteins. The induced volatile metabolite methylsalicylic acid (MeSA) may have a SAR signaling role in tobacco, but not in all plant species.

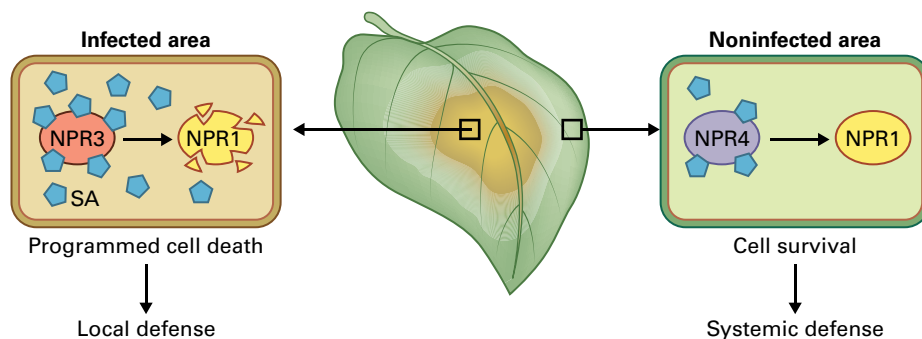

FIGURE 21.53 SA-mediated control of plant cell death and survival. Upon microbial infection, SA levels increase, its concentration decreasing gradually with increasing distance from the site of infection. At high SA concentrations—typically found in infected areas of the plant—the receptor NPR3, which binds SA with low affinity, mediates degradation of the cell-death suppressor NPR1 (left), thereby favoring programmed cell death and local effector-triggered immunity. However, at the lower SA concentrations typically found in cells distant from the infection site, SA cannot bind to the low-affinity receptor NPR3, so cell death is blocked. In these cells, SA instead binds to the high-affinity receptor NPR4 (right), blocking degradation of NPR1, thereby favoring cell survival and expression of genes associated with activation of systemic defenses.

receptor NPR4, blocking the degradation of NPR1 to favor cell survival and the expression of genes associated with SAR (Fig. 21.53).

21.8.3 Systemic responses to mechanical wound and insect attack occur in plants

Many herbivorous insects mechanically wound plant tissue while feeding and induce the rapid accumulation of proteinase inhibitors (PIs) and other systemic wound response proteins (SWRPs) throughout the plant (see Fig. 21.50). The systemic

response to chewing insects is frequently referred to as the **wound response**, because similar molecular and biochemical events are triggered after plant tissue is mechanically wounded. In tomato, although high concentrations of oligogalacturonides released from damaged plant cell walls induce PI and SWRP genes locally, these oligogalacturonides do not move systemically. Instead an 18 amino acid polypeptide called **systemin** (see Chapter 17) is the mobile systemic signal.

Systemin can initiate defense responses at a few femtomoles (10^{-15} moles) per plant. It is synthesized by cleavage from the C-terminus of pro-systemin, a 200 amino acid precursor protein, in the cytoplasm at the site of wounding. Systemin is released from damaged cells, moves throughout the damaged

leaf within 30 minutes, and is transported via the phloem to upper unwounded leaves within 60–90 minutes.

The importance of systemin to plant defense against insect attack has been demonstrated using transgenic tomato plants that produce either continuously high or lower than normal systemin levels in response to wounding. When systemin levels are high, the tomato plants constitutively express defense mechanisms even in the absence of wounding, and are more resistant to herbivory by larvae of the tobacco hornworm *Manduca sexta*. When systemin production is lower than normal, plants have a severely reduced systemic induction of defense mechanisms and are more susceptible to *M. sexta* larvae.

Once systemin reaches the target tissue in tomato plants, its perception activates several signaling pathways that lead to expression of various defense mechanisms. One pathway is similar to that elicited by P/MAMPs, involving ion fluxes across the membrane, an oxidative burst, and the activation of MAP kinases (see Fig. 21.30). This activates a lipid-based signaling cascade and JA production (see Chapter 17). JA induces transcription of PI and other SWRP genes; however, for JA induction of PI genes to occur, a third signal molecule is required, the gaseous hormone **ethylene**.

Ethylene transiently accumulates within 30–120 minutes of systemin addition to the translocation stream. When ethylene synthesis is blocked pharmacologically or by reverse genetics using transgenic plants expressing an antisense ACC oxidase gene (see Chapter 17), neither wounding nor systemic or JA treatments can induce PI gene expression. A tomato mutant in JA biosynthesis called *defenseless 1* (*def1*) has a compromised insect defense response (Fig. 21.54). SA inhibits both the octadecanoid pathway and ethylene biosynthesis. The SA inhibition of the wound response explains why PI and SWRP genes are not induced during SAR to pathogens, when high levels of SA accumulate.

Some, but not all, features of the defense response to wounding are conserved across plant species. For example, in both *Arabidopsis* and tomato, JA signaling plays a crucial role in initiation of the wound response; however, the systemin signaling pathway is found only in the Solanaceae. *Arabidopsis* has no genes that encode proteins resembling prosystemin; therefore, in *Arabidopsis*, JA is most likely the signal that directly induces the systemic wound response.

21.8.4 Insect herbivores induce production of proteinase inhibitors

In addition to activating the systemic wound response, attacking insect herbivores activate synthesis of a different group of defense proteins to microbial pathogens that interfere with the insect digestive system. They include serine, cysteine, and aspartyl PIs and polyphenol oxidases. These proteins interact with proteins and proteinases in the herbivore gut and inhibit proteolysis of the ingested food. The result is reduced availability of essential amino acids, which either retards herbivore growth and development or kills them. Nematodes induce PI accumulation, which results in similar adverse effects.

21.8.5 Jasmonic acid and ethylene mediate resistance to necrotrophs

Plant **defensins** are defense-related proteins with antimicrobial activity. This growing family of basic cysteine-rich peptides with a molecular mass below 7 kDa is of particular

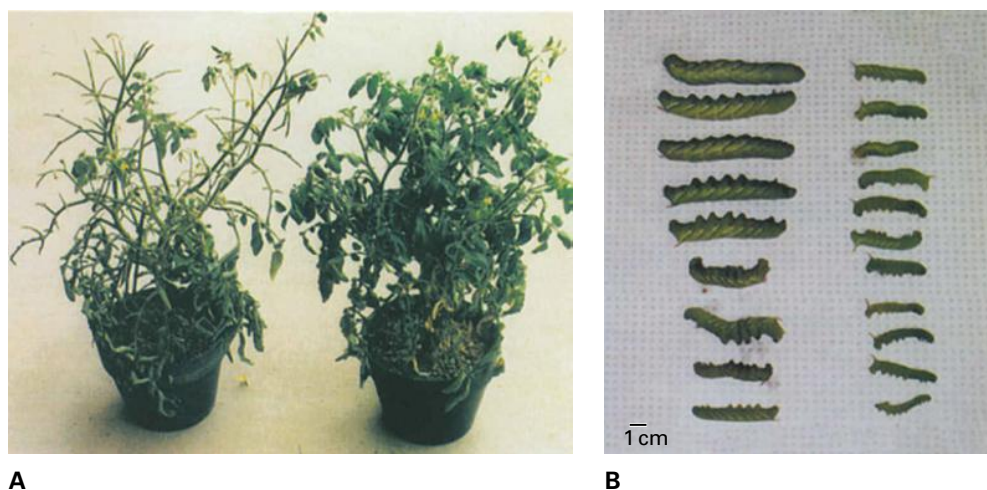

FIGURE 21.54 The tomato mutant *defenseless* (*def1*, A, left) is deficient in the biosynthesis of the octadecanoid pathway-derived signal, jasmonic acid. The *defenseless* plant has a compromised systemic wound response compared with that of the wild-type plant (A, right). When larvae of the tobacco hornworm insect (*Manduca sexta*) feed on *defenseless* plants (B, left), their growth rate is faster than when feeding on wild-type tomato plants, which can systemically synthesize PI and other systemic wound response proteins in response to feeding by larvae (B, right).

interest for three reasons. First, unlike SA-mediated defense responses, plant defensin accumulation in vegetative plant tissues is controlled by a combination of JA and ethylene. Second, JA levels rise in systemic tissues. Third, insects, birds, and mammals produce structurally and functionally similar defensin peptides following microbial attack. For example, the fruit fly *Drosophila melanogaster* produces a peptide called drosomycin that resembles plant defensins from radish. Both peptides exhibit potent antifungal activity (Fig. 21.55). This conserved structure/function relationship indicates an ancient conserved defense strategy against microbial attack involving extracellular peptide production.

Necrotrophic fungal, oomycete, and bacterial pathogens, as well as insects, trigger defense responses that are mediated by JA in combination with ethylene (Fig. 21.56). In *Arabidopsis*, the thionin gene *Thi2.1* and plant defensin gene *PDF1.2* are locally and systemically activated after infection with a necrotizing pathogen or exogenous application of ethylene and **methyl jasmonate**, but not after the leaves have been treated with SA. Coronatine is the toxin effector produced by the bacterium *P. syringae* to mimic JA and thereby assist infection (see Section 21.3.3). JA can become conjugated to different amino acids. In particular, JA-isoleucine is the JA derivative that is recognized by COI1, and is crucial for JA signaling.

Most JA responses are mediated by the F-box protein COI1 (CORONATINE INSENSITIVE 1). In *Arabidopsis*, JA-insensitive *coi1* mutants are more susceptible to necrotrophic pathogens, such as *Alternaria brassicicola* and *Botrytis cinerea*.

A key regulator of JA responses in plant–pathogen interactions is the basic helix–loop–helix transcription factor AtMYC2. In addition, JAZ (JASMONATE ZIM-domain-containing) proteins in *Arabidopsis* negatively regulate JA signaling by binding AtMYC2. In the presence of JA-Ile, these JAZ proteins interact with the COI1 protein, promoting ubiquitination of the JAZ proteins and leading to their degradation by the 26S proteasome, releasing AtMYC2 to activate the JA-responsive genes (Fig. 21.56). The crystal structure of the *Arabidopsis* JA receptor has revealed the JA responses are mediated by a complex formed between COI1 and JAZ proteins that requires the presence of both the signal JA-Ile and inositol 6-phosphate (see Chapter 17).

JA and ethylene signaling molecules often work in combination during the defense response. Ethylene is frequently synthesized during both compatible and incompatible interactions. In *Arabidopsis*, the ethylene signal is perceived by five ethylene receptors, each of which contains a protein kinase domain (see Chapter 18). These receptors are negative regulators of ethylene signaling and interact with another negative regulator, CTR1, which negatively regulates downstream components of the ethylene-signaling pathway and is inactivated by ethylene. This inactivation by ethylene abolishes negative regulation of the downstream ethylene-signaling components EIN2 and EIN3. EIN2 is a membrane protein

FIGURE 21.55 Plant defensins are small, cysteine-rich peptides that accumulate at the periphery of the plant plasma membrane and are frequently found in dry plant seeds. They are induced during the defense response in growing plants. Plant defensin peptides are structurally and functionally similar to those produced by insects, birds, and mammals after a microbial attack. (A) The *Drosophila drosomycin* defensin peptide (left) resembles MeDef1 a 45 amino acid protein from the seed of *Medicago sativa* (right). (B) MsDef1 inhibits *in vitro* growth of a filamentous fungus, *Fusarium graminearum*, at micromolar concentrations (right). It prevents normal filamentous hyphal growth; instead, only a few short and highly swollen hyphae form. (C) In *Arabidopsis*, induction of the defensin *PDF1-2* gene transcript is regulated by defense signaling cascades that require ethylene and methyl jasmonate (MeJA). Application of either of these two signaling molecules does not induce the pathogenesis-related *PR-1* gene, which is activated by salicylic acid (SA) or dichloroisocotinic acid (INA). Source: (B) Sagaram et al (2011). PLoS One 6(4):e18550.

with a C-terminal domain that is released by proteolysis upon activation of ethylene signaling, and leads to elevated levels of EIN3, a short-lived transcription factor protein that accumulates in the nucleus after ethylene levels rise. EIN3 regulates the expression of many ethylene target genes, for example ERF1 that encode ethylene-response element binding (AP2/EREBP) transcription factors involved in defense against

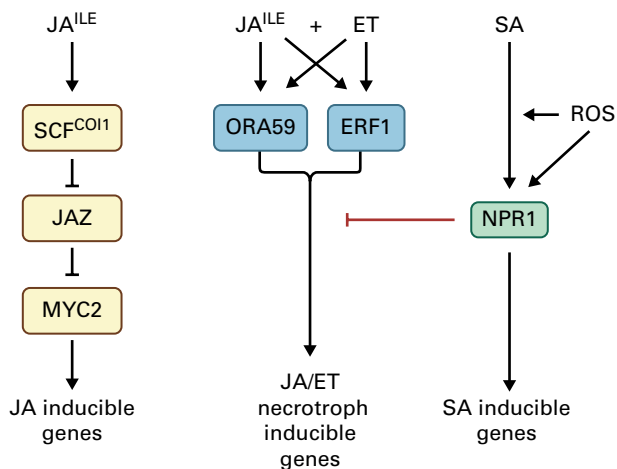

FIGURE 21.56 Comparison of the three main defense signaling pathways locally activated following pathogen infection or pest attack. The signaling pathways are activated by jasmonic acid-isoleucine (JA^{ILE}) (left), a combination of JA^{ILE} and ethylene (ET) (center), and salicylic acid (SA) and reactive oxygen species (ROS) (right). The JA^{ILE} and combined JA^{ILE}/ET response pathways are important for defense against necrotrophic fungal, oomycete, and bacterial pathogens as well as insects. In contrast, the SA defense pathway is crucial for defense against biotrophic and hemibiotrophic pathogens. (Left) Most JA responses are mediated by the F-box-containing CORONATINE INSENSITIVE 1 protein (COI1). COI1 functions as a jasmonate receptor and forms Skp1/Cullin1/F-box protein COI1 (SCF^{COI1}) complexes. In *Arabidopsis*, key regulators of JA that mediate defense activation are the basic helix-loop-helix transcription factor AtMYC2 and JAZ proteins (JASMONATE ZIM-domain-containing), which bind to AtMYC2 and negatively regulate JA signaling. When JA^{ILE} levels rise, the JAZ proteins interact with the COI1 protein, promoting ubiquitination of the JAZ proteins and their degradation by the 26S proteasome. The released AtMYC2 transcription factor goes on to activate the JA-responsive genes. (Center) The crosstalk and integration of the JA^{ILE} and ET signals in plant defense requires two members of the ETHYLENE RESPONSE FACTOR (ERF) family of transcription factors, namely ORA59, which contains an APETALA2/ERF domain and ERF protein 1 (ERF1). Cooperation between ORA59 and ERF1 activates the expression of several defense-related genes, including plant defensins (for example PDF1.2) and basic chitinases (for example ChiB). (Right) SA mediated defense signaling can be further enhanced when reactive oxygen species levels are elevated. SA signaling requires the protein NONEXPRESSOR OF PATHOGENESIS-RELATED GENES 1 (NPR1). NPR1 is an ankyrin repeat protein that exists in healthy plants in the cytoplasm in an oligomeric form. Upon pathogen infection, due to a change in redox status, monomers of NPR1 are released and migrate to the nucleus (see Section 21.8.2). Once inside the nucleus, NPR1 binds to TGA (TGACG-motif binding) transcription factors, enhancing their binding to SA-responsive promoters. This in turn leads to the activation of multiple defense-related genes, including the pathogenesis-related proteins (for example PR1). In certain situations, the SA defense signaling pathway can suppress the JA^{ILE}/ET signaling pathway. Plant defense signaling can also be influenced by the plant hormones gibberellic acid and abscisic acid.

necrotrophs. Overexpression of ERF1 enhances resistance against *Botrytis cinerea* and increases susceptibility to the hemibiotroph *P. syringae* pv. *tomato*.

21.8.6 Salicylic acid and jasmonic acid/ethylene are mutually antagonistic signals and also intersect with other signaling pathways

SA signaling triggers resistance to biotrophic and hemibiotrophic pathogens, whereas a combination of JA and ethylene activates defense against necrotrophic pathogens. These two pathways are mutually antagonistic: elevated SA levels and resistance to biotrophs are often correlated with increased necrotroph susceptibility, and elevated levels of resistance to necrotrophs are often correlated with enhanced susceptibility to biotrophs. This classical view requires revision because other hormones contribute to pathogen virulence and to plant defense. A complex crosstalk influences the levels of these induced hormones, and the eventual biological outcomes are influenced by both pathogen lifestyle and plant genetics.

Gibberellic acid (GA) signaling is regulated by the DELLA proteins (see Chapter 18). In *Arabidopsis*, loss of DELLA proteins results in increased resistance to *P. syringae* pv. *tomato*, and this is associated with increased SA biosynthesis and signaling. DELLAs can also interact with the JA signaling pathway by interacting with the JAZ proteins that prevent AtMYC2 activation; DELLAs thus promote JA signaling. This explains why *Gibberella fujikuroi*, the rice necrotrophic fungal pathogen and cause of “foolish seedling” disease, makes gibberellin: removal of DELLAs attenuates JA signaling. The binding of GA to the DELLA proteins leads to their degradation and enables JAZ proteins to reimpose suppression of AtMYC2. This also explains the increased resistance of the DELLA mutants to biotrophs and hemibiotrophs.

In summary, plant signaling molecules such as SA, JA, ethylene, and GA can influence the balance and level of activation of different facets of the plant defense response via complex mechanisms that remain an active topic of investigation. It is also clear from pathogen genome sequencing projects and targeted biochemical studies that certain pathogenic species produce some of these plant hormones and can, therefore, influence this crosstalk.

21.9 Plant gene silencing confers virus resistance, tolerance, and attenuation

Neither the HR nor the SAR is responsible for limiting the systemic spread of viruses through the plant vascular system. Thus, other defense mechanisms must be responsible for controlling virus infections.

21.9.1 The systemic long-distance spread of viruses is restricted

Arabidopsis mutants have provided genetic evidence for the involvement of specific host genes in controlling vascular movement of a tobamovirus or a potyvirus. At least three loci, *RTM1* (restricted TEV movement 1), *RTM2*, and *RTM3*, are required for restriction of long-distance tobacco etch virus (TEV) movement in the *Arabidopsis* ecotype Col-0. The *RTM1* protein is similar to the lectin jacalin. The *RTM2* protein contains several domains, including an N-terminal region with similarity to plant small heat shock proteins and a C-terminus that includes a predicted transmembrane spanning domain. These two proteins of the RTM system function within the phloem sieve elements to restrict long-distance movement of TEV.

21.9.2 RNA silencing is important for resistance to many virus species

Plants infected with some viruses can recover and produce new shoots that do not show viral disease symptoms (Fig. 21.57). This is because plants can attenuate the accumulation of many virus species by a mechanism called **RNA silencing** (see Chapter 6). Although plant viruses are highly diverse in sequence, morphology, genome organization, protein production, and host range, all virus species accumulate viral RNA as a part of their life cycle. Accumulation of viral RNA, particularly double-stranded viral RNA (dsRNA), provides the signal that activates the silencing mechanism. The formation of dsRNA can be part of the normal virus replication process, the result of an inverted repeat sequence within the single-strand RNA (ssRNA) that folds into a hairpin structure, or through the presence of a complementary RNA product from overlapping bidirectional transcription.

RNA silencing is an effective defense mechanism that has three main characteristics. First, it is homology-dependent and, therefore, specific to viral RNA. It is driven by small inhibitory RNAs (siRNAs) derived from a double-stranded form of the viral RNA; host-encoded RNAs are not affected by the viral RNA-induced silencing mechanism. Second, there is enormous potential for amplification, because siRNAs can serve as primers for production of secondary long viral dsRNAs from ssRNA templates by plant-encoded RNA-dependent RNA polymerases (see Chapter 6). Third, siRNAs also function as a mobile signal that moves ahead of or with the advancing virus. This signal ensures the virus is not able to escape the effects of silencing by movement between cells or in the phloem.

To counter this efficient RNA silencing mechanism, many plant viruses encode proteins that act as suppressors of RNA silencing. Silencing suppressors from different virus species are mostly unrelated in sequence or structure. Under the

FIGURE 21.57 RNA silencing is a general antiviral plant defense mechanism. The bottom leaves of a tobacco plant were inoculated with tobacco ringspot virus (TRSV). By 23 days post inoculation, strong ringspot symptoms developed on the lower leaves; there is, however, a gradual decline in the development of ringspot symptoms on the upper leaves, and the top leaves appear normal and are virus free. The virus causing the initial symptoms activated RNA silencing, which inhibited spread of the infection into the upper leaves and also caused them to be immune to secondary infection by the same virus. Source: Wingard (1928). *J. Agric. Res.* 37:127–153.

strong selection pressure of RNA silencing, several different mechanisms appear to have evolved independently that fulfill the same function. This is an example of **convergent evolution**. Suppressor proteins often provide the virus with additional, unrelated roles in virus replication, and their ability to suppress RNA silencing has evolved as an additional feature. The P19 protein of tomato bushy stunt virus binds siRNAs, and this prevents formation of an active RISC (see Chapter 6). In contrast, the 2b protein of cucumber mosaic virus appears to inhibit the endonuclease activity of Argonaute (see

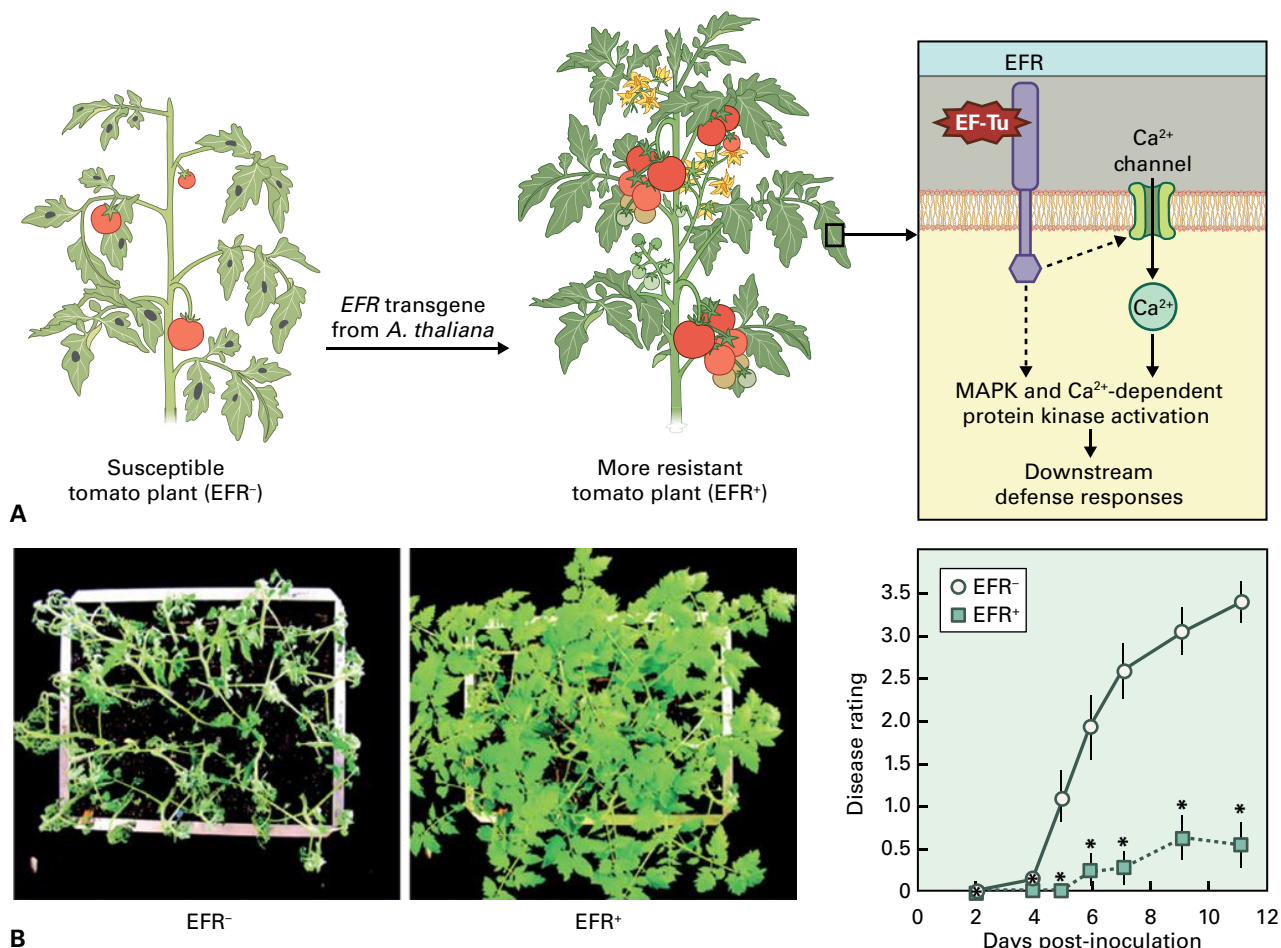

FIGURE 21.58 Transfer of a pattern-recognition immune (PTI) receptor to a crop confers resistance to several bacterial pathogens.

(A) Engineering broad-spectrum resistance in tomato, a member of the Solanaceae, by transferring a pattern-recognition receptor from *Arabidopsis* (family Brassicaceae). Elongation factor Tu receptor (EFR; purple) is absent from the solanaceous species *N. benthamiana* and tomato, and these plants are normally susceptible to infection by phytopathogenic bacteria from different genera. Transgenic expression of *Arabidopsis* EFR increases resistance to these bacterial pathogens, presumably by activating a signaling cascade that confers resistance to a range of bacteria expressing its cognate P/MAMP, elongation factor Tu (EF-Tu; orange). This interfamily transfer of EFR-mediated disease resistance suggests *N. benthamiana* and tomato contain the components necessary for EFR signaling other than the receptor. MAPK, mitogen-activated protein kinase. (B) Wild-type (EFR⁻; left) and transgenic plants expressing EFR (EFR⁺; middle) tomato plants infected with a virulent isolate of *Ralstonia solanacearum*. The time course of disease symptom formation (right) reveals the dramatic reduction in disease severity in the transgenic EFR plants.

Chapter 6). The formation of some virus disease symptoms, especially plant stunting and abnormal development, may be the result of interference by viral suppressor proteins in siRNA and microRNA processing.

21.10 Control of plant pathogens by genetic engineering

Exciting opportunities exist to use plant PRRs, plant *R* and other genes, and pathogen *Avr* and effector genes to improve crop disease resistance. In addition, processes required for

pathogenesis can be targeted for novel plant-specified inhibitory mechanisms.

21.10.1 Pattern-recognition receptors can elevate pathogen resistance in plants

Pattern-recognition receptors (PRRs) detect microbes by recognizing conserved pathogen/microbe-associated molecular patterns (P/MAMPs, see Section 21.5). However, different plant families carry distinct repertoires of PRRs that perceive distinct P/MAMPs.

The *Arabidopsis* PRR protein EFR perceives the acetylated N-terminus of the bacterial elongation factor-Tu (EF-Tu) (Section 21.5.1), but bacterial EF-Tu is not perceived in the

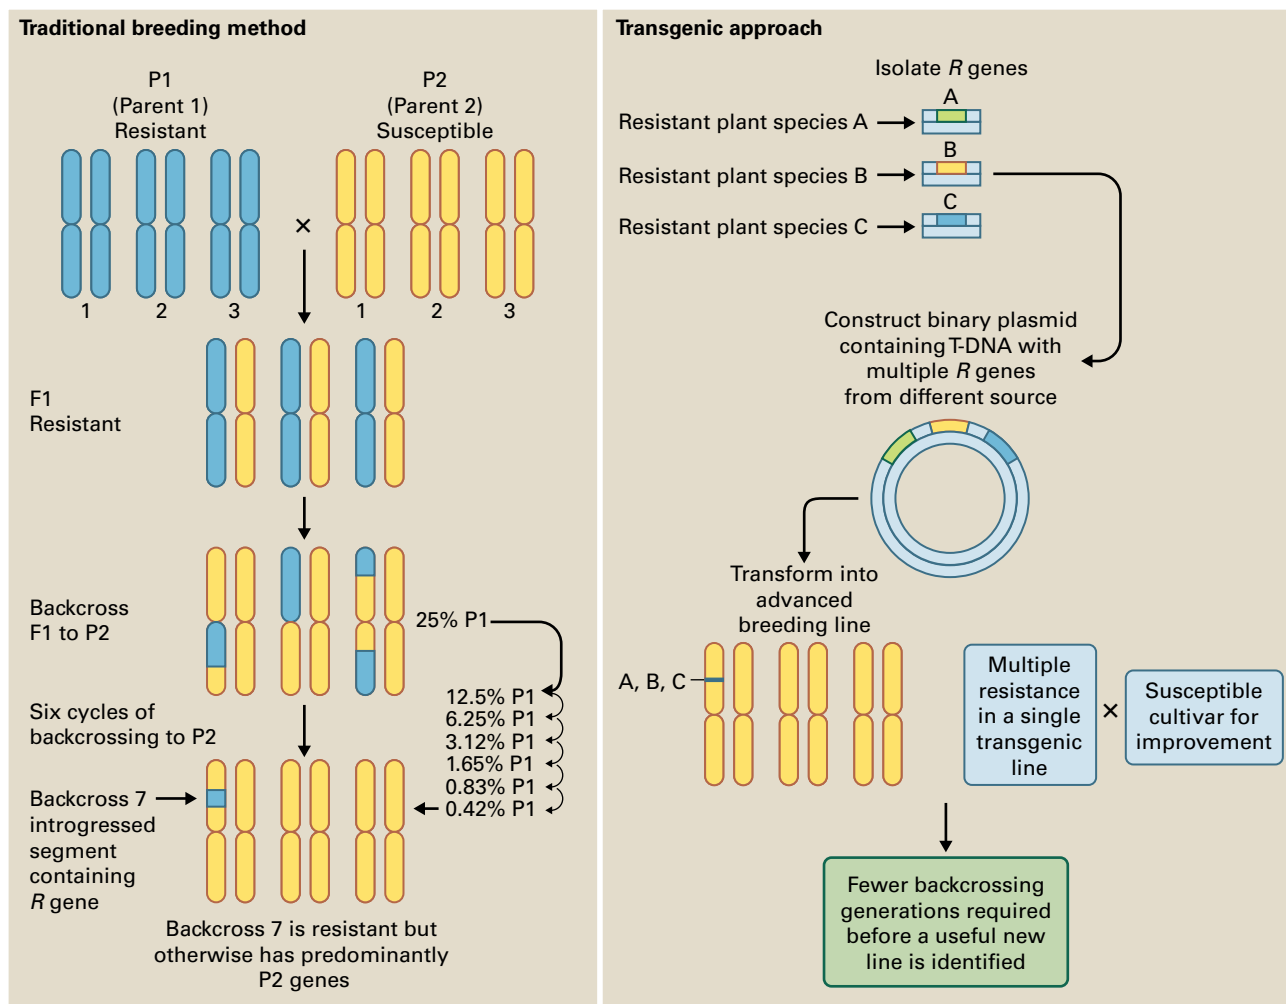

FIGURE 21.59 Traditional breeding compared with transformation technology approaches to introgress desirable genes into commercial crop plants. In a traditional breeding method (left), as much as 0.4% of the genome complement from each donor parent can remain in the seventh backcross generation along with the R gene of interest (originally from parent 1). In the transgene transformation approach, multiple R genes from several initial sources are first assembled into a single Ti plasmid. After T-DNA integration into the plant genome, these R genes co-segregate in all subsequent breeding steps, greatly simplifying the subsequent backcrossing program for introducing multiple new traits into a cultivar. When the transgenic transformation approach is used, the entire sequence of the introduced DNA is known, whereas in the traditional breeding program, neither the total extent of the introgressed DNA nor its sequence identity is known.

Solanaceae. Transfer of EFR from *Arabidopsis* into tobacco (*Nicotiana benthamiana*) and tomato (*Solanum lycopersicum*) confers responsiveness to EF-Tu and elevates resistance to phytopathogenic bacteria from different genera, including *A. tumefaciens*, *P. syringae*, *Ralstonia solanacearum*, and *Xanthomonas perforans* (Fig. 21.58). These results suggest that extending the P/MAMP recognition repertoire of crop plants can elevate their pathogen resistance.

21.10.2 R genes can confer broad-spectrum resistance

Traditionally plant breeders have introgressed, via lengthy breeding programs, novel R genes from wild relatives of crop species into elite commercial cultivars to control diseases

(Fig. 21.59 and also see Fig. 21.39, Section 21.6.1). During breeding, the R gene must be recombined away from any linked unwanted alleles of other genes that reduce crop performance (linkage drag). The availability of cloned R genes opens the possibility of their direct transfer into elite lines by genetic transformation (see Box 21.2).

Genetic transformation enables transfer of several different R genes that may be effective against a single pathogen species in a “cassette” of linked genes that cannot be separated by recombination (Fig. 21.59). This should slow pathogen evolution to overcome resistance, because the various R genes could only be overcome if, in a single pathogen isolate, several effector genes were simultaneously mutated. The introduction of R genes by transformation also means that interplant species fertility barriers can be crossed, thereby increasing the repertoire of plant species from which useful novel resistance sources can be obtained.

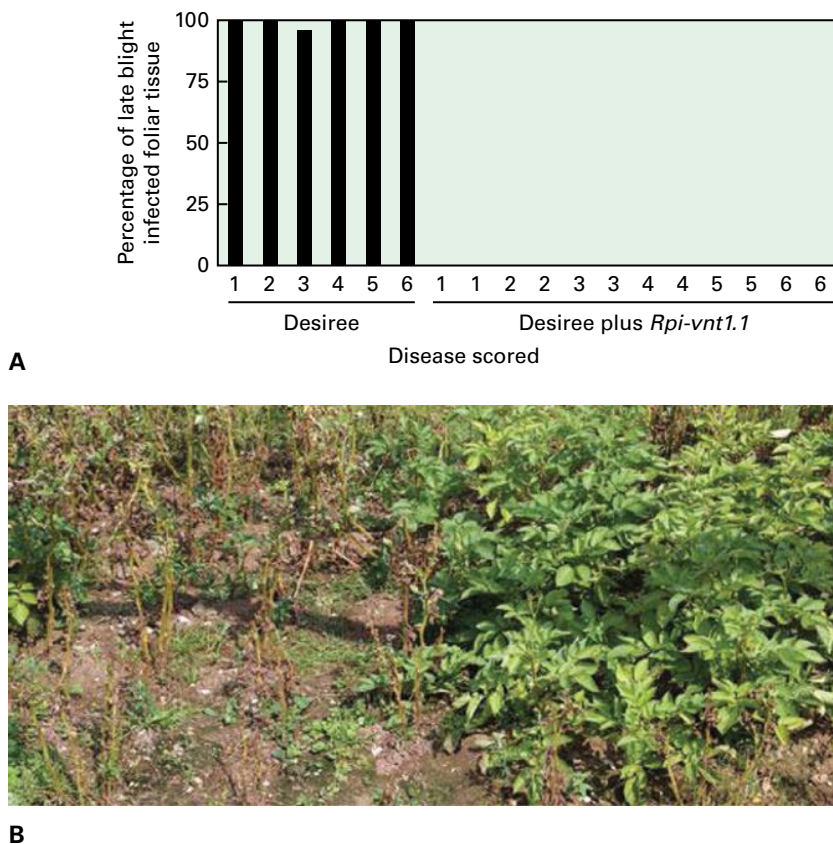

FIGURE 21.60 Comparison of severity of late blight disease caused by *Phytophthora infestans* in *Rpi-vnt1.1*-transgenic and non-transgenic var. *Desiree* potato plants. (A) Percentage of late blight infected leaf tissue during the vegetative growing stage. (B) Photograph of the control *Desiree* (left) and transgenic (right) plants almost one month after first symptoms of infection on *Desiree* plants were observed. No symptoms of late blight were present on transgenic plants during the growing season or as the crop matured.

Source: (B) Jones et al. (2014). *Phil. Trans. R. Soc. Ser. B* 369:doi:10.1098/rstb.2013.0087.

R genes that confer resistance to all or most races of a pathogen species are attractive candidates for interspecies transfer, because they may confer the same broad-spectrum resistance as occurs in their native genomes. For example, most accessions of the wild diploid potato species *Solanum bulbocastanum* are resistant to all known races of *Phytophthora infestans*. Using map-based cloning the resistance gene *RB/Rpi-blb1* was isolated. Transgenic cultivated potato plants (*Solanum tuberosum*) expressing the *RB* gene show a high level of resistance to nearly all *P. infestans* isolates, including a European “super race” that can overcome all 11 known *R* genes in cultivated potato. Two other *R* genes conferring broad-spectrum resistance to *P. infestans* have been isolated: *Rpi-blb2* from *S. bulbocastanum* and *Rpi-vnt1.1* from *S. venturii*. Transgenic cultivated potato lines expressing both *Rpi-blb1* and *Rpi-blb2* provided durable control of late blight disease in several years of field trials in the United Kingdom and mainland Europe (Fig. 21.60).

Isolating *R* genes from wild relatives and introducing them into elite lines, whether by breeding or transformation, is laborious; therefore, it is important to prioritize those *R* genes that are most likely to be durable, and analysis of pathogen effector complements can help. If an *R* gene recognizes an

effector that is conserved in all known races of a pathogen, it is more likely to be durable than an *R* gene that recognizes an effector that is absent from many races of the pathogen. Some effectors are essential for full virulence of the pathogen (see Box 21.3). Emerging knowledge of differences in the effector complement between pathogen races can thus be helpful for choosing *R* genes for prioritization. Already useful in the potato/*P. infestans* interaction, these approaches are deployed to identify durable resistance genes against the Ug99-derived races of the wheat stem rust fungus *Puccinia graminis* f. sp. *tritici*, which threatens wheat harvests in Africa and Asia (see Box 21.3 and Box 21.1). Tomato and banana are susceptible to the closely related leaf mold (*Cladosporium fulvum*) and black Sigatoka (*Mycosphaerella fijiensis*) diseases, respectively. Homologs of *C. fulvum* Avr4 and Ecp2 effectors are present in *M. fijiensis*. Since tomato Cf-4 confers recognition of Avr4 homologs from both pathogens, it may prove useful for *M. fijiensis* resistance in banana.

To control the wheat glume blotch pathogen *Stagonospora nodorum*, the ToxA and other related toxins recovered from fungal culture filtrates have been used globally to screen both existing commercial elite wheat germplasm and potential donor breeding lines for the lack of a necrotic response. This

BOX
21.3Effector-guided *R* gene deployment

Effector-guided *R* gene deployment is a disease control strategy based on the identification of core pathogen effectors that lack sequence polymorphism. It is currently being used in potato (*Solanum tuberosum*) to mitigate the impact of the late blight pathogen *Phytophthora infestans*. This pathogen undergoes major population shifts in agricultural systems via the successive emergence and migration of asexual lineages (A). A new aggressive lineage in the European *P. infestans* population termed 13_A2 is rapidly displacing other older lineages. Comparative whole-genome and transcriptome sequencing (see Chapter 9) of *P. infestans* pathogen races has revealed the core RXLR effector repertoire found in isolates from the new aggressive lineage of *P. infestans* 13_A2 and two older European *P. infestans* isolates. All three *P. infestans* isolates carry intact and in planta induced *Avrblb1*, *Avrblb2*, and *Avrvnt1* effector genes that trigger resistance in potato lines carrying the

corresponding disease resistance genes *Rpi-blb1*, *Rpi-blb2*, and *Rpi-vnt1.1* (B). *R* gene stacking can be achieved by conventional plant breeding with marker-assisted selection or by plant genetic engineering with T-DNA cassettes containing the desired *R* gene combinations. This core effector-guided approach helps to exclude any *R* genes from the elite potato germplasm improvement scheme that are already defeated by the pathogen because the cognate core effectors contain sequence polymorphisms that evade plant recognition.

(A) Disease-causing abilities of historic and current *Phytophthora infestans* (*Pi*) isolates. (B) The conserved core effectors *Avrblb1*, *Avrblb2* and *Avrvnt1* are present in all *Pi* isolates. These are recognized when the corresponding *R* genes *Rpi-blb1*, *Rpi-blb2*, and *Rpi-vnt1.1* are expressed in the host plant.

Source: Cooke et al. (2010). PloS Pathog. 8(10):e1002940.

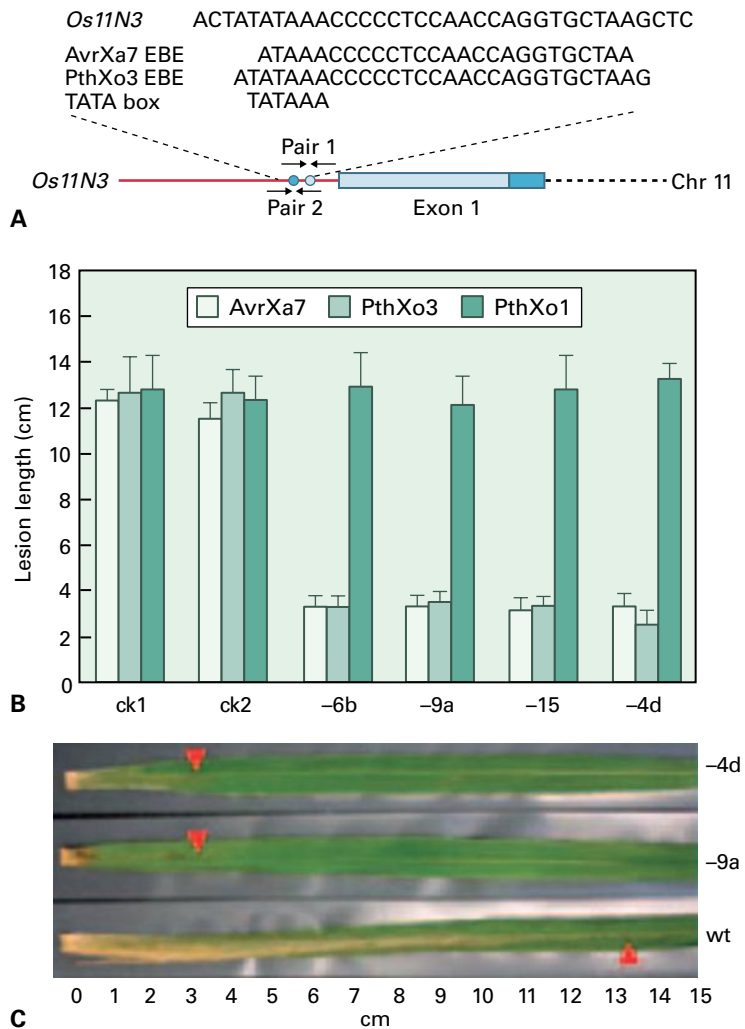

ensures that the corresponding *Tsn* locus, which confers *S. nodorum* disease susceptibility, is eliminated from all commercial wheat breeding programs.

Some *R* genes confer resistance to all races of a single pathogenic species, for example the recessive barley *mlo* resistance gene. Other *R* genes confer resistance to multiple unrelated pathogenic species, for example the tomato *Mi* gene, which confers both nematode and whitefly and psyllid resistance.

Certain *R* genes confer resistance to different but taxonomically closely related fungal species, for example the wheat *Lr34* gene, which confers resistance to leaf rust and stripe rust fungal pathogens (see Section 21.7.1). By analyzing the increasing amount of genome and transcriptome sequence information available for crop species, highly homologous *R* gene sequences can be isolated and tested for their ability to confer broad-spectrum resistance spectrum in different crop plant species.

FIGURE 21.61 TALEN technology has been used to edit a specific pathogen susceptibility (*S*) gene in rice to thwart the virulence strategy of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) and engineer heritable genome modifications for resistance to bacterial blight. The rice bacterial blight susceptibility gene *Os11N3* (also called *OsSWEET14*) was targeted for TALEN-based disruption. (A) The *Os11N3* promoter contains an effector-binding element (EBE) for *AvrXa7*, overlapping with another EBE for *PthXo3* and with the TATA box. Two pairs of designer TALENs (pair 1 and pair 2) were independently deployed to induce mutations in these overlapping EBEs of the *Os11N3* promoter and thereby interfere with the virulence function of *AvrXa7* and *PthXo3*, but not the developmental function of *Os11N3*. Each designer TALEN contained 24 repeat units for recognition of a specific set of 24 contiguous nucleotides at the target sites. (B) Severity of disease damage to wild-type and transgenic rice plants caused by *AvrXa7*-, *PthXo3*-, and *PthXo1*-dependent *Xoo* strains. Lengths of leaf lesions in wild-type plants (*ck1*), a nontransgenic plant (*ck2*) and transgenic plants homozygous for *Os11N3* promoter mutations of 6 bp (*-6b*), 9 bp (*-9a*), 15 bp (*-15*) and 4 bp (*-4d*) deletions, respectively, measured 14 days post inoculation with different *Xoo* strains expressing three different TAL effectors. (C) Resistance phenotype displayed to *Xoo* (*avrXa7*) by two transgenic rice plants (carrying either the *-4d* or *-9a* deletion constructs) compared with the disease susceptibility phenotype of a wild-type plant (*wt*). Leaves were inoculated at the left end and the extent of visible disease symptom formation is indicated by the red arrowheads.

Source: Ting Li et al. (2012). *Nat. Biotechnol.* 30(5):390.

Many race-specific R proteins are temperature-sensitive. For example, *N* gene-mediated tobacco mosaic virus (TMV) resistance fails at temperatures above 30°C and permits the virus to spread systemically throughout the plant. With climate changes now being experienced in many global regions, R genes that fail at higher temperatures may give inconsistent pathogen control. A lack of correct R protein folding or incorrect cellular localization may explain this phenomenon.

21.10.3 TAL effectors can be used for engineering resistance

Transcription activator-like (TAL) effectors of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) contribute to pathogen virulence by transcriptionally activating specific rice disease-susceptibility (*S*) genes (see Section 21.1.8). TAL effector nucleases (TALENs) are fusion proteins that combine the DNA recognition repeats of native or customized *Xoo* TAL effectors and the DNA cleavage domains of FokI nuclease. These TALENs are useful for precise genome engineering.

For example, to engineer rice plants (*Oryza sativa*) resistant to *Xanthomonas* bacterial infection, the promoter of the rice bacterial blight susceptibility gene *Os11N3* (also called *OsSWEET14*) was targeted for TALEN-based disruption. This gene encodes a member of the SWEET sucrose-efflux transporter family. The *Xoo* TAL effectors *AvrXa7* or *PthXo3* activate this gene and thus divert sugars from the plant cell to the bacteria. The promoter of *Os11N3* contains binding sites for both TAL effectors near the TATA box. TALENs were designed to mutate DNA sequences required for TAL effector binding, but not the development function of *Os11N3*. The modified *Os11N3* gene was no longer inducible when the rice plants were infected by pathogenic *Xoo* strains that could deliver either the *AvrXa7* or *PthXo3* TAL effectors into the rice cells. The stable TALEN-modified plants showed strong (though recessive) resistance to infection by the *AvrXa7*- or *PthXo3*-dependent *Xoo* strains, but not the *PthXo1*-dependent pathogenic *Xoo* strain (Fig. 21.61). So far, natural polymorphisms in the *Os11N3* gene that would prevent induction by *AvrXa7*- and *PthXo3*-dependent *Xoo* strains and also confer disease resistance have not been identified in rice germplasm. By using TALENs to edit a rice gene

FIGURE 21.62 *Papaya ringspot virus (PRSV) is a limiting factor in the production of papaya worldwide. By constitutively overexpressing the coat protein of this virus in papaya, several highly resistant varieties are now in commercial use in Hawaii and elsewhere. (A) Transgenic papaya line (left) showing resistance to PRSV compared to infected non-transgenic papaya (right). required for *Xoo* susceptibility, desirable alleles conferring resistance can be obtained that can then be used in rice breeding programs.

21.10.4 Virus sequences can induce resistance to virus infection

Virus sequence-induced resistance was based on the concept that a transgenic plant engineered to express viral proteins could interfere with the normal pathogenicity program of the virus. Coat protein (CP)-mediated resistance was proposed to operate through high CP levels, which inhibit disassembly of the virus particles in the initially infected cells, whereas the overexpression of a nonfunctional mutant movement protein (MP) was proposed to lead to competition for plasmodesmatal binding sites between the nonfunctional and the wild-type MP of the infecting virus. However, molecular analysis of transgenic CP or MP plants has revealed that resistance is RNA-mediated and sequence-specific, and likely functions by post-transcriptional silencing of viral gene expression (see Section 21.9.2).

CP sequence-induced virus resistance was one of the early success stories of plant genetic engineering and led to the development of virus-resistant papaya and squash cultivars for commercial production. For example, papaya crops in

Hawaii derived from transgenic lines carrying the CP gene of papaya ringspot virus (PRSV) provide effective control of this virus (Fig. 21.62).

21.10.5 Genetically engineered disease control is a knowledge-based approach

The transgenic disease control options described above have each taken immediate advantage of fundamental discoveries that had significantly advanced our overall understanding of host–pathogen interactions. In each example, a target of potential pathogen vulnerability was exposed through the acquisition of new knowledge, various intervention options were proposed and tested in the laboratory, growth room, or glasshouse, and only the best solutions went on to rigorous field testing and, finally, commercial release. In addition, many of the single gene-engineered disease control solutions that failed to make the grade, either in early testing or later when tested under field conditions, have provided considerable useful and novel insight into the importance of other plant components and information on the ways in which pathogens can rapidly evolve to overcome plant defenses.

Summary

Plants are resistant to most plant pests and pathogens. Every plant cell can defend itself from attacking pathogenic microorganisms and invertebrates. Some defenses, such as antimicrobial secondary metabolites, are constitutive and located in specific cellular compartments ready to be released upon cell damage. Other defense responses, such as those induced by pathogen invasion, require detection of the pathogen by the plant. Defense activation is correlated with rapid activation of defense-related genes and often culminates in the hypersensitive response that causes localized cell death to impair pathogen spread.

Plant resistance to pathogens can be mediated by dominant resistance (*R*) genes in plants that are complementary to avirulence (*Avr*) genes in pathogens. *Avr* effector proteins exhibit extensive sequence diversity, and their function in the pathogen and in the host plant is still poorly understood. In contrast, plant *R* proteins are strikingly similar in structure, sharing such motifs as leucine rich repeats (LRRs), a nucleotide binding or a serine/threonine protein kinase domain, among others. *R* proteins both detect pathogens and initiate signal transduction to activate defense mechanisms. In addition, *R* loci/genes can evolve new *R* gene specificities to keep pace with the evolution of virulence in pathogen populations.

By investigating the genomes of numerous pathogens and pests, the full repertoires of effector genes thought to function either in the suppression or inactivation of plant defenses have been predicted and their specific roles experimentally tested.

Plant defense reactions involve complex biochemical pathways and multiple signal molecules, including ROS, NO, SA, JA, and ethylene, to provoke the induction of proteins, secondary metabolites, and often cell wall fortification reactions—both at the infection site and systemically throughout the attacked plant. Specialist defenses against plant viruses include post-transcriptional gene silencing (PTGS); those against insects involve proteinase inhibitor proteins. Many aspects of induced plant defense appear to be conserved in other eukaryotes, perhaps indicating the existence of an ancient defense strategy that evolved early against pathogen attacks.

The genetic engineering of plants has started to achieve broad-spectrum and durable pest and pathogen control in crops. However, a better understanding of the factors and mechanisms involved in plant–pathogen interactions is still needed and better resistance strategies still need to be deployed to reduce crop losses.

Responses to Abiotic Stress

Kazuo Shinozaki, Matsuo Uemura,
Julia Bailey-Serres, Elizabeth A. Bray,
and Elizabeth Weretilnyk

Introduction

Plants are frequently exposed to environmental **stress**, external conditions that adversely affect growth, development, or productivity. Stress can be **biotic**, imposed by other organisms (Chapter 21), or **abiotic**, arising from an excess or deficit in the physical or chemical environment. Environmental conditions that cause damage to plants include flood, drought, high or low temperatures, excessive soil salinity, inadequate mineral nutrients, and excess or insufficient light. Phytotoxic compounds, such as ozone, can also damage plant tissues.

Stress triggers a wide range of plant responses, from alterations in gene expression and cellular metabolism to changes in growth rate and crop yield. The duration, severity, and rate at which a stress is imposed all influence how a plant responds. Several adverse conditions in combination can elicit a response that is different from that caused by a single stress. A response can be triggered directly by a stress, such as drought, or result from stress-induced injury, such as loss of membrane integrity. Moreover, resistance and sensitivity to stress vary according to species, genotype, developmental stage, and organ or tissue type (Fig. 22.1).

The molecular mechanisms underlying plant responses to abiotic stress, including changes in gene expression and cellular signal transduction, have been analyzed extensively, and various transcription factors and signaling molecules are now known to play important roles in cellular homeo-

stasis under stress conditions. The functions of these factors are described in this chapter.

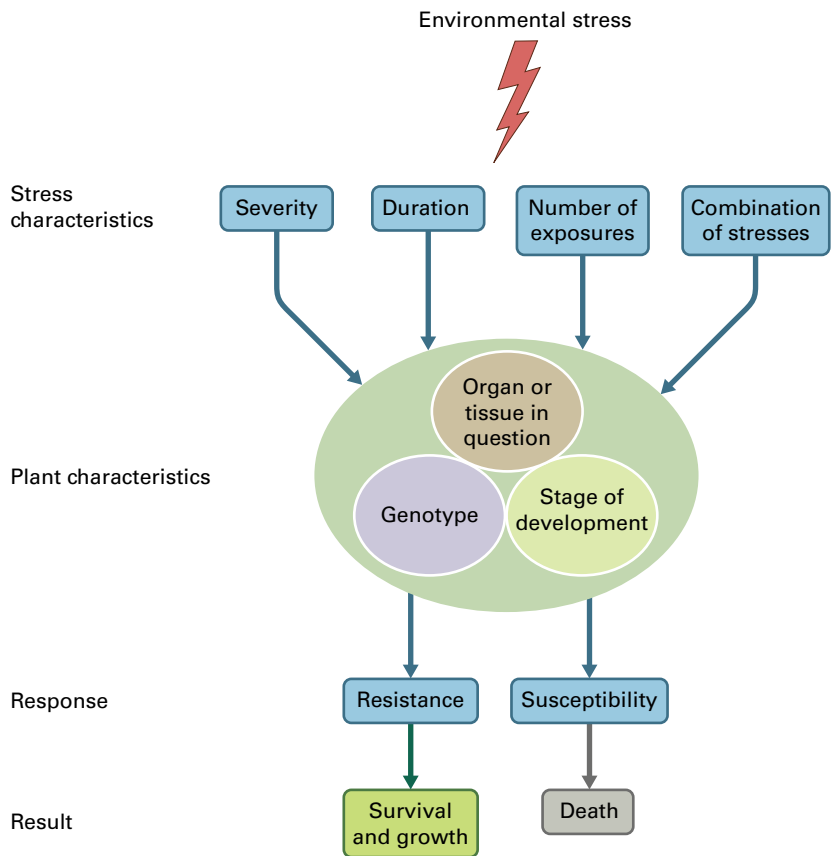

22.1 Plant responses to abiotic stress

22.1.1 Plant stress diminishes crop yield

As human populations grow, agricultural systems must feed more people while competing with urban development for premium arable land. This increasing demand, coupled with shrinking resources, has fueled research into elucidating mechanisms by which plants respond to stress and manipulating these mechanisms to enhance plant productivity in suboptimal environments.

The impact of the environment on plant productivity becomes apparent when record yields are compared to average yields. If record yields are assumed to represent plant growth under ideal conditions, then the losses associated with biotic and abiotic stress can reduce average productivity by 65–87%, depending on the crop. Successful application of biotechnological and classical breeding techniques may lead to stress-tolerant crop plants that enhance world food supplies and provide considerable economic benefit. These crops may promote survival during periods of intense or prolonged stress or maintain high plant productivity under conditions of moderate environmental stress.

FIGURE 22.1 Many factors determine how plants respond to environmental stress: the genotype and developmental conditions of the plant, the duration and severity of the stress, the number of times the plant is subjected to stress, and any additive or synergistic effects of multiple stressors. Plants respond to stress through a variety of mechanisms. Failure to compensate for severe stress can result in plant death.

22.1.2 Resistance mechanisms allow organisms to avoid or tolerate stress

Stress resistance mechanisms can be grouped into two general categories: **avoidance** mechanisms, which prevent exposure to stress, and **tolerance** mechanisms, which enable the plant to withstand stress (Fig. 22.2). Many desert plants are xerophytic—tolerant of water deficits—because their morphological characteristics facilitate survival under arid conditions. A drought-avoidance mechanism—deep roots—provides another class of plants (phreatophytes) with improved access to groundwater. In contrast, desert ephemerals evade drought by germinating and completing their life cycles while adequate water is available. Sunken stomata, light-reflective spines, and deep roots are among the constitutive, genotypically determined traits for stress resistance that are expressed whether the plants are stressed or not. They constitute **adaptations**, evolutionary improvements that enhance the fitness of a population of organisms.

Other resistance mechanisms are achieved through **acclimation**, the adjustment of individual organisms in response to changing environmental factors. During acclimation, an organism alters its **homeostasis**, its steady-state physiology, to accommodate shifts in its external environment. A period of acclimation before stress is encountered may confer resistance to an otherwise vulnerable plant. For example, during the summer, trees in the northern latitudes cannot withstand freezing but many can acclimate and eventually

withstand freezing in winter. Whether based on acclimation or adaptation, successful mechanisms for stress resistance support survival under lethal conditions or maintain productivity under circumstances that impair crop yields.

22.1.3 Gene expression patterns often change in response to stress

Stress-induced changes in metabolism and development can often be attributed to altered patterns of gene expression. A stress response is initiated when a plant recognizes a stress at the cellular level. Stress recognition activates signal transduction pathways that transmit information within individual cells and throughout the plant (Fig. 22.3). Ultimately, changes in gene expression are integrated into a response by the whole plant that modifies growth and development and that may even influence reproductive capabilities. The duration and severity of the stress dictate the scale and timing of the response.

Little is known about how plants recognize stress. Our best insights come from yeast and bacterial proteins that initiate signal transduction in response to abiotic stress, such as low osmotic potential. Though plants likely contain similar proteins, comparable functions have not yet been demonstrated. The intricate signaling pathways that are assumed to participate in altering plant gene expression in response to stress have yet to be elucidated; however, there is considerable

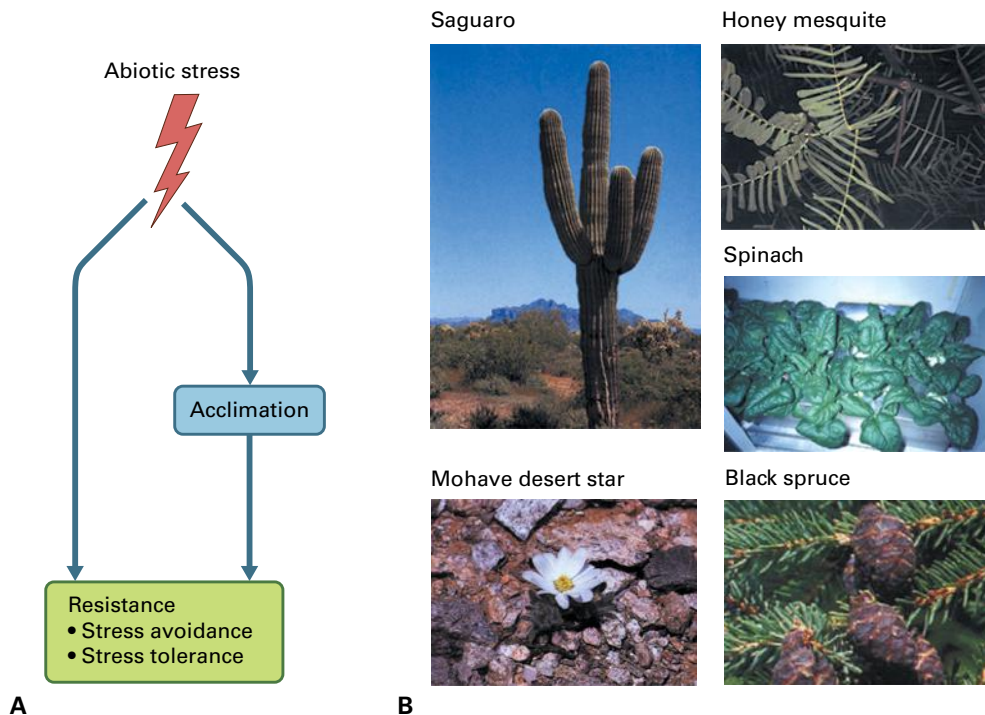

FIGURE 22.2 Stress resistance can involve tolerating or avoiding the stressful condition. (A) Some resistance mechanisms are constitutive and active before exposure to stress. In other cases, plants exposed to stress alter their physiology in response, thereby acclimating themselves to an unfavorable environment. (B) Examples of constitutive mechanisms of drought resistance include the succulent, photosynthetic stem of the saguaro cactus *Cereus giganteus*, a drought-tolerant species; the deep roots of the honey mesquite *Prosopis glandulosa* var. *glandulosa*, a drought-avoiding species; and the wet-season life cycle of the Mohave desert star, *Monoptilon bellioidea*. Examples of acclimation mechanisms include osmotic adjustment (see Section 22.2.3) in plants such as spinach (*Spinacia oleracea*) and freezing tolerance (see Section 22.4) in cold-hardy trees such as black spruce, *Picea mariana* Mill. Source: Epple & Epple (1995). *A Field Guide to the Plants of Arizona*. Falcon Press Publishing, Helena, MT.

FIGURE 22.3 Plants respond to stress both as collections of cells and as whole organisms. Stressors constitute environmental signals that are received and recognized by the plant. After stress recognition, the signal is communicated within cells and throughout the plant. Transduction of environmental signals typically results in altered gene expression at the cellular level, which in turn can influence metabolism and development of the whole plant.

evidence that regulation of plant stress responses involves hormones—especially abscisic acid (ABA), jasmonic acid (JA), and ethylene—and secondary messengers such as Ca^{2+} (see Chapters 17 and 18).

In response to stress, some genes show increases in expression, while others are repressed. Protein products of

stress-induced genes often accumulate in response to unfavorable conditions. The functions of these proteins and the mechanisms that regulate their expression are currently a central topic of research in stress physiology. Although most studies have focused on transcriptional activation of gene expression, accumulation of gene products may also be

influenced by post-transcriptional regulatory mechanisms that increase levels of specific protein-coding mRNAs or noncoding regulatory RNAs, enhance translation, stabilize proteins, and alter protein activity by various types of modifications.

Using molecular genetic techniques, researchers have dissected plant responses associated with exposure to specific abiotic stress. The stresses addressed in this chapter include water deficit, low and high temperatures, hypoxia, and environmental oxidants. Other sources of abiotic stress described elsewhere in this text include nutrient deficiencies and toxic concentrations of aluminum (see Chapter 23), cadmium (see Chapter 16) or other metals. Plant responses to these disparate stresses can incorporate similar or even overlapping strategies, such as the activation or repression of gene expression, production of proteins or compatible solutes, activation of transport activity, etc. In addition, plants are often exposed to simultaneous or sequential abiotic stresses, such as heat and drought, or flooding followed by drought. Interactions between different types of stress, whether synergistic or antagonistic, likely influence the success in coordinating the activity of many genes that together increase abiotic stress survival in crops.

22.2 Physiological and cellular responses to water deficit

22.2.1 Many environmental conditions can lead to water deficit

Water-related stress results if the environment contains excess water or if the quantity or quality of water available is insufficient to meet basic needs. Though periods of little or no rainfall can lead to drought, water deficit can also occur in environments in which water is not limited. In saline habitats, for example, high salt concentrations make it more difficult for plant roots to extract water from the environment. In addition, low temperatures can also result in water stress; exposure to freezing temperatures, for example, can lead to cellular dehydration as water leaves the cell and forms ice crystals in intercellular spaces (see Section 22.4). Occasionally, even plants that have been watered well show periodic signs of water deficit, such as a transient loss of turgor at midday. In this case, wilting indicates that transpirational water loss has exceeded the rate of water absorption. Many factors can affect the response of a plant to water deficit, including the duration of water deficiency, rate of onset, and possible acclimation to water stress by previous exposure. The response of a plant to water deficit can be complex and incorporate many of the strategies and mechanisms of tolerance and resistance used in response to other types of stress; therefore it is addressed first.

22.2.2 Two parameters that describe the water status of plants are water potential and relative water content

Water can be described thermodynamically in terms of its free energy content, also known as its chemical potential. Plant physiologists use a related parameter, **water potential** (Ψ_w ; see Chapter 15, Box 15.1, for a more quantitative discussion of this topic). Such measurements can be used to evaluate the extent to which a cell, organ, or whole plant is “hydrated.”

Equation 22.1: Water potential

$$\Psi_w = \Psi_s + \Psi_p + \Psi_g + \Psi_m$$

The Ψ_w of a plant equals the sum of various component potentials. **Solute potential**, Ψ_s , is dictated by the number of particles dissolved in water. Water potential decreases as solute concentration increases. **Pressure potential**, Ψ_p , reflects physical forces exerted on water by its environment. When water is subjected to negative pressure (tension), Ψ_p is less than 0 MPa (megapascals) and Ψ_w is diminished. (Note that water potential is typically defined in units of pressure rather than energy.) In contrast, water potential is increased by positive pressure (turgor, $\Psi_p > 0$ MPa). **Gravitational potential**, Ψ_g , can have a substantial effect when water is transported over vertical distances greater than 5–10 meters, but this term can be omitted when describing transport between cells or within small plants. A fourth factor, **matrix potential**, Ψ_m , accounts for how solid surfaces (e.g., cell walls and colloids) interact with water and depress Ψ_w . Because Ψ_m values are small and difficult to measure, however, its impact on plant water potential is usually ignored. For conditions under which Ψ_g and Ψ_m are insignificant, the water potential equation is frequently simplified as follows:

Equation 22.2: Water potential (simplified)

$$\Psi_w = \Psi_s + \Psi_p$$

Water potential can be used to predict the movement of liquid water into or out of a plant cell. The difference in water potential across a membrane determines the direction of flow: water moves spontaneously from regions of high water potential to adjoining regions of low water potential.

Physiological or metabolic changes detected in water-stressed plants are not always correlated with changes in plant Ψ_w measurements. To address these issues, a second parameter frequently used to assess water status—**relative water content** (RWC)—is often reported in conjunction with plant Ψ_w measurements.

Equation 22.3: Relative water content

$$\text{RWC} = \left[\frac{(\text{fresh wt.} - \text{dry wt.})}{(\text{turgid wt.} - \text{dry wt.})} \right] \times 100$$

FIGURE 22.4 Osmotic adjustment occurs when the concentrations of solutes within a plant cell increase to maintain positive turgor pressure within the cell. As the cell actively accumulates solutes, Ψ_s drops, promoting the flow of water into the cell. In cells that fail to adjust osmotically, solutes are concentrated passively, but turgor is lost.

When water uptake by roots closely matches water loss by leaves, the RWC of transpiring leaves typically ranges from 85% to 95%. If the RWC for an organ drops below a critical value, tissue death follows. The value for critical RWC varies among species and tissue types, but it is frequently less than 50%.

22.2.3 Osmotic adjustment is a biochemical mechanism that helps plants acclimate to dry or saline soil

While some plants are highly sensitive to water stress and wilt (dehydrate), others can endure dry or saline conditions without evident loss of turgor. To extract water from the soil, a plant root must establish a water potential gradient so that water flows toward the root surface from the soil (i.e., the water potential must be lower in the root than in the surrounding soil). Many drought-tolerant plants regulate their solute potential (Ψ_s) to compensate for transient or extended periods of water stress. This process, called **osmotic adjustment**, results from a net increase in the number of solute particles in the plant cell. The osmolalities achieved through osmotic adjustment exceed those from passive concentration of solutes by dehydration. By decreasing plant Ψ_s , osmotic adjustment can drive root Ψ_w to values lower than soil Ψ_w , thereby allowing water to move from soil to plant down a potential gradient (Fig. 22.4). Osmotic adjustment is believed to play a critical role in helping plants acclimate to conditions of drought or high salinity.

22.2.4 Compatible solutes and aquaporins play roles in osmotic adjustment

One mechanism for osmotic adjustment is the accumulation of **compatible solutes**, or **compatible osmolytes**, a chemically diverse and highly soluble group of organic compounds that do not interfere with cellular metabolism, even at high concentrations (Fig. 22.5).

Synthesis and accumulation of these compounds are widespread in plants, but their distribution varies among species. For example, whereas one such compatible solute, the amino acid proline, is accumulated by a taxonomically diverse set of plants, the quaternary ammonium compound β -alanine betaine appears to be confined to representatives of a few genera of Plumbaginaceae (Leadwort). Stress can trigger the irreversible synthesis of these compounds (for example, glycine betaine; see Section 22.3.4), alter the balance between their synthesis and catabolism (e.g., proline), or trigger their release from polymeric forms (e.g., monomeric sugars like glucose and fructose can be released from their polymeric forms, starch and fructans). Once the stress is removed, these monomers can be repolymerized to facilitate rapid and reversible osmotic adjustment, or they can be metabolized to produce primary metabolites or energy.

Unlike many inorganic solutes, which may become toxic at high concentrations, the organic character of compatible solutes greatly diminishes their potential toxicity. Many ions found in cells adversely affect metabolic processes at high concentrations, possibly by binding to and altering the

FIGURE 22.5 Chemical structures of several important compatible solutes (osmolytes) that accumulate in plant cells in response to water deficit. The organic character and nonionic or zwitterionic nature of compatible solutes greatly diminishes their potential toxicity.

properties of cofactors, substrates, membranes, and enzymes. Furthermore, many ions can enter the hydration shells of a protein and promote its denaturation. In contrast, compatible solutes tend to be neutrally charged at physiological pH, either nonionic or **zwitterionic** (dipolar, with spatially separated positive and negative charges), and are excluded from hydration shells of macromolecules (Fig. 22.6).

In addition to stereotypical charge characteristics, compounds active in osmotic adjustment show distribution patterns that support water potential equilibria among the various membrane-bound compartments of the cell. Vacuoles tend to accumulate charged ions and solutes that would perturb metabolism if present in the cytoplasm. Compatible solutes in the cytoplasm, however, allow the cytosol to achieve osmotic balance with the vacuole.

Another possible mechanism for osmotic adjustment is increasing movement of water into the cell. The hydrophobic nature of the lipid bilayer presents a considerable barrier to the free movement of water into the cell and between intracellular compartments. However, plasma membranes and tonoplasts can be rendered more permeable to water by

proteinaceous transmembrane water channels called **aquaporins** (see Chapter 3). Water movement through aquaporins can be modulated rapidly, and evidence suggests these channels may facilitate water movement in drought-stressed plant tissues and promote rapid recovery of turgor upon watering. The abundance of aquaporin mRNA is correlated with turgor changes in leaves subjected to osmotic stress. Higher transcript levels, enhanced translation, and activation of existing proteins may constitute multiple mechanisms for regulating aquaporin abundance and activity, which may be advantageous for plants coping with water deficit.

22.2.5 Some compatible solutes may have protective functions in addition to osmotic adjustment

The role that compatible solutes play in osmotically stressed plants is often defined as “**osmoprotection**”—solute accumulation is believed to have a protective function against water

FIGURE 22.6 Hydration shells of macromolecules are not disrupted by compatible solutes. Depicted is a protein with a hydration shell (i.e., surrounded by ordered H₂O molecules). Ions such as Na⁺ and Cl⁻ can penetrate these shells and interfere with the noncovalent interactions that maintain the structure of the protein. Unlike ions, compatible solutes, such as proline and glycine betaine, do not penetrate the protein's hydration shell, so protein and solute do not come into direct contact. The hydration shells of the ions and compatible solutes are not shown.

deficit. However, this term should be applied with discretion. Historically, direct physiological evidence for osmoprotection has been obtained for bacteria, but not for plants. Salt-sensitive bacteria, such as *Escherichia coli*, can be induced to grow in high-salt media supplemented with specific compounds, including the osmolytes shown in Figure 22.5. Therefore, the presence of concentrated compatible solutes in drought-tolerant and halophilic (“salt-loving”) plants has been taken as compelling, albeit indirect, evidence for the role of osmolyte in plant osmoprotection.

Compatible solutes that accumulate in plants may also act as antioxidants to minimize the impact of abiotic stress in plants. *In vitro*, many of these compounds directly offset the deleterious, perturbing effects of ions. For example, glycine betaine prevents salt-induced inactivation of Rubisco and destabilization of Photosystem II (PSII). Sorbitol, mannitol, *myo*-inositol, proline, and raffinose can also scavenge hydroxyl radicals *in vitro*, though glycine betaine cannot. This antioxidant activity suggests a protective role for these compounds in osmotic stress tolerance distinct from osmotic adjustment.

22.2.6 Genetic engineering provides an opportunity to test the adaptive significance of compatible solutes

Drought- or salt-sensitive plants can be transformed with genes encoding enzymes that are critical for the synthesis of a putative osmoprotectant. Transformed plants can then be assayed for enhanced accumulation of compatible solutes and ability to adjust osmotically to conditions of drought and high salinity. In fact, biotechnological approaches for enhancing drought tolerance typically involve dissection of the biosynthesis pathways of specific osmolytes and subsequent manipulation of enzymes operating in those pathways. Among the compounds studied to date are proline, glycine betaine, oligosaccharides such as raffinose, and polyhydric alcohols, including mannitol and pinitol. The results from these studies indicate a role for these compounds not only in responses to water and salinity stress, but to other types of abiotic stress as well.

Upon exposure to abiotic stress, many plants accumulate carbohydrates such as mannitol, trehalose, *myo*-inositol, fructan, galactinol, and raffinose. These metabolites not only serve as energy storage but are thought to play roles in balancing osmotic strength, stabilizing macromolecules, and preserving the membrane. Genetic manipulations of key enzymes involved in the biosynthetic pathways of these carbohydrates can improve abiotic stress tolerance in transgenic plants. Metabolite profiling using different types of mass spectrometry has revealed that various types of metabolite, including proline and branched chain amino acids such as valine, leucine, and isoleucine, accumulate in response to abiotic stress and serve a protective function in cells (see Fig. 22.6). The mechanisms that facilitate proline accumulation in response to environmental conditions are discussed in Chapter 7.

Glycine betaine (*N,N,N*-trimethylglycine, GB) is synthesized under various types of environmental stress and functions as a major osmoprotectant. It stabilizes the quaternary structures of the PSII protein-pigment under high salinity and maintains the ordered state of membranes at extreme temperatures. GB is synthesized mainly from choline via betaine aldehyde (BA), with the first and second steps in the pathway catalyzed by choline monooxygenase (CMO) and betaine aldehyde dehydrogenase (BADH), respectively (Fig. 22.7). A wide variety of plant species accumulate GB, but *Arabidopsis*, rice (*Oryza sativa*), and tobacco (*Nicotiana*) are considered “nonaccumulators.” Genetic engineering to introduce GB-biosynthetic pathways into nonaccumulator species is a promising approach to increase abiotic stress tolerance. Transgenic rice plants overexpressing the barley *BADH* gene convert applied BA into GB more efficiently than wild-type plants and exhibit significant tolerance to salt, cold, and heat stress.

Raffinose family oligosaccharides (RFOs), such as raffinose and stachyose and their precursor galactinol, play important roles in drought stress tolerance in plants and seeds. RFOs are important for reducing **reactive oxygen species** (ROS) that accumulate and cause oxidative stress under conditions of

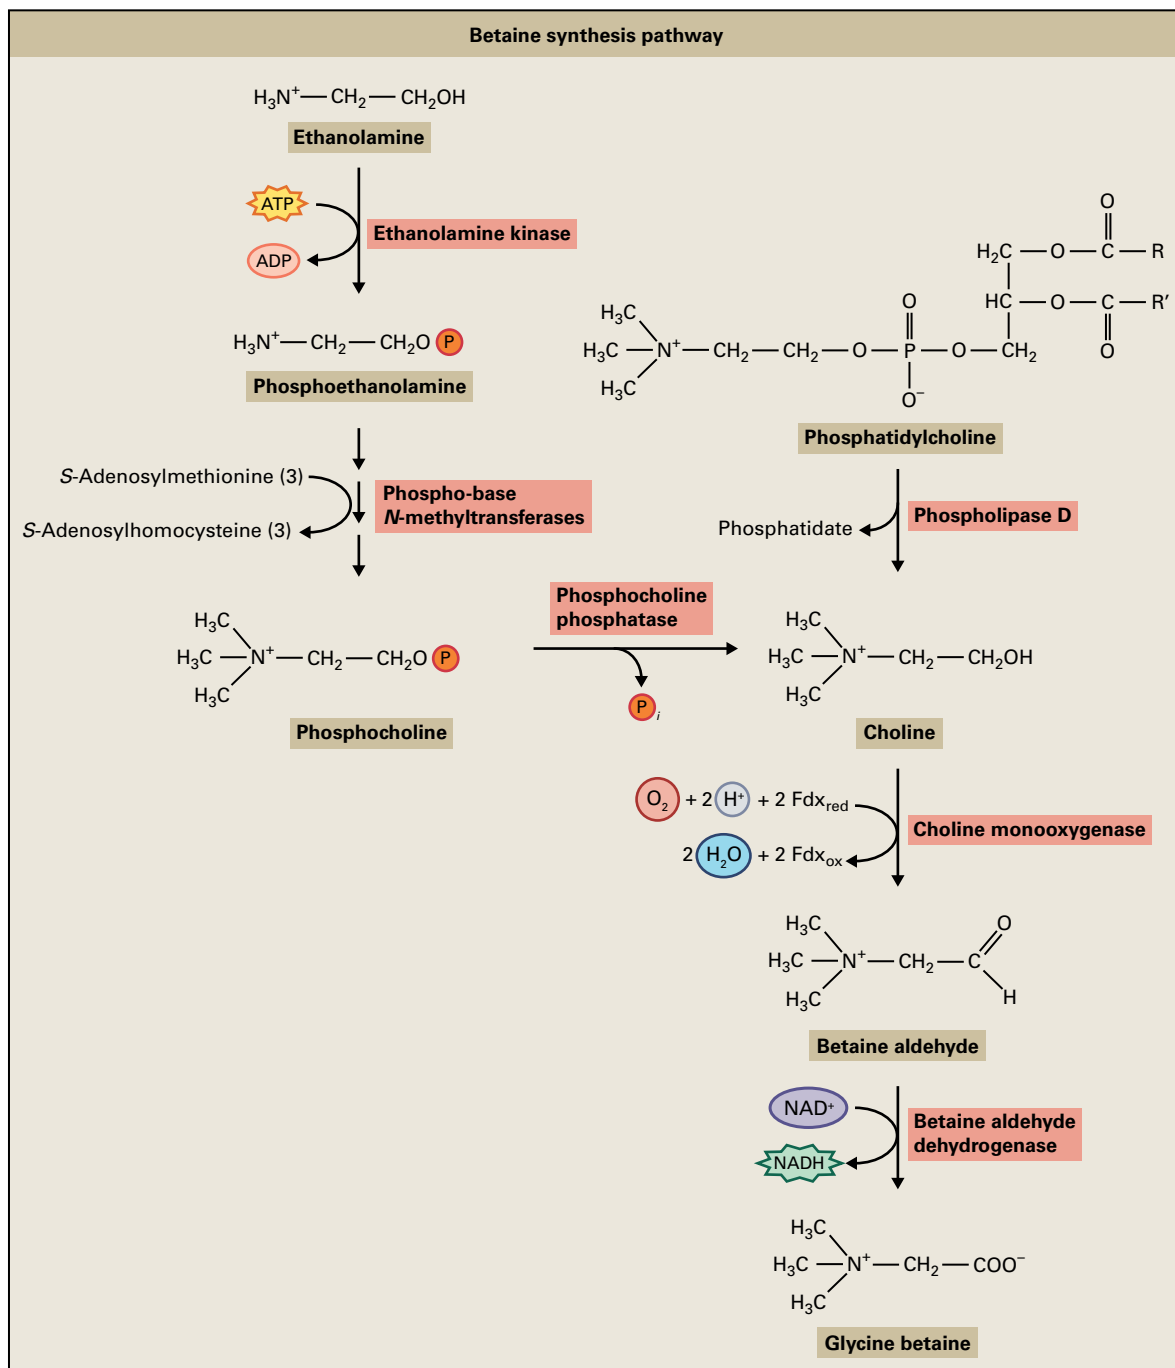

FIGURE 22.7 Proposed biosynthetic pathways of glycine betaine from choline. Introduction of such pathways into nonaccumulator species is a promising approach for increasing abiotic stress tolerance.

abiotic stress. They are synthesized from UDP-galactose (Fig. 22.8), which is converted into galactinol by galactinol synthase (GolS). Raffinose synthase then produces raffinose from the galactinol. Both raffinose and galactinol accumulate in *Arabidopsis* in response to drought, high salinity, and cold stress. These stressors induce expression of the genes for GolS and raffinose synthase, resulting in the production of RFOs. Overexpression of the stress-inducible GolS gene improves drought tolerance by activating the accumulation of galactinol and raffinose in transgenic *Arabidopsis* plants.

22.2.7 Some proteins protect macromolecules and membranes against damage

Large numbers of proteins, such as late embryogenesis abundant (LEA) proteins and heat shock proteins (HSPs), protect plant cells directly against water or osmotic stress damage. They exert their protective effects either as highly hydrophilic proteins that retain water or as molecular

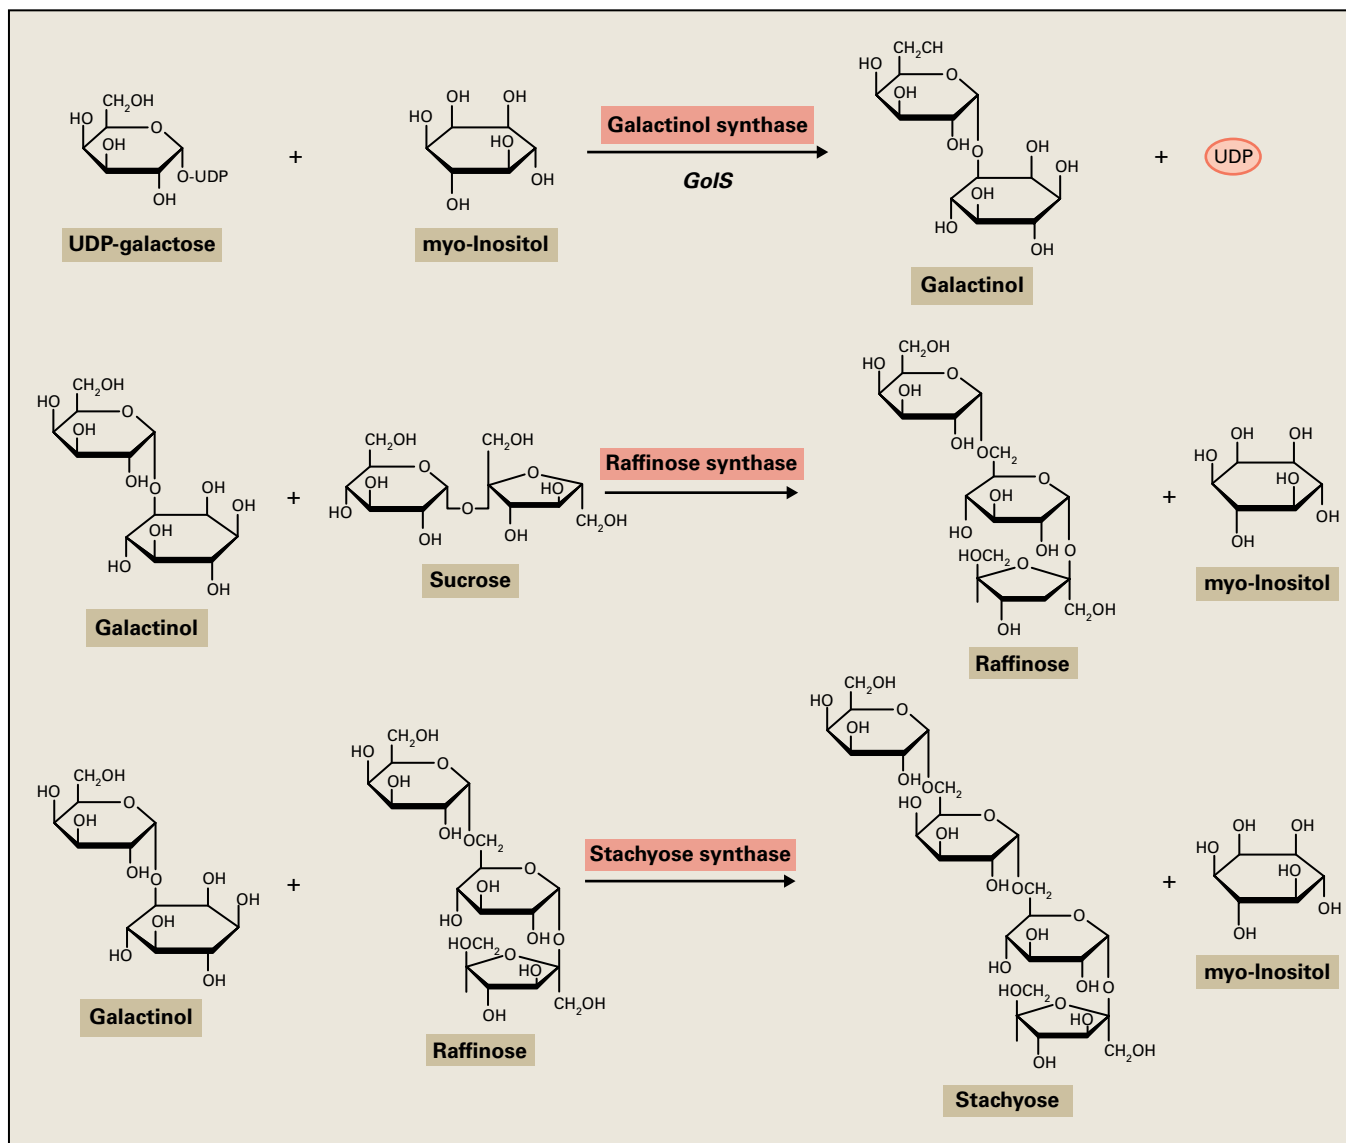

FIGURE 22.8 Biosynthetic pathway for raffinose family oligosaccharides (RFOs). RFOs are osmolytes that also reduce reactive oxygen species that cause oxidative stress.

chaperones that prevent denaturation of macromolecules and protect membranes. Plants exposed to abiotic stress usually express or accumulate higher levels of these proteins, suggesting they are necessary in plant abiotic stress protection in general.

LEA proteins were first reported as a group of proteins produced in abundance during late embryogenesis, with maximum expression during seed desiccation. Their genes have been identified and their mRNAs shown to accumulate during the seed maturation process. Some LEA family genes are also induced by cold, osmotic stress, or exogenous ABA.

Although their precise functions remain unknown, LEA proteins accumulate in stressed plants and are thought to be protective molecules that confer stress tolerance. They are associated with desiccation tolerance in seeds, pollen, and anhydrobiotic plants and may be essential for the survival of plant cells under such conditions. LEA proteins may function

in an unstructured state, with folding and conformational changes induced under conditions of water deficit. LEA proteins become more folded and develop a significant α -helical component when dried. Another hypothesis is that LEA proteins may decrease the collisions between partially denatured proteins, thereby reducing aggregation of exposed hydrophobic domains.

Drought conditions may also induce accumulation of HSPs, which accumulate in plants in response to high temperature stress (see Section 22.7); some genes encoding HSPs are also induced by drought or osmotic stress. HSPs are molecular chaperones with important roles in the folding and assembly of proteins, stabilization of proteins and membranes, protein refolding, and removal of nonfunctional and degraded proteins under conditions of stress. Manipulation of HSP gene expression not only enhances thermotolerance of transgenic plants, but also increases water stress tolerance.

FIGURE 22.9 Ion channels and transporters help maintain ionic homeostasis under conditions of salt stress. Salt treatment increases the activity of Na^+/H^+ antiporters, which then move Na^+ either out of the cell or into the vacuole. For example, salt stress triggers changes in Ca^{2+} , which regulate SOS3, which then regulates SOS2 protein kinase to activate the plasma membrane SOS1 Na^+/H^+ antiporter. Changes in ABA levels also regulate the NHX1 Na^+/H^+ antiporter and other ion transporters. Other transporters that mediate Na^+ transport into the cell include non-selective cation channels (NSCC) and $\text{HKT1}/\text{HKT2}$, the low-affinity cation transporter (LCT1), and K^+ transporters of the $\text{KUP}/\text{HAK}/\text{KT}$ and AKT families. Note that the cell wall is not shown for clarity.

22.2.8 Water deficit and salinity affect transport across membranes

Drought and salt stress both involve acclimation to low water potential; however, plants growing under high salinity must also cope with potentially toxic amounts of specific ions. Although ion uptake may provide a means of osmotic adjustment, high cytosolic concentrations of some ions such as Na^+ perturb metabolism. Thus, regulating the concentration, composition, and distribution of ions within the cell can be an essential feature of tolerance to osmotic stress.

Plants or cultured cells exposed to high NaCl concentrations tend to accumulate Na^+ as a result of Na^+ influx through channels and transporters (Fig. 22.9). Electrophysiological studies have indicated that nonselective cation channels (NSCCs) mediate primary influx of Na^+ under saline conditions, but no definitive candidate molecules have been identified. Other Na^+ transporters identified in plants include the high-affinity K^+ transporter HKT1 , which controls the internal Na^+ distribution between the root and the shoot under saline conditions, and HKT2 , which plays a role in primary Na^+ uptake under K^+ deprivation. Transporters such as the low-affinity cation transporter 1 (LCT1) and K^+ transporters of the K^+ uptake permease/high-affinity K^+ uptake/ K^+ transport ($\text{KUP}/\text{HAK}/\text{KT}$) and *Arabidopsis* K^+ transporter (AKT) families may also participate in Na^+ uptake. Na^+ inhibits a variety of biological processes, including K^+ absorption. Under conditions of salt stress, therefore, plants exclude Na^+ and accumulate K^+ in shoots to maintain a high cytosolic K^+/Na^+ ratio, especially in leaves.

Cytoplasmic Na^+ accumulation is partially prevented by the active export of cytosolic Na^+ across the plasma membrane to the extracellular space and across the tonoplast into the vacuole. In the vacuole, it can accumulate to concentrations that would otherwise have a marked effect on the osmotic

balance of plant cells. Salt treatment increases the activity of vacuolar Na^+/H^+ antiporters in several plant systems, such as sugar beet (*Beta vulgaris*) cultures and barley (*Hordeum vulgare*) roots. Operation of these carriers requires an electrochemical potential gradient across the tonoplast, usually generated through the action of H^+ pumps such as the plasma membrane H^+ -ATPase and vacuolar H^+ -ATPase and H^+ -pyrophosphatase (H^+ -PPase) (see Chapter 3).

Arabidopsis SALT OVERLY SENSITIVE 1 (SOS1) is a plasma membrane Na^+/H^+ antiporter that mediates the passive transport of H^+ into and active transport of Na^+ out of the cell (Fig. 22.9). *Arabidopsis sos1* mutants show an NaCl -hypersensitive phenotype, whereas overexpression of *SOS1* improves salt stress tolerance. Transgenic plants treated with increasing Na^+ concentrations show significant salt tolerance compared to wild-type controls, and this tolerance is due to reduced accumulation of Na^+ .

Na^+ compartmentalization into vacuoles is another mechanism of avoiding high Na^+ toxicity, and the vacuolar Na^+/H^+ antiporter Na^+/H^+ exchanger 1 (NHX1) is important in this process (Fig. 22.9). Transgenic plants overexpressing *NHX1* show increased Na^+ transport into vacuoles and can grow in salty water. Overexpression of *NHX1* in transgenic *Arabidopsis* improves salinity stress tolerance, allowing transgenic plants to grow and produce seeds even in the presence of 200 mM NaCl hydroponic solution (control plants in the same solution die). *NHX* overexpression confers salt tolerance in a wide range of plant species.

22.2.9 The hormone ABA plays an important role in plant response to water deficit

In addition to its roles in seed maturation and germination, the plant hormone abscisic acid (ABA) also plays important roles in plant responses to water deficit (see Chapter 17). ABA

FIGURE 22.10 ABA biosynthesis and degradation in response to abiotic stress. In the final process of the ABA biosynthetic pathway, xanthoxin is cleaved from 9-cis-epoxy-carotenoids by NCED and released from the chloroplast into the cytoplasm. Then, ABA is produced through abscisic aldehyde (ABAld) formation. In ABA catabolism, the major pathway seems to be an oxidative pathway that is triggered by ABA 8'-hydroxylation catalyzed by the CYP707A family. There are other pathways for ABA inactivation, such as glucosylation. Red letters indicate drought stress-responsive regulation. CYP707As are shown in orange, which indicates dehydration and rehydration-responsive regulation. For more details on ABA metabolism see Chapter 17. NCED, 9-cis-epoxy-carotenoid dioxygenase; ABA2, short-chain dehydrogenase/reductase; AAO, abscisic aldehyde oxygenase; ABA3, molybdenum cofactor sulfurase; CYP707A, ABA 8'-hydroxylase; ABA-GTase, ABA glucosyltransferase; AtBG1, β -glucosidase; ABA-GE, ABA glucosyl ester.

is produced in response to water deficit and is involved in stomatal closure, which is required to prevent water loss from leaves under conditions of dehydration. The responses of stomata to water deficit have been studied extensively (see Chapter 3). ABA production is also essential for the cellular accumulation of various metabolites and proteins that have protective roles in water deficit resistance. Moreover, accumulated ABA induces a number of stress genes, the products of which are important for plant responses and tolerance to

dehydration. Endogenous ABA levels—determined by the balance between ABA biosynthesis and catabolism—increase significantly in response to drought or high salinity.

ABA is primarily synthesized *de novo* in response to drought and high salinity, and the genes involved in ABA biosynthesis and catabolism have been identified mainly through genetic and genomic analyses (see Chapter 17). Xanthoxin, a C_{15} precursor of ABA, is produced by direct cleavage of C_{40} carotenoids by 9-cis-epoxy-carotenoid dioxygenase (NCED) in plastids. This step is critical for ABA stress responses (Fig. 22.10, see Chapter 17). NCED is encoded by a multigene family, and the stress-inducible *NCED3* gene plays a key role in ABA biosynthesis under stress conditions. In *Arabidopsis*, overexpression of *NCED3* increases endogenous ABA levels and improves drought stress tolerance, whereas disruption results in defective ABA accumulation under drought stress and impairs drought stress tolerance.

At least two regulatory pathways exist for ABA catabolism: the oxidative pathway and the sugar conjugation pathway. The oxidative pathway is catalyzed by ABA C-8' hydroxylase to produce phaseic acid. This enzyme belongs to a class of cytochrome P450 monooxygenases, the CYP707As (Fig. 22.10), of which there are four members in *Arabidopsis*. Among the four CYP707As, CYP707A3 is a major enzyme for ABA catabolism during the osmotic stress response. The CYP707A3 gene is induced by rehydration after exposure to conditions of dehydration, and CYP707A3 knockout mutants show increased endogenous ABA and dehydration tolerance. In the sugar conjugation pathway, ABA is inactivated in sugar-conjugated forms, such as ABA glucosyl ester, and stored in vacuoles or apoplastic pools (Fig. 22.10). Under conditions of dehydration, ABA is released from the glucosyl ester form by β -glucosidase. Regulation of the genes involved in ABA synthesis and catabolism by transgenic technology can improve drought tolerance.

ABA transport is also thought to be important for plant responses to abiotic stress. *NCED3* is mainly expressed in vascular tissues, and endogenous ABA is mainly synthesized in vascular tissue of leaves. ATP binding cassette (ABC) transporters function as ABA transporters in both the export and import of ABA. Regulation of ABA transport is important for both inter- and intracellular signaling in plants.

22.3 Gene expression and signal transduction in response to dehydration

Water deficit or dehydration can induce or repress the expression of thousands of plant genes with diverse functions. Many products of dehydration-inducible genes function in stress tolerance and responses at the cellular level, and their overexpression can improve stress tolerance, indicating important functions in plant responses and adaptation to dehydration or drought.

22.3.1 Microarray and other techniques provide insights into the expression of dehydration-inducible genes and their predicted functions

Microarray technology employing cDNAs or oligonucleotides (Chapter 9) is a powerful tool for analyzing the gene expression profiles of plants exposed to abiotic stress. Using this technology, many stress-inducible genes have been identified in various plants, and most of these are common among different plants, indicating their general roles in plant stress responses. Analysis of their functions is important for understanding the molecular mechanisms governing plant stress responses and tolerance. Moreover, basic knowledge regarding their functions is useful for enhancing stress tolerance in crops through transgenic technology.

Microarrays and more recently RNA sequencing technologies have been used to identify genes in *Arabidopsis* that are differentially expressed in various organs under various growth conditions, including stress conditions and phytohormone treatment. In addition, coexpression analysis of different transcriptome datasets provides a new method for the discovery of genes with similar expression profiles based on bioinformatics analysis; such genes often have similar functions, and this facilitates elucidation of stress-induced genes of unknown function. Results from these investigations show that many dehydration-inducible genes are also induced by high salinity and ABA treatment, suggesting significant crosstalk between the drought, high-salinity, and ABA response pathways. In contrast, only a small number of drought-inducible genes are also induced by cold stress.

The products of the dehydration-inducible genes identified through recent microarray analyses can be classified into two major groups:

- proteins and enzymes that function in abiotic stress tolerance, such as chaperones, LEA proteins, osmotin, antifreeze proteins, RNA-binding proteins, key enzymes for osmolyte biosynthesis, water channel proteins, sugar and proline transporters, detoxification enzymes, and various proteases
- regulatory proteins, such as protein factors involved in further regulation of gene expression and signal transduction. These include transcription factors, protein kinases, protein phosphatases, enzymes involved in phospholipid metabolism, other signaling molecules, and factors involved in posttranscriptional regulation, such as RNA-processing enzymes.

Many transcription factor genes are stress inducible, suggesting that various transcriptional regulatory mechanisms may function in regulating dehydration, cold, or high-salinity stress signal transduction pathways. These transcription factors control expression of stress-inducible genes, either cooperatively or independently, and may constitute regulatory networks.

Transcriptome analyses at the whole-genome level have also been carried out using high-throughput DNA sequencing and genome tiling arrays (see Chapter 9), and novel mechanisms of transcriptional regulation by noncoding RNAs or micro-RNAs have been reported. Micro-RNAs are involved in post-transcriptional regulation in abiotic stress responses by regulating mRNA stability (see Chapter 6). Sense and antisense RNAs for stress-responsive mRNAs have been reported to function in stress responses. Moreover, gene expression driven by stress often depends on DNA methylation or posttranslational histone modification. Modifications of DNA or histones may play important roles in gene expression and plant growth under stress conditions. Therefore, in addition to gene expression, epigenetic regulation (see Chapter 9) may play an important role in plant adaptation to abiotic stress.

22.3.2 Water deficit triggers changes in gene expression at the transcriptional level

Various transcription factors are important regulatory factors in stress-responsive gene expression. Several act as master switches for the expression of various sets of downstream genes through specific binding to the **cis-acting elements** in their promoters. Corresponding transcription factors have been isolated that bind to *cis*-elements and initiate transcription of target genes. This type of transcription unit is called a “**regulon**.” Analysis of the expression mechanisms of osmotic and cold stress-responsive genes has revealed multiple regulons in transcription. Many plant transcription factors, such as AP2/ERF, bZIP, MYB, MYC, Cys2His2 zinc-finger, and NAC, constitute multigene families involved in stress-responsive gene expression.

Dehydration triggers de novo production of ABA, which in turn induces expression of stress-related genes (see Section 22.2.7). There is evidence for both ABA-dependent and -independent regulatory systems governing stress-inducible gene expression. Many dehydration- and salinity-inducible genes can also be activated by exogenous ABA treatment, but a number of genes are also unaffected by ABA treatment. Promoter regions of dehydration-inducible genes have been analyzed extensively to identify regulatory *cis*-acting elements. Both *cis*- and *trans*-acting regulatory elements functioning in ABA-independent and -dependent gene expression induced by water deficit have been studied in detail.

22.3.3 Endogenous ABA accumulation under dehydration stress also controls gene expression

Analysis of ABA-responsive promoters has revealed a diverse range of potential *cis*-acting regulatory elements, but most ubiquitous *cis*-elements share the (C/T)ACGTGGC

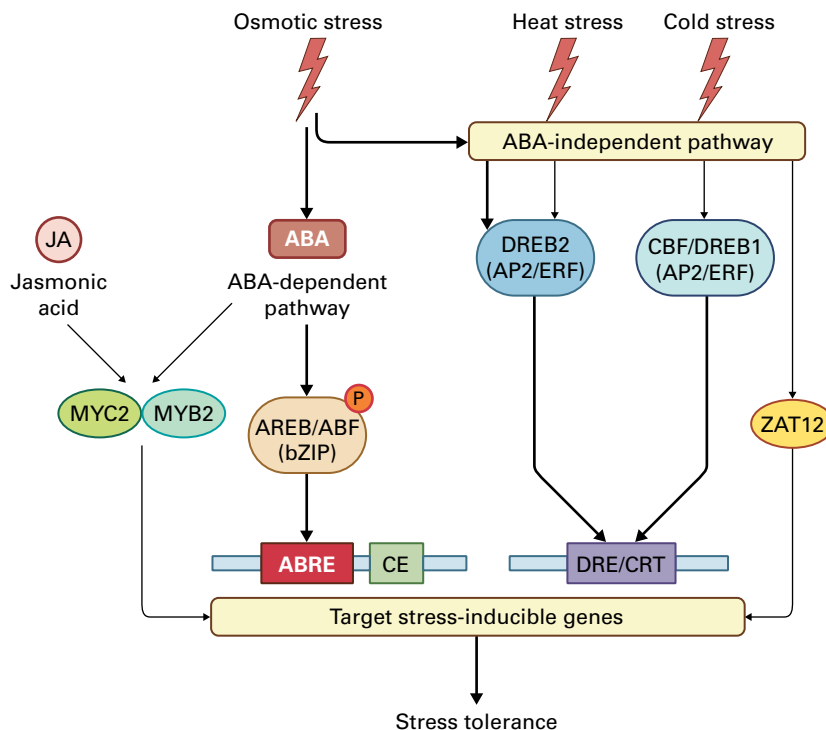

FIGURE 22.11 Overlapping transcriptional regulatory networks in plant responses to osmotic, heat, and cold stress. Transcription factors and cis-acting elements are shown in ovals and boxes, respectively. ABA-dependent pathway (shown in red): ABRE is a key cis-acting element of genes regulated by ABA-dependent stress responses. The coupling element (CE) is necessary for ABA-dependent transcription. AREB/ABF are major transcription factors in the ABA response, and are phosphorylated for their activation (see Fig. 22.12). MYC2 is not only regulated by ABA, but also by jasmonic acid (JA) and functions in crosstalk between ABA and JA responses (see Section 22.8). MYB2 is induced by ABA and functions in cooperation with MYC2 in dehydration-inducible gene expression. Other transcription factors have been identified in abiotic stress response but are not shown. ABA-independent pathways (shown in blue): DRE/CRT is a key cis-acting element of genes regulated by ABA-independent stress responses. CBF/DREB1s are major transcription factors in the cold stress response, whereas DREB2 is mainly regulated by osmotic and heat stress. CBF/DREB1 is explained in Section 22.4.7. The roles of ZAT12 in the cold stress response and DREB2 in the heat response are described in Sections 22.4.7 and 22.7.5, respectively.

consensus sequence, the **ABA-responsive element** (ABRE; PyACGTGGC). ABRE is a major *cis*-acting element in ABA-responsive gene expression (Figs. 22.11 and 22.12) that requires another *cis*-acting element, the **coupling element** (CE), for function. The basic leucine zipper (bZIP) transcription factors AREB and ABF can bind to the ABRE *cis*-acting element to activate ABA-dependent gene expression.

The AREB and ABF transcription factors require an ABA-mediated signal for activation, as indicated by their reduced activity in the ABA-deficient *aba2* and ABA-insensitive *abi1* mutants and their enhanced activity in the ABA-hypersensitive *era1* mutant of *Arabidopsis*. This is due to the ABA-dependent phosphorylation of AREB and ABF proteins by the SNF1-related protein kinases SnRK2s (Fig. 22.12 and see Section 22.3.5). Transgenic plants expressing an active form of AREB1 with multi-site mutations show induction of many ABA-responsive genes without application of exogenous ABA. These observations indicate an important role of protein phosphorylation in the activation of AREB and ABF transcription factors in response to increased levels of endogenous ABA under osmotic stress conditions. In addition to the AREB and ABF bZIP transcription factors that function as key regulators of ABA-dependent gene expression, various

transcription factors with MYB2, MYC2 (bHLH), NAC, HD-ZIP, HD, HB, AP2, and B3 domains are involved in ABA responses under osmotic stress conditions (see Section 22.8). Among them, MYB2 and MYC2 are involved in stress-regulated gene expression after the accumulation of ABA. MYC2 is also important in jasmonic acid (JA)-regulated gene expression (see Fig. 22.11).

22.3.4 ABA-independent pathways can also influence the abiotic stress response and DREB2 transcription factors

The promoters of genes such as *RD29A* and *COR15*, which induced by dehydration, high salinity, and cold, contain two major *cis*-acting elements, ABRE and DRE (**d**ehydration-**r**esponsive **e**lement)/CRT (**C**-**R**epeat), both of which are involved in stress-inducible gene expression (Figs. 22.11 and 22.12). Whereas ABRE functions in ABA-dependent pathways, DRE/CRT functions in ABA-independent gene expression in response to abiotic stress (Fig. 22.12); it also contains the conserved *cis*-acting promoter motif A/GCCGAC.

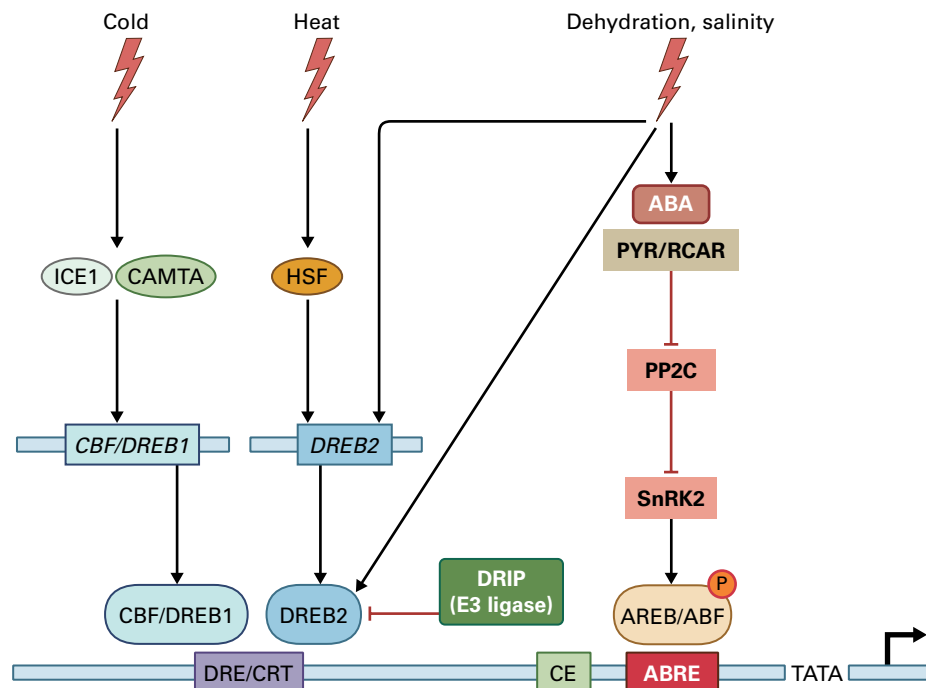

FIGURE 22.12 Function of cis-acting elements DRE/CRT and ABRE in ABA-independent and -dependent induction of RD29A, respectively. AP2/ERF transcription factors CBF/DREB1 and DREB2 bind DRE/CRT in response to different types of stress: CBF/DREB1 functions in cold-inducible gene expression, and their genes are regulated by the transcription factors ICE1 and CAMTA (see Section 22.4.7). DREB2 is involved in dehydration- and salinity-inducible gene expression and is activated by protein stabilization. AREB/ABFs are bZIP transcription factors that bind ABRE/CE and mediate ABA-dependent gene expression (see Fig. 22.11). Major ABA signaling cascades (involving ABA receptors PYR/RCARs, PP2C phosphatases, and SnRK2 protein kinases) function upstream of AREB/ABF transcription factors (see Section 22.8). The function of CBF/DREB1 in cold response is also described in Section 22.4.7, and the function of DREB2 in heat response is also described in Section 22.7.5.

Two transcription factors belonging to the AP2/ERF family, CBF/DREB1 and DREB2, bind to the DRE/CRT element. The genes encoding CBF/DREB1 are rapidly and transiently induced by cold stress, and their products activate expression of target stress-inducible genes (see Section 22.4.7); expression of DREB2, on the other hand, is mainly induced by dehydration, high salinity, and heat stress.

Overexpression of CBF/DREB1 in transgenic plants increases tolerance to drought, freezing, and salt stress, suggesting the CBF/DREB1 proteins function in the development of cold stress tolerance without posttranslational modification (Fig. 22.13A). Overexpression of DREB2 in transgenic *Arabidopsis* plants, though, does not improve stress tolerance, which suggests the involvement of post-translational activation of DREB2 proteins.

Deletion of a region of 30 amino acids adjacent to the AP2/ERF DNA binding domain, named the DREB2A negative regulatory domain (NRD), transforms DREB2A into the constitutively active form DREB2A-CA, which interacts with an E3 ubiquitin ligase (DRIP: DREB2 interacting protein 1). Posttranslational regulation may be necessary for stabilization of the DREB2A protein. *Arabidopsis* DREB2A target genes are induced to a significantly greater extent by dehydration stress than by cold stress (see Fig. 22.12).

Preference of DNA-binding activities has been compared between the DREB2A and DREB1A protein. Whereas DREB2A binds preferentially to the sequence ACCGAC, DREB1A shows affinity for the A/GCCGACNT sequence. These data indicate that the function of the DREB2-type transcription factor in the drought stress response is different from that of the DREB1 protein involved in the cold stress response (Fig. 22.13B). DREB2A is also involved in responses to heat and drought stress, as discussed in Section 22.8.

Transgenic plants that overexpress various transcription factors have more abiotic stress tolerance. For example, overexpression of the rice (*Oryza sativa*) NAC transcription factor SNAC1 improves drought tolerance of transgenic rice and induces expression of a large number of stress-regulated genes. Another good example involves the NF-Y transcription factor family; transgenic maize (*Zea mays*) plants overexpressing ZmNF-YB2 exhibit tolerance to drought based on various stress-related parameters including chlorophyll content, stomatal conductance, leaf temperature, reduced wilting, and maintenance of photosynthesis. Moreover, maize plants overexpressing ZmNF-YB2 have better grain yield under conditions of drought stress (Fig. 22.14). Constitutive or conditional expression of transcription factors has great potential for the development of drought-tolerant crops.

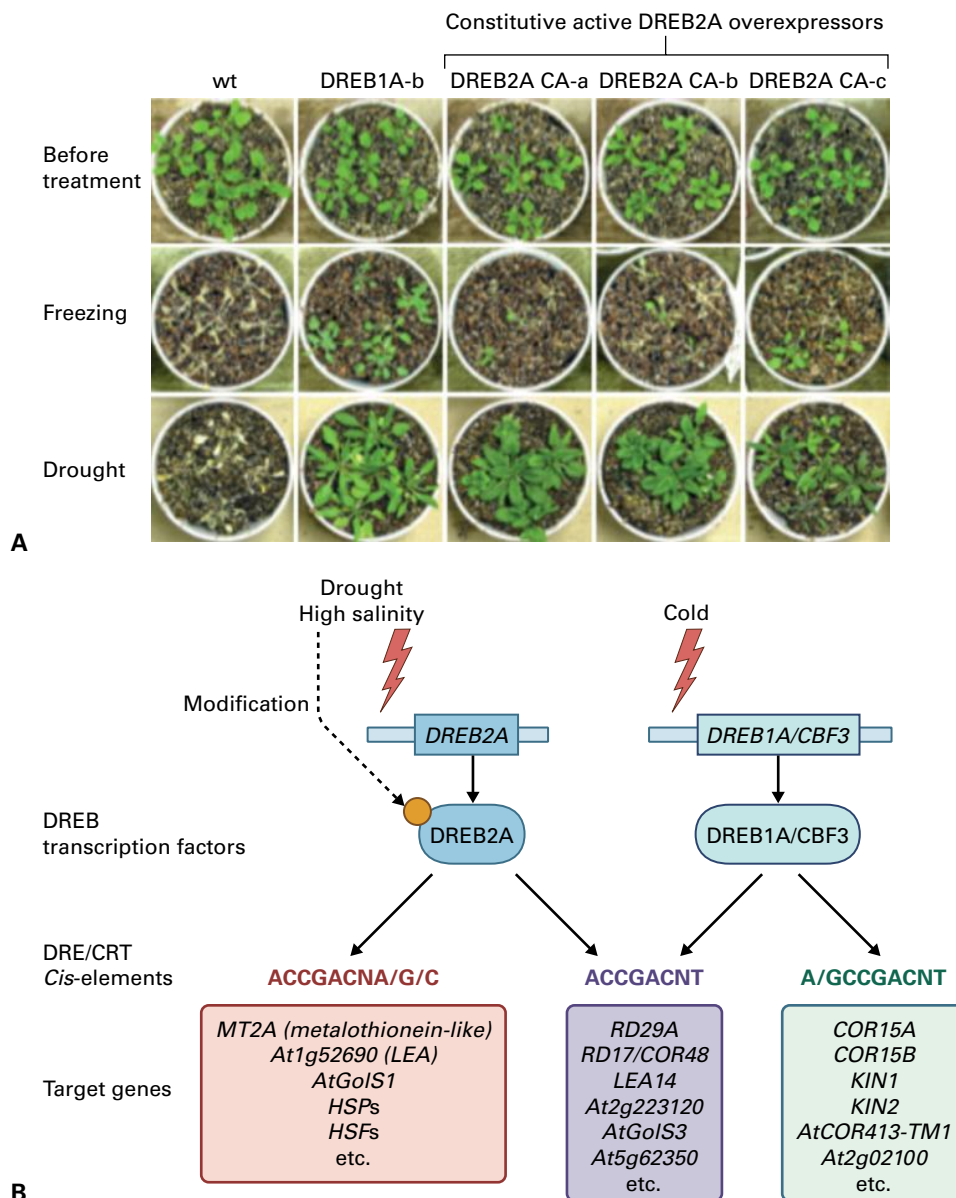

FIGURE 22.13 Arabidopsis CBF/DREB1 and DREB2 mediate overlapping and unique pathways of resistance to freezing, drought, and salt stress. (A) Transgenic Arabidopsis plants that overexpress DREB1 or the constitutively active form of DREB2 (DREB2-CA) show tolerance to both drought and freezing stress. (B) Model of the induction of genes regulated by DREB1 and DREB2A under drought, salinity, and cold stress. The genes downstream of DREB1 and DREB2A are categorized into three groups. The center group contains genes shared by DREB1A and DREB2A, and the other groups consist of DREB1A- and DREB2A-specific genes. Source: Sakuma et al. (2006). Plant Cell 18:1292–1309.

22.3.5 Osmotic stress triggers various signaling pathways in plants

Though changes in transcriptional regulation in response to osmotic stress have been analyzed extensively, their cellular signal transduction pathways are not yet fully understood. Our current understanding of cellular signal transduction in the osmotic stress response has been based largely on knowledge obtained from analysis of yeast and other microorganisms. Protein kinase homologs have been identified based on their functions in stress signaling pathways (Fig. 22.15). Genetic

screening of mutants showing abnormal responses to abiotic stress, either resistance or sensitivity, has been performed to isolate factors involved in stress responses and signaling pathways.

Stress signaling involves modification of regulatory proteins through phosphorylation and dephosphorylation, ubiquitination, and calcium binding. These groups of regulatory proteins are modified or activated to fulfill their functions quickly. Although the complexity of this signal transduction network is still not completely understood, several types of protein kinase and calcium-sensing proteins have been characterized, and their functions have also been investigated in transgenic plants.

A

B

FIGURE 22.14 Transgenic maize (*Zea mays*) plants that overexpress *ZmNF-YB2* (plants at right) grown in a greenhouse (A) and a test field (B) show significantly improved drought tolerance. The rice (*Oryza sativa*) actin gene promoter was used to overexpress *ZmNF-YB2 cDNA*.

Osmotic stress sensors have been analyzed in bacteria and yeast. In yeast, the **His-Asp phosphorelay system** functions in sensing osmotic stress. The membrane-bound histidine kinase Sln1p functions as an osmosensor, and the *Arabidopsis* histidine kinase AHK1 can complement a yeast *sln1* mutant, indicating AHK1 also functions as an osmosensor in yeast. In addition, AHK1 protein functions as a positive regulator in water deficit and osmotic stress signaling in plants (Fig. 22.15). Transcriptional profiling analysis of *ahk1* knockdown mutants has revealed that some target genes of AREB1, ANAC, and DREB2A transcription factors are downregulated in the mutant. In contrast, transgenic *Arabidopsis* overexpressing *AHK1* driven by its own promoter show markedly improved drought stress tolerance. The response regulator-like factors (ARRs) are thought to function downstream of AHK1 in osmotic stress signaling pathways like the yeast His-Asp osmosensing phosphorelay system Sln1p-Ypd1p-Ssk1p.

The **mitogen-activated protein kinase (MAPK)** cascade functions in various cell signaling cascades (see Chapter 18), including osmotic stress responses in eukaryotes. It is characterized by a three-step phosphorylation relay by MAPK, MAPK kinase (MAPKK), and MAPKK kinase (MAPKKK) on conserved threonine, tyrosine, and serine residues (see Chapter 18). In yeast, the HOG1 pathway (Ssk2/22p-Pbs1p-Hog1p) is a MAPK cascade that functions downstream of Sln1p-Ypd1p-Ssk1p. In plants, MAPK cascades are rapidly activated by various environmental stresses and pathogen infection. The *Arabidopsis* MEKK1-MKK2-MPK4/MPK6 cascade is activated by salinity and also cold stress, and plays a role in cellular stress signaling pathways (Fig. 22.15). These observations suggest that MAPK cascades function in abiotic as well as biotic stress signaling. However, the upstream signaling components in plants have yet to be determined.

ROS are produced in response to reduced metabolic activities of chloroplasts and mitochondria in biotic and abiotic stress responses (see Section 22.6). Factors involved in signal transduction pathways may function as ROS sensors to control downstream events. ROS regulate transcription factors, such as the heat shock factors (HSFs) involved in the heat stress response (see Section 22.7) and NPR1 involved in disease resistance. Protein kinases such as SOS2 and ANP1 and heterotrimeric G proteins are also regulated by ROS. Therefore, ROS can modulate abiotic stress signaling pathways and function in crosstalk in stress signaling (see Section 22.8).

Of the many second messengers involved in cell signaling pathways, Ca^{2+} is the most ubiquitous (see Chapter 18). In plants, Ca^{2+} levels increase transiently in response to various stimuli, including water deficit. Osmotic stress can trigger rapid and dynamic oscillations in cytosolic Ca^{2+} levels that are mediated by various Ca^{2+} channels and transporters (Fig. 22.15). The Ca^{2+} -dependent stress signaling pathway is important in plants and is mediated by calcineurin B-like (CBL) proteins and their downstream CBL interacting protein kinases (CIPK). CBL proteins bind Ca^{2+} via a helix-loop-helix structure motif (the EF hand), and function as Ca^{2+} signal sensors under conditions of stress in plants. The specific interactions of different CBLs with CIPKs can transmit signals to downstream proteins such as transcription factors by protein phosphorylation to activate the plant stress response. The major component in this signaling pathway is SOS3/CBL4 and its interactive partner SOS2/CIPK24. Disruption of either or both of these genes results in the severe “salt overly sensitive” (SOS) phenotype, suggesting an important role of the SOS3-SOS2 protein kinase cascade in salinity stress signaling pathways (see Fig. 22.9).

Calcium-dependent protein kinases (CDPKs) are well characterized and are also of particular interest in plant calcium-mediated signal transduction (Fig. 22.15). CDPKs have both a kinase domain and a calmodulin-like domain in a single protein. CDPKs phosphorylate their respective substrates to transduce perceived signals, and binding of calcium can stimulate their protein kinase activity.

The identification of protein kinases that activate AREB and ABF transcription factors is important for understanding

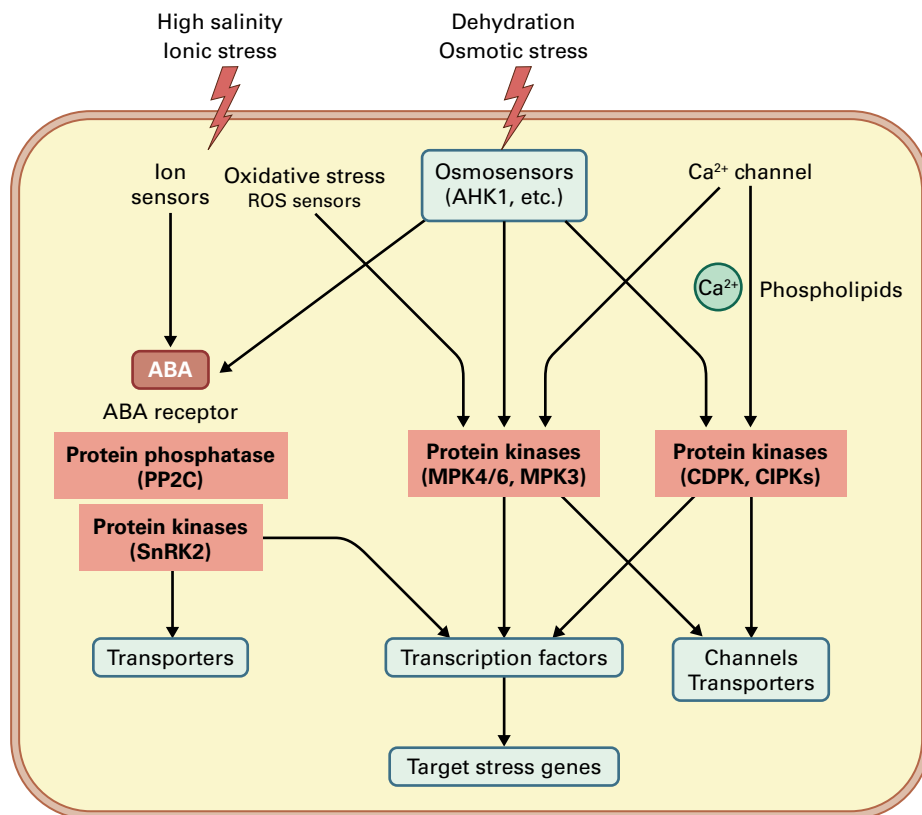

FIGURE 22.15 Cellular signal transduction cascades in response to high salinity and water deficit. Osmotic change, ionic stress, cold stress (not shown) and reactive oxygen species trigger stress responses, and many stress sensors have been identified. ABA is an important mediator of stress signals, and Ca^{2+} and phospholipids are second messengers in stress signaling pathways. Protein phosphorylation plays important roles in stress and ABA signal transduction pathway, and involves a number of different protein kinases, including SnRK2 in the ABA response, and MAP kinase, calcium-regulated protein kinases, and two-component histidine kinase in the osmotic stress response. Transcriptional regulation is most important for the regulation of stress genes, whose products function in both stress response and stress tolerance. In addition, the activities of various types of transporters are required for homeostasis during stress conditions.

upstream ABA signaling pathways. One ABA-activated SnRK2 protein kinase (OST1/SRK2E/SnRK2.6) functions in the ABA signal transduction pathway controlling stomatal closure (Fig. 22.15). SnRK2 is a member of the SNF1-related protein kinase family, which contains ten members in *Arabidopsis* and rice. SnRK2s are activated by dehydration, salinity, and ABA. Several SnRK2s of various plants can phosphorylate AREB and ABF or related proteins in vivo and in vitro, indicating that SnRK2s are upstream factors of AREB and ABF. A triple loss-of-function mutant of *Arabidopsis* SnRK2.6, 2.2, and 2.3 exhibits a strong growth defect, which is related to ABA responses such as germination, stomatal closure, and root growth. These three SnRK2 proteins are repressed by ABI1-related PP2C protein phosphatases, which are major negative components in the ABA signaling pathway. The ABI1-related PP2Cs directly and negatively regulate the activities of these three SnRK2 via dephosphorylation.

The pyrabactin resistance (PYR)/PYR-related (PYL)/regulatory component of ABA receptor (RCAR) family of ABA receptors (**PYR/PYL/RCAR protein family**) have ABA-binding activity and inhibit PP2C activity by ABA-

mediated interaction (Fig. 22.16). Furthermore, ABA-activated SnRK2 protein kinases are inhibited in loss-of-function mutants of PYR/PYL/RCARs. A signaling complex of PYR/PYL/RCAR, PP2C, and SnRK2 is important for ABA perception and the initial signal transduction process. PYR/PYL/RCARs function as cytoplasmic ABA receptors and inhibit PP2C-mediated inactivation of SnRK2 in an ABA-dependent manner (Fig. 22.16). Under normal growth conditions without ABA, PP2C inhibits SnRK2 by direct binding and dephosphorylation of SnRK2. In response to abiotic stress, endogenous ABA is synthesized and binds to the PYR/PYL/RCAR receptor, and ABA-bound PYR/PYL/RCAR inhibits PP2C activity. This activates SnRK2, which then phosphorylates its target proteins, such as AREB/ABF bZIP transcription factors and ion transporters. The structure of the ABA-PYR/PYL/RCAR-PP2C complex was determined by X-ray diffraction (Fig. 22.17). An ABA-bound receptor is capable of competitively inhibiting the phosphatase activity of PP2C. Perception of ABA and its stream signal transduction are fully understood at the molecular level to illustrate the precise molecular switch of ABA signaling (Fig. 22.16).

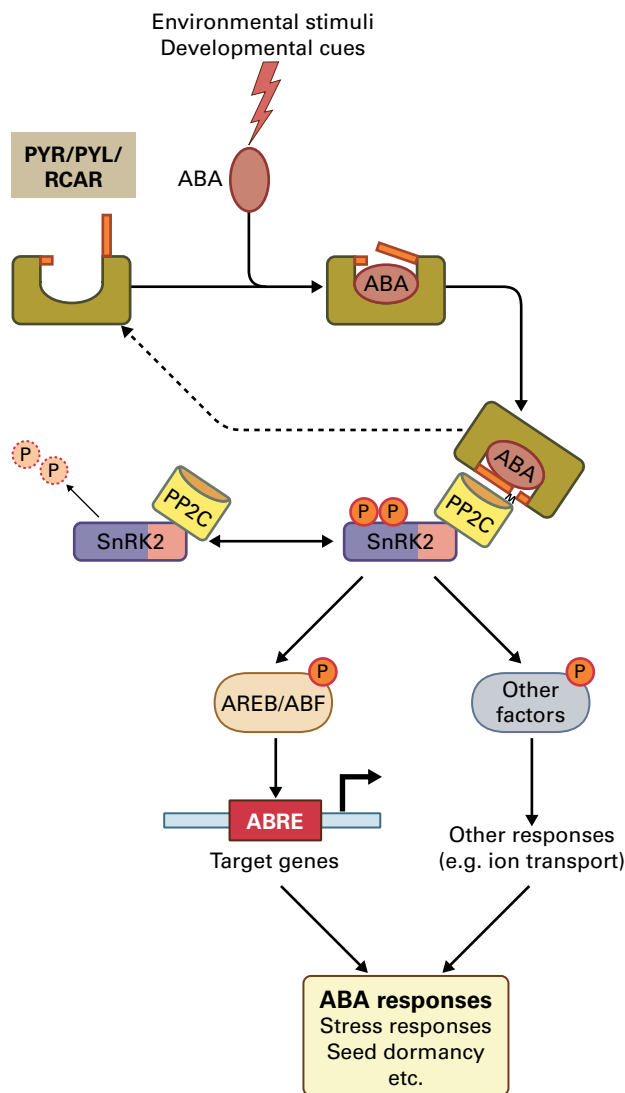

FIGURE 22.16 Proposed model of the early process of ABA perception and signal transduction. PYR/PYL/RCAR functions as an ABA receptor, and PYR/PYL/RCAR, PP2C phosphatase and SnRK2 protein kinase form a signaling complex. In the absence of ABA, PP2C binds to and inactivates SnRK2. In the presence of ABA under abiotic stress conditions, PYR/PYL/RCAR binds to ABA and inhibits PP2C activity. Then, SnRK2 is released from the inhibition by PP2C and activated to phosphorylate downstream transcription factors, including AREB/ABFs and transporters. These activated proteins then function in cellular and molecular responses to abiotic stress in an ABA-dependent manner.

22.3.6 Genetic screens have identified stress signaling proteins

Genetic analyses have also revealed genes involved in the signal transduction pathways that control stress-responsive gene expression. Various mutants with tolerance to abiotic stressors have been isolated and some of the mutant genes have been identified. For example, SOS mutants were isolated by screening salinity-hypersensitive mutants with root response to salinity stress, and the gene encoding a CIPK/

SnRK3 protein kinase was identified (see Section 22.3.5). In addition, genetic screens have been carried out using various reporter gene constructs to identify mutants with altered expression of stress-induced genes (see Box 22.1).

22.4 Freezing and chilling stress

22.4.1 Freezing and chilling stress have both similarities and differences

Freezing and chilling stress impose both direct and indirect effects on plant health. Direct effects include solidification of membrane lipids and reductions in enzymatic reaction rates, and these occur over a relatively short time. Indirect (or secondary) injury symptoms, on the other hand, appear gradually over time and include solute leakage from cells, respiration and photosynthesis imbalance, ATP depletion, accumulation of toxic substances, and wilting by water loss (see Chapter 8).

Both freezing and chilling stress are associated with some form of cellular injury caused by the direct effects of low temperature; however, freezing stress has several additional indirect effects due to ice crystal formation and growth in extracellular compartments that can damage plants at the whole-plant, tissue, and cellular levels. In addition, freezing of water in the extracellular spaces results in osmotic dehydration and, therefore, increases in solute concentrations inside the cell. These damaging effects together markedly affect plant performance, and susceptible plants will die. Another difference between the two forms of temperature is the time effect: while chilling injury occurs some time after exposure of plants to the stress (the period differs between plants, organs, tissues, and developmental stage), freezing injury may be visible instantly after freezing occurs. Thus, these two low-temperature stressors must be considered distinct and analyzed individually with suitable methods.

22.4.2 Chilling stress causes membrane destabilization and metabolic dysfunction

Membrane lipids maintain a fluid (liquid crystalline) phase at normal, warm temperatures, which ensures maintenance of cellular function (see Chapter 8). When the temperature decreases, however, lipids with high melting temperatures begin to solidify (gel phase) and become phase-separated within the membrane. Membranes become leaky or otherwise dysfunctional, intracellular water and solutes are lost, and membrane-associated reactions such as carrier-mediated transport, enzyme-mediated processes, and receptor function are inactivated.

Although low temperature affects plant cells in many different ways, one of the most important is its effect on photosynthesis. Low temperature markedly impairs the electron transport chain while showing little effect on

FIGURE 22.17 Three-dimensional structure of the complex of ABA-bound PYR/PYL/RCAR (ABA receptor) and ABI1 (PP2C). PP2C is represented by both a ribbon (left) and surface (right) model. ABA-bound PYL1 can competitively inhibit the phosphatase activity of PP2C using the gate loop like a plug.

photoenergy reception. As a result, chloroplasts are exposed to excess excitation energy, and photoreduction of oxygen molecules occurs with concomitant production of ROS (see Section 22.7). The resultant oxidative stress with increased free radical levels damages membrane lipids and proteins as well as macromolecules in chloroplasts.

The development of injury symptoms sometimes becomes more apparent after a return to normal temperatures. At low temperature, the development of symptoms requires a long time, and injury may not advance due to the slow rate of the dysfunctional process. Several studies have shown that chilling injury occurs due to the lack of or impaired cellular recovery functions. Although the D1 protein, a major component of the PSII reaction center, is affected at low temperature, the major cause of chilling injury to the PSII is the lack of recovery from damage caused by ROS after returning to warmer temperatures. ROS scavengers such as glycine betaine, a compatible solute (Figure 22.5), may increase the efficiency of PSII metabolic turnover during the recovery process from abiotic stressors. This hypothesis is supported by genetic engineering studies that indicate overexpression of ROS-scavenging enzymes improves low temperature tolerance.

22.4.3 Freezing also causes membrane destabilization and damage due to osmotic and mechanical stress

As explained in Section 22.4.1, freezing has a marked impact on cellular water and causes a type of water deficit stress that distinguishes it from the effects of chilling. The chemical

potential of ice is lower than that of unfrozen water. In addition, the vapor pressure of extracellular ice is lower than that of the water in the cytoplasm or vacuole. As ice forms in extracellular compartments, the cellular water moves down the water potential gradient, across the plasma membrane and toward the extracellular ice (Fig. 22.18). As a result, cell volume decreases and intracellular solute concentration increases; extracellular ice formation also distorts the shape of cells. These types of stress persist as long as freezing continues, and they even increase when temperature decreases, causing further injury to plant cells.

The plasma membrane is the primary site of freezing-induced injury, and much of the damage involves membrane destabilization caused by cellular dehydration. Membrane structures and interactions are altered when freezing-induced dehydration brings the plasma membrane into close apposition with the membranes of organelles, such as the chloroplast, leading to membrane destabilization. Membrane destabilization results in distinct forms of injury in some plants, such as expansion-induced lysis, loss of osmotic responsiveness associated with lamellar-to-hexagonal II phase transition in less tolerant (nonacclimated) cells, and loss of osmotic responsiveness associated with fracture-jump lesion in more tolerant (cold-acclimated) cells (Fig. 22.19).

Membrane destabilization also results from the osmotic and mechanical stress imposed during freeze-thaw cycles. Osmotic dehydration increases solute concentrations in the cytoplasm and other intracellular compartments, and this can inactivate membrane-associated enzyme and transporter activities. Direct interaction of solutes with the membrane results in dissociation of membrane proteins due to changes in electrostatic and hydrophobic interactions. In addition,

FIGURE 22.18 Exposure of plants to freezing temperatures causes a cellular water deficit as water travels down its potential gradient, crossing the plasma membrane into the cell wall and intercellular spaces. When the rate of freezing is sufficiently slow to prevent formation of ice crystals in the cytoplasm, the cell dehydrates and freezing occurs in the apoplast.

FIGURE 22.19 Freezing-induced lesions associated with the plasma membrane in isolated protoplasts. (A) When a suspension of protoplasts isolated from nonacclimated plants is frozen, freezing-induced dehydration occurs in the protoplast, gradually reducing protoplast volume. To maintain membrane tension, the plasma membrane must be removed from the surface of the protoplast, and this is accomplished through formation of endocytotic vesicles that are not continuous with the plasma membrane. Under mild but injurious dehydration conditions, the protoplasts cannot expand during thawing due to the lack of the plasma membrane materials, resulting in expansion-induced lysis. (B) When severe freezing-induced dehydration occurs at lower temperature, the plasma membrane of the protoplast is brought into close apposition to endomembranes, ultimately resulting in irreversible ultrastructural changes of the lipid bilayers (such as lamellar-to-hexagonal II phase transition) due to membrane–membrane interactions. Consequently, the protoplast does not respond osmotically when thawed (loss of osmotic responsiveness). (C) In protoplasts isolated from cold-acclimated plants, freezing-induced dehydration results in the reduction of their volume, but the plasma membrane forms exocytotic extrusions that are continuous with the plasma membrane. No lysis occurs upon thawing of protoplasts that were frozen at any temperature. Membrane–membrane interactions occur when the protoplast is subjected to severe freezing-induced dehydration, but a distinct structure associated with the plasma membrane, the fracture-jump lesion (FJL), occurs. The FJL is a result of membrane–membrane fusion and is manifested as a jump of the fracture plane from one membrane to the other in freeze-fracture electron micrographs. Consequently, the protoplast does not respond osmotically when thawing (loss of osmotic responsiveness associated with the fracture-jump lesion, but not with the hexagonal II phase formation).

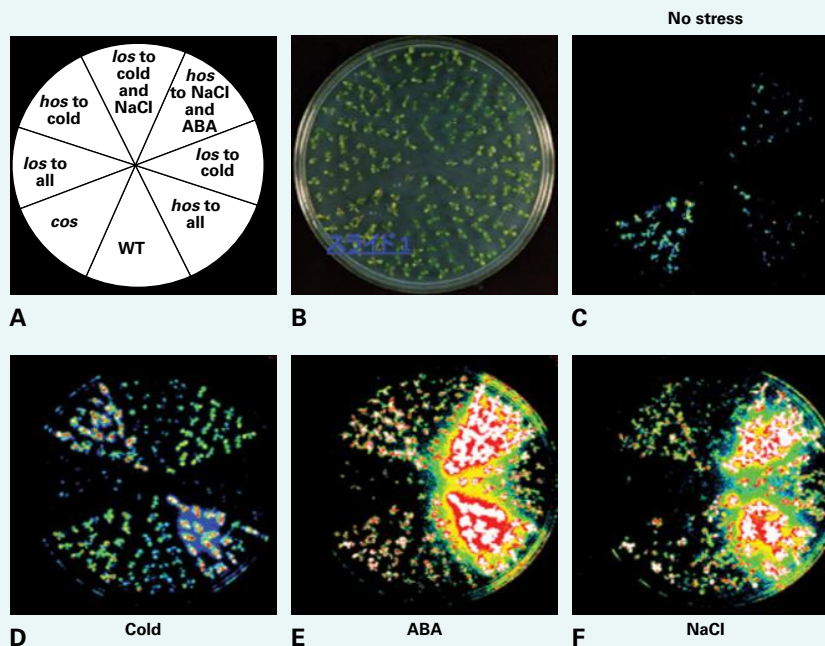

A genetic screen was used to identify mutants with altered *RD29A* gene expression in response to abiotic stress

Genetic screens have been used to identify genes involved in the plant abiotic stress response. *Arabidopsis* plants were transformed with the firefly luciferase gene fused to the *RD29A* promoter, which is induced by drought, cold, and ABA treatment. *Arabidopsis* plants containing the *RD29A* promoter-luciferase (*LUC*) transgene were then mutated by EMS or T-DNA insertion for mutant screening. Mutants were isolated that exhibited constitutive expression (*cos*), high expression (*hos*), or low expression (*los*) of luciferase in response to cold and salt stress treatments (see figure). The proteins encoded by the mutated genes function not only as transcription factors upstream of *RD29A* gene activation, but also in posttranscriptional regulation of the transcription factors.

Many factors involved in stress signaling were identified among the mutants isolated. For example, *LOS5* and *LOS6* were identified as *ABA3* (encoding molybdenum cofactor sulfurase) and *ABA1* (encoding zeaxanthin epoxidase), respectively. These are involved in ABA biosynthesis. One of the *HOS* genes, named *FRY1* (*FIERY 1*), encodes inositol

polyphosphate 1-phosphatase, which is involved in inositol-1,4,5-triphosphate signaling. *FRY1* functions as a negative regulator of ABA and stress signaling, suggesting the involvement of phospholipids in stress signaling pathways. Another *HOS* gene, *HOS15* encodes a WD40 repeat protein similar to *TBL1*, which is associated with histone deacetylation in mammals. *HOS15* is likely involved in histone H4 deacetylation to regulate stress tolerance through chromatin remodeling. Repressor of silencing (*ros*) has been identified in other mutants. *ROS1* encodes a DNA glycosylase that demethylates DNA by base excision repair and can counteract RNA-dependent DNA methylation. *ROS3* contains an RNA recognition motif and may direct sequence-specific demethylation by *ROS1* and related DNA demethylases. Therefore, this mutant screening approach provides a powerful tool not only for analysis of upstream signal transduction pathways, but also for studies of post-transcriptional regulation of gene expression and chromatin regulation.

Luminescence images of wild-type (*RD29A* promoter:*LUC* transgenic *Arabidopsis* plant) and mutants (*hos*, *los*, and *cos*) under cold, osmotic, and ABA stress. (A) Arrangement of the wild-type (WT) and mutant lines. Clockwise: wild-type *RD29A*-*LUC* transgenic parent; *cos*, mutants with constitutive *RD29A* expression; *los* to all, mutants with reduced responses to cold, ABA, and osmotic stress; *hos* to cold, mutants with enhanced response to cold; *los* to cold and NaCl, mutants with reduced responses to cold and osmotic stress; *hos* to NaCl and ABA, mutants with enhanced response to ABA and osmotic stress; *los* to cold, mutants with reduced response to cold stress; *hos* to all, mutants with enhanced response to cold, ABA, and osmotic stress. (B) Morphology of the seedlings of WT and mutants. (C) Luminescence from plants before stress and ABA treatments. Note the constitutive luminescence of the *cos* mutant. (D) Luminescence from plants exposed to cold conditions for 2 days. (E) Luminescence from plants after ABA treatment. The plants were placed at room temperature (20–22°C) for 2 days to allow the luminescence to drop to pre-cold treatment levels before spraying with 100 μ M of ABA and imaging 3 hours later. (F) Luminescence from plants under osmotic stress. Three days after ABA treatment, luminescence from the plants dropped to pretreatment levels. The plants were then treated with high salt for 5 hours by flooding the plate with 300 mM NaCl. Some of the *cos* mutant seedlings died after cold and ABA treatment and so did not emit luminescence upon NaCl treatment.

solute concentration affects lipid phase behavior due to the electrostatic interactions with charged headgroups of bilayer lipid molecules. Mechanical stress is another factor that destabilizes the membrane; ice formation in the extracellular space results in deformation of the cell, and ice crystals can directly damage the plasma membrane.

Freezing stress also causes other types of damage in cells. Cell wall–plasma membrane interactions are altered due to freezing; for example, in some plants, survival of intact cells is less than that of isolated protoplasts, which do not have a cell wall. This is because the presence of the cell wall can add extra stress from extracellular ice crystals on cells. Further, several specific proteins become detached from the plasma membrane when intact cells with a cell wall are frozen, suggesting the physicochemical interactions between the cell wall and the plasma membrane occurring during freezing cause extra damage to the plasma membrane. Freezing leads to acidification of the cytoplasm, probably as a result of disturbance of H⁺-transport systems associated with the vacuolar membrane (tonoplast). This acidification markedly affects metabolic reactions in the cytoplasm. Taken together, these observations indicate that freezing exposes cells to very complex multifaceted stress, and the rate of freezing and the temperature and rate at which ice crystals form can strongly affect the extent of damage to the cell.

22.4.4 Plants have multiple low-temperature sensing systems

To adapt to low temperature, plants must first perceive changes in temperature. The cyanobacterium *Synechocystis* PCC6803 has a putative low-temperature sensor, the histidine kinase Hik33. Low temperature activates Hik33 by signals mediated by changes in membrane fluidity, leading to autophosphorylation and subsequent phosphate transfer to the response regulator Rre26. Microarray data have shown that Hik33 regulates the expression of 21 of 36 cold-regulated genes. Thus, Hik33 is considered a low temperature regulator that activates expression of the majority of cold-regulated genes, in addition to another temperature-sensing pathway involved in cellular responses of the cyanobacterium to low temperature. Although no *Hik33* orthologs have been found in higher plants, two-component systems like the combination of His and Rre are involved in responses to some phytohormones (see Chapter 18). The participation of these two-component systems in low temperature sensing in plants remains to be determined.

There are a number of candidate low temperature sensors in plants, although these have not been confirmed. For example, changes in **membrane fluidity** are considered to play a role in sensing a temperature drop outside the cell. Alterations in membrane fluidity of alfalfa cells using treatments with dimethylsulfoxide as a membrane fluidizer and benzyl alcohol as a membrane stabilizer result in changes in both freezing tolerance and cold-induced gene expression.

Calcium influx and cytoskeleton organization are also affected under these conditions, so changes in membrane fluidity may act as sensors and induce a series of signal transduction events at low temperatures.

22.4.5 Plants can acclimate to freezing by increasing membrane stability

The ability to survive temperatures below freezing is genotype-specific. Whereas many important crop plants, including corn (*Zea mays*), tomato (*Lycopersicon esculentum*), and rice (*Oryza sativa*), are unable to withstand freezing temperatures, many temperate and sub-arctic plants can survive freezing temperatures, and some can even survive temperatures below -40°C . However, these plants are not tolerant to freezing throughout the growing season.

Freezing tolerance develops in a process known as cold acclimation, a response to low but nonfreezing temperatures that occur before freezing. As an example, *Arabidopsis* can normally survive temperatures as low as -5°C , but after exposure to temperatures in the range of 1°C to 5°C for one to seven days, it can survive much lower temperatures of -8°C to -13°C . This makes *Arabidopsis* a good model for studying the mechanisms underlying freezing tolerance. A number of seemingly disparate responses occur during cold acclimation, including alterations in membrane composition and accumulation of compatible solutes, but these changes ultimately contribute to protection of the plasma membrane, the primary site of freezing injury in plants.

The most notable changes in the plasma membrane after cold acclimation are the increase in proportion of plasma membrane phospholipids (see Chapter 8), which is widely observed in various herbaceous and woody plants, and concomitant decrease in the proportion of glucocerebrosides. These cold-induced changes in lipid composition improve water retention at the membrane surface, which can prevent thermotropic and lyotropic lipid phase alterations in the membrane bilayers during freezing. Comprehensive lipid analysis, however, does not support the suggestion that there is a single lipid component that predominantly affects maintenance of plasma membrane integrity during freeze–thaw cycles. Rather, altered lipid–lipid (or lipid–protein) interactions after cold acclimation should contribute to the increased plasma membrane stability against freezing stress.

Plasma membrane proteins and microdomains also respond dynamically to cold acclimation. Cold-responsive proteins in the plasma membrane include osmotic and other stress-related proteins, proteolysis-associated proteins, and membrane trafficking proteins. Plasma membrane microdomains are enriched in glucocerebrosides and sterol lipids, and the proportions of both lipids change after cold acclimation. Cold acclimation also results in changes in microdomain proteins, such as those associated with membrane transport, membrane trafficking, and cytoskeleton–plasma membrane interactions. Thus, microdomain analysis is a promising

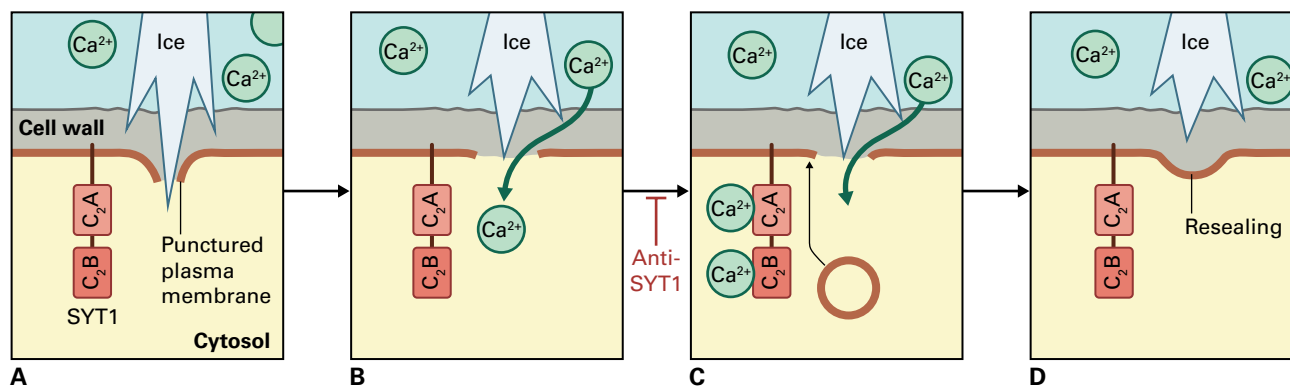

FIGURE 22.20 Model for Ca^{2+} - and SYT1-induced membrane resealing occurring during freeze/thawing. (A) The plasma membrane is mechanically punctured by ice crystals, and (B) Ca^{2+} moves from the extracellular space into the cytoplasm through the damaged sites. (C) Endomembranes may then fuse at the site of the damaged plasma membrane via Ca^{2+} binding SYT1. (D) The damaged site is resealed.

means of determining the molecular and functional responses of the plasma membrane to low temperature and freezing tolerance in plants.

Although not analyzed in detail, some cold-responsive proteins in the plasma membrane do affect freezing tolerance. Phospholipases influence freezing tolerance probably through alterations in the plasma membrane lipid composition and phospholipid-mediated signaling. In *Arabidopsis*, antisense suppression of phospholipase Da1 (PLDa1), the most abundant plant phospholipase, increases freezing tolerance. The difference in freezing tolerance is probably because suppression of PLDa1 inhibits an increase in the proportion of phosphatidic acid that promotes destabilizing phase transition of the membrane bilayers. In contrast, *Arabidopsis* phospholipase D δ (PLD δ) knockout lines show reduced freezing tolerance, and overexpressors show increased freezing tolerance. PLD δ modifications do not change the proportion of major phospholipids in the plasma membrane during freezing but selectively increase molecular species of phosphatidic acid, suggesting that specific phosphatidic acid species act as signal transducers of low temperature.

Another plasma membrane-associated protein that affects freezing tolerance is SYNAPTOTAGMIN1 (SYT1). Synaptotagmins are a family of membrane-trafficking proteins that function as calcium sensors in plasma membrane vesicle fusion processes mediated by the SNARE protein complex. The level of *Arabidopsis* SYT1 increases rapidly in the plasma membrane in parallel with the development of freezing tolerance during cold acclimation. As *Arabidopsis* freezing tolerance is enhanced by exogenous application of calcium, and both *Arabidopsis* SYT1-RNAi lines and T-DNA insertion mutants clearly have less freezing tolerance than wild-type plants, SYT1-dependent membrane resealing in the presence of calcium is considered a vital component of plant freezing tolerance (Fig. 22.20). Genetic screens for mutants showing enhanced osmotic sensitivity have also identified SYT1 as an important component in osmotic tolerance.

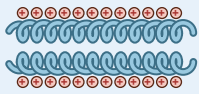

22.4.6 Cold-induced changes in metabolite profiles have important roles in cold acclimation

Compatible solutes, such as simple sugars (sucrose, glucose, fructose, raffinose, and stachyose), proline, and glycine betaine, accumulate in conjunction with the development of freezing tolerance in many plant species. The deduced molecular functions of compatible solutes in freezing stress tolerance are similar to those in osmotic and dehydration stress (see Sections 22.2.3 and 22.2.4). The *Arabidopsis* mutant *eskimo1*, which is constitutively freeze-tolerant, overproduces proline at warm temperatures. The *ESKIMO1* gene encodes a 57-kDa protein of unknown function belonging to a large gene family of DUF231 proteins. The *eskimo1* mutation alters the expression of genes that overlap with those regulated by other abiotic stressors, including salt, osmotic, and cold stress, but that are apparently independent of those mediated by CBF/DREB1 transcription factors (see Section 22.4.7). Sugars have been suggested to protect membranes and contribute to improved freezing tolerance after cold acclimation. In fact, exogenous sugar application has been used to recover the impaired increase in freezing tolerance of *Arabidopsis sensitive-to-freezing 4* (*sfr4*) mutant. However, in some cases, the accumulation of sugars alone is not sufficient for the development of freezing tolerance. Several single-gene mutants of *Arabidopsis* that are defective in freezing tolerance nonetheless accumulate sugars normally in response to low-temperature stress.

22.4.7 Freezing tolerance involves changes in gene expression

In most cases, the cold acclimation-induced alterations described above are mediated by changes in gene expression at low temperature. Since the mid-1980s, when changes in gene expression in response to cold acclimation were first

TABLE 22.1 The five groups of LEA proteins.

Hypothetical structures	Representative proteins	Structural characteristics and shared motifs	Properties	Proposed function
Group 1 (D-19 family*) 	Em (early methionine-labeled protein, wheat)	Most (70%) protein conformation is random coil with some predicted short α -helices Rich in charged amino acids and glycine	More hydrated than most globular polypeptides	Binds water to minimize loss of cellular water content Overexpression confers water-deficit tolerance on yeast cells
Group 2 (D-11 family*) 	DHN1 (maize) D-11 (cotton)	Structure variable Includes one or more conserved lysine-rich regions that may form α -helices. The consensus sequence is EKKGIMDKIKELPG. The number of repeats per protein varies May or may not contain a poly(serine) region Contain regions of variable length rich in either glycine and threonine or glutamate and lysine	Most members localize to cytoplasm and nucleus; but also associated with plasma membrane	May stabilize macromolecules under conditions of reduced water content
Group 3 (D-7 family*) 	HVA1 (<i>Hordeum vulgare</i> ABA-induced) D-7 (cotton)	Contain repeated motifs of the consensus sequence TQAAAKEKAXE Predicted to contain amphipathic α -helices Predicted to form dimers	D-7 is abundant in cotton embryos (0.25 mM) Putative dimer of D-7 may bind as many as 10 inorganic phosphates and their counterions	HVA1 promotes stress tolerance in transgenic plants
Group 4 (D-95 family*) 	D-95 (soybean)	Hydropathy plots are unremarkable and slightly hydrophobic N-terminal region contains a possible amphipathic α -helix	A gene encoding a similar protein in tomato is expressed in response to nematode feeding	
Group 5 (D-113 family**) 	LE25 (tomato) D-113 (cotton)	Shares sequence homology at the conserved N terminus, is predicted to form α -helix C-terminal domain is predicted to be a random coil of variable length and sequence Rich in alanine, glycine, and threonine	D-113 is abundant in cotton seeds (up to 0.3 mM)	May bind membranes or proteins to maintain structural integrity May sequester ions to protect cytosolic metabolism LE25 confers salt and freezing tolerance to yeast

*The protein families are named for seed proteins from cotton.

observed in spinach (*Spinacia oleracea*), numerous genes responsive to low temperature treatments have been identified. Unfortunately, no clear functional roles have yet been determined for many of these genes.

Several of the genes induced by low temperature are also induced by water deficit or ABA (see Section 22.3). Gene products that are hydrophilic and soluble when boiled, including Group 2 and Group 3 LEA proteins (Table 22.1) and the products of other unique genes, accumulate during cold acclimation. One such unique gene product is COR15a, a small, nuclear-encoded hydrophilic protein that is targeted to the chloroplast. When imported into the chloroplast, the protein is processed to form the mature protein, COR15am, a 9.4-kDa polypeptide. Protoplasts of nonacclimated transgenic *Arabidopsis* plants that constitutively express the *COR15a* gene show increased freezing tolerance. COR15am has been suggested to alter the intrinsic curvature of the chloroplast envelopes and protect chloroplast proteins through direct associations with each other.

As described in Section 22.3, many of the cold-regulated genes contain a DRE or CRT *cis*-acting DNA element in their promoter regions that binds CBF/DREB1 transcriptional activators (see Fig. 22.12). Three *CBF/DREB1* genes (*CBF1/DREB1b*, *CBF2/DREB1c*, and *CBF3/DREB1a*), which each contain sequences encoding a 60 amino acid DNA binding AP2/ERF domain, are present in tandem array on *Arabidopsis* chromosome 4 and are induced rapidly (within 15 minutes) upon exposure to low temperature, with peak expression after 2 hours. Constitutive or stress-induced *CBF/DREB1* expression (with constitutive CaMV 35S promoter or dehydration- and cold-inducible *RD29A* promoter, respectively) in *Arabidopsis* increases the abundance of *COR* and other DRE/CRT-containing target gene transcripts in nonacclimated plants, which in turn increases freezing tolerance.

Overexpression of the transcriptional activator *CBF/DREB1s* enhances freezing tolerance to a greater extent than overexpression of *COR15a* alone. Further, *CBF/DREB1* genes are widely conserved in plants, and the number of these genes and the extent of their expression are correlated with the degree of freezing tolerance in some plant groups. Taken together, these results suggest a role of cold-regulated genes in the development of tolerance to low temperature and have facilitated new research on protection of crop plants against freezing using overexpression of transcription factors.

Microarray analysis of plants overexpressing *CBF/DREB1* has identified its target genes. The number of direct *CBF/DREB1* target genes is around 40, and about 100 genes have been assigned to the *CBF/DREB1* regulon. The *CBF/DREB1* regulon genes encode proteins that fall into two groups: proteins that function in stress tolerance and those that are involved in further regulation of the expression of other genes. *COR* proteins, along with enzymes involved in proline metabolism (Δ^1 -pyrroline-5-carboxylate synthase) and raffinose synthesis (galactinol synthase, *Gols*), belong to the *CBF/DREB1* regulon and participate in enhancement of freezing tolerance. The presence of proteins with regulatory functions in the *CBF/DREB1* regulon, such as transcription factors,

suggests there may be some subregulons within the *CBF/DREB1* regulon. In fact, microarray experiments and subsequent bioinformatics analysis have revealed that approximately 20% of the *CBF/DREB1* regulon genes do not have the core DRE/CRT sequence (CCGAC) in their promoter sequences. Thus, there must be complex, elaborate gene regulatory networks within the *CBF/DREB1* regulon that control the development of freezing tolerance during cold acclimation.

The circadian system regulates the expression of *CBF/DREB1* as well as some *CBF/DREB1* regulon genes. The extent to which *CBF/DREB1* transcripts accumulate upon exposure to low temperature varies with the time of day that the plants are transferred to low temperature. Cold-induced *CBF/DREB1* transcript accumulation reaches the maximum level at 4 hours and the minimum at 16 hours after subjective dawn. Accordingly, *CBF/DREB1* target genes do in some cases show circadian rhythmic oscillation. This is of interest because freezing tolerance shows rhythmic changes within the day. However, the detailed mechanisms underlying the circadian rhythmicity of plant freezing tolerance remain to be determined.

The *INDUCER OF CBF EXPRESSION (ICE1)* gene has been identified as a regulator of *CBF3/DREB1A* gene expression. *ICE1* encodes a MYB-like basic helix-loop-helix (bHLH) transcription factor and is expressed constitutively, suggesting that cold-induced posttranslational modification is necessary to activate *ICE1* for *CBF3/DREB1A* expression. *ICE1* overexpression enhances expression of the *CBF/DREB1* regulon genes and increases freezing tolerance in plants after cold acclimation (see Fig. 22.12). Thus, *ICE1* functions as an upstream regulatory protein to control *CBF3/DREB1A* transcription. *ICE1* also functions in the regulation of stomata numbers in leaf epidermal cell development. However, it is not involved in the cold induction of other *CBF/DREB1* genes. It has been proposed that the involvement of calcium in *CBF2/DREB1C* expression is mediated by a calmodulin-binding transcription factor (*CAMTA*) (see Fig. 22.12).

The *CBF/DREB1* cold-responsive pathway likely plays an important role in cold acclimation in plants, but additional pathways must also be involved in activating cold-induced reactions in response to low temperature. The *eskimo1* mutant, which is constitutively freezing tolerant, does not show constitutive *CBF/DREB1* gene expression. Similarly, the *sfr4* mutant, which shows impaired freezing tolerance enhancement during cold acclimation, does not differ in *CBF/DREB1* gene expression on exposure to low temperature (see Section 22.4.5). The *ZAT12* cold-responsive pathway also plays a role in cold acclimation. Overexpression of *ZAT12*, which encodes a zinc-finger transcriptional repressor protein, alters gene expression profiles and increases freezing tolerance of plants. The *ZAT12* cold-responsive pathway appears to interact with the *CBF/DREB1* cold-responsive pathway: some target genes are shared by the two pathways and some genes in the *CBF/DREB1* pathway are downregulated by *ZAT12* overexpression, which suggests complicated regulatory systems for genes associated with freezing tolerance.

22.5 Flooding and oxygen deficit

Flooding (waterlogging of soil to complete submergence) can also trigger a number of different stress responses in plants. Whereas oxygen concentrations in well drained, porous soil are nearly equal to atmospheric concentrations (20.6% oxygen, 20.6 kPa), the diffusion coefficient of oxygen in water is four orders of magnitude lower than that in air. When flooding occurs, soil gases are replaced with water, thereby reducing entry of oxygen into the soil and making it difficult for roots and other organs to carry out respiration.

Like most eukaryotic organisms, plants are obligate aerobes that derive most of their energy from mitochondrial respiration of hexose sugars to ATP. Under normal aerobic conditions, plants oxidize 1 mol of hexose sugar through glycolysis, the citric acid cycle, and oxidative phosphorylation to yield 30–36 mol of ATP (see Chapters 13 and 14). In the absence of oxygen, however, plants produce ATP mainly by glycolysis, which yields only 2–4 mol of ATP per mole of hexose sugar. The function of a noncyclic flux mode of citric acid cycle can boost the ATP output by 1 mol per pyruvate metabolized (see Section 22.5.2). Cytoplasmic ATP/ADP ratios decline as mitochondrial ATP production is inhibited. Ironically, oxygen deficit associated with flooding can also prevent plants from obtaining adequate water from the soil due to gating of root cell aquaporins; this reduces the permeability of root cells to water and limits transport of water to aerial tissue.

The supply of oxygen to root cells is influenced by several factors, including soil porosity, water content, temperature, root density, and the presence of competing algae and aerobic

microorganisms. Oxygen concentrations in root tissues also vary according to root depth, root thickness, the volume of intercellular gaseous spaces, and cellular metabolic activity. Oxygen gradients exist within other organs and tissues, including meristems, tubers, and developing seeds.

Plant or cellular oxygen status can be defined as **normoxic**, hypoxic, or **anoxic** (Table 22.2). To survive short-term flooding, plants must generate sufficient ATP, regenerate NADP⁺ and NAD⁺, and avoid accumulation of toxic metabolites. Periods of oxygen deficit can trigger developmental responses that promote acclimation to hypoxic or anoxic conditions.

22.5.1 Plants vary in their ability to tolerate flooding

Plants can be generally classified as wetland, flood tolerant, or flood sensitive, according to their ability to withstand periods of soil flooding or submergence (Table 22.3).

Wetland plants possess anatomical, morphological, and physiological features that permit survival in waterlogged soils and partial submergence. Growth in a wetland environment promotes formation of a thickened root hypodermis to reduce O₂ loss to the anaerobic soil. To facilitate transport of O₂ from aerial structures to submerged roots and thereby maintain aerobic metabolism and growth, some plants develop specific structures: **aerenchyma** (continuous, columnar intracellular spaces formed in root cortical tissues (Fig. 22.21; see also Section 22.5.4 and Chapter 20), adventitious roots from the hypocotyl or stem (Fig. 22.22), **lenticels** (openings in the

TABLE 22.2 Impact of oxygen deprivation on respiratory metabolism.

Oxygen status	Effect on metabolism
Normoxic (aerobic)	Aerobic respiration proceeds normally; almost all ATP production results from oxidative phosphorylation
Hypoxic	Partial pressure of O ₂ limits ATP production by oxidative phosphorylation; glycolysis and a non-cyclic flux mode of the citric cycle account for a larger percentage of ATP yield than under normoxic conditions; metabolic and developmental changes are stimulated that result in adaptation, acclimation to a low-oxygen environment
Anoxic (anaerobic)	ATP is produced only by glycolysis and a non-cyclic flux mode of the citric cycle; cells exhibit low ATP content, diminished protein synthesis, and impaired division and elongation. If anoxic conditions persist, many plant cells die

TABLE 22.3 Plant species categorized by sensitivity to flooding.

Wetland	Flood tolerant	Flood sensitive
<i>Acorus calamus</i>	<i>Arabidopsis thaliana</i>	<i>Glycine max</i> (soybean)
<i>Echinochloa crus-galli</i> (rice grass)	<i>Echinochloa crus-pavonis</i> (barnyard grass)	<i>Lycopersicon esculentum</i> (tomato)
<i>Echinochloa phyllopogon</i> (barnyard grass)	<i>Rumex acetosa</i> (sorrel)	<i>Pisum sativum</i> (pea)
<i>Erythrina caffra</i> (coral tree)	<i>Solanum tuberosum</i> (potato)	
<i>Rumex palustris</i> (marsh dock)	<i>Zea mays</i> (corn)	
<i>Oryza sativa</i> (rice)	<i>Triticum aestivum</i> (wheat)	
<i>Phragmites australis</i> (common reed)	<i>Hordeum vulgare</i> (barley)	

FIGURE 22.21 Aerenchyma development in the root cortex of maize (*Zea mays* L.) after oxygen deprivation. Photomicrographs of transverse sections of maize roots maintained under aerobic conditions (A) or under 72 hours of hypoxia (B) demonstrate the formation of cortical aerenchyma in hypoxic roots. The hypodermis and endodermis remain intact, and the lacunae created by the death of the central cortical cells form columnar gas-conducting chambers.

FIGURE 22.22 Adventitious roots and prominent (hypertrophied) lenticels on the stem of young ash (*Fraxinus pennsylvanica* Marshall) after flooding. The black arrow indicates the water depth during flooding. Source: Kozłowski (1984) *Physiological Ecology*. Academic Press, New York.

periderm that allow gas exchange, Fig. 22.22), shallow roots, and **pneumatophores** (shallow roots that grow with negative geotrophy out of the aquatic environment, Fig. 22.23). Other adaptive strategies include elongation of stems or leaf petioles towards the water surface (Fig. 22.24) and thinning of leaves to improve underwater photosynthesis. The morphological and anatomical characteristics that improve tissue aeration can be constitutive or induced by flooding.

When inundated by water, wetland species alter cellular metabolism in root and aerial organs to increase survival. Partial submergence of deepwater rice (*Oryza sativa* L. var. Indica) promotes formation of adventitious roots and accelerates internodal stem elongation, which enables stems and leaves to be maintained above the aquatic environment

FIGURE 22.23 Pneumatophores of mangrove (*Avicennia nitida*) develop from roots submerged in estuarine mud. Source: Bowes (1996). *A Colour Atlas of Plant Structures*. Manson Publishers.

(Fig. 22.25). This escape strategy is associated with ATP production through active consumption of available carbohydrates coupled to glycolysis, fermentation, and a partially functioning citric acid cycle.

Rice seeds are among the few that can germinate in an anaerobic environment, and germinated rice seedlings promote coleoptile elongation towards light and oxygen over root growth. In this situation, a calcineurin B-like interacting protein kinase (CIPK) and sucrose nonfermenting 1 related

protein kinase 1A (SnRK1A) sense changes in ATP or sugar homeostasis to promote synthesis of starch catabolizing amylases. In addition, mitochondrial morphology is altered (Fig. 22.26), but functional electron transport chain complexes of the inner membrane and enzymes of the citric acid cycle in the matrix are maintained. This rapid coleoptile elongation is an escape strategy that is effective if photosynthetic activity can be established before seed starch reserves are fully consumed.

FIGURE 22.24 The leaf petiole of *Rumex palustris* elongates in response to submergence.

In contrast, other wetland plants, such as the marshland monocot *Acorus calamus*, respond to flooding by downregulating their metabolism, which allows them to maintain a nearly quiescent state for several months while utilizing the starch reserves stored in their rhizomes. This **quiescence strategy**, a restriction of metabolism to survive a long and deep flood, is observed in a number of wetland species and submergence-tolerant accessions of rice.

Flood-tolerant plants can endure flooding and anoxia only temporarily. Like wetland species, these plants generate ATP through anaerobic metabolism during short-term flooding. In most cases, root elongation is inhibited, overall rates of protein synthesis are diminished, and patterns of gene expression are markedly altered. *Arabidopsis* ecotypes vary in the length of time they can endure complete submergence. Whereas *Arabidopsis* plants survive two weeks or more, young seedlings of maize, for example, can survive only 3–5 days of submergence, depending on genotype and developmental age. Survival of the low oxygen stress associated with waterlogging is prolonged if maize seedlings become hypoxic before experiencing anoxia. Hypoxia promotes formation of adventitious and nodal roots with cortical aerenchyma as an acclimation to soils with low oxygen content (see Fig. 22.22) and enhances the ability to transport lactate out of roots.

Flood-sensitive plants exhibit an injury response to anoxia. As with flood-tolerant species, flood-sensitive plants carry out anaerobic respiration; these plants, however, rapidly succumb to flooding because of cytoplasmic acidification. When deprived of oxygen, flood-sensitive species exhibit greatly diminished protein synthesis, degradation of mitochondria, inhibited cell division and elongation, disrupted ion transport, and cell death within root meristems. Typically, these plants do not develop root aerenchyma and cannot survive more than 24 hours of anoxia.

FIGURE 22.25 Growth responses of seedlings of deepwater rice (*Oryza sativa* L. var. *Indica*) to flooding. (A) Seedlings are established before the annual flood. Submergence promotes rapid internodal elongation and development of adventitious roots. Once the flood waters recede, the adventitious roots grow into the soil and aerial portions of the plant grow upward. (B) Photographs comparing internode elongation in aerobic (left) and submerged (right) plants. Arrows indicate positions of nodes.

A mitochondrion from anoxic seedlings has well-developed cristae but its matrix is less dense. Source: Couée et al. (1992). *Plant Physiol.* 98:411–421.

22.5.2 During short-term acclimation to anoxic conditions, plants generate ATP through breakdown of carbohydrates, glycolysis, and fermentation

Flooding stimulates an increase in glycolytic flux known as the **Pasteur effect**, where sucrose or glucose from the phloem is directed toward glycolysis in flooded organs. However, in some cases, flooding can restrict the translocation of photosynthate from leaves; flooded organs of some species hydrolyze stored starch (see Chapter 13) to obtain additional sugars.

The availability and mobilization of carbohydrate reserves is essential in oxygen-deprived organs. Starch is slowly hydrolyzed by amylases in rhizomes of flood-tolerant *Acorus calamus* and in germinating seeds and leaves of rice plants under oxygen constraints; however, many species must rely on soluble carbohydrate reserves for energy production under hypoxia and anoxia. Sucrose breakdown generally follows an increase in production of UDP-sucrose synthase (SUS) (Fig. 22.27). Utilizing SUS rather than ATP-dependent invertase reduces the investment in ATP to produce glucose-6-phosphate and fructose-6-phosphate. Use of pyrophosphate-dependent phosphofructokinase (PFK) by rice and other species during oxygen deprivation further maximizes glycolytic ATP output.

The energy-yielding steps of glycolysis generate low amounts of ATP while reducing NAD^+ to NADH (see Chapter 13). To support ongoing glycolysis in the absence of mitochondrial respiration, the glycolytic substrate NAD^+ must be regenerated. The principal end products of glycolysis in oxygen-deprived plant tissues are lactate and ethanol (Fig. 22.27); alanine, succinate, and γ -aminobutyrate (GABA) are also formed. Alanine and succinate are the principal products of a noncyclic flux mode of the citric acid cycle that generates 1 additional mol ATP per mol pyruvate metabolized.

This consumes 1 mol of glutamate and pyruvate to generate 1 mol alanine and 2-oxoglutarate. The 2-oxoglutarate can be used for substrate level ATP production through conversion of succinyl CoA to succinate. Alternatively, 2-oxoglutarate is shunted to GABA. Oxaloacetate reduced to malate and then fumarate, can produce NAD^+ necessary to maintain succinyl CoA ligase. This alternative pathway of pyruvate consumption yields additional ATP. The relative abundance of specific end products varies according to the plant species, genotype, and organ as well as the duration and severity of oxygen deprivation.

Both lactate- and ethanol-producing fermentations yield NAD^+ , but lactate lowers cytosolic pH, whereas ethanol does not. According to the Davies–Roberts lactate dehydrogenase (LDH)/pyruvate decarboxylase (PDC) pH-stat hypothesis, anaerobic metabolism is regulated by the activities of pH-sensitive enzymes. According to this model, LDH, an enzyme with an alkaline pH optimum, converts pyruvate, which is produced initially by glycolysis, to lactate, and the lactate produced reoxidizes NADH but also lowers the cytoplasmic pH. As the cytosol acidifies, LDH is progressively inhibited and a second enzyme, PDC, is activated. The pH optimum for PDH is lower than the normal cytoplasmic pH; therefore, the accumulation of lactate ultimately stimulates the conversion of pyruvate to acetaldehyde. Alcohol dehydrogenase (ADH) subsequently reduces the acetaldehyde to ethanol while oxidizing NADH to NAD^+ .

Unlike lactate, ethanol is an uncharged molecule at cellular pH and can diffuse across plasma membranes. As a result, the switch to ethanol production stabilizes cytoplasmic pH at a slightly acidic value. Cytosolic pH may also be maintained by operation of the noncyclic flux mode of the citric acid cycle, which is coupled with production of the zwitterionic species alanine from pyruvate. In some plants, the zwitterionic species GABA is formed from pyruvate. Both alanine and GABA

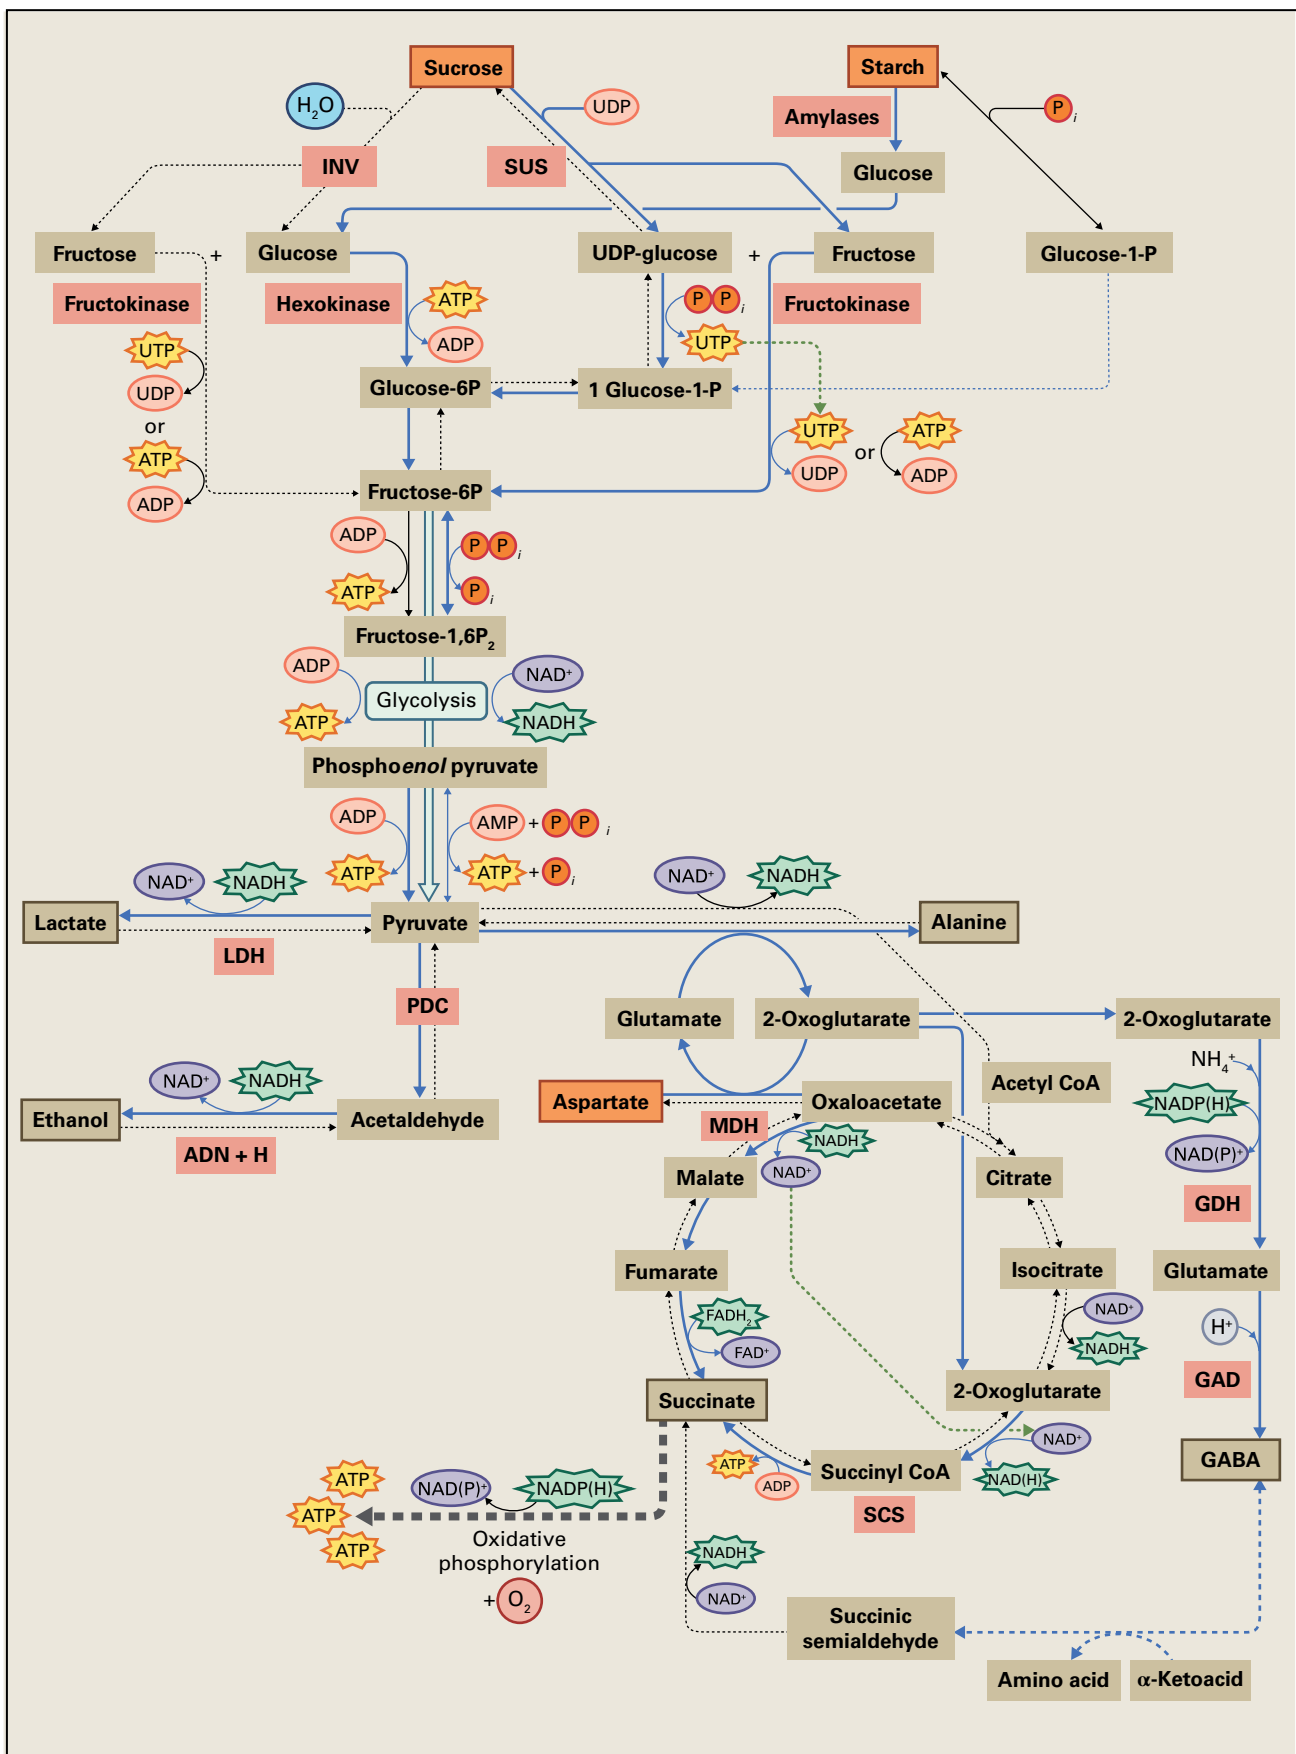

FIGURE 22.27 Metabolic acclimation under O_2 deprivation. Plants have multiple routes of sucrose catabolism, ATP production, and $NAD(P)^+$ regeneration. These include ethanol and lactate production as well as a modified noncyclic citric acid flux mode that is both an alanine and 2-oxoglutarate shunt and a γ -aminobutyric acid (GABA) shunt. Blue arrows indicate reactions that are promoted during anaerobic stress, and gray dashed lines indicate reactions that are inhibited during the stress. Metabolites indicated in brown boxes are major or minor end products of metabolism under hypoxia. Metabolites indicated in orange boxes decrease under hypoxia. ADH, alcohol dehydrogenase; GAD, glutamic acid decarboxylase; GDH, glutamate dehydrogenase; INV, invertase; LDH, lactate dehydrogenase; MDH, malate dehydrogenase; PDC, pyruvate decarboxylase; SCS, succinyl CoA synthetase; SUS, sucrose synthase.

can rapidly re-enter the citric acid cycle upon reoxygenation, minimizing the net loss of carbon (Fig. 22.27).

A different hypothesis predicts that concentrations of pyruvate, rather than cytoplasmic pH, regulate ethanolic fermentation. This PDC/pyruvate dehydrogenase (PDH)-stat hypothesis is based on the observation that the K_m of cytosolic PDC ranges from 0.25 to 1.0 mM pyruvate, while that of mitochondrial PDH ranges from 50 to 75 μM . Since cellular

FIGURE 22.28 Response of root tips of wild-type maize (solid line) and mutants deficient in ADH1 (dashed line) to anoxia. Wild-type root tips experience a rapid decrease in cytoplasmic pH, followed by a partial recovery; however, the wild-type root cells ultimately succumb to cytoplasmic acidosis. Root tips of ADH1-deficient seedlings show rapid cytoplasmic acidosis and cell death.

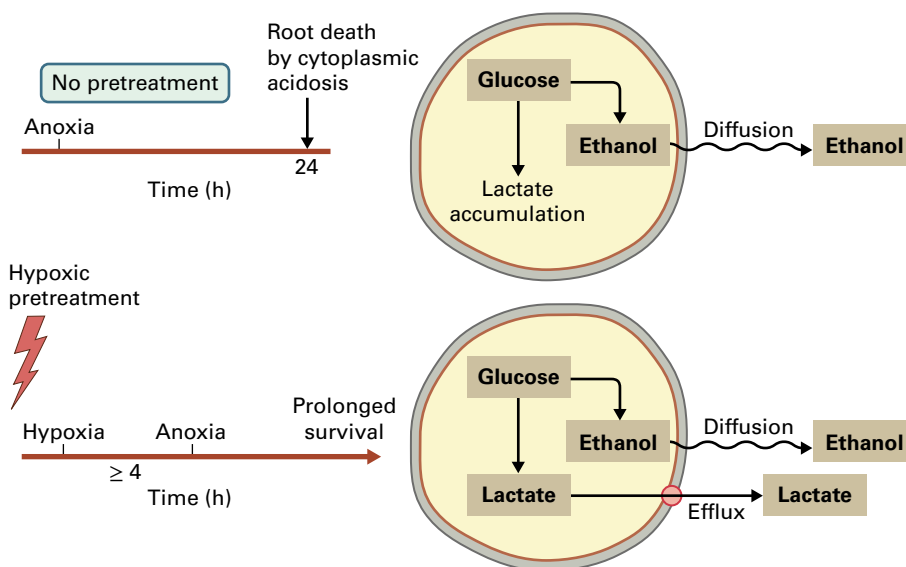

FIGURE 22.29 Effects of hypoxic pretreatment and acclimation on survival of anoxia: avoidance of cytoplasmic acidosis by lactate efflux. Flooding typically results in hypoxia, followed by anoxia. Lactate levels and ethanolic fermentation increase in both anoxic and hypoxic cells. Exposure of maize seedlings to hypoxia for several hours before being transferred to anoxia increases the capacity of roots for lactate efflux and prolongs survival.

concentrations of pyruvate are usually less than 0.4 mM, an increase in pyruvate under hypoxia or anoxia stimulates PDC activity. This model is supported by several observations. First, ethanol production can be stimulated under aerobic conditions that inhibit mitochondrial PDH activity. Second, lactate production does not accompany ethanolic fermentation in certain species. Finally, roots of transgenic tobacco plants that have twice the normal activity of PDC produce more ethanol under anoxia than do wild-type roots.

The LDH/PDC pH-stat and PDC/PDH-stat hypotheses are not mutually exclusive; the regulation of the switch to ethanolic fermentation may vary according to the species, organ and the conditions of low-oxygen stress.

Plants generally increase cellular levels of PDC and ADH in response to flooding. Mutants of maize and other plants that are deficient in ADH are more sensitive to flooding than are isogenic wild-type genotypes. In maize, genotypes severely deficient in ADH1 exhibit acetaldehyde accumulation and a more rapid and sustained drop in cytoplasmic pH than does the wild-type in response to anoxia (Fig. 22.28). However, plants engineered to overproduce PDC or ADH and flood-sensitive species such as pea (*Pisum sativum*) that can rapidly and dramatically upregulate ADH activity still succumb to flooding as a result of exhaustion of carbohydrate reserves and eventual cytoplasmic acidosis.

In nature, hypoxia frequently precedes anoxia in flooded roots. If maize or rice seedlings are transferred to hypoxic conditions (3 kPa O_2) before transfer to anoxia (0 kPa O_2), their survival rates increase considerably and the ability to continue cell elongation is greatly improved. This hypoxic pretreatment promotes acclimation by increasing glycolytic flux and ATP production. An important feature of this acclimation is development of the capacity to export lactate from the cytoplasm to the surrounding medium (Fig. 22.29), a further indication that avoidance of cytoplasmic acidosis is a major factor in survival of low-oxygen conditions.

22.5.3 Shifting from aerobic metabolism to glycolytic fermentation involves changes in gene expression

Generally, anoxia causes a rapid and dramatic shift in gene expression patterns, including a significant reduction in total protein synthesis. Protein synthesis is also reduced and altered under hypoxia, but to a lesser extent. Modifications in the pattern of protein synthesis observed in anoxic and hypoxic tissues result from transcriptional and post-transcriptional regulation of gene expression. Although most gene transcription is generally repressed in response to oxygen deprivation, an important subset of genes is upregulated. These include transcription factors, metabolic enzymes, and uncharacterized proteins. A number of the proteins synthesized in high amounts in hypoxic and anoxic organs are enzymes involved in sucrose and starch degradation, glycolysis, ethanol fermentation, and alanine production.

The *ADH* gene promoters of maize and *Arabidopsis* possess functional *cis*-acting elements that are required for expression in hypoxic and anoxic cells. These elements include G-box type motifs and the **anaerobic response element** (ARE), which is found in the promoter region of many genes that are transcriptionally induced by low oxygen in monocots and dicots. Transcription factors that interact with *Arabidopsis ADH1* have also been identified. Dimethyl sulfate footprinting and DNase I hypersensitivity analyses of *ADH* promoters have demonstrated both constitutive and dynamically modified DNA–protein interactions that correlate with transcriptional activity. The submergence of rice seedlings causes histone H3 lysine methylation (H3K4) in both 5' and 3' regions of *ADH1* that is associated with decreased chromatin compaction and increased gene transcription. Together, these observations indicate the higher-order structure of the chromatin of *ADH* genes is influenced by oxygen availability. *Arabidopsis ADH1* is also transcriptionally induced by application of ABA, dehydration, and cold stress.

Changes in gene expression cannot be attributed solely to transcriptional controls. In maize and *Arabidopsis*, many cytosolic transcripts accumulate at approximately the same amount under normal and oxygen deprivation conditions, but are poorly translated under oxygen deprivation. At least in maize, these mRNAs are constitutively transcribed. The majority of the stress-induced mRNAs, including *ADH1*, are translated efficiently in anoxic/hypoxic cells. The translation of maize *ADH1* mRNA under low-oxygen conditions depends on the presence of particular sequences in the 5' and 3' untranslated regions. The reduced synthesis of many normal cellular proteins reflects the failure of their mRNAs to effectively maintain initiation of translation during stress. These transcripts are limited in translation and protected from degradation by storage in an mRNA ribonucleoprotein particle, also called **stress granules** (Fig. 22.30), as a means of conserving cellular energy, as evidenced by their rapid relocation to polyribosomes upon reoxygenation. Distinctions in mRNA binding proteins and changes in translational machinery,

including phosphorylation of translation factors and ribosomal proteins, may allow for discrimination in translation of cellular mRNAs in oxygen-deprived cells.

22.5.4 The plant hormone ethylene promotes long-term acclimative responses in wetland and flood-tolerant species

Flooding or submergence stimulates production and limits outward diffusion of the gaseous hormone ethylene, a key trigger for adaptive responses to submergence and low oxygen levels (<12.5–3 kPa). The levels of 1-aminocyclopropane-1-carboxylic acid (ACC) synthase and ACC oxidase, enzymes of the ethylene biosynthesis pathway, increase in response to hypoxia in maize root tips. In hypoxic roots, ethylene promotes the formation of aerenchyma in the central portion of the root cortex; anoxic roots develop fewer aerenchyma because O₂ is essential for ethylene synthesis (Fig. 22.31A; see also Chapter 17).

Aerenchyma (see Fig. 22.21) provide a conduit for gas diffusion between roots and aerial organs, and can form by cell death and dissolution (**lysigeny**), separation of cells without collapse (**schizogeny**), or a combination of lysigeny and schizogeny (**schizolysigeny**). The aerenchyma of rice and maize are lysigenous and most likely result from programmed cell death (see Chapter 20). In many wetland species, aerenchyma formation is a normal developmental process in young plants that is initiated before flooding and further promoted in response to flooding.

Plants that have aerenchyma are able to maintain synthesis of high amounts of ATP in root cells submerged in an poorly oxygenated environment. The formation of aerenchyma reduces the severity of hypoxia and facilitates growth of submerged roots in species such as rice. When flooding inhibits the growth of existing roots or causes their death in nonwetland species, new roots develop at the upper portion of the primary root, on the hypocotyl, or from internodes above the air–water/air–soil interface. These adventitious roots form aerenchyma that facilitate the transport of O₂ from aerial portions of the plant to O₂-deprived root tissues. Adventitious root formation is also an ethylene-regulated process.

The role of ethylene in aerenchyma development has been confirmed by exposing aerobic roots to inhibitors of ethylene synthesis, antagonists of ethylene action, and exogenous ethylene. Development of aerenchyma also involves a Ca²⁺-mediated signal triggered by ethylene. At least two cell wall-degrading enzymes, cellulase and xyloglucanase, are present or synthesized in large amounts in hypoxic roots and also play a role in aerenchyma formation (Fig. 22.31B).

Ethylene is also involved in the flooding response of deepwater rice varieties that can grow in water as deep as 4 meters (see Fig. 22.25). Submergence of the young plants increases ethylene entrapment and biosynthesis, which is followed by a decrease in ABA concentration and an increase in responsiveness to the hormone gibberellin (GA)

FIGURE 22.30 Transcriptional and posttranscriptional mechanisms control gene expression in hypoxic and anoxic cells of plants. In maize, nuclear run-on experiments have shown that genes encoding a number of housekeeping proteins are constitutively, but poorly transcribed under hypoxia and anoxia. These mRNAs do not associate efficiently with ribosomes during oxygen deprivation. mRNAs encoding enzymes important for anaerobic metabolism, such as *Adh1*, increase in response to transcriptional induction and are efficiently translated during the stress. In *Arabidopsis*, repression of mRNA translation during hypoxia/anoxia is selective, with only about 6% of cellular mRNA displaying efficient translation. mRNAs that are poorly translated during stress are sequestered in translationally inactive messenger ribonucleoprotein complexes with similarities to stress granules. Upon reoxygenation, these mRNAs are rapidly recruited to active translation complexes (i.e., polyribosomes). In this manner, the cellular investment of energy in protein synthesis is limited during stress. Protein synthesis rapidly recovers once aerobic respiration resumes.

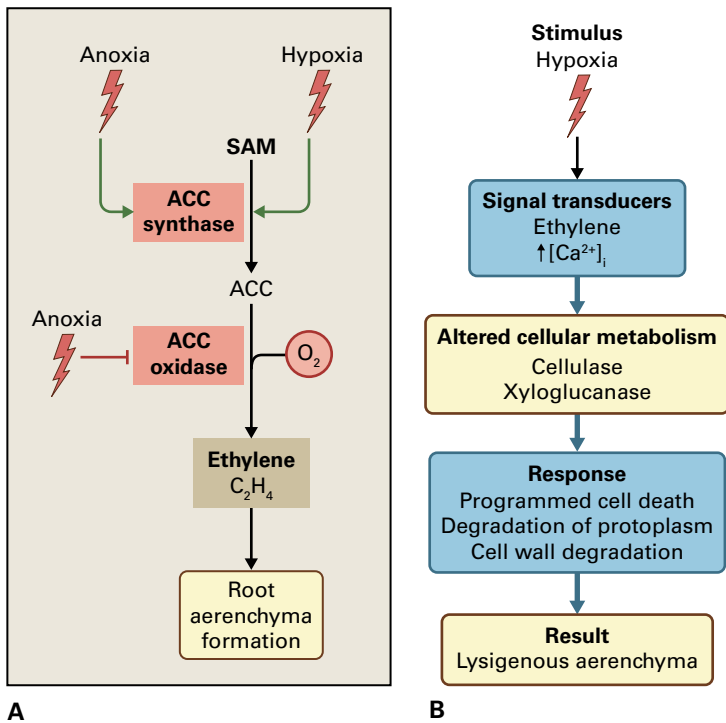

FIGURE 22.31 Formation of aerenchyma is stimulated by hypoxia but not by anoxia. (A) Ethylene production leads to lysigenous aerenchyma in the root cortex, and the conversion of SAM and ACC to ethylene requires O_2 . (B) Transduction of the signal for low O_2 in maize leads to programmed cell death during the formation of lysigenous aerenchyma (see Chapter 20). Chemicals that increase the cytosolic Ca^{2+} concentration under aerobic conditions promote aerenchyma formation, whereas compounds that block Ca^{2+} movement under anoxia inhibit aerenchyma formation.

FIGURE 22.32 Ethylene and flooding responses in rice. The elongation of stem and leaf cells is positively regulated by GA. Under normal growth conditions, ABA inhibits GA activity. When plants are submerged, cellular ethylene levels rise due to biosynthesis and entrapment by the surrounding water. This promotes the breakdown of ABA, increasing cellular responsiveness to GA, which then stimulates cell elongation. In deepwater rice (*Oryza sativa* L. var. *Indica*), this is accompanied by increased accumulation of bioactive GA. (A) The escape strategy of deepwater rice involves rapid stem elongation to maintain leaf tissue above the water level, in response to a slow, progressive flood. This growth is mediated by GA biosynthesis and action. Quantitative trait locus (QTL) mapping identified two closely linked ethylene responsive factor (AP2/ERF) family transcription factors, SNORKEL1 and 2 (SK1 and SK2), on chromosome 12 that drive the deepwater escape response. Ethylene accumulation in underwater stems promotes transcription of SK1 and SK2, triggering internode elongation. These genes are present in some wild rice species, but are absent or nonfunctional in non-deepwater domesticated rice. (B) In the quiescence strategy of submergence-tolerant varieties, shoot elongation is suppressed to conserve carbohydrates and increase survival under short-term complete inundation conditions. GA signaling and cell elongation are inhibited by the ethylene-induced action of SUBMERGENCE-1A (SUB1A-1 allele) on the growth-inhibition genes SLENDER RICE-1 (SLR1) and SLR LIKE-1 (SLRL1). Submergence-induced SUB1A is present in a cluster of two or three ERF transcription factor on rice chromosome 9 in submergence-tolerant rice accessions.

(see Chapter 17). Subsequently, cell division in the intercalary meristem increases, as does cell elongation in the stem internodes. In the wetland species *Rumex palustris*, ethylene entrapment within the leaf petiole inhibits the ABA biosynthetic enzyme 9-*cis*-epoxycarotenoid dioxygenase (NCED) and promotes ABA catabolism to phaseic acid (Fig. 22.10), enhancing GA-activated elongation of cells. A more pronounced elongation of cells on the adaxial side of the petiole allows leaves of plants in shallow floods to become more erect and extend above the air–water interface. The rapid elongation growth that permits escape from submergence in rice and *R. palustris* (see Fig. 22.24) is associated with increases in xyloglucan endotransglycosylase/hydrolases (XTHs) and expansins, nonenzymatic cell wall loosening proteins. Thus, ethylene accumulation in response to flooding facilitates the escape strategy that enables better photosynthate production and O₂ entry necessary for maintenance of growth.

Two major quantitative trait loci (QTL) involved in flooding responses in rice encode multiple transcription

factors in the ethylene responsive factor (AP2/ERF) family that control GA-regulated elongation growth under submergence. Remarkably, these genes orchestrate opposing responses (Fig. 22.32).

The *SUB1* (*SUBMERGENCE1*) locus on chromosome 9 of rice controls tolerance of prolonged periods of submergence by limiting growth and encodes at least two related AP2/ERF genes, *SUB1B* and *SUB1C*. In rice that tolerates 14 days or more of complete submergence, this locus has a third related AP2/ERF transcription factor gene, *SUB1A*. The ethylene-induced expression of *SUB1A* during submergence limits further ethylene synthesis, the consumption of starch and soluble carbohydrates, and the responsiveness to GA, despite the decline in ABA concentration. This repression of elongation growth is manifested by *SUB1A* through maintenance of GRAS family transcription factors that repress GA-mediated gene expression. These include the rice DELLA domain protein SLENDER RICE-1 (SLR1) and a related protein SLR-like 1 (SLRL1) that lacks a DELLA domain (see Chapter 18).

Altogether, the submergence-induced expression of *SUB1A* invokes an energy conservation strategy that limits elongation growth and prolongs meristem viability.

Deepwater rice has three QTL responsible for promoting rapid underwater elongation growth in response to increased GA production and responsiveness. Genetic mapping identified the *SNORKEL* locus on chromosome 12, which encodes two AP2/ERF genes, *SNORKEL1* (*SK1*) and *SNORKEL2* (*SK2*), that are in the same phylogenetic subgroup as the *SUB1s* (Fig. 22.32). *SK1/SK2* genes are absent or nonfunctional in rice varieties that lack the rapid internode elongation response characteristic of deepwater rice. Both *SKs* are ethylene-regulated and highly induced in internodes upon submergence. Transfer of these genes to nondeepwater rice confers a significant increase in underwater internode elongation.

22.5.5 How do plants sense oxygen deprivation?

Plant responses to flooding include transient alterations in gene expression and metabolism, as well as long-term developmental responses. Are these responses triggered directly or indirectly by low concentrations of available O_2 ?

A direct sensing mechanism generates a response to a decline in O_2 used by an enzyme or other specific process. An indirect mechanism involves the diminished production of ATP, increased production of NADH, and decreased cytosolic pH that result from anaerobic respiration. Temporal and spatial changes in calcium and ROS (H_2O_2 and NO) also occur as O_2 availability diminishes. Evidence implicates Ca^{2+} as an important second messenger in transducing the low-oxygen signal, altering gene expression, and promoting aerenchyma formation. Any or all of these consequences of oxygen deprivation could participate in signal transduction processes. Plant hormones, such as ethylene and ABA, may also be involved in transducing the low-oxygen signal.

A homeostatic sensor of oxygen availability in plants is mediated by the N-end rule pathway of targeted turnover of a group of transcription factors. The N-end rule controls the degradation of proteins based on the presence of specific N-terminal residues that trigger destabilization. There are 11 N-terminal destabilizing residues in plants, but only Cys is involved in oxygen sensing. For proteins that begin Met-Cys, a methionine aminopeptidase can remove the first residue, resulting in a protein with an N-terminal Cys. This residue is susceptible to conversion to Cys-sulfinate or Cys-sulfonate through spontaneous or enzymatic oxidation. The N-terminus then becomes a substrate for an arginyl tRNA transferase, which adds an N-terminal Arg. The protein then has an N-terminus that is an N-degron, which can be recognized by a specific N-recognin E3 ligase, leading to ubiquitination at a specific Lys and degradation by the 26S proteasome.

In *Arabidopsis*, five constitutively expressed or hypoxia-induced AP2/ERF proteins are stable under oxygen deficient conditions, but degraded under oxygen replete conditions.

The second amino acid of these proteins, a Cys, is necessary for their N-end rule turnover. Oxidation of the cysteine by oxygen, ROS, or NO is proposed to initiate the N-end rule turnover process of these proteins. Thus, low oxygen conditions stabilize certain AP2/ERFs that regulate the transcription of genes associated with anaerobic metabolism.

Additional plant proteins associated with signal transduction processes that control survival of low-oxygen conditions include the monomeric RHO of plant (ROP) G-proteins, CIPK, and SnRK1A. Plant hemoglobin-like proteins may also be involved in regulation of signaling or anaerobic ATP production. Despite the absence of clarity on the mechanisms governing low oxygen sensing and response, studies in several model species indicate that survival involves effective management of the reconfiguration of metabolism so that carbohydrate reserves are not rapidly exhausted under prolonged stress.

22.6 Oxidative stress

22.6.1 Oxidative stress results in production of ROS and causes severe cellular damage

Oxidative stress results from conditions that promote formation of ROS, which can damage or kill cells. Environmental factors that cause oxidative stress (Fig. 22.33) include air pollution (increased amounts of ozone or sulfur dioxide), oxidant-forming herbicides such as Paraquat (methyl viologen, 1,1'-dimethyl-4,4'-bipyridinium), heavy metals, drought, heat and cold stress, wounding, the transition to anoxia and reoxygenation, UV light, and intense light conditions that stimulate photoinhibition (see Chapter 12). Oxidative stress also occurs in response to senescence (see Chapter 20) and pathogen infection (see Chapter 21).

FIGURE 22.33 Environmental factors that increase the concentrations of reactive oxygen species (ROS) in plant cells.

Compound	Shorthand notation(s)	Structural representation(s)	Sources
Molecular oxygen (triplet ground state)	$O_2 ; ^3\Sigma$	$\begin{array}{c} \cdot\ddot{O}=\ddot{O}\cdot \\ 1s^2 2s^2 (\sigma_s)^2 (\sigma_s^*)^2 (\sigma_x)^2 (\pi_y)^2 (\pi_z)^2 (\pi_y^*)^1 (\pi_z^*)^1 \end{array}$	Most common form of dioxygen gas
Singlet oxygen (first excited singlet state)	$^1O_2 ; ^1\Delta$	$\begin{array}{c} \cdot\ddot{O}=\ddot{O}\cdot \\ 1s^2 2s^2 (\sigma_s)^2 (\sigma_s^*)^2 (\sigma_x)^2 (\pi_y)^2 (\pi_z)^2 (\pi_y^*)^2 \end{array}$	UV irradiation, photoinhibition, photosystem II e^- transfer reactions (chloroplasts)
Superoxide anion	$O_2^{\bullet -}$	$[\cdot\ddot{O}=\ddot{O}]^-$	Mitochondrial e^- transfer reactions, Mehler reaction in chloroplasts (reduction of O_2 by iron–sulfur center FX of Photosystem I), glyoxysomal photorespiration, peroxisome activity, plasma membrane, oxidation of paraquat, nitrogen fixation, defense against pathogens, reaction of O_3 and OH^- in apoplastic space
Hydrogen peroxide	H_2O_2	$H-\ddot{O}-\ddot{O}-H$	Photorespiration, β -oxidation, proton-induced decomposition of $O_2^{\bullet -}$, defense against pathogens
Hydroxyl radical	OH^\bullet	$\cdot\ddot{O}-H$	Decomposition of O_3 in presence of protons in apoplastic space, defense against pathogens
Perhydroxyl radical	O_2H^\bullet	$\cdot\ddot{O}=\ddot{O}-H$	Reaction of O_3 and OH^- in apoplastic space
Ozone	O_3	$\begin{array}{c} \cdot\ddot{O} \\ \cdot\ddot{O}=\ddot{O} \\ \cdot\ddot{O} \end{array}$	Electrical discharge or UV radiation in stratosphere, reactions involving combustion products of fossil fuels and UV radiation in troposphere

FIGURE 22.34 Molecular structure of reactive oxygen species (ROS) active in plants: singlet oxygen, hydrogen peroxide, superoxide anion, hydroxyl radical, and perhydroxyl radical.

In plants, production of ROS (Fig. 22.34) such as singlet oxygen (1O_2), hydrogen peroxide (H_2O_2), and superoxide ($O_2^{\bullet -}$), hydroxyl (HO^\bullet), and perhydroxyl ($HO_2^{\bullet -}$) anions is an inescapable consequence of aerobic metabolic reactions. The chloroplast electron transfer chain, for example, produces 1O_2 at PSII and $O_2^{\bullet -}$ at PSI and PSII. Mitochondria produce $O_2^{\bullet -}$ at complexes I and III. Peroxisomes and NADPH oxidases (respiratory burst oxidases, RBOHs) at the plasma membrane also produce $O_2^{\bullet -}$ and H_2O_2 , and $O_2^{\bullet -}$, respectively. H_2O_2 is relatively stable and travels relatively long distances, but other ROS have very short half-lives and, therefore, can travel only short distances. For example, ROS produced by plastids and mitochondria are implicated in retrograde signaling to the nucleus. Although all ROS are highly reactive and can destroy lipids, nucleic acids, and proteins, some ROS such as $O_2^{\bullet -}$ and H_2O_2 are required for lignification (see Chapter 2 and 24) and function as signals in

defense responses to pathogen infection (see Chapter 21) as well as in response to a number of abiotic stresses. Plants scavenge and dispose of excessive ROS through use of antioxidant defense systems (nonenzymatic and enzymatic) present in several subcellular compartments. When these defenses fail to halt the self-propagating autooxidation reactions associated with ROS, cell death ultimately results.

22.6.2 Cells have both enzymatic and nonenzymatic antioxidant defense systems

Plant antioxidant defense systems include nonenzymatic and enzymatic systems (Fig. 22.35) involving compounds and enzymes that are not distributed uniformly and that vary among subcellular compartments.

FIGURE 22.35 Localization of reactive oxygen species (ROS) generation and scavenging pathways in plant cells. The water–water cycle detoxifies $O_2^{\bullet-}$ and H_2O_2 and alternative oxidase (AOX) reduces the production rate of $O_2^{\bullet-}$ in thylakoids [bottom left; in some plants iron superoxide dismutase (FeSOD) might replace CuZnSOD in the chloroplast]. ROS that escape this cycle or are produced in the stroma undergo detoxification by SOD and the stromal ascorbate–glutathione cycle. Peroxiredoxin (PrxR) and glutathione peroxidase (GPX) are also involved in H_2O_2 removal in the stroma (bottom right). Excited chlorophyll (Chl) in its triplet state at the light-harvesting complex (LHC) can generate 1O_2 when the

The major nonenzymatic antioxidants in plants (Table 22.4) include ascorbate (vitamin C), reduced glutathione (GSH), α -tocopherol (vitamin E), and carotenoids; polyamines and flavonoids also provide some protection from free radical injury. Upon interaction with ROS, GSH is oxidized to GSSG, and ascorbate is oxidized to monodehydroascorbate and dehydroascorbate. These three oxidized compounds are then reduced back to GSH and ascorbate through the

ascorbate–glutathione cycle, the major antioxidant pathway in plastids. ROS are generated in plastids as a part of normal biochemical processes that include photosynthetic electron transfer. The photosynthetic apparatus receives additional protection from oxidative damage by the exothermic production of the xanthophyll zeaxanthin (see Chapter 12).

The major enzymatic ROS scavenging systems (Table 22.5) include superoxide dismutase (SOD), catalase (CAT), and

TABLE 22.4 Subcellular locations of antioxidants.

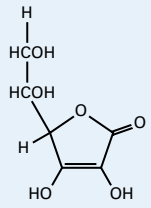

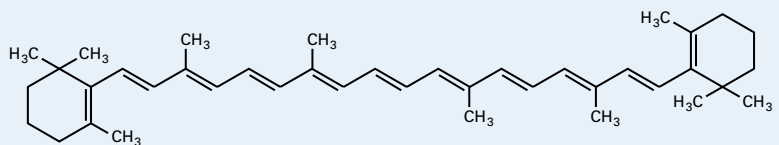

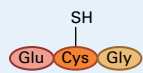

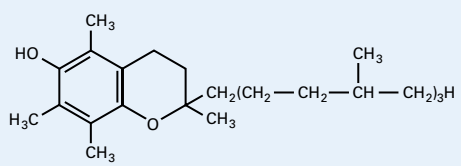

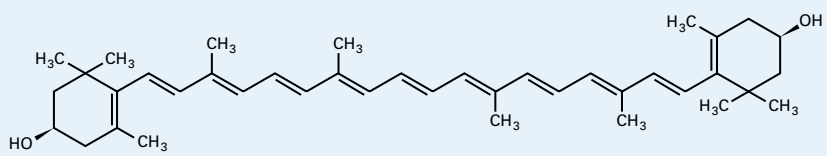

Antioxidant	Structure	Subcellular location
Ascorbate (vitamin C)		Apoplast, cytosol, mitochondrion, nucleus, peroxisome, plastid, vacuole
β -Carotene		Plastid
Glutathione, reduced (GSH)		Cytosol, mitochondrion, plastid, nucleus
Polyamines (e.g., putrescine, shown here)	$\text{H}_2\text{N}(\text{CH}_2)_4\text{NH}_2$	Cytosol, mitochondrion, nucleus, plastid
α -Tocopherol (vitamin E)		Membranes (including plastid membranes)
Zeaxanthin		Chloroplast

FIGURE 22.35 (Continued) electron transport chain is over-reduced. ROS are produced in peroxisomes during fatty acid oxidation, photorespiration or other reactions are decomposed by SOD, catalase (CAT) and ascorbate peroxidase (APX) (middle right). SOD and other components of the ascorbate–glutathione cycle are also present in mitochondria. In addition, AOX prevents oxidative damage in mitochondria (top right). In principle, the cytosol contains the same set of enzymes found in the stroma (bottom). NADPH oxidases (respiratory burst oxidase homologs [RBOHs]) are the major producers of ROS-associated signals required in a wide range of biological activities. The enzymatic components responsible for ROS detoxification in the apoplast and cell wall are only partially known, and the ROS-scavenging pathways at the vacuole and nucleus are unknown. GPX pathways are indicated by dashed lines and PrxR pathways are indicated by dotted lines in the stroma and cytosol. Although the pathways in the different compartments are mostly separated from each other, H_2O_2 can easily diffuse through membranes and antioxidants such as glutathione and ascorbic acid can be transported between the different compartments. DHA, dehydroascorbate; DHAR, DHA reductase; FD, ferredoxin; FNR, ferredoxin NADPH reductase; GLR, glutaredoxin; GR, glutathione reductase; GOX, glycolate oxidase; GSH, reduced glutathione; GSSG, oxidized glutathione; MDA, monodehydroascorbate; MDAR, MDA reductase; PGP, phosphoglycolate phosphatase; PSI, photosystem I; PSII, photosystem II; RuBP, ribulose-1,5-bisphosphate; Rubisco, RuBP carboxylase oxygenase; Trx, thioredoxin.

TABLE 22.5 Subcellular locations of antioxidant enzymes.

Antioxidant enzyme	Abbreviation	Subcellular location
Ascorbate peroxidase	APX	Cytosol, mitochondrion, plastid, peroxisome, root nodules
Catalase	CAT	Peroxisome
Dehydroascorbate reductase	DHAR	Cytosol, root nodules
Glutathione reductase	GR	Cytosol, mitochondrion, plastid, root nodules
Glutathione peroxidase	GPX	Cytosol, mitochondrion, plastid
Monodehydroascorbate reductase	MDAR	Cytosol, mitochondrion, plastid, root nodules
Peroxiredoxin	PrxR	Chloroplast, mitochondrion
Superoxide dismutase (grouped by metal cofactor)	Cu/ZnSOD	Cytosol, peroxisome, plastid, root nodules
	MnSOD	Mitochondrion
	FeSOD	Plastid

ascorbate peroxidase (APX). SODs are the first enzymes for detoxification of ROS, dismuting $O_2^{\cdot-}$ to H_2O_2 and CAT and APX subsequently convert H_2O_2 to H_2O . Glutathione peroxidase (GPX) consumes GSH to convert H_2O_2 to GSSG and H_2O . Other enzymes such as glutathione reductase (GR), dehydroascorbate reductase (DHAR) and monodehydroascorbate reductase (MDAR) are antioxidant enzymes of the ascorbate–glutathione cycle, but they do not detoxify ROS directly. Regulation of the concentrations of antioxidants and antioxidant enzymes constitutes an important mechanism for avoiding oxidative stress.

22.6.3 Ozone exposure causes severe oxidative stress in plants

One of the best-characterized oxidative stressors is exposure to high concentrations of ozone. Ozone is harmful because it is a highly reactive oxidant (Fig. 22.36), and exposure to it decreases rates of photosynthesis, growth of shoots and roots, and crop yields. It also causes leaf injury (Fig. 22.37) and accelerates senescence.

Plants vary greatly in their ability to survive in high-ozone environments, and their resistance involves both avoidance and tolerance mechanisms. Avoidance involves physically excluding the pollutant by closing stomata, the principal sites of ozone entry. Tolerance can result from biochemical responses that induce or activate the antioxidant defense system and possibly also various repair mechanisms. Resistance is also influenced by environmental factors that can cause oxidative stress (e.g., water status, temperature, and light intensity) as well as by the developmental age of the plant or plant organ. Although ozone-induced injury can increase the susceptibility of plants

to pathogens, ozone exposure paradoxically can induce pathogen resistance by upregulating the antioxidant enzymes that are induced by the hypersensitive response (HR; see Chapters 20 and 21) and systemic acquired resistance (SAR; see Chapter 21).

Although the mechanisms of ozone toxicity are not completely understood, damage is likely a consequence of oxidative destruction of plasma membrane lipids and proteins and production of free radicals or other reactive intermediates (Fig. 22.38). Upon entering cells, ozone may react with ethylene and other alkenes in the apoplastic fluid to form $HO^{\cdot-}$, $O_2^{\cdot-}$, and H_2O_2 , which damage cellular components. Damage to membrane lipids alters ion transport, increases membrane permeability, inhibits H^+ -pump activity, collapses membrane potential, and increases Ca^{2+} uptake from the apoplast. Proteins, nucleic acids, and carbohydrates are among targets of ozone-derived ROS. The mechanism of ozone action can differ, depending on whether the exposure is acute, chronic, or repeated. The term ozone dose is used to describe the combination of duration and level of exposure. Tolerance to ozone-induced injury is inherited as a quantitative trait in many species.

Ozone exposure causes a rapid inhibition of photosynthesis, which is reflected in changes in the activity or synthesis of chloroplast proteins. In several plants (e.g., potato, radish, poplar, and wheat), chronic exposure to ozone reduces the abundance of ribulose biphosphate carboxylase/oxygenase (Rubisco) in mature but not immature leaf tissue. This loss of Rubisco is the result of increased degradation of the protein, but it may also involve changes in transcription, accumulation, and translation of *rbcS* and *rbcL* mRNAs. In potato, induction of ethylene synthesis is followed by a decrease in *rbcS* and *rbcL* transcript levels, suggesting that gene expression may be regulated by the stress production of this phytohormone. Degradation of the large subunit of Rubisco is also

FIGURE 22.36 Stratospheric consumption and atmospheric generation of O₃. Ninety percent of atmospheric O₃ is in the stratosphere, 10% in the troposphere. Stratospheric ozone beneficially decreases the penetration of solar radiation to the troposphere. Anthropomorphic release of chlorofluorocarbons (CFCs) leads to depletion of stratospheric ozone, especially over polar regions. The burning of fossil fuels increases the production of carbon compounds that react in sunlight with oxygen to form ozone in the troposphere.

FIGURE 22.37 Ozone-damaged oat (*Avena sativa* L.) leaves. Chlorotic lesions develop in the middle of the leaves. Leaf tips (oldest leaf cells) and leaf bases (youngest leaf cells) show the least damage. Source: Jacobson & Hill (1970) Recognition of Air Pollution Injury to Vegetation: A Pictorial Atlas. Air Pollution Control Association, Pittsburgh, PA.

observed in response to two other forms of oxidative stress, high-intensity light and oxidant herbicides (e.g., Paraquat). Collectively, unifying evidence links the loss of photosynthetic capacity to one or more of the following: reduced activity of PSI, PSII, or Rubisco; declining steady-state concentrations of Rubisco; increased turnover of the PSII protein D1, and possibly photoinhibition (see Chapter 12).

22.6.4 Various abiotic and biotic stressors cause oxidative stress

Various abiotic and biotic stresses also disturb the equilibrium of ROS production and scavenging to rapidly increase ROS concentrations in cells. Temperature stresses, such as excessive heat, chilling, or freezing, also increase cellular ROS

FIGURE 22.38 Ozone action and plant responses. Because O₃ is polar and hydrophilic, it is unable to penetrate the leaf cuticle and penetrates the plasma membrane only poorly. Stomatal closure can diminish O₃ entry into the periplasmic space. Damage from O₃ occurs primarily as a result of peroxidation of plasma membrane lipids and stimulation of ROS production. Exposure to O₃ activates the antioxidant defense mechanisms within the cell. Whether antioxidant defenses are successful depends on the concentration of O₃, the duration of exposure, the age of the plant, and the genotype.

levels and render membranes and proteins dysfunctional. Heat stress impairs the mitochondrial respiratory electron transport chain, which causes oxidative damage to membrane lipids by peroxidation. Chilling stress inactivates cytochrome *c* oxidase and increases ROS production, and in chloroplasts, chilling and freezing damage the photosynthesis machinery and increase ROS concentrations. Oxidative stress during temperature stress can be further enhanced by high light; in cucumber (*Cucumis sativus*), for example, Cu/Zn SOD is the primary target of chilling stress combined with high light, which stimulate production of ROS and inactivation of PSI. Increases in ROS and ROS-associated injury are also observed in response to salinity, drought, osmotic stress, and reoxygenation following flooding.

Oxidative burst, the rapid production of ROS (primarily O₂^{•-} and H₂O₂) at the site of invasion, is the primary defense system of plants to pathogen attack. Plasma membrane-associated NADPH-oxidase (RBOH) and apoplastic peroxidase systems are responsible for oxidative burst, which produces reduced ROS that trigger programmed cell death to block the spread of infection (hypersensitive responses, see Chapters 20 and 21). A balance between the ROS production and scavenging under stressful conditions is clearly important for maintaining cellular activities and for cell survival.

22.6.5 Increased synthesis of nonenzymatic and enzymatic antioxidants can improve tolerance to oxidative stress

In many plants, oxidative stress can stimulate synthesis of both nonenzymatic and enzymatic antioxidants (Table 22.6). Mutants with altered nonenzymatic antioxidants, such as GSH and ascorbate, exhibit different levels of environmental stress sensitivities. As mentioned above, oxidative stress results in oxidation of GSH to GSSG, and ascorbate to monodehydroascorbate and dehydroascorbate, and these oxidized compounds can then be reduced and reformed to GSH and ascorbate through the ascorbate–glutathione cycle. Eventually, many plants increase enzyme activities (or amounts) of GSH and ascorbate biosynthesis and the ascorbate–glutathione cycle. Therefore, the balance of various nonenzymatic antioxidants must be controlled to maintain proper redox state of cells. Elevated glutathione biosynthetic capacity in the chloroplasts of transgenic tobacco plants unexpectedly causes oxidative stress. Overexpression of an enzyme (β -carotene hydroxylase) in *Arabidopsis* increases a nonenzymatic antioxidant, xanthophyll (a flavonoid), in chloroplasts and enhances oxidative stress tolerance under high light conditions.

TABLE 22.6 Stress conditions that stimulate increased levels or activities of antioxidants and antioxidant enzymes of various species.

Antioxidant or enzyme*	Stress conditions
α -Tocopherol (vitamin E)	Drought
Anionic peroxidases	Chilling, high CO ₂
Ascorbate peroxidase	Drought, high CO ₂ , high light intensity, ozone, Paraquat, salinity
Catalase	Chilling
Glutathione	Chilling, drought, γ -irradiation, heat stress, high CO ₂ , ozone, SO ₂
Glutathione reductase	Chilling, drought, high CO ₂ , ozone, Paraquat, salinity
Polyamines	Drought, heat, ozone, deficiency of K, P, Ca, Mg, Fe, Mn, S, or B
Superoxide dismutase	Chilling, high CO ₂ , high light, increased O ₂ , ozone, Paraquat, salinity, SO ₂

*Changes in the amounts of these compounds and enzyme activities are dependent on the developmental stage of the plant and the experimental parameters.

Studies in *Arabidopsis* and other plant species have revealed redundancy of genes encoding enzymes associated with antioxidants and antioxidant enzymes. The differential expression of these genes appears to be regulated in a specific manner by different forms of abiotic or biotic stress. The over- and underexpression of genes encoding antioxidant enzymes has confirmed their roles as ROS scavenging enzymatic systems in numerous plant species. In some cases, ectopic overexpression of ROS-scavenging enzymes or transcription factors that enhance their expression has relieved susceptibility to abiotic stresses. APX overexpression decreases accumulation of H₂O₂ and increases chilling tolerance of rice, whereas knock out of cytosolic APX activity reduces tolerance to a variety of conditions with an oxidative component in *Arabidopsis*. Overexpression of pea (*Pisum sativum*) chloroplast SOD in tobacco (*Nicotiana tabacum*) increases Paraquat-induced membrane damage. Further, transgenic alfalfa (*Medicago* sp.) overexpressing tobacco Mn-SOD shows enhanced tolerance to freezing stress, and a salt-tolerant tomato (*Lycopersicon esculentum*) cultivar has higher levels of an Mn-SOD than a salt-sensitive cultivar under saline conditions.

Subcellular compartmentation influences the roles of antioxidant metabolites in detoxification; duplicate biochemical functions are often accomplished by distinct, spatially segregated antioxidant systems. For example, H₂O₂ is scavenged by both catalase (in the cytosol and peroxisomes) and ascorbate peroxidase (in the cytosol and plastids). Because compartmentation, and even location within an organelle, can be critical for function, the simple overexpression of antioxidant enzymes may not necessarily improve stress tolerance. Increased concentrations of a single antioxidant or antioxidant enzyme may not protect plant tissues if other oxidant-scavenging mechanisms are limiting

or if overexpression results in increased production or reduced scavenging of ROS. In certain cases, however, overexpression of one or more antioxidant enzymes may provide protection from oxidative stress.

Oxidative stress tolerance probably depends on the successful induction of functional detoxification systems in the subcellular compartments that are exposed to high concentrations of free radicals. Overexpression of antioxidant enzymes can result in tolerance to single and multiple causes of oxidative stress, including pathogens, Paraquat, and osmotic stresses (e.g., chilling, salinity, and drought). However, increases in these compounds and enzymes are not always beneficial, most likely because of the complex compartmentalized networks involving ROS as a signaling and the antioxidants and antioxidant enzymes that control the damaging activities of ROS.

22.6.6 ROS can be signaling molecules in cells

While ROS are considered toxic byproducts of aerobic metabolic reactions that must be eliminated, they also act as signaling molecules that control a variety of cellular processes in plants, such as abiotic and biotic stress responses, programmed cell death, growth, development, pathogen defense, and stomatal responses. ROS generation in chloroplasts or mitochondria causes changes in nuclear gene expression, which indicates intracellular transmission of ROS information. ROS signals can be sensed by ROS sensors, such as two-component histidine kinase systems and redox-sensitive transcription factors and phosphatases. ROS eventually elicit changes in gene expression that modify various cellular processes.

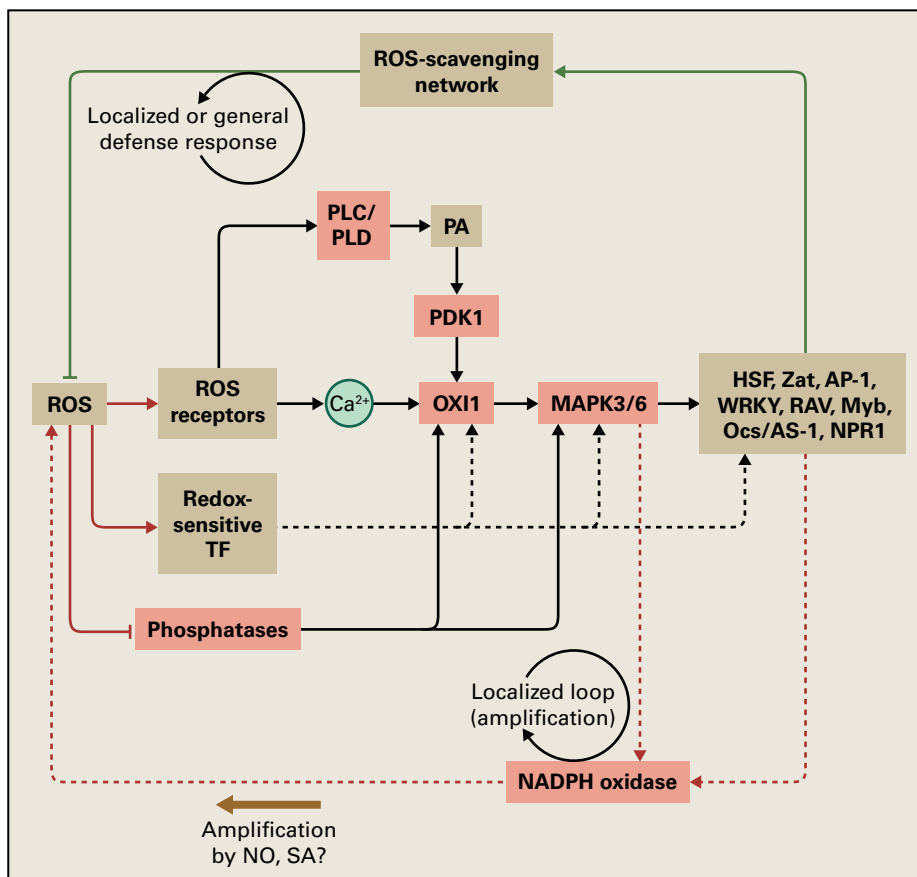

FIGURE 22.39 Proposed model of the ROS signal transduction pathway. ROS can be detected by at least three mechanisms: ROS receptors, redox-sensitive transcription factors, and phosphatases. Detection by ROS receptors generates Ca^{2+} signals and activates phospholipase C/D (PLC/PLD) to generate phosphatidic acid (PA). PA and Ca^{2+} are thought to activate the protein kinase OXI1, which then activates a mitogen-activated-protein kinase (MAPK) cascade (MAPK3/6) to induce or activate different transcription factors that regulate the ROS-scavenging and ROS-producing pathways. Activation or inhibition of redox-sensitive transcription factors by ROS might also affect the expression of OXI1 or other kinases, and the induction of ROS-specific transcription factors. Inhibition of phosphatases by ROS might result in the activation of kinases, such as OXI1 or MAPK3/6. Two loops are involved in the ROS signal transduction pathway: a localized or general defense response (a negative feedback loop; solid green line) can be activated to suppress ROS, and a localized amplification loop (positive feedback loop; red dashed line) can be activated to enhance ROS signals via NADPH oxidases. Salicylic acid (SA) and nitric oxide (NO) might be involved in this amplification loop as enhancers. HSF, heat shock factor; PDK, phosphoinositide-dependent kinase; TF, transcription factor.

Several components involved in ROS signaling downstream of detection have been identified (Fig. 22.39). After ROS are detected, Ca^{2+} signals involving calcium-binding proteins, such as calmodulin, are generated and phospholipases (C and D) are activated to produce phosphatidic acid. Ca^{2+} and phosphatidic acid are thought to activate a protein kinase (OXI1) and, subsequently, a mitogen-activated protein kinase (MAPK) cascade, which results in modulation of several transcription factors. ROS signals detected by redox-sensitive transcription factors are thought to affect OXI1, MAPKs, and ROS-specific transcription factors. ROS signals detected by inhibition of phosphatases may activate OXI1 and MAPKs. Ultimately, ROS signals, independent of detection systems, stimulate various ROS defense systems, such as changes in ROS-production/scavenging balance and production of ROS stress-protective proteins and compounds.

ROS (i.e., H_2O_2) application induces global alterations in gene expression in plants. In *Arabidopsis* and tobacco (*Nicotiana tabacum*), 1–2% of genes show changes in their expression levels in response to H_2O_2 . ROS also alter several transcription factors, including HSFs, NPR1, WRKYs, and Myb-type transcription factors. Upregulation of these transcription factors ultimately causes changes in expression of downstream genes for kinases, peroxisome biogenesis-related proteins, antioxidant enzymes, and defense-associated proteins. Exposure to ROS also results in changes in protein profiles in subcellular compartments. In mitochondria, for example, levels of antioxidant defense proteins (such as peroxiredoxins and protein disulfide isomerase) increase, as do levels of enzymatic antioxidants (peroxidases and SOD) and enzymes associated with the ascorbate–glutathione cycle in chloroplasts.

ROS may also act on the transcriptome to induce oxidative stress by reducing antioxidant activity. Antisense lines of

FIGURE 22.40 HSPs, particularly those of low molecular mass (smHSPs), accumulate in soybean (*Glycine max*) seedlings in response to high temperatures. Total protein was extracted from seedlings that were incubated in the presence of ^3H -leucine at 28°C (A,B) or 40°C (C,D) for 3 hours, and then resolved by two-dimensional polyacrylamide gel electrophoresis. Proteins were visualized by silver staining (A,C) or by fluorography (B,D). Source: (A–D) Mansfield & Key (1987). *Plant Physiol.* 84:1007–1017.

CAT and APX show elevated expression of SOD and GR, which may be compensatory mechanisms in plants to reduce oxidative stress. There is considerable interest in identifying “ROS gene network” components in plants, which requires controlling ROS toxicity by using ROS themselves as signaling molecules. In *Arabidopsis*, the ROS gene network contains approximately 150 genes that encode ROS-producing and -scavenging enzymes including CAT, APX, alternative oxidase, peroxiredoxin, and Cu-SOD. Further analyses with additional mutants and knockouts of multiple genes in the ROS gene network will enable further investigation of the roles of the network in oxidative stress responses; it may reveal crosstalk between ROS and other abiotic/biotic stress signaling pathways.

22.7 Heat stress

22.7.1 Heat stress alters cellular function

As with other abiotic stress conditions, heat stress can be chronic or long-term (as experienced in hotter habitats), or it can be more acute (as a result of seasonal or daily temperature extremes). Heat stress may occur under numerous temporal and developmental conditions, with results ranging from retarded growth to damaged organs and plant death. In the field, leaves may experience heat stress when transpiration is insufficient (i.e., when water is limiting and temperature is high) or when stomata are partially or fully closed and irradiance is high; in germinating seedlings, when the soil is warmed by the sun; in organs with reduced capacity for transpiration (e.g., fruit); and overall, from high ambient temperatures. The duration and severity of stress, susceptibility of different cell types, and stage of development all influence the ability of a particular genotype to survive heat stress.

Many features of the responses of plants to chronic heat stress are conserved in all organisms. The signature response to acute heat stress is a rapid and transient reprogramming of gene expression, including a decrease in the synthesis of normal proteins and accelerated transcription and translation of **heat shock proteins** (HSPs). This response is observed when plants are exposed to temperatures 5°C or more above their optimal growing conditions (Fig. 22.40).

In addition to altering patterns of gene expression, heat also damages cellular structures, including organelles and the cytoskeleton, and impairs membrane function. Organisms amenable to genetic manipulation, especially *E. coli*, yeast, and *Arabidopsis*, have been used to determine the cellular and metabolic changes required to survive high temperatures. Transcription factors, including HSFs involved in the expression of HSPs and other heat-inducible genes, have been identified, and their different roles in stress responses and tolerance have been investigated. There is overlap and crosstalk between heat stress and other abiotic stress signaling and response pathways, which have been analyzed using reverse genetic approaches.

22.7.2 Plants can acclimate to heat stress

Plants and other organisms can acquire thermotolerance if subjected to a nonlethal (**permissive**) high temperature for several hours before encountering normally lethal (**nonpermissive**) heat stress conditions. Acclimation to otherwise damaging high temperatures can also occur if the temperature increases gradually to the nonpermissive temperature, as may occur from morning to mid-afternoon on a hot day. *Arabidopsis* plants acclimated to survive a normally lethal 45°C treatment are shown next to nonacclimated plants in Figure 22.41. The acclimation process involves the synthesis of HSPs, some of which have been directly shown to be

FIGURE 22.41 Acclimation of *Arabidopsis* seedlings to high temperature. For acclimation, 10-day-old seedlings were treated for 90 min at 38°C and returned to 22°C for 2 hours before treatment at 45°C for 2 hours. Nonacclimated seedlings were directly exposed to 45°C. Seedlings were photographed after 5 days at 22°C. Nonacclimated seedlings died after treatment and did not produce more leaves.

TABLE 22.7 HSPs and their characteristics.

Protein classes	Subfamilies	Size (kDa)	Major functions	Subcellular location
HSP100/Clp	Class I: ClpB, A/C, D Class 2: ClpM, N, X, Y	100–114	Protein disaggregation, unfolding, degradation (Clp protease)	Cytosol, mitochondria, chloroplast
HSP90	Hsp90	80–94	Maturation of signaling molecules, genetic buffering	Cytosol, chloroplast, mitochondria, endoplasmic reticulum
HSP70	DnaK BiP and GRP Hsp110/SSE	69–71	Prevention of aggregation, assisting refolding, protein import and translocation, signal transduction, and transcriptional activation	Cytosol, chloroplast, mitochondria, endoplasmic reticulum
HSP60/Chaperonin	Cpn60 CCT	60	Folding, assisting refolding	Chloroplast, mitochondria, cytosol
Small HSP (sHSP)		15–30	Prevention of aggregation, stabilization of nonnative proteins	Cytosol, chloroplast, mitochondria, endoplasmic reticulum, nucleus, peroxisome

required, as well as many other poorly understood changes in cellular metabolism. This type of rapid acclimation is transient, and begins to decay after 24 hours or less. Despite this capacity for acclimation, there is, of course, a limit to how much heat a plant can withstand. The relationships between this type of acclimation and overall differences in the ability of various plant genotypes and species to grow at different optimal temperatures remain to be resolved.

22.7.3 HSPs are conserved among different organisms

The rapid, high-level expression of HSPs in response to heat stress has led to significant focus on these proteins. Major classes of HSPs are conserved among all organisms, both prokaryotic and eukaryotic. These proteins function as molecular chaperones and are involved in various aspects of the folding of nascent proteins or refolding of proteins denatured by heat. Some HSPs are expressed throughout the life cycle of the plant. Indeed, some proteins designated as HSPs

are not induced by heat at all, but rather are defined as HSPs according to sequence homology and possible functional similarities. The roles played by some plant HSPs have been inferred from complementation studies in yeast. For example, an HSP104 deletion mutant of yeast that is not thermotolerant can be partially rescued by a member of the *Arabidopsis* HSP100 family. However, the plant protein affords the yeast mutant less thermotolerance than the native yeast counterpart. Recently, T-DNA or Ds-tagged mutants have been used to analyze the functions of HSPs and HSFs to determine their roles in stress tolerance of plants.

22.7.4 Five major classes of HSPs function as molecular chaperones

HSPs are grouped into five distinct classes named for their approximate molecular masses (Table 22.7). HSPs are thought to work in concert for the protection of complex cellular systems. They act as a protein quality control network to promote folding and proper localization of nascent proteins,

prevent irreversible aggregation of denatured proteins, and facilitate recovery of denatured protein function. HSPs can also direct damaged proteins to the cellular degradation machinery as another way to maintain normal cellular function and promote recovery from stress. Different classes of HSPs play complementary and overlapping roles in the protection of cells from stress-mediated cellular damage.

HSP100/ClpB family proteins are members of the AAA+ family of proteins, which are ATPases that function in disaggregation of denatured proteins. Plants possess cytosol-, chloroplast-, and mitochondrion-localized HSP100/ClpB proteins. Cytosolic HSP100 is essential for heat stress tolerance in plants, but is not essential for plant growth. Genetic analysis of *Arabidopsis* HSP101 has shown that it interacts with small HSPs to resolubilize aggregated proteins after exposure to heat stress. Chloroplast Hsp100/ClpB protein plays an essential role in chloroplast development as well as the heat stress response.

Proteins of the HSP90 family are found in bacteria and in the cytosolic, nuclear, and endoplasmic reticulum (ER) compartments of eukaryotic cells. In yeast, HSP90 is essential for growth at all temperatures. HSP90 has ATPase activity and has been shown in yeast and mammalian cells to be involved in a complex cycle with other auxiliary proteins to regulate the maturation and activity of numerous signaling proteins. How this activity is related to the plant heat stress response is still under investigation, but even *Arabidopsis* has four genes encoding cytosolic Hsp90 proteins.

HSP70 proteins (known as DnaK in prokaryotes) are ATPases essential for normal cell function. Some members are expressed constitutively, whereas others are induced by heat or cold. Present in multiple compartments (e.g., the cytoplasm, ER, mitochondria, and chloroplasts), HSP70 proteins are ATP-dependent molecular chaperones that interact with many different proteins, given their involvement in protein folding, unfolding, assembly, and disassembly (see Chapters 4 and 10). The most highly conserved feature shared among HSP70 proteins is the N-terminal ATP binding domain; the C-terminus, however, varies and may determine substrate specificity. Additional proteins, termed cochaperones, including DnaJ

(Hsp40 in eukaryotes) and GrpE, stimulate Hsp70 ATPase activity and facilitate interactions of HSP70 proteins and their targets. A dramatic feature of plants compared to other organisms is their very large number of DnaJ proteins, which may each have specific adaptor functions for one or more Hsp70s.

Members of the HSP60 protein family are also known as **chaperonins**, and were the first proteins defined as molecular chaperones. Chaperonins are present in the bacterial cytosol (GroEL), the mitochondrial matrix (first termed Hsp60), and the chloroplast stroma. Chaperonins are abundant even at normal temperatures; their major role is thought to be in protein folding and assembly (see Chapters 4 and 10). They share a common oligomeric structure of two seven-member rings, and require ATP for their function. In plants, the best-studied family member is chaperonin 60, a nuclear-encoded chloroplast protein that is involved in Rubisco assembly, but its expression is not increased in response to heat stress. In vitro, chaperonins prevent other proteins from aggregating at physiologically relevant temperatures and are important in protein refolding.

One unique aspect of the heat shock response in plants is the abundance of small HSPs (sHSPs). Higher plants express 11 classes of sHSP, and plants are the only organisms in which sHSPs are targeted to virtually every intracellular compartment (Table 22.7). Although sHSPs are also found in all organisms, with the exception of a few prokaryotes, the diversification of plant sHSPs occurred after the divergence of plants and animals. Furthermore, sHSPs are the most strongly induced of all the HSPs in plants. It has been suggested that sHSPs evolved in response to the multiple stressors, including heat, that plants encountered on migration to land and because unlike animals they are sessile and cannot move to a more favorable environment. The defining feature of sHSPs is a C-terminal domain that is homologous to α -crystallins, proteins of the vertebrate eye lens. Although sHSP monomers are small (≈ 15 – 22 kDa in plants), in their native state the majority form large oligomers of 12 or more subunits. The most detailed structural information for any eukaryotic sHSP comes from determination of the 3D structure of the oligomeric form of a cytosolic sHSP from wheat, which is a dodecamer (Fig. 22.42). Current models from work performed in

FIGURE 22.42 Structure of the native, oligomeric wheat sHSP, Hsp16.9 (Protein Database accession number 1GME). (Left) The dodecameric oligomer, with six subunits in the top ring (three dimers) and six subunits in the bottom ring, each uniquely colored. The diameter of the ring is approximately 95 Å. (Right) A dimer of subunits.

vivo in yeast and *E. coli*, and in vitro with plant and other sHSPs, indicate that sHSPs bind denatured proteins in an ATP-independent manner and make these proteins available for refolding by ATP-dependent chaperones, primarily HSP70.

22.7.5 Expression of many HSPs is controlled by HSFs that recognize a conserved promoter sequence

HSFs are transcription factors that function as terminal components in heat stress signal transduction and are activated to transcribe their target genes, including HSPs. The *cis*-acting DNA target of HSFs, the **heat shock element** (HSE), is made up of 5-bp repeats in alternating orientations with the consensus nGAAn. An HSF-regulated promoter may contain five to seven of these repeats close to the TATA box. Many HSEs contain the DNA element 5'-CTnGAAnnTTCnAG-3'. Notably, the HSF DNA binding domain and the HSE are common to all eukaryotes. HSEs were also the first *cis*-acting transcriptional control element to be described. When an HSP gene promoter containing HSEs is linked to the firefly luciferase reporter gene and expressed in plants, tightly regulated, high-level luciferase expression can be observed. The level of gene expression is proportional to the time and temperature of heating, indicating the remarkable heat-sensing mechanism involved.

Although HSFs and HSEs are conserved, plants have an unusually large number of HSFs. For example, *Arabidopsis* has 21 HSF genes, and there are three classes of plant HSF (A–C), which are distinguished mainly by the structures of their oligomerization domains. Interestingly, not all HSFs are involved in regulation of gene expression in response to high temperature; however, several HSFs constitute a regulatory network and control transcription of HSPs as well as other genes. In tomato (*Lycopersicon esculentum*), HsfA1a is a master regulator that is expressed constitutively to regulate heat shock-induced expression of HsfA2 and HsfB1. HsfA2 is the major HSF in thermotolerant tomato cells, and forms a heterooligomeric complex with HsfA1a, which functions as a nuclear retention factor and a coactivator.

The *HsfA3* gene is regulated by DREB2A, an AP2/ERF transcription factor that functions mainly in dehydration-inducible gene expression. DREB2A is regulated by heat stress as well as dehydration, indicating HSF-mediated crosstalk between heat shock and dehydration stress responses. Regulatory networks composed of transcription factor cascades are important in crosstalk between abiotic stress signaling pathways.

Similar to other HSFs, the HSF of *Arabidopsis* can only bind DNA as trimers (Fig. 22.43), and heat stress is required for trimerization. The oligomerization and DNA-binding domains of HSF are conserved among different organisms. Trimerization depends on the presence of a leucine zipper configuration of hydrophobic heptad repeats located adjacent to the DNA binding domain. The mechanism that controls trimerization is poorly understood, but recent studies have indicated that

trimerization, DNA binding, and transcriptional activity are repressed in the absence of heat stress (Fig. 22.43). When the HSF is overexpressed in *Arabidopsis*, the transcription factor is not active; overexpression of HSF in heterologous systems, however, such as *E. coli*, *Drosophila*, and HeLa cells, results in constitutively active HSF. This indicates that the mechanism of repression is selective for homologous HSF but not heterologous HSF. The *Arabidopsis* HSF can be derepressed when it is tagged with a reporter gene and then overexpressed.

Overexpression of transcription factors may prove an efficient way to improve stress tolerance, because a single transgenic protein can induce an entire battery of coordinately regulated genes. There is considerable interest in determining whether overexpressing this HSF construct in crop plants improves heat tolerance in the field.

22.7.6 Important questions remain about heat stress sensing and signaling

Many important questions remain about heat stress responses. How is heat stress sensed and the signal transduced? Is there a central network in heat stress responses? How do HSPs recognize target proteins for refolding or degradation?

There are clearly multiple signaling pathways in the heat stress response, as well as crosstalk between heat and oxidative stress responses. This means that heat stress triggers H₂O₂ production in cells and can lead to cellular damage. Under some conditions, this oxidative burst is correlated with the induction of heat stress-inducible genes, which may be due to the direct sensing of H₂O₂ by HSFs. Mutants of two NADPH oxidases show defects in thermotolerance, suggesting the involvement of ROS in the heat response. Moreover, other signaling molecules, such as calcium, are also involved. Calcium levels transiently increase in response to heat stress, but calcium transients are often observed in response to various types of stimuli. Phytohormones, such as ABA, salicylic acid (SA), and ethylene, are also suggested to have some link with heat stress responses, as they accumulate in response to heat stress, but are not correlated with thermotolerance.

22.8 Crosstalk in stress responses

Plants have developed survival strategies to cope with various types of environmental stress. Different types of abiotic stress affect plant growth under natural environmental conditions, and different stress signaling pathways interact to allow the plant to cope with complicated stress conditions. The plant hormones ABA, JA, SA, and ethylene are produced endogenously to regulate protective responses against various stressors through synergistic and antagonistic actions. ROS also function as common stress signal factors in stress responses. Abiotic stressors regulate the expression of

FIGURE 22.43 Model for HSF activation of gene expression. In the unstressed cell, HSF is maintained as a monomer and cannot bind DNA. Upon heat shock, the HSF is assembled into a trimer capable of binding a specific DNA sequence. This model is mainly based on the research of bacterial HSFs.

different but overlapping sets of genes—some are regulated differentially by plant hormones, and others are induced similarly by ROS. Thus, signaling pathways consist of complex networks with crosstalk that allow plants to respond to different types of environmental stress. Important factors involved in the points of convergence between biotic and abiotic stress signaling pathways, especially transcription factors and protein kinases, are particularly implicated in ROS and hormone signaling.

Rapid production of ROS in response to various types of stress plays a pivotal role in abiotic stress responses. To prevent cell injury or death due to excess ROS, ROS-scavenging enzymes such as SOD and APX regulate the steady-state level of ROS. Large-scale transcriptome analyses of plants subjected to various abiotic stress treatments have revealed the induction of a large set of genes encoding ROS-scavenging enzymes under these conditions. Several scavenging enzymes have been used to engineer abiotic stress-tolerant plants.

Whereas the plant hormones SA, JA, and ethylene play central roles in biotic stress signaling upon pathogen

infection, ABA mediates abiotic stress signaling. However, recent studies have indicated the involvement of ABA in defense signaling via synergistic or antagonistic interactions with other hormone signaling pathways. In many cases, ABA acts as a negative regulator of disease resistance. Antagonistic interactions between the ABA and JA/ethylene pathways have also been studied in detail. Taken together with the observation that exogenous methyl jasmonate and ethylene do not affect suppression of defense gene expression induced by exogenous ABA, the ABA-mediated abiotic stress response may be a dominant process.

JA and ethylene are also involved in abiotic stress responses. Recent studies have shown that the bHLH transcription factor AtMYC2 plays a role in multiple hormone signaling pathways, suggesting that AtMYC2 is a key regulator of the crosstalk between biotic and abiotic stress responses via hormone signaling. Genetic analysis of the JA-insensitive *jin1* mutant has indicated that *JIN1* is allelic to *AtMYC2*, which was initially identified as a transcriptional activator involved in ABA-mediated drought stress signaling.

Transcriptional regulation also functions in crosstalk in stress signaling. The DREB2A transcription factor is a good example. Many heat shock-inducible genes as well as typical drought-inducible genes are upregulated by DREB2A, and transgenic *Arabidopsis* plants overexpressing the constitutively active form (CA) of DREB2A are more resistant to high temperature stress than wild-type controls. Thus, the DREB2A protein is believed to be involved in both water deficit and heat stress-responsive gene expression.

Genes regulated by the DREB2A transcription factor are categorized into three groups: those induced by drought, by

heat stress, and by both drought and heat. The heat shock transcription factor gene *AtHsfA3* was identified as a target gene of DREB2A that contains at least two DRE/CRT core sequences in its promoter. It can be highly upregulated by the overproduced DREB2A-CA protein in transgenic plants even under normal conditions. Therefore, a new cascade of plant heat shock signaling has been established in which high temperature stress can rapidly induce *DREB2A* gene expression, and then DREB2A protein can bind the DRE/CRT sequence in *AtHsfA3* promoter and activate its transcription to control downstream *HSP* genes (see Fig. 22.12).

Summary

Abiotic stresses, including drought, chilling, heat, and flooding, are prevalent in nature and can substantially diminish crop yields. Plant responses to stressful environmental factors can permit the plant to withstand the stress; alternatively, such responses may be a manifestation of injury that has occurred in response to the abiotic stress. The response depends on the severity and duration of the stress, the developmental stage of the affected plant, the tissue type, and the interactions of multiple stresses. Mechanisms that permit stress survival are termed resistance mechanisms and can allow an organism to avoid or tolerate stress. Acclimation, a process that improves stress resistance, may occur in response to a mild nonlethal stress. Changes in gene expression may be involved in the mechanism of stress resistance or may be a result of injury. Recent advances in functional analyses of stress regulated genes and their products have revealed detailed molecular processes of plant responses to different types of abiotic environmental stresses. Cellular signal transduction pathways as well as gene expression in response to abiotic stresses have been extensively analyzed. Described in this chapter are the abiotic stresses arising from drought, salinity, low temperature, flooding, air pollution, and high temperature.

Stresses involving water deficit may arise from drought conditions, saline soils, or low temperature. To quantify the effect of stress on the plant, one can determine the water status of the plant by using either Ψ_w or RWC. Measuring the water status of the plant is important for determining the impact of the environmental condition. Decreases in plant water potential may be brought about by osmotic adjustment, the accumulation of compatible solutes that promote acclimation to dry or saline soils. In addition to osmotic adjustment, some compatible solutes, such as glycine betaine, mannitol, raffinose, pinole, and proline, serve other protective functions. Effects of water deficit and perturbing ions on the membrane may be minimized by the action of carriers,

pumps, and channels. Various types of genes are induced by water deficit, including those that may protect the plant from abiotic stresses like LEA proteins and HSPs. The mechanisms of gene induction are regulated by specific DNA elements: two classes of elements, ABRE and DRE, have been found in many water-deficit-induced genes. Major transcription factors that control dehydration-responsive gene expression have been analyzed, and their target genes have been identified by microarray analysis. Regulatory factors including signaling factors and stress sensors have been studied extensively. Receptors and transporters of ABA were identified for further understanding of cellular and inter cellular signal transduction pathways. Application of the stress genes for molecular breeding of drought stress tolerance is now in progress by transgenic technology.

Freezing and chilling stresses cause cellular injuries in plants in different ways. Chilling stress causes membrane destabilization and metabolic dysfunction while freezing stress has several indirect damage effects due to ice crystal formation and its growth in extracellular compartments. Plants respond and adapt to low temperature stress at cellular level. Plants can acclimate to subfreezing temperatures as a result of increasing membrane stability and accumulation of specific protective metabolites and proteins. There are many genes with different functions that are induced in response to low temperature. The gene products mainly function in protection of cells from freezing. Regulation of low-temperature-induced genes has been analyzed extensively and *cis*-regulatory elements in gene promoters and transcription factors, like CBF/DREB1, have been identified for further analysis of their regulatory networks. Sensing and signal transduction in plant responses to cold stress have been analyzed to identify important signaling components.

Flooding can cause an oxygen deficit in the cell that impacts respiratory metabolism. The ability to tolerate flooding varies greatly among species and can be altered

by acclimation processes involving exposure to severe hypoxic conditions (i.e., <3 kPa oxygen). During short-term acclimation to anoxic conditions, plants generate ATP through glycolysis and fermentation; this shift from aerobic metabolism to glycolytic fermentation involves changes in gene expression. The plant hormone ethylene promotes long-term acclimative responses to waterlogging and submergence, including formation of aerenchyma and stem elongation. Some wetland genotypes are adapted to long-term flooding. QTL analysis revealed two important genes in flooding responses, *SUBMERGENCE1* (*SUB1A*) locus involved in submergence tolerance and *SNORKEL1* (*SK1*) and *SNORKEL2* (*SK2*) loci found in deepwater rice that enable submergence escape. All three of these rice genes encode related ERF transcription factors, are ethylene induced and influence GA-mediated elongation growth. But they confer opposing strategies of flooding survival. These indicate important roles of ethylene and the growth regulation it modulates during responses in rice.

Oxidative stress may arise from any abiotic or biotic stress that causes the formation of a reactive oxygen species (ROS), such as hydrogen peroxide (H_2O_2), superoxide anion ($O_2^{\cdot-}$), and hydroxyl radical (HO^{\cdot}), or perhydroxyl radical ($HO_2^{\cdot-}$). Plants scavenge and eliminate these reactive molecules by using antioxidant defense systems including antioxidants and antioxidant enzymes, which are present in various subcellular compartments. Ozone exposure to plants can be used as a model system to determine how ROS cause oxidative damage to cellular processes. Studies in which antioxidant enzymes, such as SODs, APX, and CAT, are overexpressed in transgenic plants have emphasized the important role of subcellular compartmentation in detoxification mechanisms. ROS functions as signaling molecules to control various cellular responses to abiotic and biotic stresses. ROS signals can change gene expression to regulate downstream genes and various cellular processes. Sensing systems of ROS signals have not been elucidated, yet.

Heat stress responses are widely conserved among different organisms. Thermotolerance can be developed

as plants acclimate to a nonlethal high temperature. During heat stress in plants, as in other organisms, gene expression patterns, including transcription and translation, are altered to promote the accumulation of HSPs. The five major classes of HSPs, defined according to size, are conserved among different organisms. In general, the HSPs function as chaperones to promote proper folding of proteins. Expression of HSPs is controlled by a transcription factor that recognizes a conserved DNA element, 5-nGAAn-3', present in multiple copies in the promoter. The HSF transcription factor is active as a trimer and must be derepressed to activate gene expression. Heat sensing systems are likely to be general among various organisms.

Understanding of plant cellular responses to a variety of abiotic stress has proceeded extensively based on molecular biology and genomics. Many stress-inducible genes have been identified to function in abiotic stress responses and tolerance, which indicates importance of transcriptional regulation in plant stress response. Plants have many more transcription factors than animals. In addition to transcriptional modulation, post-transcriptional regulation and epigenetic regulation have been shown to function in plant abiotic stress responses. Plant hormones play important roles in abiotic stress responses in gene expression as well as signal transduction. Among them, ABA, ET, JA, and SA are major hormones in abiotic stress responses. These hormones also function in crosstalk between biotic and abiotic stress responses. Many genes associated with mammalian signal transduction cascades, such as protein kinases, phospholipid-related enzymes, receptor kinases, and G-proteins, are also present in plants. Functional analyses of these signaling molecules have been in progress using various mutant lines. However, numerous important questions remain unanswered. Most of the mechanisms by which higher plants perceive abiotic stresses have not been elucidated. Progress in this crucial area will advance our knowledge of stress-initiated signal perception and transduction events substantially. Crosstalk in stress signaling will provide us complex regulatory networks in response to complex environment responses of plants.

Mineral Nutrient Acquisition, Transport, and Utilization

Emmanuel Delhaize, Daniel Schachtman, Leon Kochian, and Peter R. Ryan

Introduction

The importance of mineral nutrients to crop production has been recognized for more than 2,000 years. Plant mineral nutrition is unique because green plants, the only multicellular autotrophic organisms, can mine inorganic elements from the environment without having to rely on high-energy compounds synthesized by other organisms. Plant nutritionists have contributed in many ways towards increasing crop yields. In the past 60–80 years the industrial scale production and distribution of mineral fertilizers has been directly correlated with higher crop production globally. This has been essential for increasing food production and meeting the needs of a growing population. The major mineral nutrients phosphorus and potassium are obtained by mining natural deposits and therefore can be viewed as limited resources. This is especially true of phosphorus where the known major deposits of high quality phosphate rock could be depleted before the end of this century. This is not a concern for nitrogen following the invention of the Haber–Bosch process that allows nitrogenous fertilizers to be produced through the fixation of nitrogen gas.

Recently, there has been an upsurge in research and a renewed interest in the field of plant mineral nutrition now that contemporary experimental approaches are being used to dissect mechanisms underlying transport and utilization of mineral ion nutrients. This resurgence is fueled by the availability of new powerful tools, including molecular techniques, complete genome sequences, the development

of model plant systems, high-resolution electrophysiological methods, and sophisticated tools for studying plant physiology. These tools have allowed physiologists to move from studies on whole tissues where single transport mechanisms could not be resolved, to an era where both molecular and genetic methods have revealed underlying mechanisms for transport and utilization of mineral nutrients. The current challenge is to fit these individual pieces back together to begin to understand the molecular physiology of mineral nutrient acquisition and utilization in the intact plant.

This chapter focuses on recent findings concerning the physiology of transport in relation to two macronutrients (potassium and phosphorus), two micronutrients (copper and iron) and a toxic element (aluminum). Recent research has begun to elucidate the mechanisms involved in homeostasis of several mineral nutrients, and the central roles of microRNAs in these mechanisms are discussed. Topics related to mineral nutrition have been addressed in other chapters of this text. Plant uptake and assimilation of nitrogen and sulfur, for example, are discussed in Chapters 7 and 16. Anabolic and catabolic reactions involving the most abundant mineral nutrients—carbon, hydrogen, and oxygen—appear throughout the text and constitute the primary focus of Chapters 12 to 14. Long-distance transport of selected mineral nutrients is discussed in Chapter 15, and Chapter 3 provides the basis for understanding processes involved in the transport of ions across plant membranes.

23.1 Overview of essential mineral elements

Plant mineral nutritionists define **essential minerals** as ones that (a) are required to complete a plant's life cycle, and (b) are components of an essential plant metabolite or constituent. Their absence results in distinct deficiency symptoms as shown in Figure 23.1. The most common classification of the

17 essential mineral nutrients is based on the relative concentration of each in the plant when the nutrient is present in adequate concentration for normal plant function. The **macronutrients** are carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, and sulfur. Except for the more abundant oxygen and carbon, the concentrations of macronutrients generally found in plants range from 1,000 to 15,000 μg per gram of dry weight. In contrast, the concentrations of **micronutrients** (chlorine, boron, iron, manganese,

TABLE 23.1 Concentrations of essential mineral nutrients considered to be in the adequate range for plants.

Element	Chemical symbol	Concentration in dry material ($\mu\text{g g}^{-1}$)	Concentration in fresh tissue*
<i>Macronutrients</i>			
Nitrogen	N	15,000	71.4 mM
Potassium	K	10,000	17 mM
Calcium	Ca	5,000	8.3 mM
Magnesium	Mg	2,000	5.5 mM
Phosphorus	P	2,000	4.3 mM
Sulfur	S	1,000	2.1 mM
<i>Micronutrients</i>			
Chlorine	Cl	100	188 μM
Boron	B	20	123 μM
Iron	Fe	100	120 μM
Manganese	Mn	50	61 μM
Zinc	Zn	20	20.4 μM
Copper	Cu	6	6.2 μM
Molybdenum	Mo	0.1	0.07 μM
Nickel	Ni	0.005	0.006 μM

*Fresh weight concentrations were calculated by assuming a 15:1 fresh weight–dry weight ratio.

zinc, copper, molybdenum, and nickel) usually found in plants are 100- to 10,000-fold less than those of the macronutrients.

Of the 17 nutrient elements determined to be essential in plants, 14 are shown in Table 23.1, and the last element listed, nickel, was shown to be essential only within the last 30 years. The three elements most abundant in plant tissues (carbon, hydrogen, and oxygen) are not included in the table. Also not listed are sodium, silicon, and cobalt, which some researchers view as beneficial but not essential.

23.2 Mechanisms and regulation of plant K^+ transport

23.2.1 K^+ transport in plants has been studied extensively

Potassium (K^+) is the most abundant cellular cation, with cytoplasmic concentrations regulated between 80 mM and 200 mM, and total tissue concentrations of approximately

20 mM. It plays roles in myriad cellular and whole-plant functions, serving as an osmoticum for cellular growth and stomatal function, balancing the charges of diffusible and nondiffusible anions, activating more than 50 plant enzymes, and participating in numerous metabolic processes, including photosynthesis, oxidative metabolism, and protein synthesis. K^+ is a very mobile nutrient and its uptake from soil and transport within cells and around the whole plant has been studied intensively for the last 50 years. Many of these studies have focused on K^+ transport in roots because roots are the primary mineral-absorbing organs and are amenable to studies of ion transport. A major contribution to our understanding of K^+ transport has also come through the study of stomatal guard cells which are probably the best characterized cells for ion transport processes in plants. Although the importance of controlling and facilitating K^+ entry into the plant at the plasma membrane of root cells and guard cells is unquestioned, other K^+ transport sites within the plant are equally important, particularly when K^+ transport and translocation at the whole-plant level are considered. K^+ recirculation within the plant is well documented, as are complex patterns of K^+ translocation between tissues and organs (see Chapter 15). In white lupine (*Lupinus albus*), about one-half of the absorbed K^+ that is translocated to the

shoot by the xylem is returned to the root by the phloem, and nearly 75% of phloem-borne K^+ returning to the root reenters the xylem stream and is again transported to the shoot. Some sites of K^+ transport are diagrammatically outlined in Figure 23.2.

K^+ enters the root symplasm following transport across the root cell plasma membrane. From these cells, K^+ can travel through the symplasm to the vascular tissues, where it is unloaded from xylem parenchyma into xylem vessels for long-distance transport to the leaves. K^+ is reabsorbed from the xylem into leaf cells. After efflux from fully expanded source leaves, it can be loaded into phloem cells for translocation to actively growing sink tissues (e.g., shoot and root apices), where it can be unloaded by way of symplasmic or apoplastic pathways. K^+ can also cross the tonoplast membrane for storage in vacuoles of both root and shoot cells. The integration and regulation of K^+ transport systems at different sites along the long-distance pathway allows the plant to regulate the partitioning and circulation of K^+ . The integration of these K^+ transporters plays a central role in plant growth and development and in the allocation of mineral nutrients in response to changes in nutrient availability. Note that this model is equally relevant for all essential mineral nutrients, because a range of different transporters localized to specific cell types must function to move each essential element throughout the plant.

23.2.2 Early physiological and biochemical studies indicated the existence of multiple K^+ transporters

Prior to the application of radioisotopes and tools of molecular biology, early studies on plant K^+ transport focused on the use of excised roots. Seedlings were grown in dilute hydroponic media, typically dilute Ca-salt solutions (e.g., $CaCl_2$ or $CaSO_4$) because Ca^{2+} was needed to maintain normal membrane function. Roots of these seedlings exhibited extremely high initial rates of mineral ion absorption and thus were useful experimental material. These “low-salt roots” contain low concentrations of mineral salts, high concentrations of sugar (a replacement osmoticum for K^+ salts) and a large transport capacity all of which make it easier to measure the uptake of mineral nutrients. This experimental system is still used even after the introduction of radioisotope methods.

The availability of radioisotopes for biological research enabled new techniques for measuring transport processes to be developed. Investigators could label a solution with a radioisotope or a radioactive analog of the mineral ion of interest (e.g., $^{42}K^+$ or $^{86}Rb^+$ for K^+) to quantify the uptake, translocation, or efflux of the radioactivity administered. Pioneering work in the use of radiotracers to measure mineral ion fluxes advanced the field of ion transport (Box 23.1). Plant biologists were the first to treat mineral ion transporters as enzymes and to apply analysis from enzyme kinetics to studies of K^+ absorption by roots. When low-salt barley (*Hordeum vulgare*)

FIGURE 23.2 Diagrammatic depiction of K^+ transport into and within the plant. K^+ is transported within the xylem (red arrows) and phloem (blue arrows). The numbers represent important transport sites along the long-distance K^+ -transport pathway. For four of the five numbered sites, enlargements depict K^+ transport at the cellular level. (1) K^+ is absorbed across the root cell plasma membrane (longitudinal view). (2) K^+ is transported into nonliving, thick-walled xylem vessels by way of efflux across the xylem parenchyma plasma membrane (cross-sectional view). (3) K^+ is transported by the xylem to the shoot (leaf), moves from the xylem vessel to the apoplast surrounding the neighboring leaf cells, and is absorbed into the leaf parenchyma cells (cross-sectional view). (4) K^+ is loaded into the phloem of a fully expanded source leaf after K^+ efflux from leaf cells. Transport into the sieve tube-companion cell complex can occur by a combination of apoplastic and symplasmic routes (cross-sectional view). (5) K^+ moves through the phloem to the shoot and root apices, where it is unloaded for subsequent use.

BOX
23.1

Radioisotopes are used to measure ion fluxes in cells

Radioisotopes have been used to monitor mineral ion transport processes in plants for almost 50 years. It is relatively easy to immerse plant roots (or other tissues such as excised leaves) for a prescribed time in an uptake solution labeled with radioisotope, wash the tissue to remove adhering radiolabeled solution, and quantify the radioisotope associated with the tissue by detecting either β - or γ -radiation. Using radioisotopes to measure ion flux accurately, however, is not easy. The difficulty arises from the anatomical characteristics of plant cells. As shown in the accompanying figure, a plant cell contains three major compartments: cell wall, cytoplasm, and vacuole. When the cell is placed in an uptake solution containing $^{42}\text{K}^+$ or $^{86}\text{Rb}^+$, cation-binding sites and pores in the cell wall are the first sites to bind or accumulate the radiotracer. As the concentration of radiotracer within the cell wall near the plasma membrane surface increases, the K^+ that is transported across the plasma membrane becomes a mixture of unlabeled ions and the radioisotope analog ion. Given longer uptake times, the radioisotopic fraction of the K^+ pool in the cytoplasm will increase. When the amount of radioisotope in the cytoplasm becomes great enough, a substantial radioisotope efflux out of the cell and influx into the vacuole will occur. This combination of efflux and influx confounds attempts to measure a unidirectional influx.

Under steady-state conditions, the entry of mineral ions into cells is a net flux consisting of unidirectional influx and efflux components. Because researchers are usually interested in the unidirectional influx of an ion, the duration of the uptake period is crucial: enough time must elapse for quantifiable concentrations of radioisotope to enter the symplast. However, an overly long uptake period provides time for a substantial efflux

of absorbed radioisotope out of the cell and can create conditions in which the entry of ions into the cell is limited by the rate of transport into the vacuole.

Because the cell wall can bind and accumulate a large amount of cationic radioisotope, a desorption regime must be developed that effectively removes the radiolabel from the cell wall. This desorption period must also be timed carefully, so that a large fraction of the cell wall label is removed but not the radioisotope that has been transported into the cytoplasm. Generally, for a monovalent cation such as K^+ , unlabeled uptake solution is an effective desorption solution. Alternatively, solutions that contain high concentrations of K^+ and Ca^{2+} can be used to optimize desorption of $^{42}\text{K}^+$ or $^{86}\text{Rb}^+$ from negatively charged cell wall binding sites.

The graph shows a time course for radioisotope accumulation and subsequent desorption in plant roots. After an initial rapid phase of isotope accumulation as label equilibrates with and binds within the wall, there is a slower phase of radioisotope accumulation, resulting from unidirectional cation influx into the cytoplasm. The effect of terminating radiotracer uptake by transferring the radiolabeled roots into desorption solution is also indicated. Under ideal conditions, the desorption phase rapidly removes most of the radiolabel in the cell wall without affecting the radiolabel accumulated in the symplast. The difference between the amount of desorbed radiotracer, and the total amount of radiotracer present in the plant tissue before desorption, represents a measure of unidirectional influx into the cytoplasm.

To obtain a reasonable measure of unidirectional K^+ influx into root cells, one effective uptake-desorption

regime for robust plant roots such as maize or barley, or for smaller roots such as those of *Arabidopsis*, utilizes a radiotracer uptake period of 10 to 20 minutes, followed by a desorption period of 10 to 20 minutes. If uptake is continued for longer periods (several

hours), a third, slower phase of accumulation, caused by radiotracer efflux out of the cell or significant flux into the vacuole, is often seen. This process tends to be slower than the ion influx through the plasma membrane.

FIGURE 23.3 Dual isotherm depicting the rate of K^+ absorption in barley roots over a wide range of K^+ concentrations in the absorption solution. Note change in the concentration scale after 0.2 mM K^+ .

roots were exposed to solutions containing low concentrations (0 to 200 μM) of the K^+ analog $^{86}\text{Rb}^+$, the resulting high-affinity uptake demonstrated saturating (Michaelis–Menten) kinetics. The high-affinity K^+ transporter, which was designated Mechanism I, was subsequently shown to transport K^+ (and Rb^+) preferentially over other alkali cations. Over a broader concentration range for K^+ , the uptake kinetics of K^+ had a complex appearance that could be more clearly represented by two separate saturating curves (Fig. 23.3). It was proposed that roots also contain a low-affinity uptake system, Mechanism II, which is active at higher external concentrations of K^+ . This pattern of K^+ uptake was described as the **dual isotherm** and was hypothesized to reflect the activities of two

families of transporters. High-affinity K^+ transport was thought to dominate at low concentrations of K^+ in soil, whereas at higher K^+ concentrations, a low-affinity K^+ transporter operated that was less specific for K^+ over other alkali cations (such as Na^+). The concept that mineral uptake involves distinct transporters with different substrate affinities is further supported by thermodynamic evidence. At low external concentrations of K^+ (less than 100 μM), root cells often take up K^+ against the electrochemical potential gradient for the cation (see Chapter 3). Under these circumstances, uptake cannot occur by diffusion and instead must be mediated by either an ATP-driven ion pump or a transporter that is coupled to the energy stored in a transmembrane gradient of H^+ or Na^+ .

Subsequent physiological studies provided evidence for separate high- and low-affinity transporters of K^+ in roots. For example, Figure 23.4 illustrates the kinetics of K^+ influx in maize (*Zea mays*) roots, investigated by studying Rb^+ as an analog of K^+ . The transport kinetics are complex and appear to result from the functioning of a saturable high-affinity transporter and a low-affinity K^+ transporter that exhibits first-order kinetics. With the use of specific inhibitors such as *N*-ethylmaleimide (NEM), the high-affinity uptake could be selectively inhibited without impairing the linear transport component. In other experiments, the application of a K^+ -channel blocker such as tetraethylammonium (TEA) ion selectively inhibited the linear, low-affinity transport component. Further physiological studies showed that the high-affinity K^+ uptake system exhibited increased transport activity induced by K^+ starvation, a very high affinity for K^+ ($K_m = 5\text{--}30 \mu\text{M}$), and a strong selectivity for K^+ and Rb^+ over

FIGURE 23.4 Kinetics of $^{86}\text{Rb}^+$ influx into maize roots grown in high salt conditions. (A) The control curve (white) has been separated into its saturable high-affinity (dark symbols) and linear low-affinity (lighter symbols) transport components. (B) Influence of the sulfhydryl modifier *N*-ethylmaleimide (NEM) on $^{86}\text{Rb}^+$ influx in maize roots grown in high salt conditions. Root segments were pretreated with 0.3 mM NEM for 10 seconds (dark symbols) or 30 seconds (lighter symbols), then washed for 10 minutes in 1 mM dithioerythritol to bind and inactivate unreacted NEM before $^{86}\text{Rb}^+$ uptake. NEM inhibits the high-affinity transporter but does not affect the low-affinity transporter.

other alkali cations. In contrast, the low-affinity K^+ transporter was found to be less selective for K^+ and Rb^+ over Na^+ , and less influenced by changes in the K^+ status of the plant. However, more-definitive evidence supporting the existence of multiple K^+ transporters has been derived from the molecular and biophysical studies detailed below.

23.2.3 The carrier-kinetic approach for analyzing ion transport

When Michaelis–Menten enzyme kinetic analysis was first applied to concentration-dependent studies of root K^+ uptake, it had a big impact on the field of ion transport. This approach gave researchers a new way to look at and analyze ion transport processes, both in plants and in a wide range of other organisms. Transport of a wide range of substrates by many

plant and animal tissues was observed to involve complex kinetics. Often, ion uptake curves contained several different phases or components. From the results of the molecular cloning and genetic dissection of different plant K^+ transporters, including several different root K^+ transporters, we now know of the existence of multiple K^+ transporters operating over a range of K^+ concentrations; however, the identity and function of high- and low-affinity transporters in roots is still not fully elucidated. While there are multiple K^+ transporters that play distinct and sometimes overlapping roles in high and low affinity uptake, characterization of several of them has shown that a single transporter can yield complex kinetics which may be regulated by post-translational modifications. For example, K^+ transport by cells of *Arabidopsis* and of yeast (*Saccharomyces cerevisiae*) expressing the K^+ transporter AtKUP or studies in *Xenopus laevis* oocytes on the nitrate transporter NRT1.1 show that a single protein can mediate both high or low affinity ion uptake.

BOX
23.2

Yeast complementation: a powerful tool for plant mineral nutrition

The single-celled yeast, *Saccharomyces cerevisiae*, has proved of immense value to researchers wishing to isolate new genes encoding ion transport proteins from plants. The genome of *S. cerevisiae* is completely sequenced and routine methods allow knockout mutations to be generated in any gene. Yeast is a good model for plant cells because like plants, yeast pumps protons across its plasma membrane to generate an electrochemical gradient. This gradient in pH and electrical potential drives the flux of many ions across the plasma membrane. The characterization of ion transport processes in yeast and the isolation of the corresponding genes have typically preceded such studies in plants. The availability of yeast mutants defective in specific transport processes allows related genes to be cloned from plants by *functional complementation*. This method allows cDNAs encoding transport proteins with a particular function to be isolated from a bank or library of thousands of cDNA clones. The cDNA library is first constructed from the mRNA of the tissue of interest (e.g., roots) and cloned into a vector that will express the cDNA in yeast. Once the plasmid library has been introduced into a specific yeast mutant (e.g., a mutant for K⁺ transport), the yeast can be screened on selective medium (e.g., low K⁺ concentration) where the only cells that grow are those expressing the plant cDNA that complements the mutation. Many hundreds of thousands of yeast cells, each expressing a single plant cDNA,

can be screened rapidly. This procedure has been instrumental in the discovery of many plant genes encoding transport proteins for K⁺, phosphate, sulfate, Fe²⁺, Zn²⁺, Cu⁺, Mn²⁺, Ca²⁺, and borate.

Yeast complementation can also be used to establish the function of a specific cDNA that shows sequence homology to other transport proteins. In this case the mutant yeast is transformed with a single plasmid–cDNA construct rather than a population of plasmids, and complementation of the mutation confirms the proposed function. In the example shown, the *trk1trk2* mutant of *S. cerevisiae* defective in K⁺ transport shows restored growth after transformation with pKAT1 (vector containing a plant K⁺ transport gene) but not with the empty pRS316 vector (control). Note that the control and the mutant expressing *KAT1* grow equally well on high-K⁺ medium (100 mM; left), whereas at a low concentration of K⁺ (0.2 mM), only cells expressing *KAT1* are able to grow (right). Yeast has also been used to isolate cDNAs that confer tolerance to toxic concentrations of ions and many of these encode transport proteins. Once it is demonstrated that the plant proteins function in yeast this simpler system provides enormous advantages for studying their transport properties in more detail.

23.2.4 Model biological systems and high-resolution molecular and electrophysiological tools have provided new insights into the mechanisms of mineral transport in plants

Over the past 30–40 years our understanding of K⁺ transport systems in plants has greatly increased with the advent of new technologies and by the use of biological systems (termed heterologous systems) for cloning and characterizing the

function of plant mineral ion transporters. Starting in the 1990s *Saccharomyces cerevisiae* was used very effectively as a heterologous system to clone genes encoding K⁺ transporters as well as those of many other ion transporters (Box 23.2). While *S. cerevisiae* proved to be difficult for electrophysiological studies, these cells could be very easily used with radiotracers for studying substrate specificity of individual transporters. By contrast, oocytes of *Xenopus laevis* provide a high-resolution system for electrophysiological characterization (see Chapter 3.4.2). *X. laevis* oocytes are relatively large (≈1 mm diameter), single-celled structures that are readily injected and impaled with microelectrodes. Typically, the

cDNA of a transport protein to be studied is transcribed to cRNA and then injected in the oocyte. The oocyte translates the cRNA and after several days of incubation, transport function can be studied by comparison with water-injected controls. *Xenopus* oocytes allowed for high-resolution characterization of K^+ channel kinetics and substrate selectivity using sophisticated electrophysiological techniques.

The patch clamping technique developed in the 1980s for the study of membrane transport mechanisms was another important technological advance. Although the patch clamp technique was first applied to animal cells, it was quickly adapted for studies of plant cell membranes. Patch clamping was applied to plants in the study of K^+ channels in the guard cell plasma membrane (see Box 3.6). Patch clamp analysis of protoplasts derived from various cell types (e.g., root cells, guard cells, leaf cells, and cereal aleurone cells) revealed the presence of two types of K^+ channels: inward-rectifying channels, which open on hyperpolarization of the membrane potential (E_m) to facilitate K^+ uptake, and outward-rectifying channels (K^+ channels), which open on depolarization of E_m and transport K^+ out of the cell. Outward-rectifying channels are involved in osmotic adjustment, stomatal function, regulation of E_m , and the unloading of salts from xylem parenchyma into xylem vessels for long-distance transport to the shoot. Plant K^+ channels differ from their animal counterparts by remaining open for long periods. This property is important because they function as a major transport pathway for acquisition of K^+ from soil as well as during the slow opening and closing of stomata that require sustained fluxes of K^+ into or out of the guard cells.

Electrophysiological and molecular tools are now routinely used to resolve questions concerning plant K^+ transport. Whereas heterologous expression systems provide information about single transport molecules, electrophysiological experiments in which root cells are impaled with a single salt-filled glass microelectrode provide information about the voltage gradient across the plasma membrane (i.e., **membrane potential**, or E_m , see Box 3.2 Chapter 3). Early studies indicated that high-affinity K^+ uptake is **electrogenic** (see Chapters 3 and 14) meaning that it is associated with current flow across the membrane. More recently microelectrodes have been used together with genetic tools to dissect the function of specific K^+ channels. In *Arabidopsis*, a mutant disrupted in *AKT1* (see Section 23.2.5) revealed that this K^+ channel contributed between 55 and 63% of the K^+ transport capacity of the cell when external K^+ concentration is between 10 and 1,000 μM . Initially this result was surprising because it had been thought that channels would be ineffective at absorbing K^+ from low external concentrations since they only facilitate the passive movement of ions across membranes (i.e., down their electrochemical gradient). The electrochemical gradient comprises the sum of the electrical (membrane potential) and chemical gradients (inside vs. outside concentration of K^+). It was subsequently shown that membrane potentials of root cells reach negative potentials as low as -235 millivolts, which is sufficient to drive the uptake of K^+ at these low external K^+ concentrations. Recently, double

mutants of *Arabidopsis* confirmed that *AKT1* and a high-affinity K^+ transporter contribute to K^+ uptake in root cells when external K^+ concentrations are very low. These findings highlight how molecular, genetic, electrophysiological, and radioactive tracer technologies can be combined to fully dissect and understand membrane transport processes in higher plants.

23.2.5 K^+ transporters are encoded by numerous plant genes

Although the physiological and biophysical studies discussed above have increased our understanding of plant K^+ transport and nutrition they do not fully describe the complexity of K^+ transport mechanisms in plant tissues such as roots. As researchers gain new information about the range of K^+ transporters present in plants along with the relationship between transporter structure, function, and regulation, they can elucidate the multiple roles K^+ transport plays in the growth and development of intact plants.

Biochemical approaches have primarily been successful for characterizing H^+ -ATPases because these transport proteins are relatively abundant in the plasma membrane and tonoplast compared to channels or carrier-like transporters. Screening cDNA libraries with heterologous probes that encode K^+ transporters was unsuccessful when only animal or microbial genes were available. However, as noted above, complementation of yeast (*S. cerevisiae*) mutants has been a successful method in cloning plant K^+ transport genes as well as a range of other plant solute transporters (Box 23.2).

The first K^+ transport genes to be characterized from plants, *KAT1* and *AKT1*, were cloned by complementation of the yeast K^+ transport-defective mutant *trk1trk2* with an *Arabidopsis* cDNA library. *KAT1* and *AKT1*, which share extensive homology, were both found to encode members of the Shaker superfamily of K^+ channels (see Chapter 3) that contain distinctive structural features such as pore loops. The function of these proteins as inward-rectifying K^+ channels was established on the basis of their current-voltage properties in *Xenopus* oocytes and later confirmed in yeast and insect cells. Figure 23.5, depicting a typical current-voltage relationship for *KAT1* expressed in *Xenopus* oocytes, shows that the channel is activated by the shift of E_m to more negative voltages and then mediates a strong inward current (K^+ influx). The transport characteristics of *KAT1*- and *AKT1*-encoded proteins possess the hallmark properties of inward K^+ channels studied by patch-clamping plant cells, including their voltage dependence, selectivity for K^+ over other cations, time-dependent kinetics, lack of inactivation, and responses to the K^+ channel blockers TEA and Ba^{2+} .

For many years it was a mystery as to why the *AKT1* channel could not be functionally expressed in *Xenopus* oocytes. Not all transport proteins can be studied in oocytes for reasons such as low and therefore undetectable currents, lack of protein targeting to the plasma membrane, toxicity to the

FIGURE 23.5 Current–voltage relationship for uninjected *Xenopus oocytes* (white) and oocytes injected with *KAT1* mRNA 4 days before this experiment (dark). *KAT1* mRNA leads to development of inward current in response to hyperpolarizing voltages more negative than -100 mV, which is typical of an inward-rectifying K^+ channel.

oocytes, lack of post-translational modification, or missing subunits. In the case of *AKT1* it was discovered that the channel must be phosphorylated for it to be functional in oocytes. A specific kinase called CIPK23 (CBL-interacting protein kinases) phosphorylates *AKT1* in *planta*. The CIPK kinases are found as large families in plants (at least 25 in *Arabidopsis*) and are most similar to the sucrose nonfermenting (SNF) kinases of yeast and the AMP-dependent kinases of animals. The CIPK kinases interact with small Ca^{2+} sensors that act as downstream effectors. These small sensors are named CBLs, standing for calcineurin **B**-like proteins. This CBL/CIPK/*AKT1* pathway implicates Ca^{2+} signaling in the regulation of K^+ uptake. When K^+ is limiting it is likely that increases in reactive oxygen species trigger Ca^{2+} fluctuations, which in turn regulates K^+ uptake.

KAT1 and *AKT1* share structural features with other channels possessing P-loops (Fig. 23.6). These proteins contain six membrane-spanning domains near the N-terminus (S1–S6), a conserved voltage-sensing region within S4, and the amphipathic P-domain (also called H5) between S5 and S6. The P-domain is highly conserved in the K^+ selective P-loop and in Shaker-type channels and has been shown to form the channel pore that governs ion permeation and selectivity. The common motif that is the signature for K^+ selectivity is comprised of the core amino acid residues GYG. This motif is present in the K^+ selective channels of all organisms and is a major determinant of the selectivity of these pores. These channels are formed by four of the individual subunits shown in Figure 23.6 (see also Fig. 3.26). Carbonyl groups in each of the four filters in the channel tetramer coordinate two K^+ ions. The crystal structure of certain K^+ channels has been determined from many organisms, but not from plants. These studies have provided a detailed understanding of K^+ channel structure and the critical features that determine most aspects of their function. The structure of the channel and its interaction with the hydrated K^+ ions helps explain why the V_{max} of K^+ channels is near the diffusion limit as well as the strong discrimination against smaller cations such as Na^+ . The S4

FIGURE 23.6 Proposed structural model for *AKT1*, a plant K^+ channel. Six membrane-spanning domains are present near the N-terminus. A nucleotide-binding sequence (NB) and ankyrin-like domains (ANK) are found near the C-terminus. The S4 region, believed to be the voltage sensor, contains several positively charged amino acids within the membrane-spanning region. The P-domain, also referred to as H5, is thought to form the mouth of the pore and to play a critical role in channel selectivity.

transmembrane domains contain positively charged basic amino acids at every third or fourth position that serves as the voltage sensor for the channel. Movement of this region within the membrane in response to a polarization voltage results in opening and closing of these channels.

The cloning of *KAT1* and *AKT1* led to the identification of additional related genes in *Arabidopsis* and other plant species, indicating the existence of a multigene family encoding K^+ transporters (Table 23.2, Shaker-type cation transporters). In the past 20 years as more sequence information became available and whole genomes sequenced, there have been a large number of *KAT1*- and *AKT1*-like genes identified. One explanation for the large numbers of genes in these families may be related to their localization in specific plant tissues or cell types. For example *KAT1* and its ortholog in potato (*Solanum tuberosum*), *KST1*, are expressed in guard cells and presumably encode K^+ channels involved in stomatal function. *AKT1*, on the other hand, is localized to the root epidermis and cortex where it plays a role in plant uptake of K^+ . *AKT2* (also sometimes designated *AKT3*), which shares 60% identity with *AKT1*, is expressed in leaves but not roots, suggesting that it encodes the same K^+ transport function in leaves as *AKT1* mediates in roots. The C-terminal domain of the potato K^+ channel, *KST1*, has been used as bait in the yeast two-hybrid system (Box 23.3) to identify proteins that associate with *KST1*. This approach, expected to identify proteins that regulate the channel or anchor it in the membrane, instead has led to the cloning of

**BOX
23-3**

The yeast two-hybrid system is a genetic method that can identify protein–protein interactions within a cell

The yeast two-hybrid system is based on the modular nature of transcription factors, which generally are composed of two domains: a DNA-binding domain (DBD) and an activation domain (AD). An intact transcription factor, such as the yeast Gal4 protein, binds to specific recognition sequences within a promoter by way of the DBD. Next, the AD recruits the general transcription machinery to the promoter-activating expression of the downstream gene (1; see figure). These two domains can be separated and expressed as fusion proteins either alone or together within yeast cells. When only the DBD (fused to a protein of interest [X]) is expressed, the promoter is bound but transcription cannot be activated because the AD is lacking (2). Similarly, when the AD is fused to a second protein (Y) and expressed, the AD is unable to bind to the promoter and therefore also cannot activate transcription of the downstream gene (3). If X and Y are able to interact, however, coexpression of the two hybrid proteins brings the DBD and the AD into proximity, thereby re-forming an active transcription factor (4). If reporter genes (blue box) are used that confer an easily scoreable phenotype, such as nutrient prototrophy, the

ability of X and Y to associate can be easily assessed. The two-hybrid system is widely used to identify new binding proteins, to map binding domains of known interactions, and to generate mutations that affect those interactions.

two new K^+ channel genes, *SKT1* and *SKT2*, which exhibit substantial similarity to *Arabidopsis* *AKT2*. Subsequent investigations have determined that the C-termini of all K^+ channels contain conserved sequences that are involved in

the association of K^+ channel subunits. The heteromeric composition of the K^+ channel tetramer may be another way in which subtle differences in K^+ channel function are determined.

23.2.6 Genome sequences and molecular techniques have revealed multiple gene families encoding K⁺ transporters

K⁺ channels and transporters control the fluxes of K⁺ into and out of plant cells as well as control intracellular concentrations of K⁺ in the cytoplasm and in organelles. As for animal cells, plant cells possess both inward (K⁺_{in}) and outward rectifying K⁺ (K⁺_{out}) channels. In plant cells these channels appear to have a similar structure to each other, both having six transmembrane domains and a classical pore loop as described above. The physiological function of inward rectifying K⁺ channels ranges from a critical role in the osmoregulation of guard cells to the uptake of K⁺ from soils. The opening of inward rectifying K⁺ channels is triggered by the hyperpolarization of the membrane potential. In the case of guard cells the inward flux of K⁺ through channels leads to the swelling of guard cells and the opening of stomata. In roots, channels play a critical role in K⁺ uptake over a wide range of concentrations. While outward rectifying K⁺ channels were clearly measurable upon depolarization of the membrane potential in the earliest electrophysiological studies, their molecular identification came much later. One well-characterized outward rectifying channel is called SKOR, the stelar K⁺ outward rectifying channel. When expression of this channel was knocked out using genetic methods xylem K⁺ concentrations were decreased. This phenotype coupled to the function and localization of the channel in root stelar cells pointed to an important role of SKOR in loading K⁺ into the xylem.

Using electrophysiological methods K⁺_{out} channels were localized to xylem parenchyma cells. To isolate xylem parenchyma protoplasts from barley roots for patch clamping, the stele was dissected from the root, after which the cell walls were digested enzymatically. Patch clamp studies with these cells identified three types of ion channels in the xylem parenchyma plasma membrane: an inward-rectifying K⁺ channel and two outward-rectifying channels—one selective for K⁺ and the other a nonselective cation channel. The molecular identification and physiological characterization of this K⁺ channel revealed an important mechanism that is involved in the regulation of K⁺ translocation from root to shoot.

In addition to the highly selective K⁺ channels with six transmembrane domains, there are two other major classes of related channels that include the CNGCs (cyclic nucleotide gated channels) and TPKs (twin-pore K⁺ channels). The CNGCs have six transmembrane domains, a pore region and a C-terminus that contains a cyclic nucleotide-binding domain. The CNGCs are allosterically regulated by cyclic nucleotides and are not activated by membrane potential. Because of the structure of the pore in these channels, they are not selective for K⁺ but also transport most divalent cations. The physiological roles of the CNGCs are not well defined, except for a few that have been shown to be involved in plant response to pathogens. In contrast to the nonselective nature of CNGCs, the TPKs are highly selective for K⁺ over other cations. These channels contain four transmembrane and two pore domains. TPKs are also known as VKs (vacuolar K⁺

channels) because they were first identified in vacuolar membranes of guard cells where they are activated by elevated concentrations of cytosolic Ca²⁺ of about 1 μM. TPK1 has two EF-hand Ca²⁺ binding domains in the C-terminus which are likely to be the basis of how the channel is regulated directly by changes in cytosolic Ca²⁺ concentrations. *Arabidopsis* mutants in which TPK1 has been disrupted lack detectable VK channel activity as measured using electrophysiological methods and exhibit slower stomatal closing in response to ABA. This suggests an important role for this channel in release of K⁺ from the vacuole that is required for guard cell shrinkage and stomatal closure.

Plant, fungal and bacterial genomes all possess genes encoding a similar type of transporter that was originally named KUPs (K⁺ uptake permease), but in plants they are also known as the K⁺ transporters KT_s and HAK_s. These transporters have 10–14 predicted transmembrane domains. Whereas bacterial and fungal genomes contain only one or two genes encoding these transporters, plant genomes contain many more, with 13 in *Arabidopsis*, 25 in rice (*Oryza sativa*) and 28 in poplar (*Populus* spp.) (Table 23.2). The function of most of the KUP transporters in plants and the reason for the large number of genes encoding these transporters remains a mystery. Disruption of a few of the KUPs in *Arabidopsis* show a distinct phenotype. These include Shy3-1 (short hypocotyl in the dark) whose phenotype results from a point mutation in *AtKUP2*. The mutant *Trh1* (tiny root hair) is caused by a disruption in *AtKUP4*. Both of these phenotypes show reduced cell size and implicate the KUP family of K⁺ transporters in cell expansion, one of the key roles that K⁺ plays in plant nutrition. An elegant study on cotton (*Gossypium hirsutum*) fiber, one of the largest single cells in the plant kingdom, provided a temporal correlation between the expression of a member of the KUP family and elongation of the cotton fiber. This study provides additional support for the role of these KUP transporters in cell elongation that is presumably driven by the uptake of K⁺. Although it is clear that AtHAK5 functions as a high affinity K⁺ transporter it cannot be assumed that other members of this family function only in the high affinity mode. In fact *AtKUP1* has been shown to be a dual affinity (high and low) transporter and information from fungi and bacteria show that some of the KUPs function as low affinity transporters (Fig. 23.7).

23.2.7 Sodium and sodium–potassium transporters play roles in sodium transport and salt tolerance

The founding member of the HKT family was cloned by complementation of the yeast *trk1trk2* K⁺ transport mutant with a cDNA library isolated from K⁺-starved wheat (*Triticum aestivum*) roots. The deduced amino acid sequence of HKT1 contains eight predicted transmembrane domains and four pore loops. The four pore loops in this single peptide suggest that these transporters function as monomers that resemble the

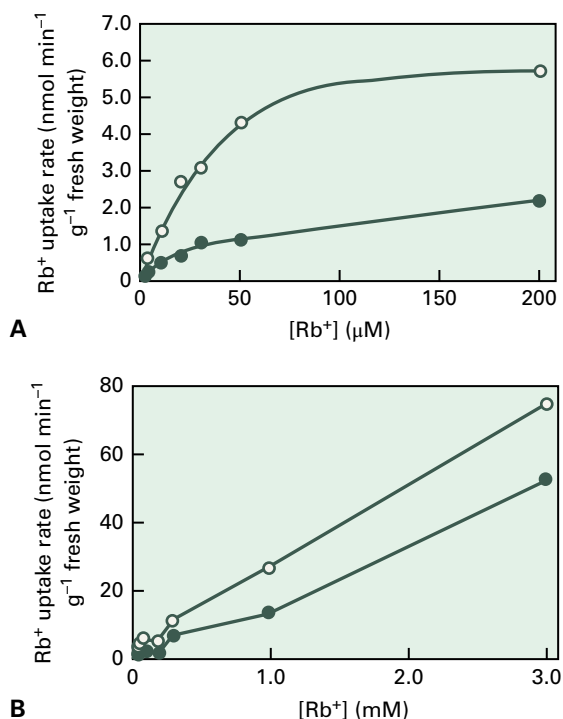

FIGURE 23.7 Concentration-dependent kinetics of Rb⁺ (a K⁺ analog) uptake in transgenic *Arabidopsis* suspension cells expressing AtKUP1. (A) Kinetics of Rb⁺ uptake from a micromolar solution by cells transformed with 35S:AtKUP1 (white symbols) or an empty vector (dark symbols). Here, AtKUP1 is shown to mediate high-affinity K⁺ uptake. (B) Kinetics of Rb⁺ uptake from a millimolar solution reveal that AtKUP1 can also facilitate low-affinity K⁺ uptake.

Shaker channels formed by four monomers that each contains a single pore loop. Initially, wheat HKT1 was characterized as a high affinity K⁺ transporter, only later to be shown to function as a K⁺/Na⁺ cotransporter or channel. Only one gene encoding HKT is found in the *Arabidopsis* genome, but multiple genes have been found in rice and poplar (Table 23.2).

Early clues as to the function of HKT came from the localization of wheat HKT to the inner root cortex and stele, as well as to the vasculature of leaves and stems. HKTs have been functionally characterized in *Xenopus* oocytes, yeast and tobacco (*Nicotiana tabacum*) suspension cultured cells. There appear to be multiple genes encoding two types of HKT transporters in plant genomes. One type is characterized as a Na⁺ channel and the other as a K⁺/Na⁺ cotransporter that transports Na⁺ in the absence of K⁺. Although the function of these transporters has been somewhat controversial, several studies have implicated them as an important determinant that controls Na⁺ transport particularly in monocots such as rice and wheat. A current model for how these transporters function in modulating Na⁺ levels in leaves is that they reabsorb Na⁺ from the xylem into bordering xylem parenchyma cells. It has also been suggested that the uptake of Na⁺ by xylem parenchyma cells is associated with K⁺ efflux as a result of depolarized cell membranes, thereby enhancing the K⁺ concentrations of leaves under saline conditions.

The link between Na⁺ and K⁺ uptake in many plant species is well known. When plants are grown under saline conditions there is an inverse relationship between Na⁺ and K⁺ concentrations such that as Na⁺ increases in leaves, K⁺ concentrations decrease. This knowledge was used to select rice lines under saline conditions that maintained K⁺ concentrations in leaves and are salt tolerant because they exclude Na⁺. Genetic methods were used to map a QTL in a salt-tolerant rice line (Nona Bokra) to a gene encoding OsHKT1;5. A mutation in this gene was found in Nona Bokra rice that enhances overall Na⁺ transport activity when characterized in *Xenopus* oocytes. Within the rice plant, expression of this transporter was localized to xylem parenchyma cells. Based on its localization and function, a model was proposed that OsHKT1;5 reabsorbs Na⁺ from the xylem which reduces its transport and accumulation in leaves.

In wheat, two genetic loci have been identified that also lower Na⁺ transport to leaves. Both loci (*Nax1* and *Nax2*) possess members of the HKT family that reduce Na⁺ transport from root to shoot by removing Na⁺ from the xylem and storing it in the vascular parenchyma or in the leaf sheath. *Nax2* was identified in durum wheat with an enhanced ability to exclude Na⁺. A gene closely related to HKT1;5 in rice was identified as underlying the *Nax2* locus in durum wheat. Similar to results with rice, this locus in wheat resulted in a higher K⁺ to Na⁺ ratio in leaves. The gene underlying *Nax1* in wheat was also identified as a member of the HKT family and reduces the rate of Na⁺ transport from root to shoot by retaining Na⁺ in the leaf sheath. Overall, significant progress has been made in the last 10 years in our understanding of the transport proteins that control plant K⁺ accumulation and Na⁺ transport under saline conditions.

23.3 Phosphorus nutrition and transport

Phosphorus (P) is one of the most important fertilizer inputs for crop plants. P can exist in plants as both soluble inorganic phosphate anions (abbreviated as P_i), and organophosphate compounds. Unlike nitrate and sulfate, P_i is not reduced in plants during assimilation but instead remains in its oxidized state, forming phosphate esters with a wide range of organic compounds. P is an important structural component of nucleic acids and phospholipids, and plays a critical role in energy conversion in the form of high-energy phosphoester and diphosphate bonds. P is important both as a substrate and regulatory factor in photosynthesis and oxidative metabolism, it participates in signal transduction, and it regulates the activities of a diverse array of proteins by way of covalent phosphorylation/dephosphorylation reactions.

Poor P_i availability is one of the major constraints to plant growth because of its low solubility and high sorption capacity in soil. Indeed, some soils contain a high total P content but only have a small fraction that is available to plants as P_i. Soil P_i concentrations are often 1 μM or less, and P_i is rapidly

depleted from the rhizosphere by roots. The majority of P_i in the rhizosphere moves to the root by diffusion, which is a slow process in biological terms and considerably slower than the movement of other macronutrients by mass flow. Plants have evolved specialized mechanisms for obtaining P_i from the soil and roots exhibit an impressive plasticity in response to low availability of P_i .

23.3.1 Phosphate is transported into roots by an active, high-affinity mechanism

Experiments using radiolabeled $^{32}P_i$ have shown that $H_2PO_4^-$ is the primary form of P transported into root cells from the soil. Since root cells must transport this anion against a sizeable negative membrane potential and concentration gradient (low μM in the soil compared to mM in the cytoplasm) the uptake of P_i into root cells is an active process requiring expenditure of energy. This active uptake occurs by transport coupled to the transmembrane electrochemical H^+ gradient generated by the plasma membrane H^+ -ATPase. This is supported by the following observations:

- Root P_i uptake is often accompanied by an alkalinization of the external media, which translates into a H^+ : $H_2PO_4^-$ flux stoichiometry of between two and four protons for every P_i taken up.
- Root P_i uptake is enhanced when the pH of the uptake solution is lowered.
- Electrophysiological measurements of root P_i influx show that the process is accompanied by a transient depolarization of E_m , followed by a repolarization (and often a hyperpolarization) of E_m . This is consistent with the operation of a H^+ - P_i cotransporter that transports net positive charge into the cell. The acidification of the cytoplasm stimulates the H^+ -ATPase, which explains the subsequent repolarization.
- Studies using pH microelectrodes and pH-sensitive fluorescent dyes show that P_i absorption acidifies the cytoplasm.
- Protonophores such as CCCP, a molecule that collapses transmembrane H^+ gradients, abolishes root P_i uptake.

Studies using roots, leaves, and cell suspensions from different plant species and physiologically relevant concentrations of P_i (low micromolar range) show the existence of high-affinity P_i transport ($K_m = 1\text{--}5 \mu M$). This high-affinity transport is tightly regulated by plant P status. For example, if P is withheld from roots of tomato (*Solanum lycopersicum*) and barley for several days, high-affinity P_i influx is markedly stimulated in these plants. When P_i is resupplied to the roots, the influx of P_i declines within 1–2 hours. The inverse relationship between root P_i influx and plant P status can be seen in electrophysiological traces. Addition of P_i to roots of P-replete plants results in little or no depolarization of E_m , which correlates with the magnitude of P_i influx (Fig. 23.8A,B). However, in plants starved of P for 7 days (Fig. 23.8C) or 14 days (Fig. 23.8D), the membranes are depolarized in proportion to the severity of P

FIGURE 23.8 Phosphate-induced transients in transmembrane electrical potential in roots of *Trifolium repens*. The solid arrows indicate the addition of $125 \mu M P_i$ to media buffered at pH 5 with MES buffer and the resulting change in the root membrane potential. The open arrows indicate the addition of $63 \mu M$ sulfate as a control for the general effect of mineral anions on the membrane potential. (A) Plant grown on P_i for the entire 29-day period; (B) P_i withheld for final day of growth; (C) P_i withheld for last 7 days of growth; (D) P_i withheld for last 14 days of growth.

deficiency. The relationship of root P_i uptake to P nutrition will be revisited in Section 23.3.3 when discussing molecular regulation of root P_i uptake.

23.3.2 Roots use various mechanisms to increase the bioavailability of P in the rhizosphere

P is the macronutrient least available to plant roots, because it is readily bound to soil particles and soluble ligands. In acid soils P_i forms insoluble complexes with Fe(III) and Al cations and forms strong chemical bonds with metal oxides on mineral surfaces. In calcareous soils, similar reactions occur between P_i and calcium carbonate. Additionally, soil microbes can effectively convert P_i to organic forms of P that are not readily taken up by roots. Plants have developed an array of mechanisms to mine otherwise unavailable soil reserves of P. In response to P deficiency, the structure and function of root systems can be altered to increase the solubility of soil P and to enhance the exploration of soils by root systems. Root

characteristics that enhance the uptake of P_i under conditions of low P availability include the following:

- Associations between roots and **mycorrhizal** fungi which help plants acquire P_i from a greater soil volume.
- Alterations in root architecture and branching to allow more effective exploration of the soil.
- Increases in root hair density and length to increase the absorptive surface area of roots and to reduce the length of the diffusive pathway for P_i to reach the root surface.
- Release of organic acids and H^+ to solubilize inorganic forms of P.
- Exudation of phosphatases to release P_i from organic forms of P in the soil.
- Upregulation of high-affinity P_i transporters in the root cell plasma membrane.

Utilization of these mechanisms varies among genotypes, not only between different plant species but also between cultivars within species. This suggests that breeding and molecular approaches have the potential to enhance the ability of crops to use soil P more efficiently.

The beneficial effects of mycorrhizal associations on plant growth largely relate to the increased uptake of immobile nutrients from the soil, notably P_i . The predominant mycorrhizal associations that influence root P absorption involve the **ectomycorrhizae** and **vesicular-arbuscular mycorrhizae** (VAM; Fig. 23.9). VAM are the most abundant mycorrhizae and colonize roots of a wide range of plant species in almost all types of soils. They form extensive hyphal networks in the soil and within root cortical tissues, forming intimate associations in cells without penetrating the plasma membrane of host cells. VAM are characterized by the formation of branched haustoria (arbuscules) within the tissues of the root cortex that are the sites of solute exchange between the fungus and the host plant. Solutes that are exchanged by plant and fungi must therefore traverse the plasma membranes of both organisms. The fungal mycelium extends into the soil, and in low P soils, VAM can enhance P_i absorption by root systems two- to six-fold over nonmycorrhizal roots. The stimulation of root P_i absorption by VAM is a result of a more thorough exploration of soil P reserves. Extensive hyphal growth, similar to increased root hair growth, reduces the distance that P must diffuse to reach the sites of absorption. The relationship between fungus and plant is a symbiotic one because the movement of P_i from the fungus to the plant is exchanged for a flow of fixed carbon from the plant to the fungus. The regulation of P nutrition in plants is substantially influenced by mycorrhizal interactions with roots (see below).

In response to P starvation some plant species form cluster roots (also known as proteoid roots) that exude large quantities of organic anions. This phenomenon has been extensively studied in white lupine and members of the Proteaceae. P deficiency triggers proliferation of short secondary lateral roots that form a tight “bottlebrush-like” cluster densely covered in root hairs. These specialized root structures enable the plant to effectively extract immobile nutrients such as P_i from a limited soil volume

FIGURE 23.9 Light micrographs of vesicular–arbuscular mycorrhizae (VAM, or endomycorrhizae) showing the structure of vesicles (A) and arbuscules (B).

(Figs. 23.10 and 23.11). Cluster roots release organic anions at a particular stage of development. These organic anions include citrate and malate, which are effective chelators of Al and Fe in the soil. The high concentrations of organic anions around the cluster roots solubilize mineral forms of P to increase the availability of P_i which is rapidly taken up by the dense mat of root hairs that cover the roots. White lupine can release as much as 25% of its total fixed C as organic anions into the soil illustrating the priority that plants place on obtaining scarce sources of P.

When P-deficient many plants also release phosphatases from roots. Plants synthesize a wide range of phosphatases, which are classified as alkaline or acid phosphatases based on their pH optima. The enzymes secreted from roots in response to P deficiency are acid phosphatases, which hydrolyze a wide range of P-containing substrates. These secreted phosphatases are capable of hydrolyzing esterified forms of P (e.g., ATP) *in vitro* and therefore may enhance P_i availability from soil

FIGURE 23.10 Cluster roots of Australian native *Hakea* spp. grown in nutrient solution with low P_i concentration (less than $1 \mu\text{M}$). (A) Cluster roots on *Hakea petiolaris* showing distinct “bottlebrush-like” structures separated by unbranched regions. The youngest cluster roots are on the right side of photograph. Bar = 20 mm. (B) Six stages of cluster-root development in *H. prostrata*, labeled from left to right, are arranged according to their age. The numbers indicate the days following rootlet emergence from the swollen axis (day 0) until cluster-root senescence (day 20 to 21). A noncluster root is shown on the far left. Bar = 10 mm. (C) Close up of a young cluster root of *H. prostrata* approximately 2–3 days after rootlet emergence. Thousands of densely-spaced rootlets emerge from the parental root axis in longitudinal rows. Bar = 5 mm.

in the rhizosphere by releasing P_i from organic sources. Although many of these enzymes have been characterized, direct evidence that they play roles in P nutrition is available for only a few. For example, a mutation in the *AtPAP26* gene, a member of the secreted acid phosphatase family of *Arabidopsis*, results in mutant plants that grow more slowly than wild type in low P conditions. In addition to being secreted, a proportion of *AtPAP26* resides in the vacuole and the impaired growth may be related to an inability to effectively recycle P_i within the plant as well as a reduced capacity to utilize organic P in the soil.

(B) Secondary lateral root excised from *L. albus* plant grown without *P*. The root was cleared with sodium hypochlorite and stained with methylene blue. By 8 days after emergence, tertiary lateral roots are beginning to emerge through the epidermis (solid arrow). Bar = 1 mm. Source: (A,B) Johnson et al. (1996). *Plant Physiol.* 112:31–41.

23.3.3 Molecular studies provide insights into the complex regulation of P acquisition and homeostasis in plants

The molecular regulation of P nutrition is being revealed by the characterization of mutants perturbed in P_i acquisition and homeostasis. Central to the homeostasis of P nutrition in plants is the regulation of P_i uptake by roots from the external medium. The *Pht1* (**Phosphate transporter1**) P_i transporter genes from plants were originally cloned based on their sequence similarity to PHO84, a high-affinity P_i transporter of the yeast *S. cerevisiae*. Indeed many of these plant genes are able to complement the *pho84* yeast mutant defective in P_i uptake. Members of the *Pht1* family of P_i transporters share important structural similarities (Fig. 23.12). Predicted secondary structures are characterized by six N-terminal transmembrane domains and six C-terminal transmembrane domains separated by a central hydrophilic region. Additional structural motifs that are conserved in these P_i transporters include sites for protein kinase C- and casein kinase II-mediated phosphorylation and for N-linked glycosylation.

Many *Pht1* transporters function in high affinity P_i uptake when expressed in plants that is consistent with a role in P_i

FIGURE 23.12 Proposed structural model for plant plasma membrane high-affinity P_i transporters showing the six-loop-six motif of 12 membrane-spanning domains. The predicted sites for phosphorylation by protein kinase C and casein kinase II and for N-glycosylation are shown.

uptake from soil. Additional evidence for this role includes: (1) their expression in root epidermal cells and root hairs, critical sites for P_i uptake; (2) regulation of their expression by plant P-status which mirrors the observed changes in P_i uptake rates (see above); (3) their localization to the plasma membrane; (4) physiology consistent with H^+ - P_i cotransporter function; and (5) the reduction of P_i uptake by *Arabidopsis* plants carrying knockout mutations in certain members of the *Pht1* family.

Once P_i is taken up from the external medium, transporters are also responsible for moving P_i between and within cells. These P_i transporters are less well defined and may include members of the *Pht1* family as well as three additional families distinct from *Pht1*. Members of the *Pht2*, *Pht3* and *Pht4* families have all been shown to be P_i transporters and are located on organelle membranes where they are thought to participate in intracellular transport between the organelles and cytosol. Two of the proteins are located on chloroplast membranes (*Pht2* and *Pht4*) and others are located on mitochondrial (*Pht3*) and Golgi apparatus membranes (*Pht4*).

The isolation and characterization of mutants has helped unravel the regulatory mechanisms involved in P homeostasis of plants. The first P-nutrition mutants of *Arabidopsis* were isolated based on their perturbed accumulation of P in shoots. Shoots of the *pho1* (*phosphate1*) mutant are P-deficient even when plants are grown on substrate that is high in P_i . The mutant is impaired in its ability to load P_i into the xylem resulting from a mutation in a membrane protein thought to transport P_i into the xylem. By contrast, the *pho2* mutant accumulates excess P_i in shoots and is clearly perturbed in a mechanism that regulates P_i uptake and homeostasis. Detailed analysis has identified a regulatory system that involves microRNAs and PHO2 in the post-transcriptional regulation of two P_i transporters of the *Pht1* family (*Pht1;8* and *Pht1;9*, Fig. 23.13A,B). The *PHO2* gene encodes an ubiquitin-conjugating enzyme (UBC) that under high P conditions is

thought to target the degradation of the transporters themselves or regulators of their expression. Details on the role of UBCs in degradation of proteins by the ubiquitination pathway is discussed in Chapter 10 and summarized in Figure 10.33. Mutants lacking functional PHO2 protein accumulate excess P_i because they are unable to downregulate the two P_i transporters even when they have sufficient P (Fig. 23.13C). *PHO2* mRNA possesses five target sites in its 5' UTR for binding of miR399 resulting in degradation of *PHO2* transcript (see Chapter 9 for details of gene regulation by miRNAs). Expression of *MIR399* is itself upregulated under P-deficiency. Furthermore, *MIR399* is primarily expressed in shoots and the processed miRNA399 acts as a phloem-mobile signal to regulate *PHO2* activity in roots. Therefore, when sufficient P is available, *PHO2* transcripts are abundant resulting in active *PHO2* proteins that downregulate the activity of *Pht1;8* and *Pht1;9*. When P-deficient, *MIR399* expression is increased in shoots and processed miRNA is translocated to roots. *PHO2* mRNA is then degraded relieving the suppression of *Pht1;8* and *Pht1;9* which results in enhanced P_i transport. Overexpression of *MIR399* mimics the *pho2* mutant consistent with the proposed model (Fig. 23.13D).

While this mechanism for regulating P_i uptake, with some modifications, appears to be common to many plant species, it is a subcomponent of a more complex network. The *phr1* (*phosphate starvation response1*) mutant of *Arabidopsis* was originally identified as being impaired in a broad range of P-deficiency responses. The mutant is unable to upregulate a range of genes normally induced by P-deficiency including those encoding *Pht1* transporters, RNases and acid phosphatases. PHR1 is a transcription factor of the MYB superfamily that binds to a motif (PIBS) present in the promoters of many genes that respond to P_i starvation and acts to enhance transcription under P deficiency. The induced expression of *MIR399* is an example of a gene regulated by PHR1, and the perturbed uptake of P_i in *phr1* mutants can be attributed to an

FIGURE 23.13 Model of a module that regulates P_i homeostasis in plants. Shown is a simplified schematic of a plant comprising 4 cells: a root cell, a xylem vessel, a phloem cell and a shoot cell. The yellow arrows depict P_i transport with the thickness denoting the rate of transport. Phosphate ions are shown as small yellow circles and red lines denote the flow of microRNA (*miR399*) that targets *PHO2* transcript. Lines terminating with a “T” junction denote suppressive action and the thickness of the lines indicate the degree of suppression. (A) When the plant has adequate P, the ubiquitin conjugase activity of *PHO2* suppresses the function of phosphate transporters. (B) When P-deficient, expression of a specific microRNA (*miR399*) is induced primarily in shoots. *miR399* is translocated via the phloem to roots where it targets the degradation of *PHO2* transcript. With reduced *PHO2* levels, suppression of P_i transporters is relieved and P_i uptake increases. (C) The *pho2* mutant lacks the ubiquitin conjugase activity and is unable to downregulate P_i transport even when the plant has sufficient P resulting in P toxicity. (D) Constitutive overexpression of *MIR399* confers the same phenotype as the *pho2* mutant since high levels of *miR399* degrade *PHO2* transcripts.

indirect effect on *Pht1* transport through the *PHO2*/*miR399* mechanism. An inability to upregulate *MIR399* expression in *phr1* mutants maintains active *PHO2* and hence suppressed *Pht1* transport activity.

The influence of *PHR1* on P-homeostasis is more global than *PHO2* as it acts on a wide range of processes involved in P-deficiency including the ability to alter metabolic pathways. *PHR1* is subject to regulation and is the target of a small ubiquitin-like modifier (SUMO) E3 ligase which serves to activate *PHR1*. This SUMO, named *SIZ1*, also regulates gene expression in response to stresses other than P-deficiency. As more mutants are discovered it is becoming apparent that the regulation of P homeostasis in plants is far more complex than originally envisioned and comprises components that interact with pathways specific for maintaining P_i homeostasis and with mechanisms that serve to regulate other aspects of plant development.

Recent research on species that form effective mycorrhizal associations (e.g., *Medicago truncatula*) has identified mechanisms that regulate P_i uptake by the symbiosis between fungus and plant host. The symbiosis with VAM adds complexity to the way that P_i is taken up by plants with direct (roots and root hairs) and indirect (VAM) pathways that need to be regulated. As discussed above for nonmycorrhizal roots, P-deficiency upregulates the activity of high-affinity P_i transporters at the plasma membrane of root cells. However, when roots are infected with VAM that are actively absorbing P from the soil, these plant P_i transporters become almost inactive. Instead P_i is taken up into plants by other transporters of the same family that are specifically expressed in the infected cells. In particular, two subfamilies of the *Pht1* transporter gene family are expressed predominantly in cortical root cells colonized by VAM fungi. The promoters of these genes possess regulatory elements that respond to mycorrhizal infection by increasing their expression. These *Pht1* transporters are thought to be the primary mechanism that takes up the P_i

provided by VAM into plant cells, and their location in the host plasma membrane that surrounds the branches of an arbuscule is consistent with this idea. An essential role of specific *Pht1* transporters in mycorrhizal symbiosis has been demonstrated by knock down of expression of these genes resulting in reduced P_i uptake by the symbiosis and in loss of effective colonization of root cells by the VAM.

23.4 The molecular physiology of micronutrient acquisition

Micronutrients such as Fe, Zn, Mo, and Cu are important to agriculture because their low availability in many soils limits crop production. There is also growing interest in how the micronutrient content of foods might be modified to benefit human health and nutrition. This is especially true in developing countries where diets are often based on one major crop. Furthermore, nonessential heavy metals such as Cd can be taken up via the same transport processes that plants use to acquire essential micronutrients, providing a primary site for the entry of toxic heavy metals into the food chain. Even some essential micronutrients such as Zn and Cu are toxic if accumulated and ingested at high concentrations. Moreover, scientists have realized that terrestrial plants might constitute an inexpensive mechanism for cleaning soils contaminated with heavy metals, a technology termed **phytoremediation** (see Box 23.4).

Research into micronutrient transport and acquisition from soil is complicated by the low concentrations of these minerals in the soil and their complex chemistry. The concentrations of available (soluble) micronutrients in the soil are typically orders of magnitude less than the concentrations

BOX
23.4

The conceptual basis for phytoremediation, the use of plants to clean contaminated soils, came from identifying plants that hyperaccumulate metals

Contamination of the environment with heavy metals and radionuclides is a serious problem both for human health and agriculture. In many locations throughout the world, sizeable land areas contain surface soils contaminated with hazardous amounts of toxic heavy metals such as Cd, Zn, Pb, Cu, Cr, Hg, Ni, and U. The engineering-based technologies currently in use to

remediate surface-contaminated soils (e.g., removal of topsoil for storage in landfills) can be prohibitively expensive and often disturb the landscape. As an alternative, the use of plants as an inexpensive method for remediation of soils polluted with heavy metals has attracted enormous interest. Some plant species can grow in soils that are heavily contaminated with metals and even

accumulate these metals to high concentrations in shoots. The existence of these metal hyperaccumulator species suggests that plants could be used to **bioremediate** metal-contaminated soils (i.e., to detoxify them by means of biological activity).

Phytoremediation (plant-based bioremediation) can involve **phytoextraction** (removal of toxins from soil), **phytostabilization** (complexation and immobilization of toxins within the soil), and **phytodegradation** of organic contaminants in the rhizosphere (see figure). Phytoextraction involves the use of terrestrial plants to absorb heavy metals from the soil and transport them to the shoots. Phytoextracted metals may accumulate in plant shoot tissues (e.g., Pb, Ni) or may be released as volatile species (e.g., Se). For metals that become concentrated within plant tissues, remediation involves harvesting the shoot biomass, which is reduced in volume (e.g., ashed) and then disposed of in a final repository. Moreover, for Se, the toxicity of the volatile species dimethylselenide and dimethyldiselenide is much lower than that of the soluble oxyanions, such as selenite (SeO_3^{2-}), present in soil solution.

Metal-hyperaccumulating plant species are endemic to metalliferous soils and can tolerate and accumulate high amounts of heavy metals in their shoots. Hyperaccumulators were first identified more than 100 years ago; this fascinating collection of different plants not only can grow in soils contaminated with high concentrations of a specific heavy metal, but also often have a higher tolerance for that metal. To date,

hyperaccumulating plant species have been identified in nearly 400 taxa representing about 45 plant families. There is strong evidence for hyperaccumulators of Zn/Cd, Ni, and Se and some indications of plants that accumulate Co, Cu, and possibly Pb.

One well-known heavy metal hyperaccumulator is *Noccaea caerulescens*, a member of the Brassicaceae that accumulates Zn and Cd (see figure). Certain ecotypes of *N. caerulescens* have been shown to accumulate and tolerate as much as 40,000 μg of Zn per gram dry weight in their shoots (foliar Zn in hydroponically grown plants is ordinarily around 100–200 $\mu\text{g g}^{-1}$; 30 $\mu\text{g g}^{-1}$ is considered sufficient). This species also accumulates high concentrations of Cd and has also been suggested to accumulate high amounts of other heavy metals. Several studies conducted with *N. caerulescens* to remediate soils contaminated with Zn and Cd have had moderate success. One drawback to using *N. caerulescens* (or most other hyperaccumulators) for phytoremediation is that the species is slow-growing and does not produce substantial shoot biomass. To maximize phytoextraction, a species should have high shoot biomass and should accumulate metals to high concentrations in their shoots. Nonetheless, the unique physiology of heavy metal transport and tolerance in *N. caerulescens* makes it an interesting experimental plant for basic research aimed at elucidating the mechanism of heavy metal hyperaccumulation, especially with the goal of transferring hyperaccumulating traits to species with a higher biomass.

of most of the macronutrients, and they rarely exist as free cations. Instead they form complexes with ligands that vary in stability, size, and charge. Consequently the study of micronutrients must address the presence of metal chelates in the rhizosphere, the forms in which the micronutrients are transported into plant cells, and the nature of the metal–chelate complexes present within cells as they are either stored or transported long distances by the xylem and phloem. The present section will focus on the physiology and molecular biology of Fe and Cu acquisition and distribution by plants.

23.4.1 How do plants acquire Fe from the soil?

Fe is an essential nutrient for plants. Although abundant in the Earth's crust, the concentration of soluble Fe in the soil is usually very low. Most Fe in the soil exists in one of two oxidation states: Fe(III) or ferric Fe has the +3 oxidation state and Fe(II) or ferrous Fe has the +2 oxidation state. The ability to change oxidation state is central to the participation of Fe in

the reversible oxidation–reduction (redox) reactions essential for mitochondrial respiration and the light reactions of photosynthesis. Fe also functions as a co-factor in Fe–sulfur clusters, in the porphyrin ring of heme and as nonheme Fe. Multiple Fe–sulfur clusters are present in Complexes I and II of **oxidative phosphorylation** as well as certain **metalloproteins** such as ferredoxin.

In aerobic conditions and when soil pH is above 6.0, Fe(II) is readily oxidized to Fe(III) and exists mostly as sparingly-soluble ferric oxides. Under these conditions the concentration of soluble inorganic Fe is typically $<10^{-16}$ M, many orders of magnitude below the concentrations required for sustained plant growth. As a consequence, plants grown on alkaline or calcareous soils are especially prone to Fe deficiency. Typical symptoms of deficiency include interveinal chlorosis (yellowing, see Fig. 23.1), stunted growth and poor yields. Fe availability improves when solution pH is reduced to \approx pH 4 because the concentration of soluble Fe increases by a factor of 10^8 and more of it occurs as the reduced Fe(II) form which can be absorbed directly by some plants. Fe(II) is also more common in anaerobic conditions such as the flooded paddy fields where rice is grown.

Regardless of oxidation state, most soluble Fe in soil solution is chelated by organic and inorganic ligands. The organic ligands are a diverse range of compounds derived from soil bacteria and fungi or degraded organic matter. The concentration of soluble Fe:chelates in the soil solution remains very low and plants employ several mechanisms to acquire Fe from soil to meet their growth requirements.

23.4.2 Plants use two main strategies for absorbing Fe from the soil

In eudicots and nongrass monocots, Fe(III) chelates are reduced to Fe(II) at the root surface and Fe(II) is taken up by a transport protein located at the plasma membrane, called the Strategy I mechanism. By contrast, members of the grass family (Poaceae), release **phytosiderophores** from roots that chelate and solubilize Fe(III) to make it available for uptake, called the Strategy II mechanism. The term phytosiderophore derives from the well-characterized Fe uptake system in microorganisms that involves the release of specific Fe-chelating compounds named **siderophores** (Greek: “iron bearers”) to mobilize Fe from their surroundings. These strategies are described in more detail below.

Strategy I plants respond to Fe deficiency with (1) enhanced efflux of protons (H^+) from root cells; (2) induction of a plasma membrane ferric reductase in root epidermal cells to reduce extracellular Fe(III) to Fe(II) at the root surface; and (3) induction of an Fe(II) transporter at the root-cell plasma membrane to facilitate Fe(II) uptake (Fig. 23.14). Some Fe-deficient plants also release organic anions from their roots that may increase the solubility of Fe. The increase in H^+ efflux occurs from the upregulation of a H^+ -ATPase on the plasma membrane of root epidermal cells. The resulting acidification of the rhizosphere increases Fe solubility. In *Arabidopsis* the H^+ -ATPase is encoded by the gene *AHA2*. The reduction of Fe(III) to the more soluble Fe(II) at the root surface is critical for Fe absorption in eudicots. This is controlled by the NADPH-dependent ferric chelate reductase, *FRO2* (Fig. 23.15), a member of a superfamily of flavocytochromes that transport electrons across membranes. *FRO2* expression in the root epidermis is enhanced during Fe deficiency, and the *Arabidopsis* mutant (*frd1*) that lacks *FRO2* reductase activity rapidly becomes chlorotic. Conversely, plants engineered to overexpress *FRO2* perform better than wild-type plants when Fe supply is restricted. Additional *FRO* genes are expressed in other parts of the plant during Fe deficiency including the vasculature and shoots and these are probably involved in reabsorbing Fe from the apoplast of various tissues.

Once Fe(III) is reduced to Fe(II) it is taken up by IRT1 (iron-regulated transporter), a member of the ZIP (Zrt/Irt-related protein) family, localized to the plasma membrane of root epidermal cells. ZIPs occur in plants, animals, bacteria and fungi where they transport a range of metals including Fe, Zn, Mn and Cd. *IRT1* expression is enhanced in Fe-deficient

FIGURE 23.14 Model of Fe uptake by eudicots and nongrass monocots. The model depicts the key plasma membrane-localized components that are induced in roots by Fe deficiency in *Arabidopsis*. These include a plasma membrane H^+ -ATPase (*AHA2*) which acidifies the rhizosphere and increases Fe solubility, the ferric reductase *FRO2* that reduces Fe(III) chelates in the rhizosphere releasing Fe(II), and the high-affinity transporter *IRT1* which transports Fe(II) across the plasma membrane.

FIGURE 23.15 Predicted protein structure for *FRO2*, the root plasma membrane ferric chelate reductase in *Arabidopsis*. *FRO2* is predicted to include six membrane-spanning domains within the C-terminal region and two membrane-spanning domains within the N-terminal region. Four histidine residues are predicted to coordinate two heme groups localized to two of the internal membrane-spanning domains, forming a complex that may play a role in transmembrane electron transport. Near the C-terminus is a cytoplasmic loop that includes putative FAD- and NADPH-binding domains.

Arabidopsis plants, and mutants lacking *IRT1* function die before setting seed unless supplied with high levels of soluble Fe. *IRT1* was first identified from its ability to complement a yeast strain (*fet3fet4*) impaired in high and low affinity Fe

FIGURE 23.16 Predicted protein structure of the members of the ZIP family of micronutrient transporters. The notable structural features include eight membrane-spanning domains and a cytoplasmic loop of variable length situated between the third and fourth transmembrane helices. This cytoplasmic domain contains histidine repeats that may function in metal-binding.

uptake (see Box 23.2). IRT1 was the first member of this family of micronutrient transporters to be characterized in plants and its discovery led to the isolation of other Fe and Zn transporters in plants and yeast. IRT-type proteins are predicted to have eight membrane-spanning regions and a histidine-rich motif between the third and fourth transmembrane domains, which may act as the metal-binding site (Fig. 23.16). IRT1 can transport other micronutrients and even Cd, albeit with a lower affinity, and this can sometimes induce toxicity in Fe-deficient plants. The 16 members of the ZIP family in *Arabidopsis* are expressed in various tissues. While several ZIPs can complement the *fet3fet4* yeast mutant most do not contribute directly to Fe uptake from soil. Instead they perform similar functions transporting Fe and other metals.

Responses to Fe deficiency outlined above are regulated by members of the basic helix-loop-helix (bHLH) family of transcription factors. The role of these regulators was discovered by characterizing a tomato mutant (*fer*) defective in this gene. Plants carrying the *fer* (Fe reductase) mutation are unable to induce the normal physiological responses to Fe deficiency and rapidly become chlorotic at low Fe concentrations. A gene called *FIT* performs a similar function in *Arabidopsis* and *fit* mutants also need high Fe concentrations to survive beyond the seedling stage.

Grasses differ from eudicots in their response to Fe deficiency. They do not increase H^+ excretion or ferric chelate reductase activity and they are unable to absorb Fe supplied as very stable Fe(III) chelates such as ethylenediamine-*N,N'*-bis(2-hydroxyphenyl)acetic acid (EDDHA). Despite these apparent limitations grasses tend to grow better than eudicots on calcareous (alkaline) soils where the concentrations of available Fe are extremely low. Grasses achieve this by releasing compounds from their roots (Strategy II) that efficiently

chelate and solubilize ferric iron (Fig. 23.17). These compounds are nonprotein imino acids called phytosiderophores, the synthesis of which starts with L-methionine (Fig. 23.17). Phytosiderophore function is less affected by pH than the ferric chelate reductase activity which has an optimum below pH 7.

Fe deficiency stimulates the synthesis of many different phytosiderophores in grasses, with deoxymugineic and avenic acids being among the best characterized. Grass species such as barley that release large amounts of phytosiderophore tend to be more efficient at extracting Fe from alkaline soils than those such as rice and wheat that release smaller amounts. Deoxymugineic acid release from rice and barley is mediated by proteins belonging to the major facilitator family of transporters. The genes encoding these proteins in rice and barley are called *TOM1* and *HvTOM1*, respectively (transporter of mugineic acid family phytosiderophores 1) (Fig. 23.18). *TOM1* and *HvTOM1* are predominantly expressed in roots and developing seed but Fe deficiency strongly induces their expression in the vascular bundle of leaf sheaths as well as roots. Transgenic plants over-expressing *TOM1* and *HvTOM1* show enhanced deoxymugineic acid release and greater tolerance to low Fe.

Once Fe(III) is chelated by a phytosiderophore in the soil the entire complex is transported into the root cells by proton-coupled transporters belonging to the oligopeptide transporter family (OPT). The first Fe(III):phytosiderophore transporter to be characterized was named yellow-stripe 1 (YS1) because it was identified as the cause of the *yellow stripe* (*ys1*) mutation of *Z. mays* which produces distinctive interveinal chlorosis. *Yellow stripe 1-like* (YSL) genes are present in monocots and eudicots (18 in rice and 8 in *Arabidopsis*) but only the grasses use them for acquiring Fe from the soil. Some of these YSLs are likely to transport Fe complexes across membranes in other cells and tissues as well (see below).

Rice is unusual among the grasses because it also displays aspects of the Strategy I mechanisms for Fe uptake. In addition to releasing phytosiderophores, Fe-deficient rice roots enhance expression of an IRT-type transporter, OsIRT1, which allows Fe(II) uptake from the reducing environment common in flooded paddy fields. This extra facility to take up reduced Fe may compensate for the relatively low exudation of phytosiderophores in rice.

These responses to Fe deficiency in grasses are also regulated by basic helix-loop-helix (bHLH) transcription factors. In rice the bHLH protein OsIRO2 (iron-related transcription factor2) regulates genes involved in phytosiderophore synthesis and Fe uptake. The expression of OsIRO2 and many other genes involved in Fe uptake and homeostasis is controlled by IDEF1, a transcription factor from the ABI3/VP1 family that specifically binds to the Fe-deficiency responsive *cis*-acting element IDE1. A different subset of Fe deficiency-induced genes (including certain YSLs in rice) is upregulated by another transcription factor belonging to the NAC family called IDEF2. These findings indicate that plants have a complex network of regulatory genes to control their responses to Fe deficiency.

FIGURE 23.17 Biosynthetic pathways for phytosiderophores can vary between different grass species. Here, the different phytosiderophores released by oat (*Avena sativa*) and barley share a common biosynthetic precursor, L-methionine, but are synthesized by two different pathways. The intermediate product nicotianamine is important for the transport and distribution of Fe and other micronutrients in all plants.

FIGURE 23.18 Model of Fe uptake by graminaceous plants. Phytosiderophores (PS) are synthesized in the cytoplasm from methionine by way of nicotianamine (1); a transporter on the plasma membrane induced by Fe deficiency (called TOM1 in rice) releases the PS into the rhizosphere (2); and a transporter belonging to the YSL family is also induced by Fe deficiency and transports the Fe(III)-PS complex into the cytoplasm (3).

23.4.3 Transport of Fe within the plant

Fe travels from root to shoot via the xylem. Once in the cell Fe is chelated by ligands to prevent it from precipitating at the neutral pH of the cytosol. Chelation of Fe also protects cells from the damaging effects of Fenton reactions which are catalyzed by free Fe and that generate reactive oxygen species. The compounds that chelate Fe in the cytosol are not known but an Fe:ligand complex of some type is likely to diffuse through the symplasm to the stele where it is released into the xylem (apoplast). In the xylem (pH 5.5) Fe is bound by citrate and perhaps other compounds, which chaperone Fe to shoots in the transpiration stream. In grasses, these other compounds might include phytosiderophores. The role of citrate in the movement of Fe to the shoots of *Arabidopsis* was revealed by examining a mutant called *frd3* (*ferric reductase defective3*). *frd3* mutant plants are constitutively upregulated in the Fe-deficiency responses and show typical symptoms of Fe deficiency under normal growth conditions. The *FRD3* gene underlying this mutation encodes a transport protein from the multidrug and toxic compound extrusion (MATE) family (see Chapter 3) that releases citrate into the xylem from the root pericycle and cells internal to the pericycle. The reduced citrate concentration in the xylem of *frd3* mutant plants prevents the effective retrieval of Fe from the xylem by shoot cells.

Fe is also transported throughout the plant in the phloem. Phloem is a living tissue that conducts sugars and nutrients from the leaves to other plant tissues (see Chapter 15). The phloem is particularly important in delivering nutrients to developing roots, shoots and seeds which are poorly served by the xylem due to their low transpiration rates. Since the pH of the phloem is similar to the cytosol (≈ 7.2) Fe must be chelated to remain soluble. In castor bean (*Ricinus communis*) most Fe in the phloem is bound to a 17-kD protein called the iron transport protein (ITP). ITP is a dehydrin protein that has a stronger binding affinity for Fe(III) than Fe(II). Nicotianamine (NA) is another compound in the phloem that forms stable complexes with Fe(II) at neutral pH. It is an

intermediate of phytosiderophore synthesis and is synthesized from S-adenosyl L-methionine by nicotianamine synthase (NAS) (see Fig. 23.17). NA is critical for the internal transport and distribution of Fe and other micronutrients in all plants.

The involvement of NA in Fe nutrition was first revealed by characterizing the *chloronerva* (*chl**n*) mutant of tomato. *chl**n* mutants lack nicotianamine synthase (NAS) activity and develop Fe deficiency symptoms despite accumulating high concentrations of Fe in their roots and shoots. The absence of NA from the vasculature of *chl**n* mutant plants inhibits their capacity to retrieve Fe from the phloem and distribute it to other tissues. *Arabidopsis* has four *NAS* genes, two of which are upregulated in roots by Fe deficiency. Mutations in any one of these genes cause no discernible phenotype but the quadruple mutant generates the same interveinal chlorosis observed in *chl**n* mutant plants. In grasses, phytosiderophores might also assist Fe transport in the phloem.

These findings support a model in which Fe(III) moves in the phloem as a complex, perhaps with ITP, but where loading or unloading from the phloem occurs as Fe(II):NA complexes, probably via YSL transporters. An extra reductase step would also be required to reduce Fe(III) to Fe(II) prior to binding with NA. YSLs also mediate reabsorption of Fe from the xylem and from senescing leaves to the phloem for long distance transport to sink cells. For example, OsYSL2 is a phloem-localized transporter in rice critical for the translocation of Fe-NA to shoots and developing seeds.

23.4.4 Storage of Fe within cells

Mitochondria, plastids, and vacuoles are important organelles for storing intracellular Fe (Fig. 23.19). These compartments provide a buffer which maintain safe concentrations of Fe in the cytosol. This enables cells to satisfy their nutrient requirements while minimizing the risk of oxidative stress. Most Fe in leaf cells is located in chloroplasts as ferritin, a storage

FIGURE 23.19 Transport of Fe within plant cells. It is unclear how Fe is taken up by shoot cells but it is likely to involve similar mechanisms to those described for roots, involving a FRO-like ferric chelate reductase and a transporter. Once Fe is taken up into the cytosol, the main organelles involved in Fe homeostasis are vacuoles, chloroplasts and mitochondria, and many transport processes controlling the distribution of Fe between these compartments are yet to be discovered. In *Arabidopsis*, loading Fe into vacuoles requires the transporter VIT1 and retrieval from vacuoles involves NRAMP3 and NRAMP4. Fe is complexed in the vacuole perhaps with nicotianamine (NA), phosphate or phytate. Uptake of Fe by chloroplasts requires ferric chelate reductase activity (FRO7) and release is facilitated by YSL4 and YSL6. Fe-binding proteins ferritin and frataxin chelate Fe in the chloroplasts and mitochondria respectively.

protein that has the ability to bind several thousand atoms of Fe. Mitochondria contain another Fe-binding protein called frataxin. Ferritin and frataxin help regulate Fe concentrations in cells especially during germination and early development. Mutant plants that are unable to synthesize ferritin are smaller, less fertile and their leaves contain higher levels of reactive oxygen species compared to wild-type plants. Chloroplasts are very sensitive to Fe deficiency. They have a high requirement for Fe due to the redox reactions occurring in thylakoids and the metabolism of photosynthetic pigments. Fe uptake by chloroplasts requires the activity of a ferric chelate reductase (FRO7) and unidentified transporters (Fig. 23.19) while efflux is mediated by members of the YSL family. In *Arabidopsis*, for example, YSL4 and YSL6 mediate Fe efflux from chloroplasts during senescence or when Fe is supplied in excess. The double mutant, *ysl4ysl6*, retains Fe in its chloroplasts and is hypersensitive to high concentrations of Fe.

Fe transport into the vacuoles of *Arabidopsis* cells is mediated by VIT1 (Vacuolar Iron Transporter1). VIT1 expression is enhanced in vascular tissues during seed development and *vit1* mutants grow poorly when Fe supply is restricted. The Fe stored in vacuoles is chelated possibly by

NA, phosphate, or even phytate. Retrieval of Fe from vacuoles involves members of the NRAMP family of transporters but other proteins may also be involved. *Nramp* genes form a diverse family in bacteria, fungi, plants, and animals which encode metal transporters with a broad range of specificity. Although the *Arabidopsis* genome contains several *Nramp* genes that can complement yeast mutants deficient in Fe uptake, the AtNRAMP3 and AtNRAMP4 proteins localize to the tonoplast of root and shoot cells and show enhanced expression during Fe deficiency. These transporters play critical roles in Fe nutrition and may also transport other transition metals such as Mn and Cd. Seedlings carrying the double mutation, *atnramp3atnramp4*, stop growing when Fe supply is restricted and are unable to retrieve Fe from vacuoles during germination, especially from the vascular tissues. Other members of this family are primarily expressed in roots and some of these (e.g., *AtNRAMP1*) may also be involved in Fe transport.

23.4.5 Interactions between Fe nutrition and other transition elements

There is considerable overlap in the mechanisms for acquiring and managing different mineral nutrients. This is especially true for the transition elements such as Fe, Mn, Cu, and Zn as well as for nonessential elements such as Cd. This overlap extends to the complexes they form in the soil and cytosol, their susceptibility to reductase activity, and to the transporters that absorb and distribute them throughout the plant. For instance, although IRT1 is more specific for Fe(II) than for other divalent cations, Fe-deficient plants sometimes enhance the uptake of other metals including Cu, Mn, Zn, Ni, Cd and Co. Furthermore the *frd3* mutant of *Arabidopsis* with disrupted Fe nutrition can also accumulate excess Mn, Zn and Cu. Transition elements can also affect plant responses to Fe deficiency. For example, the onset of Cu deficiency in *Arabidopsis* induces FRO2 activity even when Fe supply is adequate and this increases the reduction of Cu(II) to Cu(I). Conversely, high external Zn concentrations can repress the induction of IRT1 and FRO2 expression in Fe-deficient *Arabidopsis* plants even though reduction of Zn is not required for uptake. Similar interactions occur in grasses, an example being Zn-deficient barley plants that release phytosiderophores from their roots, enhancing the uptake of both Zn and Fe. Overexpression of NAS in transgenic plants to increase internal NA levels elevates Fe, Zn, Ni and Mn in shoots indicating that these metal ions are bound by similar compounds as they move from the root to the shoot. These complexes may also share YSL proteins to shuttle them between vasculature tissues or load and unload them from the phloem. For example, OsYSL2 in rice is important for the translocation of Fe(II):NA and Mn(II):NA to the shoots. Therefore, cells need to balance the demands of Fe nutrition with the risks of inadvertently absorbing other nonlimiting minerals to excess.

23.4.6 Copper taken up as the reactive Cu^+ ion is bound by chaperones within the cell

Copper shares the important attribute with Fe in that it exists as multiple oxidation states under physiological conditions. This allows Cu to act as an essential cofactor of enzymes involved in redox reactions. Copper metalloenzymes play important roles in photosynthesis, mitochondrial respiration, cell wall biosynthesis and superoxide scavenging. Under physiological conditions free Cu exists as Cu^{2+} or Cu^+ and these ions can rapidly disrupt cellular function by binding nonspecifically to a range of molecules. Indeed, Cu^{2+} is able to displace other ions, such as Mn^{2+} and Zn^{2+} , from their binding sites within metalloenzymes resulting in inactive proteins. Furthermore, free Cu readily generates reactive oxygen species that can cause oxidative stress within cells. For these reasons, the uptake, accumulation and delivery of Cu to target proteins are tightly regulated within plants.

Cu is generally found in trace amounts in soils with Cu deficiency being a larger problem for agriculture than Cu toxicity. Similar to Fe, Cu(II) in soil solution is first reduced to Cu(I) by the action of reductases prior to uptake by roots. As discussed above, ferric reductase activity induced by either Fe or Cu deficiency reduces Cu(II) to Cu(I) in addition to reducing Fe(III) to Fe(II). Members of the Cu transporter family of membrane proteins located on the plasma membrane transport Cu^+ from the external solution into the cytoplasm (Fig. 23.20). These proteins are known as the COPT family in *Arabidopsis*, and share considerable sequence and functional similarities to related proteins from other eukaryotes. Members of the COPT family were first identified based on sequence homology to other previously characterized Cu transporters, and by their ability to complement yeast mutants impaired in high-affinity Cu uptake. COPT proteins are predicted to possess three transmembrane domains and most possess methionine-rich domains at their amino-terminus. In yeast, Cu transporters that belong to the same family, the methionine rich domains serve to sequester Cu from an oxidizing environment allowing the metal ion to be stabilized by the thioester residues prior to transport. Subsequent transfer of Cu across the plasma membrane is thought to occur by a succession of Cu exchange reactions between binding sites within the pore of the transporter. As noted above, free Cu in the cytosol can disrupt cell function and chaperones serve to bind and sequester the Cu as required. These chaperones are small, water-soluble proteins possessing cysteine-rich motifs that provide thioester residues for complexing Cu. The loaded, chaperones then deliver the Cu to other transport proteins for uptake into organelles or to recently-synthesized Cu metalloenzymes that lack the cofactor metal (apo-form).

Other transport proteins involved in trafficking Cu include P-type ATPases that are specifically involved in the transport of heavy metals (named HMA transporters). Unlike COPT proteins, HMA transporters hydrolyze ATP as an energy source for Cu transport. The proton pump is an example of a P-type

FIGURE 23.20 Cu transport within plants cells showing the reduction of Cu^{2+} to Cu^+ at the plasma membrane by reductase activity (yellow), the role of COPT1 proteins in Cu^+ uptake, chaperones in binding reactive Cu^+ in the cytosol allowing it to be trafficked around the cell without causing damage, and HMA P-type ATPases that transport Cu into organelles or out of the cell.

ATPase and its function is discussed in detail elsewhere (see Chapter 3). The HMA transporters share many attributes with other P-type ATPases but differ in possessing metal-binding domains in their membrane-spanning domains as well as at their termini. Members of the HMA family transport Cu into chloroplasts where it is incorporated as a metal cofactor into Cu/Zn superoxide dismutase (SOD) and plastocyanin. Other members of this family transport Cu out of the cell and serve to protect cells when Cu concentrations become excessive whereas others transport Cu into organelles such as the Golgi. Figure 23.20 summarizes the cellular processes involved in the uptake and distribution of Cu.

23.4.7 Copper homeostasis in plants involves specific transcription factors and microRNAs

The homeostasis of Cu in plants shares features in common with P_i homeostasis in that both involve microRNAs and transcription factors that respond to nutrient deficiency to regulate gene expression. When plants become Cu deficient, the expression of a range of genes is upregulated and these serve to increase the acquisition of Cu as well as redirecting Cu away from nonessential metalloproteins towards essential ones. Central to this regulation in *Arabidopsis* is the transcription factor SPL7 (Squamosa Promoter-binding Like). SPL7

recognizes and binds to a GTAC core motif found as multiple copies within the promoters of genes upregulated by Cu deficiency. When *Arabidopsis* is Cu deficient, the expression of a range of genes including *COPT1*, *COPT2* (two members of the Cu transport family discussed above), *FRO3* (Fe reductase), *Fe SOD* (iron superoxide dismutase), *CCH* (a copper chaperone) and several microRNAs are all increased in wild-type plants but unaltered in an *spl7* mutant plant.

These responses serve to not only enhance the capacity of the plant to take up Cu, but also to make more efficient use of Cu within the plant. The induced miRNAs target the degradation of mRNAs encoding Cu-binding proteins considered to be nonessential thus redirecting Cu to those proteins with an essential function. Some of the proteins that decrease in abundance with Cu deficiency include Cu/Zn SOD, plantacyanin and the laccases, whereas the levels of plastocyanin, which plays an essential role in photosynthesis, are maintained. SOD activity is critical for preventing oxidative stress and the reciprocal regulation of the Cu/Zn and Fe SODs maintains this important cellular function as Cu nutrition changes. Therefore as Cu/Zn SOD activity declines in Cu deficient plants due to the action of miR398 targeting its mRNAs for degradation, an increase in Fe SOD expression maintains the overall SOD activity. The production of Cu/Zn SODs is further suppressed by miR398 because it also targets the mRNA encoding a Cu chaperone required for delivering Cu to SOD apoproteins. Therefore in Cu-deficient plants these regulatory pathways allow Cu to be retrieved from nonessential proteins and to be directed towards the essential Cu metalloenzymes (Fig. 23.21).

23.5 Plant responses to mineral toxicity

23.5.1 Aluminum toxicity is a major limitation to crop production on acid soils

Soil acidity affects 30% of total global land area and limits agricultural productivity around the world. Acid soils are especially widespread in tropical and subtropical regions where it impacts food production in many developing countries. Excessive use of ammonium fertilizers and other high-input farming practices can also accelerate soil acidification in developed countries. Liming (application of calcium carbonate) can neutralize soil acidity, but this is neither an economic option for poor farmers nor an effective strategy for alleviating subsoil acidity in the short term.

The major factor limiting plant production on acid soils is aluminum (Al) toxicity. Al is the most prevalent metal in the Earth's crust and its chemistry in soils and aqueous solutions is complex. Above \approx pH 5.5 most of the Al occurs as insoluble minerals but in more acidic conditions these minerals dissolve releasing several soluble monomeric Al species. Among these, the trivalent cation species, Al^{3+} , is most damaging to plants. Figure 23.22 illustrates the monomeric hydrolysis products of Al in solution and shows how the phytotoxic Al^{3+} dominates as pH decreases below 5.0. Monomeric Al also forms complexes with various ligands including carboxylates, sulfate, and phosphate even when these groups are in macromolecules such as proteins and nucleotides.

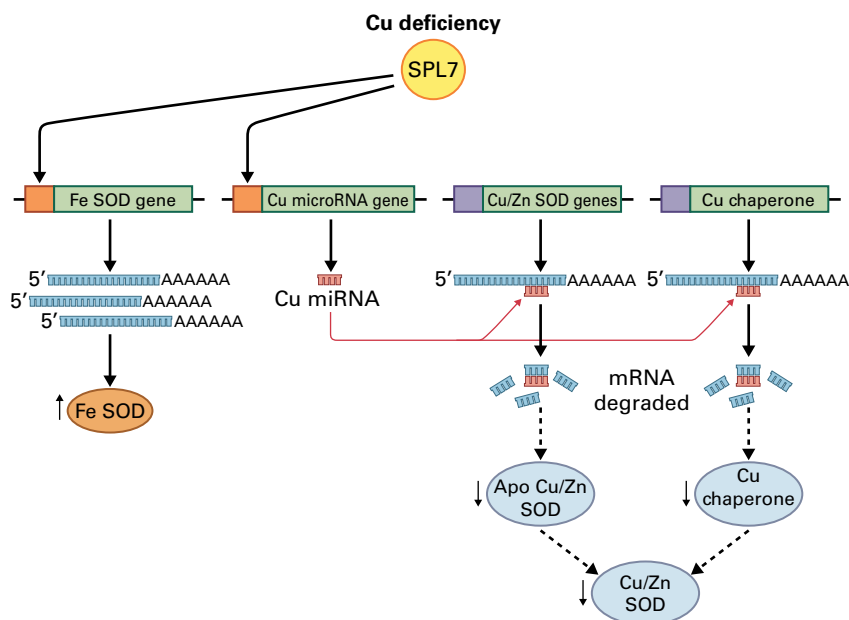

FIGURE 23.21 Model showing the regulation of SOD activity in Cu-deficient plants. When plants sense Cu deficiency, the transcription factor SPL7 binds to gene promoters that possess core GTAC motifs and activates gene transcription. Increased expression of miRNA398 targets the degradation of mRNA for both Cu/ZnSODs and a chaperone responsible for insertion of Cu into the apo-SOD protein. Production of active Cu/ZnSOD is suppressed by both pathways and the Cu can be redirected towards the production of essential Cu metalloproteins. Another gene regulated by SPL7 encodes FeSOD. Enhanced FeSOD transcription results in increased active protein thus maintaining overall SOD activity in the cell.

FIGURE 23.22 Distribution of mononuclear aluminum ion species in aqueous solution, showing the mole fraction of each species as a function of solution pH. Note the predominance of phytotoxic Al^{3+} at pH 5 or lower.

Stunted roots are the most obvious symptom of Al toxicity and this restricts the capacity of plants to access water and nutrients. Root apices are particularly sensitive and only a few millimeters need to be exposed to Al for growth to be inhibited (Fig. 23.23). Al toxicity results from multiple interactions between Al and important biological ligands in the cell wall, the plasma membrane and cytosol. For instance, Al can block Ca^{2+} and K^+ channels and inhibit Mg uptake that in the long term will induce mineral deficiencies. At the cellular level Al induces oxidative stress, destabilizes phospholipid bilayers, disrupts cytoplasmic Ca^{2+} homeostasis, and disrupts components of the cytoskeleton. This complex array of responses makes it difficult to determine which are the primary causes of toxicity and which are secondary responses to stress.

23.5.2 Al tolerance relies on exclusion and internal mechanisms

Some plant species and even genotypes within species grow better on acid soils than others and the mechanisms involved have been the focus of considerable research. Figure 23.23 shows Al-tolerant (Atlas) and Al-sensitive (Scout) cultivars of wheat grown in an acidic CaSO_4 solution containing Al. The inhibition of root growth and damage to root apices is more severe in Scout than Atlas whereas shoot growth is less affected by Al. Early studies established that tolerant genotypes within some species (e.g., wheat and barley) accumulate less Al in their roots than sensitive genotypes. By contrast other highly tolerant species such as tea (*Camellia sinensis*) and *Hydrangea* sp. accumulate high concentrations of Al in their root and shoot tissues. These examples illustrate the two types of tolerance mechanisms that operate in plants: **exclusion mechanisms** which reduce Al uptake or minimize its interaction with root cells, and **internal mechanisms** which enable plants

to safely accommodate any Al that enters the cells. Al could be excluded from the symplasm by binding to cell walls, decreasing its permeability across the plasma membrane, chelating it with ligands released from the root, exporting it out of the cell or by increasing rhizosphere pH to reduce the local concentration of Al^{3+} near the root surface. Internal mechanisms could involve chelating Al in the cytosol or sequestering it to subcellular compartments such as the vacuole.

Al tolerance is a multigenic trait in important crops such as wheat, rice and maize. This means that more than one gene contributes to the phenotype and that their effects may be additive. Nevertheless a single genetic locus often accounts for most of the phenotypic variation in Al tolerance in wheat suggesting that many of the other loci contribute relatively low levels of tolerance. The situation in maize is more complex and at least five different loci contribute to Al tolerance. The genes underlying these loci may encode multiple physiological mechanisms.

23.5.3 Exclusion of Al relies on the efflux of organic anions from roots by ALMT and MATE transporter proteins

The exclusion of Al from wheat roots relies on the release or efflux of malate anions from roots (Fig. 23.24). Indeed, Al tolerance among a wide range of wheat genotypes is highly correlated with malate efflux from the root apices and shows a saturating dependence on the concentration of Al in the external media (Fig. 23.25). Since malate anions form a stable complex with Al^{3+} it reduces the concentration of Al^{3+} near the sensitive root apices. Subsequent studies showed similar mechanisms operate in other members of the Poaceae (e.g., maize, barley, *Sorghum* spp., *Secale cereale*) as well as species in the Araceae (e.g., taro, *Colocasia esculenta*), Polygonaceae (e.g., buckwheat, *Fagopyron esculentum*), Brassicaceae (e.g.,

Arabidopsis, *Brassica napus*), and the Fabaceae (e.g., rice bean, *Vigna umbellata*; bean, *Phaseolus vulgaris*; soybean, *Glycine max*). The organic anions released vary from species to species. Malate and citrate are most common but oxalate efflux

FIGURE 23.24 Acid soils contain high concentrations of soluble Al^{3+} that can inhibit root growth. Increased tolerance to Al in wheat relies on Al-activated efflux of malate anions from root apices. Malate protects the roots by chelating toxic Al^{3+} cations in the apoplast, reducing Al uptake and minimizing damage to Al-sensitive root apices. Note that the malate is unlikely to diffuse far into the soil as shown diagrammatically in the cartoon. Malate efflux is facilitated by *TaALMT1*, a malate-permeable anion channel which is more highly expressed in root apices of Al-tolerant genotypes than sensitive genotypes. Organic anion release from roots (especially malate and citrate) is a mechanism for Al exclusion in a wide range of species. Efflux of these anions is mediated by transport proteins from the ALMT and MATE families.

occurs from a few species (buckwheat, taro). All three anions form strong complexes with Al^{3+} that serves to lower the free concentration of Al^{3+} and reduce its uptake by roots.

The gene encoding the Al-activated efflux of malate in wheat is *TaALMT1* (*Triticum aestivum* aluminum-activated malate transporter). *TaALMT1* was discovered because it is more highly expressed in the root apices of Al-tolerant wheat plants than Al-sensitive plants. *TaALMT* is a member of a previously uncharacterized protein family with five to seven transmembrane domains in the N-terminal half of the protein and a long hydrophilic C-terminal region. *TaALMT1* localizes to the plasma membrane of root cells and its higher expression in Al-tolerant genotypes is driven by tandemly repeated sequences in the *TaALMT* promoter that enhance gene transcription. Heterologous expression of *TaALMT1* in several different plant species confers an Al-activated efflux of malate and greater Al tolerance. Electrophysiological studies in *Xenopus* oocytes and suspension-cultured cells of *N.*

A

B

FIGURE 23.25 Malate efflux from root apices is correlated with Al tolerance among different cultivars of wheat. (A) Malate release from excised root apices over 80 minutes was measured in 28 cultivars of wheat treated with $100 \mu\text{M AlCl}_3$ and 0.2 mM CaCl_2 (pH 4.2). Al tolerance was estimated from measurements of relative root growth (RRG) in 0.2 mM CaCl_2 with 0 and $10 \mu\text{M AlCl}_3$ and (pH 4.2) over 7 days. (B) External Al activates malate efflux and the response saturates at high Al^{3+} concentrations. Data are shown from the Al-tolerant and sensitive wheat cultivars ET3 and ES3, respectively.

tabaccum are consistent with *TaALMT1* encoding a ligand-gated ion channel which facilitates malate efflux. *TaALMT1* confers the major component of Al tolerance in wheat but additional mechanisms also contribute in some genotypes.

An understanding of the genetics and physiology of Al tolerance in sorghum (*S. bicolor*) and barley led to the discovery of a second family of Al tolerance genes. Tolerance in these species is controlled by a single major genetic locus that segregates with the Al-activated efflux of citrate. Fine mapping of these genetic loci identified the *SbMATE* gene in sorghum and the *HvAACT1* (*Hordeum vulgare* aluminum-activated citrate transporter1) gene in barley, both of which belong to the MATE (multidrug and toxic compound exudation) family. The MATE family of transporter proteins is a large and diverse group present in prokaryotic and eukaryotic cells. Many MATE proteins function as cotransporters (often as antiporters with protons or sodium) to transport secondary

metabolites and small organic compounds out of the cytosol. The *SbMATE* and *HvAACT1* proteins localize to the plasma membrane of root cells and function as Al-activated transporters facilitating citrate efflux from root apices. *SbMATE* expression in *S. bicolor* is enhanced by Al treatment whereas the expression of *HvAACT1* is constitutively higher in tolerant genotypes of barley than sensitive genotypes. However, in both cases, the Al tolerance among genotypes is strongly correlated with the level of gene expression.

Members of the *ALMT* and *MATE* families confer Al tolerance in many other species as well. For example, *AtALMT1*, one of the 14 members of the *ALMT* family in *Arabidopsis*, appears to function in a similar manner to *TaALMT1* in wheat even though their amino acid sequences are only 44% identical. *Arabidopsis* plants carrying a knockout mutation in *AtALMT1* (*Atalmt1*) show reduced Al-activated malate efflux and increased sensitivity to Al. Other *ALMTs* are likely to contribute to the Al tolerance of *B. napus* and *S. cereale* and *MATEs* are likely to contribute to the Al tolerance of maize and some wheat genotypes. The emerging picture from these studies is that *ALMT* genes control the release of malate anions whereas *MATE* genes control the release of citrate anions. Therefore the primary determinant for whether malate or citrate release occurs from roots is the type of transport protein expressed and not differences in metabolism.

Al activates the transport function of most *ALMT* and *MATE* proteins involved in Al tolerance. The details of this activation are not known but it is likely that Al interacts directly with the proteins themselves. This interaction may alter the tertiary structure of the proteins that then activates transport activity. The activation of organic anion efflux occurs rapidly in some species, while in others, it is delayed by several hours or even days after the addition of Al and then increases gradually through time. The rapid response (Type I) is interpreted as Al activating proteins already present in the membrane (Fig. 23.26). Examples include malate efflux from wheat and citrate efflux from barley that is consistent with the constitutive expression of the *TaALMT1* and *HvAACT1* genes in these species. The delayed response (Type II) reflects the requirement for Al to first induce gene and protein expression before function can begin (Fig. 23.26). Examples of this response include malate efflux from *Arabidopsis* and citrate efflux from maize, sorghum and rye. Regardless of whether Al induces expression of the *ALMT* and *MATE* proteins most still require external Al to activate transport function.

23.5.4 Al-tolerance genes identified by mutational analysis

Rice has a high basal level of Al tolerance compared to most cereals that cannot be explained by organic anion efflux. Some of the genes controlling Al tolerance in rice, as well as additional tolerance genes in *Arabidopsis*, were discovered by screening mutagenized seedlings for altered sensitivity to Al. These screens identified *STAR1* (sensitive to Al rhizotoxicity)

FIGURE 23.26 Model for Al-activated efflux of organic acid anions (OA) from roots. In Type I response, Al³⁺ rapidly triggers organic anion release from root cells by activating a pre-existing transport protein on the plasma membrane (solid orange line). To date, these transporters have been shown to be members of the ALMT (malate efflux) or MATE (citrate efflux) protein families. Al is likely to interact directly with the transport proteins to activate efflux. Organic anions then chelate the Al³⁺ cations in the apoplast preventing them from damaging root cells (broken black line). In the Type II response, efflux is delayed by several hours after Al is added. In this mechanism Al first induces the expression of the transport proteins and perhaps other proteins (broken orange line). Al then activates transport function in the newly synthesized proteins in a similar manner to that described for Type I responses (solid orange line).

in rice and *ALS1* and *ALS3* (Al sensitive) in *Arabidopsis* that encode full or partial ABC-like transport proteins. STAR1 interacts with another protein called STAR2 to form a functional ABC (ATP binding cassette) transport protein. The STAR1/2 complex appears to export secondary metabolites

from the cell (e.g., UDP-glucose or phenolic compounds) possibly via exocytosis of vesicles but exactly how this confers tolerance is uncertain. These exported compounds might bind with Al³⁺ in the apoplast or they could be substrates for subsequent enzyme reactions that modify cell walls to minimize Al³⁺ damage. Mutant screens also identified C2H2-type zinc-finger transcription factors encoded by *ART1* (*Al resistance transcription factor1*) in rice and *STOP1* (*sensitive to pH1*) in *Arabidopsis*. *ART1* and *STOP1* are required for the induction of these ABC-type genes and many other genes involved in tolerance and therefore appear to be important regulators of plant responses to Al and pH stress.

23.5.5 The engineering of Al tolerance in plants

Some plant crop species grow well on acid soils and others can be improved by conventional breeding strategies. For important crop species that possess insufficient natural variation to breed for tolerance, biotechnology provides opportunities of increasing food production on acid soils. Once the role of organic anion efflux in Al tolerance was understood, many researchers attempted to genetically engineer this trait into model plant species. Two main strategies were employed to increase organic anion efflux from roots. The first increased the expression of genes involved in the synthesis of malate or citrate (e.g., citrate synthase, malate dehydrogenase), while the second increased the capacity for organic anion transport out of the cells. Most success has been achieved by transforming plants with the *ALMT* and *MATE*-type tolerance genes discussed above. For example, over-expression of the wheat *TaALMT1* gene in barley results in a 25-fold increase in organic anion efflux compared to controls and a significant increase in root growth in nutrient solution and soils containing toxic levels of Al.

Summary

Plants use a wide range of mechanisms and responses to acquire essential mineral nutrients from the soil and to tolerate toxic soil environments. Some of these approaches are exceptionally complex. Diverse, nutrient-specific strategies allow terrestrial plants to increase the availability of essential minerals in the soil, transport them into the root, and translocate them throughout the plant. Plants must also regulate the acquisition of potentially toxic but essential elements such as Fe and Cu to prevent both nutrient deficiency and metal toxicity.

The field of plant mineral nutrition, rooted in physiological investigations, has recently moved into a new era of discovery in which molecular research approaches are being applied to questions of mineral nutrition. A current challenge faced by plant scientists is to integrate the information gained from molecular dissections of these intricate processes with previous and current research into the physiology of mineral nutrition at the levels of cell, organ, and whole plant. The ultimate goal of this work is to further the scientific understanding of how intact plants grow, whether in a farmer's field or in a native ecosystem.

Natural Products

*Toni M. Kutchan, Jonathan Gershenzon,
Birger Lindberg Møller, and David R. Gang*

Introduction

Plant secondary metabolites, also referred to as natural products or specialized metabolites, constitute an enormously rich reservoir of chemical biodiversity. More than 200,000 diverse chemical structures have been identified. In comparison with primary metabolites, which are essential to plant growth and development, secondary metabolites have internal roles in plants and also are integral to the communication of a plant with its environment. This interaction takes many forms. It can be an accumulation of pigments in flower petals, or a release of volatile chemicals by flowers to attract pollinators. It can be the release of volatiles by a leaf damaged by a grazing caterpillar to attract predatory wasps in a tritrophic interaction, or the production of bitter or toxic chemicals that serve as antifeedants. It can also be the release by roots of secondary metabolites into the rhizosphere to attract beneficial soil microorganisms.

Primary and secondary metabolites cannot be readily distinguished by their precursor molecules, chemical structures, or biosynthetic origins. For example, the diterpenes kaurenoic acid and abietic acid are formed by a similar sequence of related enzymatic reactions (Fig. 24.1); whereas the former is an essential intermediate in the synthesis of gibberellins (see Chapter 17), the latter is a resin component largely restricted to members of the Fabaceae and Pinaceae. Similarly, the essential amino acid proline is classified as a primary metabolite, whereas the C_6 analog pipercolic acid (Fig. 24.1) is considered an alkaloid and, thus, a secondary metabolite. Even lignin, the essential structural polymer of wood and second only to cellulose as the most abundant organic substance in plants, has been considered a natural product rather than a primary

metabolite. In the absence of a valid distinction between primary and secondary metabolites based upon structure or biochemistry, a functional definition is used herein: primary products participate in nutrition and essential metabolic processes in the plant, and secondary products influence communication between the plant and its environment.

Organic chemists have long been interested in secondary metabolites for their practical utility as dyes, polymers, fibers, glues, oils, waxes, flavors, fragrances, drugs, insecticides, and herbicides. Scientists have investigated their chemical properties extensively since the 1850s, and these investigations stimulated development of the chromatographic separation techniques, spectroscopic methodologies, and synthetic approaches that are the foundations of contemporary organic chemistry. Today it is recognized that natural products have important ecological roles in plants, and their study has transitioned into the realm of modern biology.

Plant natural products can be divided into several major groups based on their chemical structures, with the best studied being the terpenoids, cyanogenic glucosides and glucosinolates, alkaloids, and phenolics. In this chapter, we provide an overview of the biosynthesis of these major classes of plant natural products as well as their physiological functions, human uses, and potential biotechnological applications. Overarching issues that may apply to all these classes of compounds, such as the role of multienzyme complexes (metabolons) in their biosynthesis and their storage in specialized structures and subcellular compartments (e.g., resin ducts, subcuticular sacs, and vacuoles), are presented in the sections that deal with the classes of natural product in which these topics have been best studied.

FIGURE 24.1 Kaurenoic acid and proline are primary metabolites, whereas the closely related compounds abietic acid and pípecolic acid are considered secondary metabolites.

24.1 Terpenoids

24.1.1 Terpenoids are classified by the number of five-carbon units they contain

Terpenoids—with over 30,000 members described to date—take the honors for being the largest class of small molecule natural products in plants. They exhibit enormous structural diversity, but are united by a common biosynthetic origin. Derived from the joining of five-carbon isopentane units, terpenoids are also referred to as isoprenoids and as terpenes. The terms “terpene” and “terpenoid” originate from the word turpentine (“terpentin” in German) because some of the first terpenes described were isolated from turpentine.

The five-carbon units from which terpenoids are formed are sometimes called isoprene units, because some terpenoids decompose to give off the gas isoprene at elevated temperatures (Fig. 24.2). The classification of terpenoids has a long history (see Box 24.2, later in the chapter). The 10-carbon terpenoids were once thought to be the smallest naturally occurring representatives of this class. Hence, these were called **monoterpenes**, and the name persists. Designating the 10-carbon terpenoids as monoterpenes (one terpene) makes it necessary to name the five-carbon terpenoids as **hemiterpenes** (half terpenes), the 15-carbon terpenoids as **sesquiterpenes** (one and one-half terpenes), the 20-carbon terpenoids as **diterpenes** (two terpenes), the 30-carbon terpenoids as **triterpenes** (three terpenes), and so on.

24.1.2 Terpenoids fulfill many different functions in plants

Although terpenoids are found in all living organisms, they reach their greatest structural and functional diversity in plants. Many terpenoids have a well-characterized function in

FIGURE 24.2 The structure of the basic five-carbon (C_5) units of terpenoids. Isopentane (left) is a branched C_5 hydrocarbon, and isoprene (right) is a gas formed when certain terpenoids decompose.

basic plant growth and development and so can be classified as primary, rather than secondary metabolites.

These primary metabolites include several types of plant hormones: the gibberellins (diterpenes, C_{20} , see Chapter 17), brassinosteroids (triterpenes, C_{30} , see Chapter 17), abscisic acid (see Chapter 17), and the strigolactones (see Chapter 17). The natural cytokinins (see Chapter 17) have a C_5 terpenoid side chain. While abscisic acid is formally a sesquiterpene (C_{15}) and strigolactones have 19-carbon atoms in their basic skeleton, both are actually derived by cleavage of a group of tetraterpenes (C_{40}), the carotenoids.

Carotenoids are another major group of plant terpenoids with well-understood functions. These red, orange, and yellow substances participate in the energy-transfer processes of photosynthesis (see Chapter 12), protect photosynthetic tissues from oxidation under high light conditions, and attract animals to flowers and fruits for dispersal of pollen and seeds. Sterols are triterpene derivatives that are essential components of cell membranes, which they stabilize by interacting with the phospholipids (see Chapter 1).

Chains of terpenoid five-carbon units are usually very lipophilic. When attached to other molecules, they may anchor those molecules to proteins or lipid membranes. For example, phytol, a side chain of four five-carbon units (C_{20}) helps insert chlorophyll into the photosystem complexes that are, in turn, embedded in the thylakoid membrane. The antioxidant tocopherols and electron carriers, including ubiquinones, plastoquinones, and phyloquinones, are anchored into membranes by side chains of 4–10 five-carbon units. Some plant proteins are inserted into membranes or directed into protein–protein interactions by means of 15- or 20-carbon terpenoid side chains that are added post-translationally to a cysteine residue near the C-terminus. Finally, very long terpenoid molecules known as dolichols (15–23 five-carbon units) are involved in sugar transfer reactions that take place during cell wall and glycoprotein synthesis.

24.1.3 Most plant terpenoids have important ecological roles as well as utility for humans

Most of the thousands of terpenoids produced by plants have no discernible roles in growth and development and are, therefore, secondary metabolites. Many of these are volatile compounds or constituents of essential oils, resin, latex, and

FIGURE 24.3 Terpenoids can be used for plant defense. These compounds often form oily, sticky, or irritating mixtures that deter herbivore feeding and pathogen invasion. (A) The resin of conifers comprises mainly monoterpenes (C_{10}) and diterpenes (C_{20}). When the tree is damaged and resin ducts are severed, the smelly monoterpenes quickly evaporate from the extruded resin, leaving behind the sticky diterpenes, which become polymerized. (B) The monoterpene-rich oil of peppermint (*Mentha* sp.) is stored in glandular hairs on the surface of leaves and other organs. Shown in this cutaway view of a young leaf is a single glandular hair, about 0.5 mm in diameter, on the leaf surface. (C) Plant latex is a milky fluid that is made up of an emulsion of proteins, natural products, and other cellular constituents that often contains diterpenes, triterpenes, or higher order terpenes, including rubber. Stored in ducts known as laticifers, it is exuded after injuries, such as that caused by herbivory. Source: (A) Reiderer, University of Würzburg, Germany; (B, C) Wittstock & Gershenzon (2002). *Curr. Opin. Plant Biol.* 5:300–307.

waxes. Once thought of as metabolic waste products, these terpenoids actually serve a suite of ecological roles: they can defend against herbivores and pathogens, inhibit germination and growth of competing plants, or attract animals that disperse pollen and seeds.

Many terpenes form sticky, oily, smelly, or irritating mixtures (Fig. 24.3), so it is easy to appreciate their defensive properties. For example, the triterpene azadirachtin (Fig. 24.4) from the seed oil of the Asian neem tree (*Azadirachta indica*) is a powerful insect feeding deterrent and exerts a variety of toxic effects on insects as well. This complex, highly oxygenated terpenoid was isolated following centuries of use of neem foliage by Indian farmers to protect stored grain from pests. Because of its low toxicity to mammals, azadirachtin has considerable potential for controlling agricultural and household insect pests, and several preparations containing it are now on the market. Few terpenoids have been investigated as thoroughly as azadirachtin.

Mono- and sesquiterpenes are generally volatile compounds and are the principal constituents of herb and spice plants, such as basil, oregano, mint, bay, parsley, and dill (see Fig. 24.5). These compounds also serve as defenses against chewing herbivores. They are stored in glandular hairs or secretory cavities in leaves or fruit and are volatilized when the tissue is crushed. Terpenoids are volatilized from the foliage of nearly all plant species investigated, especially after insect feeding. For example, plants such as maize (*Zea mays*), cotton (*Gossypium hirsutum*), lima bean (*Phaseolus lunatus*), and *Arabidopsis* respond to herbivore damage by emitting a blend of monoterpenes and sesquiterpenes. These substances repel additional herbivores and attract herbivore enemies, such as parasitic wasps and predatory arthropods.

The emission of certain terpenes from plant leaves can also be independent of herbivory. The hemiterpene isoprene and several monoterpenes are emitted by many plant taxa, especially

woody species, in substantial amounts and have a major impact on the levels of ozone, carbon monoxide, and other gases in the atmosphere. In the plant, isoprene and monoterpenes appear to protect against thermal and oxidative stress, perhaps by stabilizing membranes or combining directly with reactive oxygen species, such as singlet oxygen, hydroxyl radicals, and nitrous oxides.

Terpenoids also play important roles in human society. They are used as flavors and fragrances of foods, beverages, soaps, perfumes, toothpaste, and other products. Some find use as industrial materials (resins and rubber) or pigments (carotenoids), and yet others are insecticides that are of value because of their low toxicity to humans and lack of persistence in the environment (azadirachtin and pyrethrins). Many terpenoids are also of nutritional or pharmaceutical significance, including vitamins A, D, E, and K as well as some well-known drugs (see Fig. 24.4): Taxol is a diterpene from yew (*Taxus brevifolia*) that has become a blockbuster drug for the treatment of ovarian and breast cancer, artemisinin is a sesquiterpene from *Artemisia annua* used against malaria, and the cardenolides (triterpenes, such as digitoxigenin) extracted from foxglove (*Digitalis lanata*) are prescribed to millions of patients for the treatment of heart disease. Carotenoids are also becoming more popular as “nutraceuticals” (foods with health benefits) believed to help prevent cancer, heart disease, and macular degeneration.

24.1.4 Terpenoids are formed by the fusion of five-carbon “isoprene units”

The five-carbon isopentane or isoprene units that make up terpenoids are usually joined in a “head-to-tail” fashion (Fig. 24.6). This pattern was first recognized in the

FIGURE 24.4 Structures of some economically important terpenes. Azadirachtin is a triterpene (C₃₀) derivative from the seed oil of the Asian neem tree (*Azadirachta indica*) used in insect pest control. Taxol, a diterpene (C₂₀) derivative, is from the yew tree (*Taxus brevifolia*) and used in cancer treatment. Digitoxigenin is an aglycone of digitoxin, a steroid glycoside used to treat heart disease. Artemisinin is a sesquiterpene from *Artemisia annua* used against malaria.

late 1800s and updated in the 1930s upon the realization that other types of reactions could occur in terpenoid formation because of the chemical mechanisms involved (Box 24.2). However, all terpenoids were proposed to be formed from a “biological” isoprene unit. These units can be joined in head-to-tail, head-to-head, and by various head-to-middle fusions, and substantial structural rearrangement can occur during biosynthesis. In such modified terpenoids, it may be difficult to discern the original organization of the isoprene units (Fig. 24.6). Nevertheless, dissection of terpenoid skeletons into isoprene units is often valuable for understanding their mode of biosynthesis.

The biosynthesis of terpenoids can be conveniently divided into four stages described in subsequent sections: (i) the synthesis of the biological five-carbon isoprene unit, (ii) repetitive condensations of the five-carbon unit to form a series of larger and larger prenyl diphosphates, (iii) conversion of prenyl diphosphates to the basic terpenoid skeletons, and (iv) further modifications to the basic skeletons, including oxidation, reduction, isomerization, conjugation, and other transformations.

24.2 Biosynthesis of the basic five-carbon unit

The basic five-carbon unit of terpenoid biosynthesis is represented by **isopentenyl diphosphate** and **dimethylallyl diphosphate**. These intermediates are synthesized in plants by two completely different routes that are spatially separated but exchange intermediates: the mevalonate pathway (see Section 24.2.1) and the methylerythritol 4-phosphate (MEP) pathway (see Section 24.2.2).

24.2.1 The mevalonate pathway converts acetyl-CoA to isopentenyl diphosphate and dimethylallyl diphosphate

The first route proceeds via the reactions of the mevalonate pathway (Fig. 24.7). Demonstrated initially in yeast and mammals, this well-characterized sequence begins with the condensation of three molecules of acetyl-CoA in two steps to

FIGURE 24.5 Volatile terpenes are often stored in specialized structures in herb and spice plants, or are released directly as volatiles from many species of plants. Isoprene is a hemiterpene (C₅); α-pinene (conifer resin), (E)-β-ocimene, and menthol (peppermint oil) are monoterpenes (C₁₀); (E)-β-caryophyllene (an essential oil of many plants, including clove, rosemary, and hops) and zingiberene (ginger oil) are sesquiterpenes (C₁₅). The high vapor pressure of these compounds arises from their low molecular weights and lack of polar oxygen functions.

FIGURE 24.6 Terpenoids are formed from the fusion of five-carbon isopentane units (isoprene units), which are usually joined in a head-to-tail fashion. The division of terpenoids into such units helps to visualize their biosynthetic assembly, although extensive metabolic rearrangements may complicate this task. Myrcene and menthone are monoterpenes (C₁₀—two C₅ units); (E)-β-farnesene and amorpha-4,11-diene are sesquiterpenes (C₁₅—three C₅ units); and pimaric acid is a diterpene (C₂₀—four C₅ units).

form the six-carbon compound, 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA). This intermediate is reduced by **HMG-CoA reductase** in two coupled, NADPH-requiring reactions to form mevalonic acid. Next come two sequential ATP-dependent phosphorylations that produce mevalonic acid-5-diphosphate. Finally, a decarboxylation-elimination

reaction involving a third phosphorylation yields isopentenyl diphosphate, which can be isomerized to dimethylallyl diphosphate by isopentenyl diphosphate isomerase, an enzyme which also catalyzes the reverse reaction.

The third enzyme of the mevalonate pathway, HMG-CoA reductase, has been studied intensively because it catalyzes a

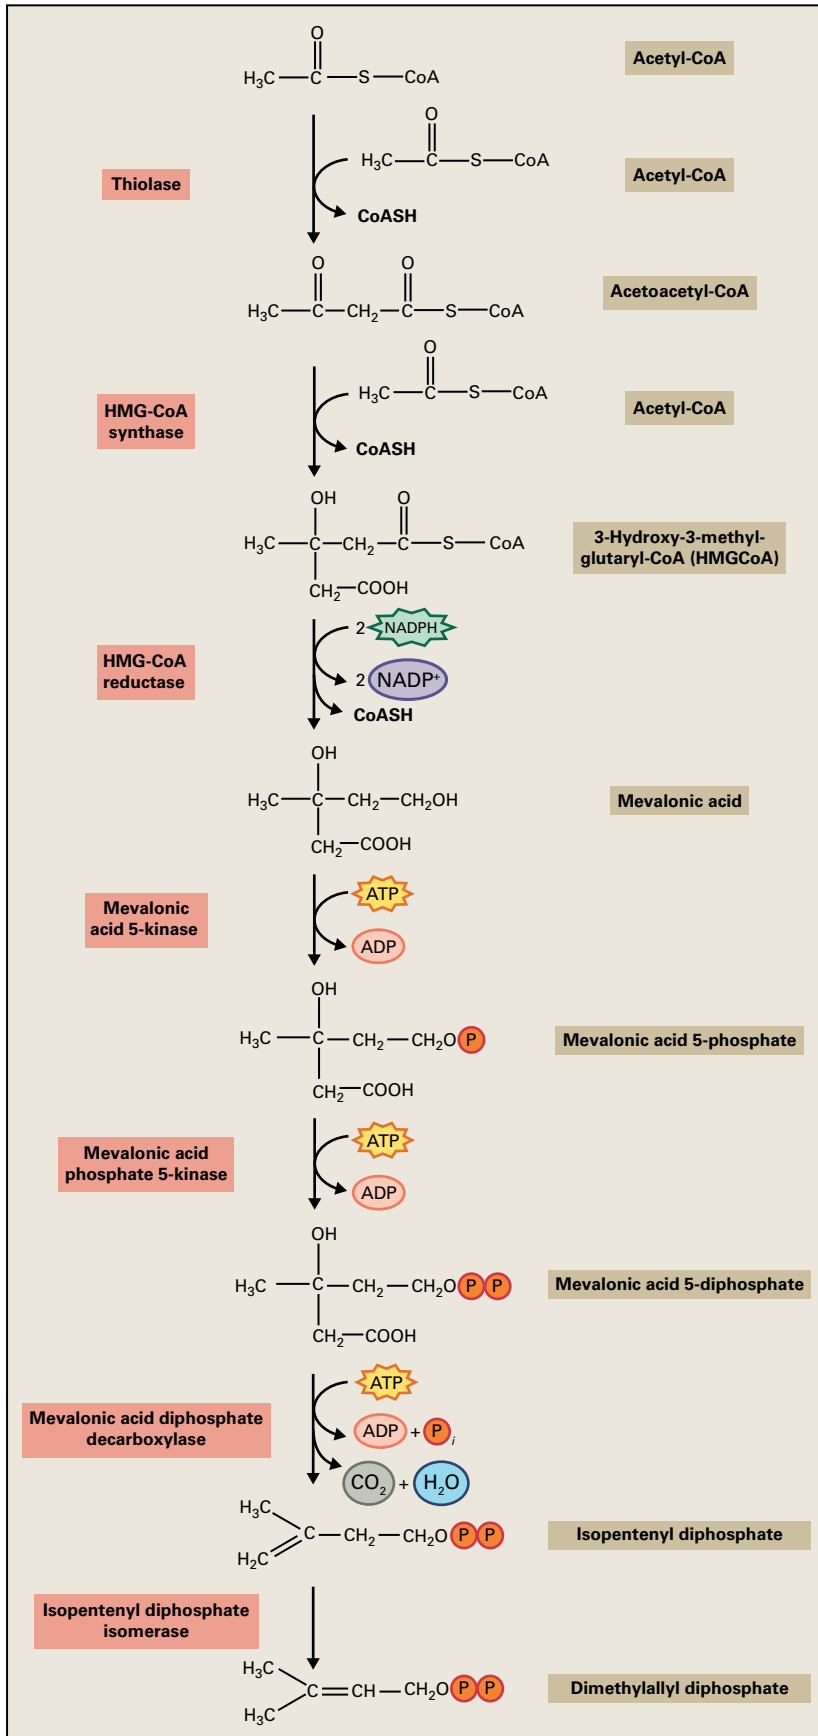

FIGURE 24.7 The mevalonate pathway for the formation of isopentenyl diphosphate, the basic five-carbon unit of terpenoid biosynthesis. Synthesis of each isopentenyl diphosphate unit requires three molecules of acetyl-CoA. The mevalonate pathway occurs in the cytosol of plant cells.

rate-determining step in the biosynthesis of sterols, such as cholesterol, in animals. HMG-CoA reductase in plants has been assumed to be an important regulatory step in terpenoid biosynthesis as well. In fact, many studies have reported a close correlation between changes in HMG-CoA reductase activity and alterations in the rate of terpenoid biosynthesis. The mechanism of this control may lie in part at the level of transcription, since all plants examined possess multiple HMG-CoA reductase genes exhibiting tissue-, development-, or stress-specific expression patterns. The activity of HMG-CoA reductase is also subject to posttranslational regulation by a protein kinase cascade that phosphorylates, and thereby inactivates, the enzyme.

24.2.2 The methylerythritol 4-phosphate pathway converts pyruvate and glyceraldehyde 3-phosphate to isopentenyl diphosphate and dimethylallyl diphosphate

One of the most exciting advances in plant biochemistry in recent years was the discovery of a second route for producing the basic five-carbon building blocks of terpenoid biosynthesis, a route completely distinct from the mevalonate pathway (Fig. 24.8). This route begins with pyruvate and glyceraldehyde 3-phosphate and is usually named for its second intermediate, 2C-methyl-D-erythritol 4-phosphate (MEP).

The existence of a second, nonmevalonate pathway to isopentenyl diphosphate in plants had been suspected for many years based on the poor incorporation of mevalonate into certain types of terpenoids. In the early 1990s, researchers found that the incorporation of ^{13}C -labeled precursors into terpenoids in plants gave a different pattern of labeling than would have been expected from the mevalonate pathway. They went on to identify the intermediates, enzymes, and genes of the pathway, an effort greatly facilitated by the presence of this pathway also in *Escherichia coli* with all its genetic and genomic resources.

The initial step of the MEP pathway is the condensation of pyruvate and glyceraldehyde 3-phosphate to form a 1-deoxy-D-xylulose 5-phosphate intermediate. This condensation is catalyzed by a thiamine pyrophosphate-utilizing enzyme that mediates C_2 transitions like the transketolases of the Calvin-Benson cycle and the oxidative pentose phosphate pathway (see Chapter 12). This intermediate is rearranged and reduced to form 2C-methyl-D-erythritol 4-phosphate. Next, a nucleotide-5'-triphosphate, cytidine triphosphate, is transferred followed by an additional phosphate group from ATP to give 4-diphosphocytidyl-2C-methyl-D-erythritol 2-phosphate. Linking of the additional phosphate group to a phosphate moiety of the nucleotide leads to formation of a cyclic diphosphate and loss of cytidyl monophosphate. The last two steps are catalyzed by iron-sulfur reductases that first convert the cyclodiphosphate to (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate via a reduction and elimination. This final intermediate is then reduced further to give isopentenyl diphosphate and its allylic isomer, dimethylallyl diphosphate, in a 5:1 ratio. Both isopentenyl diphosphate and dimethylallyl diphosphate are needed for later steps in terpenoid biosynthesis.

24.2.3 The MEP and mevalonate pathways play different roles in plant terpenoid biosynthesis

The MEP pathway is present in vascular plants, algae, cyanobacteria, eubacteria, and Apicomplexan protists; it is absent, however, in archaea, fungi, and animals, all of which use the mevalonate pathway for making terpenoids. Only plants possess both the MEP and mevalonate pathways, and the two pathways reside in separate compartments: the mevalonate pathway is localized in the cytosol, and the MEP pathway is present in plastids. Since the MEP pathway is common to cyanobacteria, this spatial separation is consistent with the presumed origin of plastids from free-living cyanobacteria that retained their terpenoid biosynthetic machinery after becoming endosymbionts.

The two pathways for producing the C_5 units of terpenoid biosynthesis do not contribute equally to the formation of all terpenoids. The plastid-localized MEP pathway supplies most or all of the substrate for formation of terpenoids whose later biosynthetic steps also take place in plastids, including C_5 (isoprene), C_{10} (monoterpenes), C_{20} (diterpenes, side chain of chlorophyll), and C_{40} (carotenoids) compounds. The mevalonate pathway supplies most of the C_5 units for the biosynthesis of C_{15} (sesquiterpenes), C_{30} (triterpenes and sterols), and larger compounds (dolichols), substances whose later steps are largely cytosolic. However, the exchange of intermediates between the pathways is well documented. The simultaneous existence of two, spatially separated pathways for making the five-carbon units of terpenoid biosynthesis may help explain how plants can produce such a wide range of terpenoid metabolites in a regulated manner.

24.3 Repetitive additions of C_5 units

24.3.1 Isopentenyl diphosphate and dimethylallyl diphosphate condense to form larger intermediates

The second stage of terpenoid biosynthesis involves fusion of the basic C_5 building blocks, isopentenyl diphosphate and dimethylallyl diphosphate, into larger prenyl diphosphates and other metabolic intermediates (Fig. 24.9). As the smallest prenyl diphosphate with an allylic double bond, dimethylallyl diphosphate is a primer to which varying numbers of isopentenyl diphosphate units can be added in sequential chain elongation steps. Thus, isopentenyl diphosphate and dimethylallyl diphosphate condense in head-to-tail fashion to form the allylic C_{10} compound, **geranyl diphosphate**. Another molecule of isopentenyl diphosphate may then condense head-to-tail with geranyl diphosphate to generate the C_{15} allylic diphosphate, **farnesyl diphosphate**. Addition of a further isopentenyl diphosphate gives the C_{20} **geranylgeranyl diphosphate**.

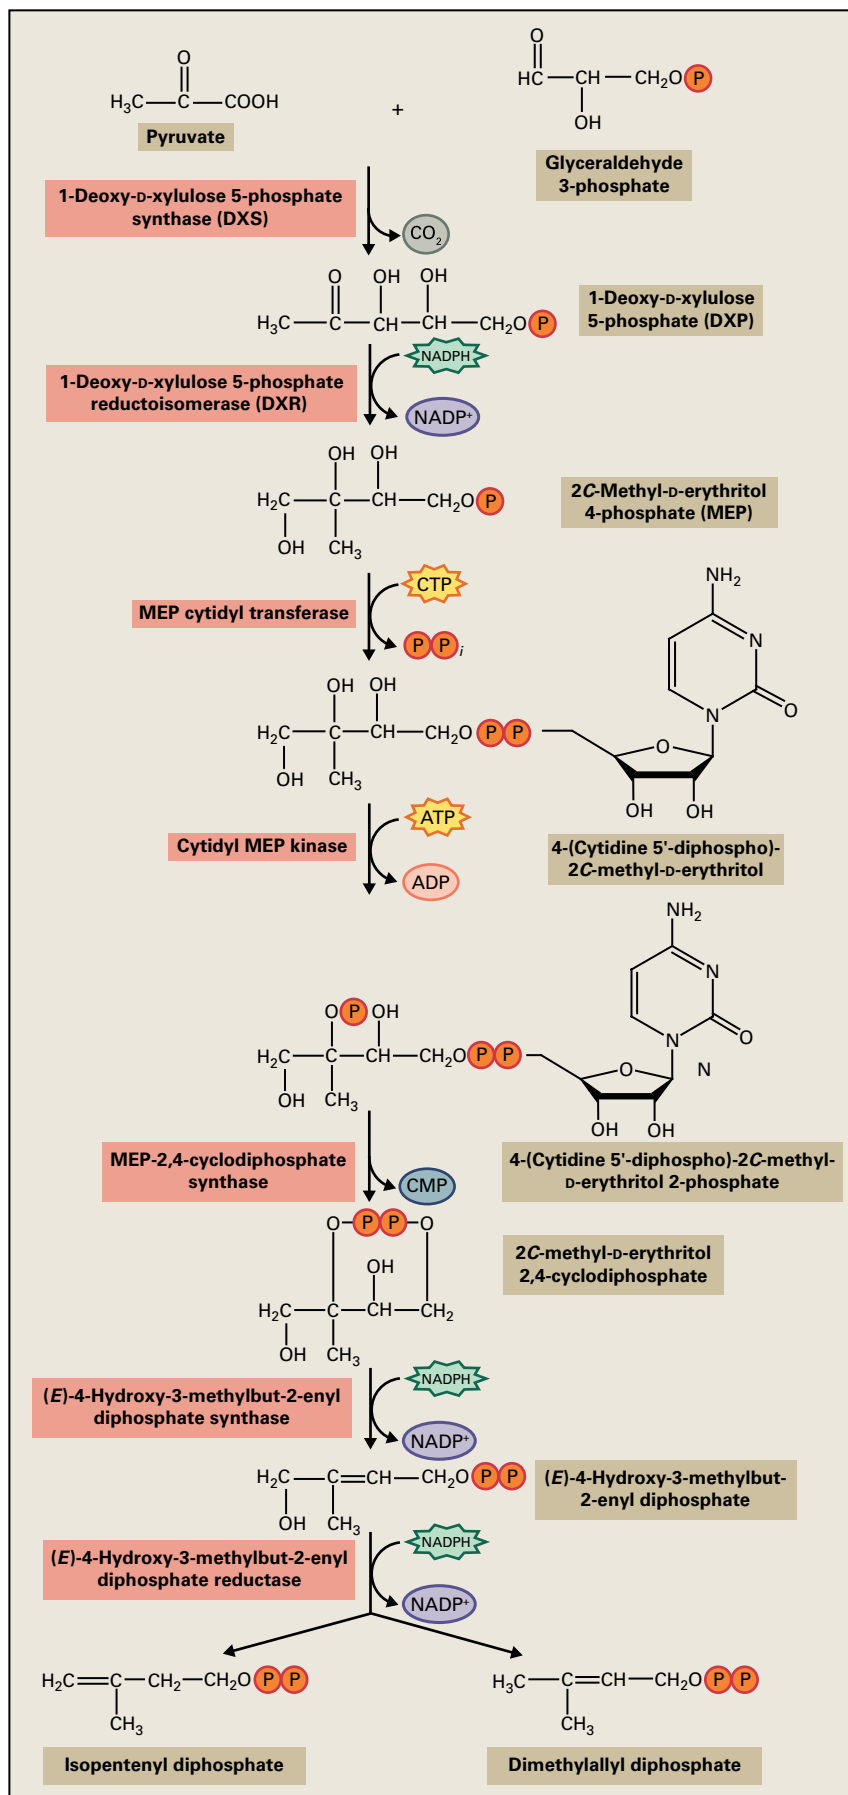

FIGURE 24.8 The MEP pathway, a second route for the formation of isopentenyl diphosphate in plants, occurs in plastids.

FIGURE 24.9 The major subclasses of terpenoids are biosynthesized from the basic C₅ building blocks, isopentenyl diphosphate and its isomer, dimethylallyl diphosphate, which is formed from isopentenyl diphosphate via isopentenyl diphosphate isomerase. Reactions catalyzed by prenyltransferases condense varying numbers of isopentenyl diphosphate and dimethylallyl diphosphate units to geranyl diphosphate, the precursor of monoterpenes (C₁₀), farnesyl diphosphate, the precursor of sesquiterpenes (C₁₅), and geranylgeranyl diphosphate, the precursor of diterpenes (C₂₀). To make triterpenes (C₃₀), two farnesyl (C₁₅) units are combined, while to make tetraterpenes (C₄₀), two geranylgeranyl (C₂₀) units are joined.

The formation of the major C₃₀ and C₄₀ terpenoids in plants, however, does not occur by stepwise C₅ addition. Instead, the C₃₀ terpenoids (triterpenes) arise by head-to-head addition of two molecules of the C₁₅ intermediate farnesyl diphosphate to produce squalene. In an analogous manner, C₄₀ terpenoids (tetraterpenes) arise by head-to-head addition of two molecules of the C₂₀ intermediate geranylgeranyl diphosphate producing phytoene (Fig. 24.9).

24.3.2 Condensation of prenyl diphosphates is catalyzed by prenyltransferases

The chain elongation reactions of terpenoid biosynthesis are mediated by enzymes known as **prenyltransferases**. Geranyl diphosphate, farnesyl diphosphate, and geranylgeranyl diphosphate are each formed by specific prenyltransferases

FIGURE 24.10 The prenyltransferase reaction.

that catalyze one, two, or three consecutive C_5 additions, respectively, starting from the allylic dimethylallyl diphosphate and the homoallylic isopentenyl diphosphate. The prenyltransferase reaction is driven by the ionization of the diphosphate moiety of the allylic substrate to form a resonance-stabilized allylic carbocation (Fig. 24.10). After addition of isopentenyl diphosphate, a proton is eliminated to form a new allylic prenyl diphosphate with five additional carbon atoms. Depending on the proton removed, the double bond can have an (*E*)- or (*Z*)-configuration. Most short-chain prenyl diphosphates that are intermediates in plant terpenoid biosynthesis have all (*E*)-double bonds.

Not all prenyltransferases make isoprenyl diphosphates. Some produce very long terpenoid polymers, such as rubber, which is formed from the head-to-tail condensation of thousands of isopentenyl diphosphate units in which the double bonds have mostly (*Z*)-configurations. Other prenyltransferases condense isoprenyl diphosphates with nonterpenoid acceptors, including chlorophyll, proteins, quinones, or other aromatic compounds to give rise to complex substances with terpenoid side chains.

24.4 Formation of parent carbon skeletons

24.4.1 Terpene synthases catalyze the conversion of prenyl diphosphates to parent terpene carbon skeletons

The prenyl diphosphates geranyl diphosphate (C_{10}), farnesyl diphosphate (C_{15}), and geranylgeranyl diphosphate (C_{20}) are the central intermediates of terpenoid biosynthesis. Under catalysis of a large family of enzymes called **terpene synthases**, they are converted to monoterpenes, sesquiterpenes, and diterpenes, respectively (see Fig. 24.9). The enzyme products of terpene synthases are usually cyclic, often have multiple ring systems, and comprise the primary representatives of each of the many diverse terpene skeletal types.

Terpene synthases employ a **carbocationic reaction mechanism** similar to that of the prenyltransferases (Fig. 24.11). The reaction is initiated by ionization of the diphosphate group, which requires a divalent metal ion, such as Mg^{2+} . The resulting enzyme-bound, allylic carbocation may then cyclize by addition of the resonance-stabilized cationic center to one of the other carbon-carbon double bonds in the substrate. Cyclization can be followed by a series of rearrangements, including hydride and alkyl shifts, and additional cyclizations, mediated through enzyme-bound carbocationic and neutral intermediates. The multiple fates of these reactive carbocations are responsible for the great diversity of terpene synthase products. The reaction cascade eventually terminates by deprotonation of the cation to form a new double bond or by capture by a nucleophile, such as water.

The typical substrates of most known monoterpene and sesquiterpene synthases, geranyl diphosphate and farnesyl diphosphate, respectively, cannot cyclize directly because of the (*E*)-geometry of their double bonds. In enzymes such as in limonene synthase (Fig. 24.11), cyclization is preceded by isomerization of the initial carbocation to an intermediate capable of cyclization. Other terpene synthases do not carry out cyclizations, and reaction involves just diphosphate ionization and termination, resulting in an alkene or alcohol with the same acyclic carbon skeleton as the parent prenyl diphosphate.

24.4.2 Terpene synthase and prenyltransferase proteins have similar mechanisms and structures

Both terpene synthases and prenyltransferases employ similar electrophilic reactions involving carbocation intermediates to form new carbon-carbon bonds. In the terpene synthase reaction, the initial cationic center and the double bond attacked reside on the same molecule leading to cyclization, whereas in prenyltransferases they are on different molecules leading to elongation. The formation of carbon-carbon bonds by such electrophilic addition is unusual in plant

FIGURE 24.11 A monoterpene synthase reaction. Depicted is the cyclization of geranyl diphosphate to limonene, which forms α - and β -pinene as additional products. (1) Ionization of the substrate is promoted by a divalent metal cation, yielding a charge-delocalized cation that is converted (2) to the tertiary linalyl cation. (3) Rotation around a single bond provides an intermediate capable of cyclization. In a charge-delocalized form (4), the α -terpinyl cation undergoes cyclization (5) and then deprotonation to form limonene (6). The α -terpinyl cation can undergo a second cyclization (7), involving folding of the isopropyl tail over the ring to generate the pinyl cation. This cation, in turn, can be deprotonated in two different ways (8,9) to form either α - or β -pinene.

metabolism. The carbon–carbon bonds of most other substances, such as amino acids, carbohydrates, fatty acids, and nucleic acids, are usually constructed by nucleophilic condensation reactions involving carbonyl groups.

Crystallographic studies reveal that the structures of terpene synthases and prenyltransferases share marked similarities, even though their amino acid sequences do not have significant similarity. Both types of protein contain “terpene folds,” domains made up of α -helices in which the diphosphate moieties of substrates bind to aspartate-rich regions via divalent metal ions (Fig. 24.12). The substrate is bound in an orientation that directs the reaction once the diphosphate has ionized. Small changes in the shape of the active site can change the conformation of the substrate and alter the products formed. After substrate

binding, the active site is closed to the outside environment to protect the carbocationic intermediates from being quenched by water.

24.4.3 Terpene synthases are major contributors to the enormous diversity of terpene products in plants

An interesting feature of terpene synthases is the ability of a single enzyme to catalyze the formation of more than one product from a single substrate. For example, some enzymes that produce limonene also produce the bicyclic monoterpenes, α - and β -pinene (see Fig. 24.11). About half of all known terpene

FIGURE 24.12 Structure of *SbTPS1* from sorghum (*Sorghum bicolor*), a terpene synthase that makes multiple sesquiterpenes. (A) Two domains of α -helices form the overall structure of *SbTPS1*. The active site cavity is located in the central part of the C-terminal domain. (B) A cross-section of the active site is depicted that contains the substrate analog, 1-hydroxyfarnesyl phosphonate, instead of the native substrate, farnesyl diphosphate. Two aspartate residues of the protein (in red as D294 and D297) are involved in binding the three Mg^{2+} ions, which in turn bind the substrate by coordinating with the diphosphate group.

synthases form significant amounts (>10%) of more than one product, and some of these enzymes produce as many as 50 different products. Such amazing catalytic versatility can be attributed to the multiple chemical fates of the highly reactive carbocationic intermediates produced by the enzyme. The great diversity of terpene structures in plants is also a result of the large families of terpene synthase genes (40–150 members) found in all plant genomes investigated.

Among the different classes of terpenes, diversity is generated by terpene synthases in slightly different ways. Sesquiterpene synthases produce a greater variety of carbon skeletons from farnesyl diphosphate than monoterpene synthases do from geranyl diphosphate because of the additional five-carbon unit and extra double bond in the substrate. Formation of larger rings from farnesyl diphosphate can proceed without any preliminary isomerization steps.

Diterpene synthases carry out two different kinds of cyclization of their substrate geranylgeranyl diphosphate (Fig. 24.13). The first resembles the reactions catalyzed by monoterpene and sesquiterpene synthases, in which the diphosphate group is ionized and the resulting carbocation attacks one of the double bonds. In the second, however, the carbocation is generated by protonation of the terminal double bond, as exemplified by the conversion of geranylgeranyl diphosphate to copalyl diphosphate, an intermediate to many types of diterpene skeletons. The product copalyl diphosphate retains its diphosphate group and so can serve as a substrate for other diterpene synthases that employ the first kind of cyclization method. Some diterpene synthases carry out both kinds of cyclization in sequential fashion.

Triterpene synthases do not employ prenyl diphosphate substrates. After two molecules of farnesyl diphosphate (C_{15}) combine head-to-tail to produce the C_{30} intermediate squalene (see Fig. 24.9), epoxidation yields oxidosqualene. Plant triterpene cyclases use oxidosqualene as a substrate, employing

a protonation-initiated cyclization to form a variety of carbon skeletons containing three to five rings (Fig. 24.14). Cycloartenol is the precursor of the sterols.

24.5 Modification of terpenoid skeletons

The parent carbon skeletons produced by terpene synthases are often modified to generate more variability in plant terpenoids. These modifications most commonly involve oxidation, reduction, isomerization, acylation, and glycosylation reactions, and their effects can be seen in such complex terpenoid end products as taxol and azadirachtin (see Fig. 24.4). Compared to other aspects of terpenoid biosynthesis, however, skeletal modifications of terpenoids are poorly studied.

Among the better known modification pathways are those leading to menthol (see Figs 24.3 and 24.5), the major component of peppermint oil, and artemisinin, an important antimalarial drug isolated from *Artemisia annua* (see Fig. 24.4 and Section 24.2.3). The pathway to the sesquiterpene artemisinin begins with the action of a prenyltransferase that forms farnesyl diphosphate from three C_5 units, followed by the action of a terpene synthase that cyclizes farnesyl diphosphate to amorpha-4,11-diene (Fig. 24.15). Skeletal modification follows, which as for other terpenes involves various oxidation and reduction reactions. Amorphadiene is first subjected to the two-step oxidation of a methyl group to an aldehyde, catalyzed by a cytochrome P450 (Box 24.1). Then, a terminal carbon-carbon double bond is reduced by an enoate reductase, and the aldehyde function is oxidized to a carboxylic acid. The resulting dihydroartemisinic acid is converted to the final product by a nonenzymatic photo-oxidation that

FIGURE 24.13 Diterpene synthases use two different types of reactions. (A) In the first type, ionization of the diphosphate group leads to a carbocation that cyclizes like the carbocations formed by monoterpene and sesquiterpene synthases. (B) In the second type, protonation of the terminal double bond leads to cyclization with retention of the diphosphate group. The product of the second type can be cyclized by an ionization-initiated diterpene cyclization of the first type. (C) Some diterpene synthases carry out both types of cyclization in sequence.

FIGURE 24.14 Triterpene synthases employ a cyclization mechanism that begins with a proton triggering the opening of the epoxide ring. Cycloartenol is the precursor to all plant sterols, and β -amyrin is a widespread pentacyclic triterpene.

FIGURE 24.15 Biosynthetic pathway to the antimalarial drug artemisinin in the wormwood plant (*Artemisia annua*). After formation of farnesyl diphosphate by a prenyltransferase, this acyclic C₁₅ intermediate is converted to amorpha-4,11-diene by a terpene synthase. Next, skeletal modification is carried out by cytochrome P450s and a double bond reductase to yield dihydroartemisinic acid. The final step may involve nonenzymatic photo-oxidation.

is not completely characterized. Extensive research on artemisinin has revealed much more than just the sequence of the pathway. For example, this sesquiterpene accumulates within the plant in glandular trichomes on leaves and floral parts, and its formation is regulated by a WRKY transcription factor that activates transcription of certain biosynthetic genes.

24.6 Metabolic engineering of terpenoid production

Many of the terpenoids that are in high demand as flavors, fragrances, pigments, or drugs are produced in low amounts by plants. It is also often difficult to chemically synthesize these compounds in an economic manner or to induce high levels of accumulation in plant cell or organ cultures. Therefore, enthusiasm has grown for creating transgenic plant lines capable of producing increased levels of valuable terpenoids.

Recent successes in cloning genes that encode enzymes of terpenoid biosynthesis have provided the necessary tools for this effort. A typical strategy is to overexpress one or more genes that either lead to a new terpenoid (not usually present in the plant) or that speed up the rate of biosynthesis for an endogenous terpenoid. Expression of these genes must be targeted to tissues and cells that have a sufficient supply of precursors (such as isopentenyl diphosphate), an adequate capacity for accumulating high levels of the target compound (such as cells of glandular trichomes or

resin ducts), and a lack of enzymes that could cause further metabolism.

Perhaps the best-known example of terpenoid engineering in plants is the creation of “golden rice,” a variety of rice (*Oryza sativa*) with increased β-carotene in its kernels (Fig. 24.16A). A vitamin A precursor, β-carotene is scarce in the staple crops of many developing countries, causing a variety of ailments, especially in children. Overexpression of enzymes from four terpenoid biosynthetic steps diverted enough geranylgeranyl diphosphate to β-carotene via phytoene to cause a 20-fold increase in carotenoids in normally white rice, turning it golden in color.

In another example, plant terpenoid genes were used to engineer microbes to produce artemisinic acid, a precursor to the antimalarial sesquiterpene artemisinin (see Fig. 24.16B). This was achieved using *E. coli* that were modified for high levels of terpenoid biosynthesis through insertion of the entire mevalonate pathway (not normally present), rather than by trying to speed up the endogenous MEP pathway, which was subject to regulatory controls.

Other approaches to enhance terpenoid production include identification and transformation with regulatory genes, such as those expressing transcription factors. Attempts have also been made to increase the number of terpenoid storage structures (i.e., glandular trichomes, resin ducts, and secretory cavities). In addition, some researchers have tried to engineer specific enzymes for increased or altered product specificity. For example, certain terpene synthases that make multiple products have been modified to make a single product with only a few sequence changes.

BOX
24.1

Cytochrome P450 enzymes play a role in natural product biosynthesis

The plant cytochrome P450 (CYP) family of monooxygenases is a large gene family, and enzymes of this class are often called P450s or CYPs for short. Each is given a CYP designation, for example, CYP73A5 (*Arabidopsis* cinnamate 4-hydroxylase), that is based on sequence homology to other P450s and effectively categorizes individual enzymes into CYP subfamilies according to phylogenetic relationships. Genes with the same subfamily designation often catalyze the same or similar reactions. The moss *Physcomitrella patens* has 73 CYP subfamilies, but angiosperms typically have 55–60, 51 of which are universal to all plants (some subfamilies are clade specific and have affinities to other common subfamilies). *Arabidopsis* has 246 P450 genes.

P450 monooxygenases have diverse functions and catalyze reactions that typically involve redox state changes (oxidations, hydroxylations, epoxidations, dehydrations, etc.), carbon–carbon bond formation, or rearrangements (e.g., methylene dioxybridge formation, demethylations, isomerizations). The active site of a P450 contains a heme functional group that is held in a conformation such that its absorption spectrum contains

a strong peak at ≈ 450 nm when it is reduced and CO (carbon monoxide) is bound, hence the name cytochrome P450. Obtaining a CO-difference spectrum is a diagnostic test for these enzymes, which are strongly inhibited by CO and ketoconazole.

Most P450s require molecular oxygen for activity, although some, such as allene oxide synthase, can utilize endogenous peroxides that are part of the substrate. Most are also membrane-bound and use NADPH as a cofactor. Some P450s, especially animal enzymes, have broad substrate preferences, and serve to act as general oxygenases, involved in elimination of xenobiotics from the body. Most plant P450s have limited or strict substrate selectivities (e.g., the signature CYP79 enzyme in cyanogenic glucoside biosynthesis (Section 24.8.1) or the P450 enzymes in the biosynthesis of the alkaloid berberine (Section 24.12.3) and are regio- and even enantiospecific. Cytochrome P450 enzymes that act on terpenoids can carry out multistep oxidations, such as the sequential conversion of a saturated carbon to an alcohol, aldehyde, and a carboxylic acid as shown in the biosynthesis of the diterpenes in conifer resins.

24.7 Cyanogenic glycosides

Cyanogenic glycosides (Fig. 24.17) are β -glycosides of α -hydroxynitriles (**cyanohydrins**). They are characterized by their ability to liberate hydrogen cyanide (HCN) when hydrolyzed by β -glycosidases; this process (cyanogenesis) typically occurs when plant tissue containing cyanogenic glycosides is disrupted, for example, when bitten, chewed, or ingested by animals or insects. Cyanogenic glycosides are important components of plant defense against generalist herbivores due to their bitter taste and release of toxic HCN upon tissue disruption (see Section 24.9.1).

Cyanogenic glycosides are derived from five protein amino acids (Val, Ile, Leu, Phe, and Tyr) and the nonproteinogenic amino acid cyclopentenyl glycine (Fig. 24.18). These core

structures of cyanogenic glycosides may be further modified by single or multiple hydroxylations. The number of cyanogenic glycosides found in nature is further expanded by the structural diversity of the sugar moiety. Cyanogenic glycosides are widely distributed among more than 2,600 different species of pteridophytes, gymnosperms, and angiosperms. Whereas pteridophytes and gymnosperms contain cyanogenic glycosides derived from aromatic amino acids, angiosperms may contain cyanogenic glycosides derived from either aliphatic or aromatic amino acids (Figs. 24.18 and 24.19). Many crops, including **sorghum** (*Sorghum bicolor*), **cassava** (*Manihot esculentum*), and **barley** (*Hordeum vulgare*), are cyanogenic; understanding the roles of cyanogenic glycosides, their biosynthetic pathways, and underlying regulatory mechanisms in these species is crucial for the development of nontoxic varieties and food products.

BOX 24.2

Early investigators formulated rules for identifying and classifying terpenoid structures

In the late 1800s, chemists struggled to determine the structures of monoterpenes, and these difficulties are illustrated in the numerous structures proposed for camphor (see structures at left of figure, which include the names of the proposers and the dates proposed). Chromatographic purification techniques and spectroscopic methods for structure elucidation were not available to these chemists, who relied on the preparation of crystalline derivatives to assess purity and on chemical degradation studies to determine structures. Systematic study of the monoterpenes led early investigators to recognize that many terpenoid compounds might be constructed by joining isoprene units, in a repetitive head-to-tail fashion (see pathway illustrated and Fig. 24.6) and correctly proposed the structure for camphor. This concept is known as the **isoprene rule**.

By the 1930s, faced with a bewildering array of terpenoid substances, investigators sought to develop a unifying principle that could rationalize the natural occurrence of all of the known terpenoids, even those that did not strictly fit the isoprene rule. The ingenious solution was to focus on reaction mechanisms and ignore the precise character of the biological precursor, assuming only that it had a terpenoid structure during reaction. It was hypothesized that electrophilic reactions generated carbocationic intermediates, which underwent subsequent C_5 addition, cyclization, and in some cases skeletal rearrangement before elimination of a proton or capture by a nucleophile to yield the observed terpenoid products. This proposal, called the **biogenetic isoprene rule**, can be stated simply: a compound is “isoprenoid” if it is derived biologically from an “isoprenoid” precursor, with or without rearrangements.

This concept emphasizes the biochemical origin rather than structure. The great strength of the biogenetic isoprene rule lay in its use of biosynthetic mechanism to classify the bulk of known terpenoids, including structures that did not strictly follow the original isoprene rule. Application of the biogenetic isoprene rule is illustrated by

the way several of the common monoterpene skeletons can be derived from a precursor with simple head-to-tail coupling of two isoprene units (right of figure). It was found that these reactions could occur via carbocations. Note the bornane skeleton from which camphor is derived. Also note that the Bredt 1893 structure is correct.

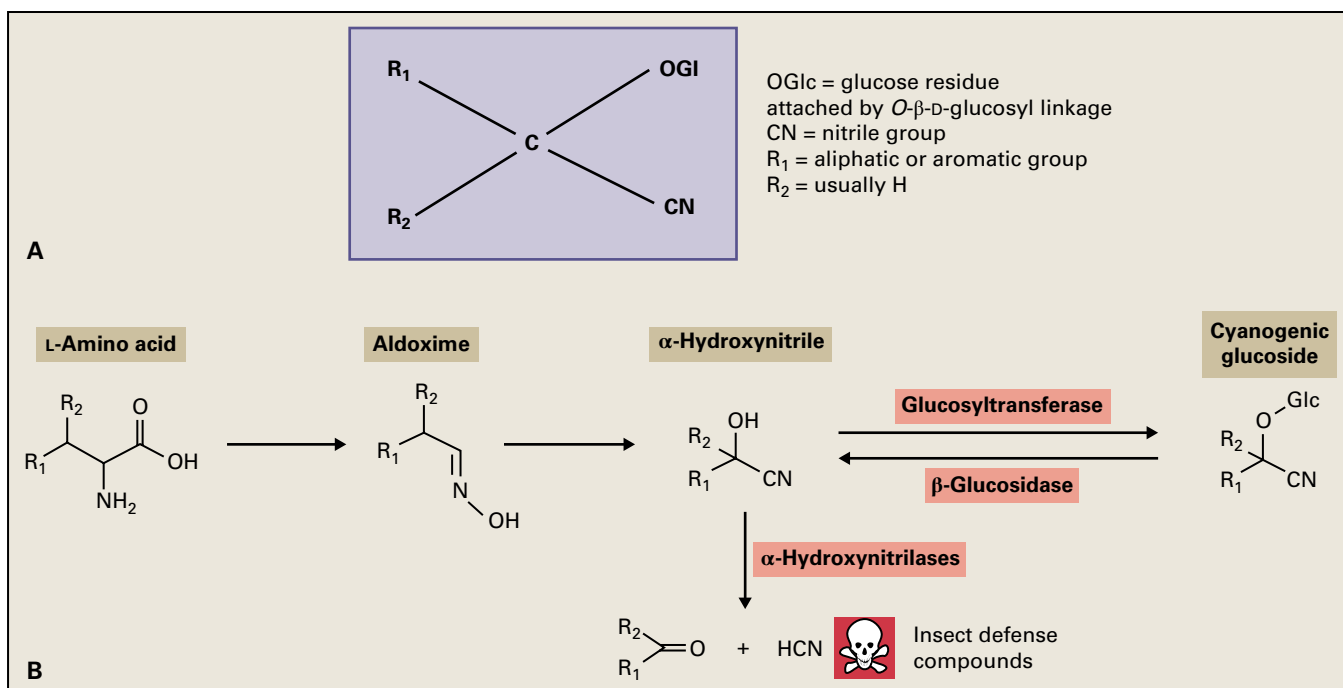

FIGURE 24.17 (A) General structure of cyanogenic glycosides. The sugar residue is always a D-glucose that is joined by an *O*- β -D-glucosyl linkage (referred to more specifically, then, as cyanogenic glucosides), but additional sugars present may be different. (B) Cyanogenesis. Cyanogenic glycosides are formed from a limited number of L-amino acids and converted to cyanogenic glycosides with *E*-oximes and α -hydroxynitriles as key intermediates. Upon hydrolysis of the cyanogenic glycoside by the action of β -glucosidases and α -hydroxynitrilases, toxic hydrogen cyanide (HCN) and ketones or aldehydes are produced.

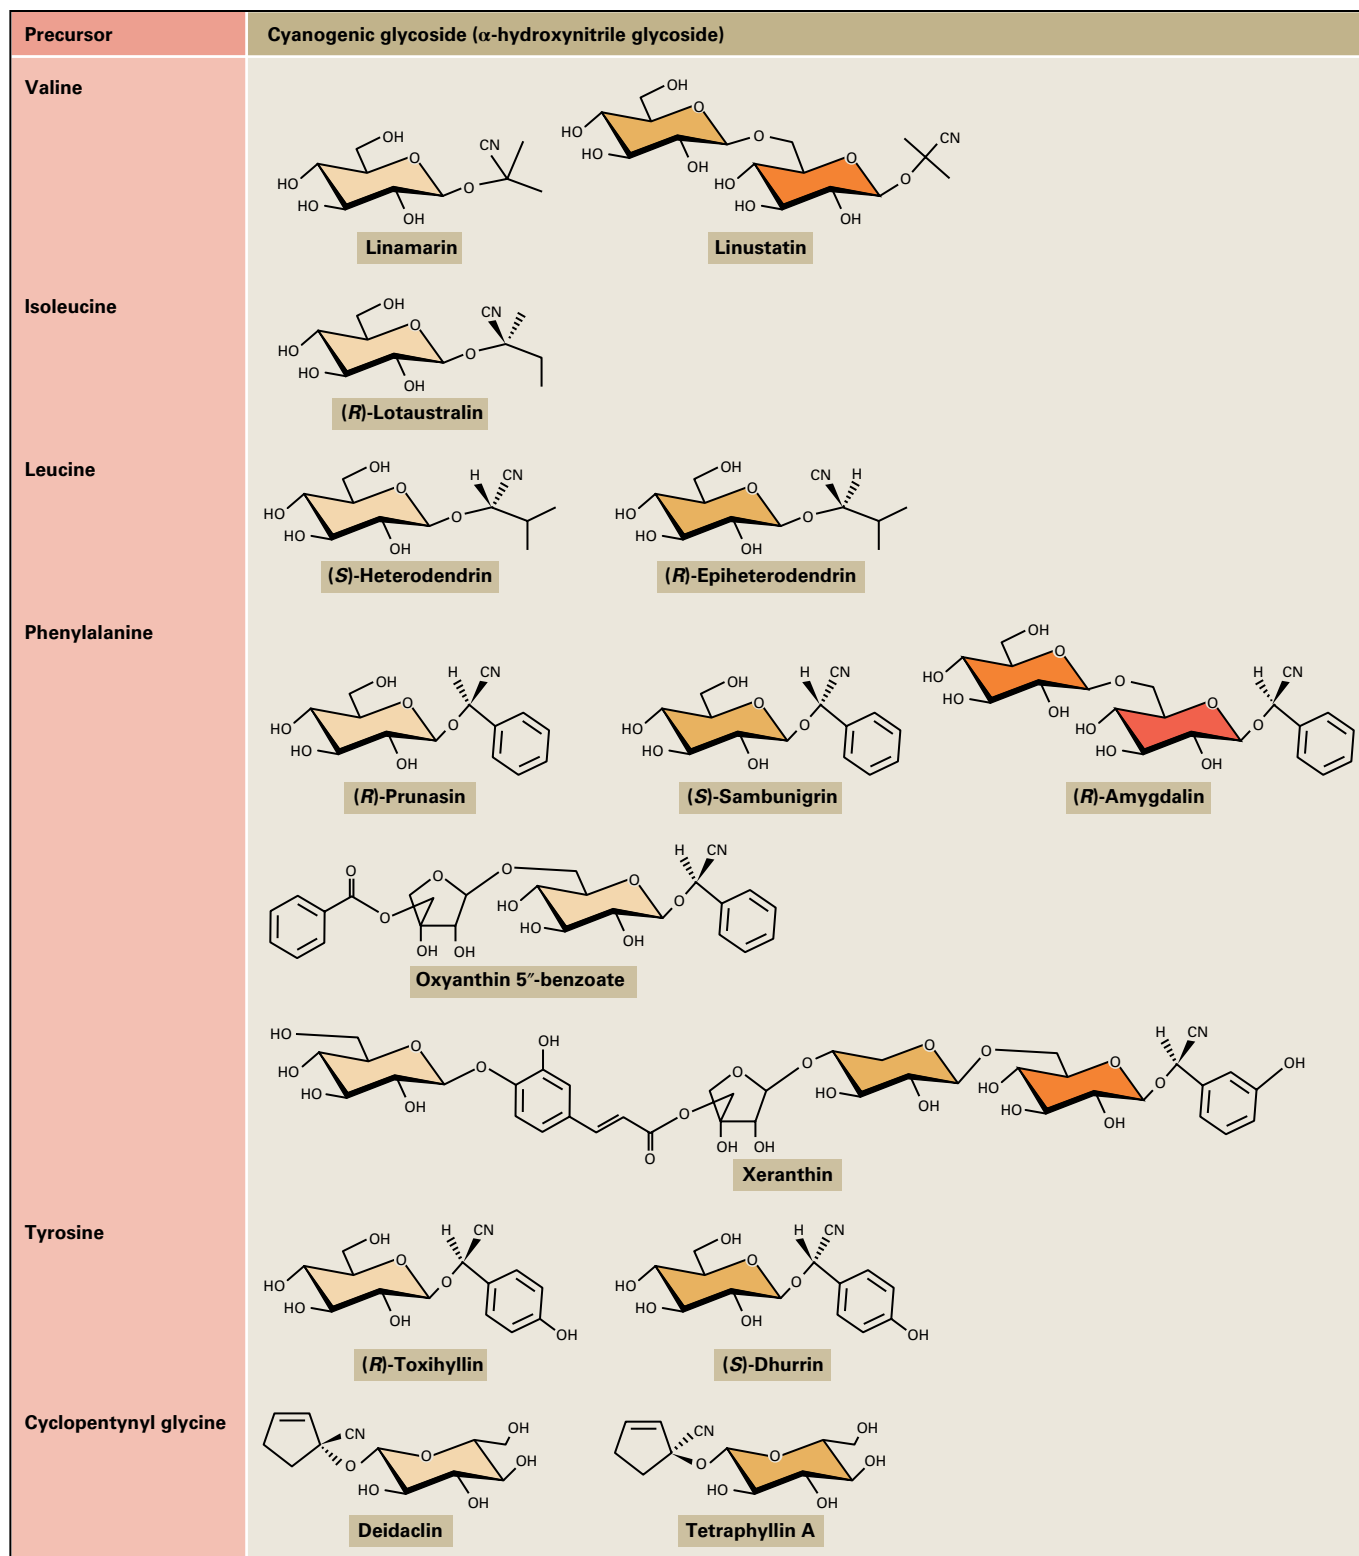

FIGURE 24.18 Structures of selected cyanogenic glycosides (α -hydroxynitrile glycosides).

FIGURE 24.19 Evolutionary trees depicting the evolution of arthropods and plants and the presence of different classes of defense compounds, including cyanogenic glycosides. Plants and insects have coevolved for the last ≈400 million years, and both groups of organisms produce toxic secondary metabolites like cyanogenic glycosides to defend themselves. A few arthropod families also accumulate cyanogenic glycosides, for example, *Zygaena* larvae that has evolved the ability to either sequester cyanogenic glycosides from *Lotus* plants or, if reared on acyanogenic *Lotus*, to synthesize cyanogenic glycosides *de novo*.

BOX 24.3

Cyanogenesis can be used for high-throughput mutant screening

Several plant species are polymorphic with respect to **cyanogenesis**, and cyanogenic and acyanogenic plants occur together in nature. The best-studied example is white clover (*Trifolium repens*), which is polymorphic with respect to the ability to both synthesize and degrade cyanogenic glycosides. To rapidly identify individual natural variants in cyanogenic plant species among a large plant population (e.g., in white clover) and to identify mutants obtained following mutagenesis programs (e.g., in the crop plant forage sorghum and in the genetic model plant *Lotus japonicus*), a fast screening system was developed.

Tiny pieces of plant tissue stamped out using a cork borer were placed in the wells of microtiter plates covered by Feigl–Anger paper and sealed. Freezing the plates disrupted the subcellular structure of the plant tissue, resulting in cyanide release from samples containing cyanogenic glycosides as well as the β -glucosidase and α -hydroxynitrilase required for their degradation. The volatile HCN released reacted with the exposed part of Feigl–Anger paper to produce a blue area corresponding to the diameter of the well. Plants with a reduced content of cyanogenic glycosides or devoid of

hydrolytic enzyme activity gave either reduced or no color reaction. The biochemical screen thereby enabled identification of mutants in biosynthetic, regulatory, or catabolic genes that could be classified into separate groups and characterized in detail using the reverse genetic technique of targeted induced local lesions in genomes (TILLING).

High water-use efficiency and tolerance to drought and elevated temperatures make sorghum an ideal cereal crop for arid and semi-arid regions of the world. The screening program identified acyanogenic mutants in forage sorghum that lacked the ability to synthesize the cyanogenic glycoside, **dhurrin** (see Fig. 24.18). These mutants were of interest because they removed the risk of cyanide intoxication of grazing animals. Sorghum mutants cyanogenic at the seedling stage but devoid of cyanogenic glycosides at the adult stage were also identified, as were mutants with an overall reduced content.

In parallel to the screening of field-grown sorghum mutants, a screening program was carried out in the model legume *L. japonicus* to identify mutants in which the synthesis of the two cyanogenic glycosides,

lotaustralin and linamarin (see Fig. 24.18), were uncoupled. The results showed that different β -glucosidases are involved in degradation of cyanogenic glucosides and that β - and γ -hydroxynitrile glucosides are also present in

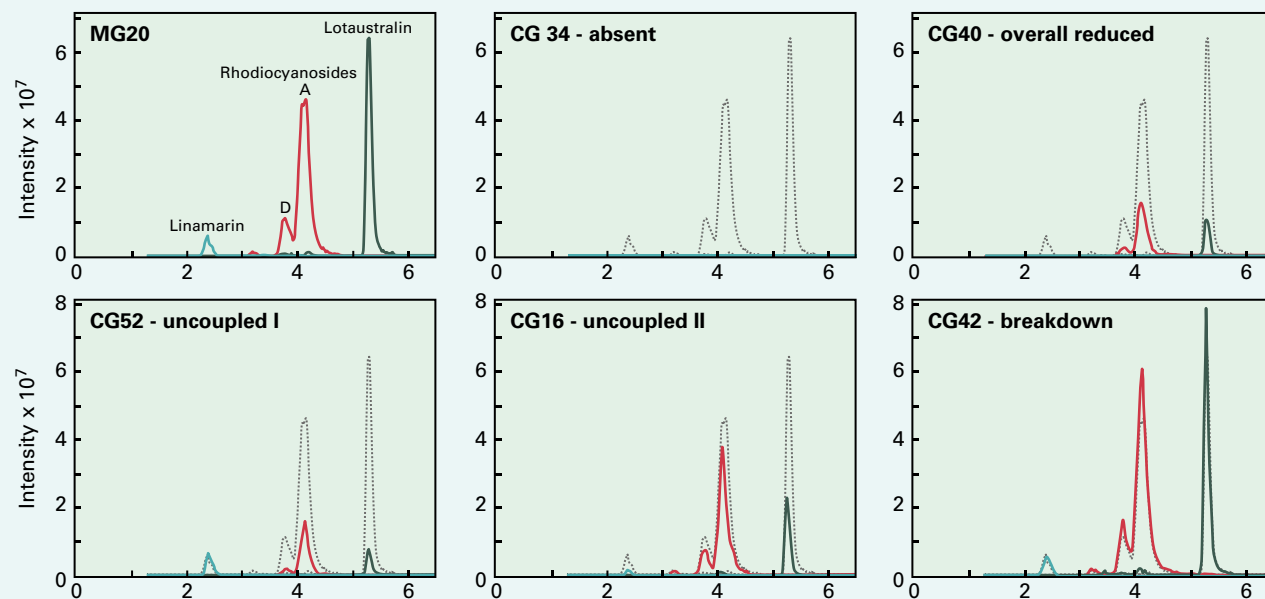

L. japonicus. The availability of the genome sequence and of an efficient transformation system makes *L. japonicus* an excellent genetic model plant for future genetic studies of cyanogenic glucoside metabolism.

(C) Targeted LC-MS analysis of the content of α -, β -, and γ -hydroxynitrile glucosides present in MG20 *L. japonicus* wild-type and mutant plants. Some mutants are totally devoid of hydroxynitrile glucosides, whereas others show altered ratios and some have wild-type levels but have lost the ability to hydrolyze the compounds.

24.8 Cyanogenic glycoside biosynthesis

24.8.1 Cyanogenic glycoside biosynthesis is catalyzed primarily by two groups of enzymes

The biosynthesis of cyanogenic glycosides is catalyzed by cytochrome P450 enzymes (see Box 24.1) and UDP-glycosyltransferases. Both belong to multienzyme families in which

other members are involved in synthesis of other classes of bioactive natural products, including phenylpropanoids, alkaloids, and terpenoids.

The pathway for cyanogenic glycoside biosynthesis was first elucidated in sorghum (*Sorghum* sp.) using biochemical approaches. Sorghum contains the tyrosine-derived cyanogenic glucoside dhurrin, and the dhurrin biosynthetic pathway involves the intermediates *N*-hydroxytyrosine, *N,N*-dihydroxytyrosine, (*E*)- and (*Z*)-*p*-hydroxyphenylacetaldoxime, *p*-hydroxyphenylacetonitrile, and *p*-hydroxymandelonitrile (Fig. 24.20). These intermediates all contain functional groups

FIGURE 24.20 Biosynthesis and degradation of the tyrosine-derived cyanogenic glycoside dhurrin in *Sorghum bicolor*. The enzymes catalyzing the different steps are shown. Each cytochrome P450 enzyme catalyzes more than one step in the pathway. These steps are indicated by red (CYP79A1) and blue (CYP71E1). Degradation of dhurrin occurs when the plant tissue is disrupted, and can proceed nonenzymatically. The NADPH cytochrome P450 oxidoreductase (POR) provides reducing power from NADPH in single electron transfer steps.

not commonly seen in metabolites of primary metabolism. Microsomal preparations from etiolated sorghum seedlings formed the starting material for isolation of two multifunctional membrane-bound cytochrome P450 enzymes that catalyze the tyrosine-to-*p*-hydroxymandelonitrile conversion (Fig. 24.20): CYP79A1 catalyzes conversion of the amino acid L-tyrosine to (*E*)-*p*-hydroxyphenylacetaldoxime, and CYP71E1 catalyzes the conversion of (*E*)-*p*-hydroxyphenylacetaldoxime into *p*-hydroxymandelonitrile. A soluble UDP-glucosyltransferase (UGT85B1) catalyzes conversion of *p*-hydroxymandelonitrile into dhurrin. The corresponding P450 cDNA and genomic clones were also obtained.

Subsequent studies in other cyanogenic species involved metabolomics, proteomics, and transcriptomics, genome sequencing, heterologous expression of candidate genes, and natural variation and mutants. They have shown the pathway for cyanogenic glycoside biosynthesis in these species also utilizes cytochrome P450 enzymes and UDP-glucosyltransferases and follows the same sequence of transformation of intermediates as identified in sorghum. Sequence comparisons, however, indicate that the genes encoding the biosynthetic enzymes in different cyanogenic plant species are not necessarily orthologous. Independent evolution of cyanogenic glycoside biosynthesis in several higher plant lineages by gene duplication from related gene

families and diversification (assumption of a totally new function) is a likely scenario. This is supported by the demonstration that some insects synthesize cyanogenic glucosides *de novo* using the same set of intermediates, two multifunctional cytochrome P450s, and a membrane-bound UDP-glucosyltransferase, which evolved by convergent evolution and not by horizontal gene transfer or divergent evolution (see Box 24.4).

The substrate specificity of the plant CYP79 enzymes that catalyze formation of oximes from amino acids is restricted to a single amino acid or two structurally similar amino acids. In contrast, the enzymes that catalyze the subsequent steps in cyanogenic glycoside synthesis exhibit broader substrate specificity. This promiscuity may have provided the starting point for evolution of new functions and thus, for repeated evolution of cyanogenic glycoside synthesis following the emergence of the CYP79 enzyme.

When the genes encoding the pathway for cyanogenic glycoside formation were identified in *L. japonicus*, *S. bicolor*, and cassava (*M. esculentum*), it became apparent that the genes were clustered within all three species (Fig. 24.21). This indicates a strong evolutionary mechanism promoting this type of genomic organization; however, the clusters differ substantially in size, gene density, and with respect to the additional genes present. Self-organization of biosynthetic

BOX 24.4

Reduction of cyanogenic glucoside levels in cassava requires extensive processing, but may also be accomplished through genetic engineering

The high levels of cyanogenic glycosides that accumulate in some plant species pose health hazards when the plant material is used for human consumption or as animal feed. Examples include cassava tubers, bitter almonds, and forage sorghum.

Cassava (*Manihot esculenta*) is a tropical and subtropical crop favored for its drought tolerance and high yields of starchy tubers, even on marginal soils. In rural populations, especially in sub-Saharan Africa, cassava tuber is a major staple food eaten regularly and in such quantities that it constitutes a dominant portion of the diet for millions of people. To avoid cyanide intoxication from the cyanogenic glucosides linamarin and lotaustralin, the tubers require extensive processing (see figure). The processing, however, is associated with loss of proteins, minerals, and vitamins, which decreases the nutritional value.

The biosynthesis of cyanogenic glucosides in cassava occurs mainly in young leaves, and the compounds are then transported to the tubers, as demonstrated through removal of the phloem tissue by stem girdling. *De novo*

biosynthesis also takes place in the tuber peel. Using RNA interference (RNAi) technology, the level of cyanogenic glucosides can be reduced to 1% of wild-type levels in leaves. In contrast, reduction of the tuber levels to below 10% of wild-type levels is difficult, possibly reflecting the strong sink nature of the tuber tissue. In the seedling stage, cyanogenic glucosides serve as important transporters of reduced nitrogen, so RNAi seedlings have long and slender stems, long internodes, poorly developed leaves, and shorter and thicker roots (if any at all) when grown *in vitro* at low nitrogen. Transfer to standard media or soil restores the wild-type phenotype.

Farmed cassava is vegetatively propagated from stem cuttings, so the negative phenotype observed at the seedling stage following depletion of cyanogenic glucoside availability is not of direct practical relevance. The seedling phenotype illustrates that the presence of cyanogenic glucosides may offer specific advantages, for example at selected developmental stages or as a response to certain environmental challenges.

CYP79 genes are shown in pink, CYP71E and CYP736 genes in green, and UGT85 genes in blue.

pathways into gene clusters may reduce the likelihood of crossover events that result in the accumulation of toxic intermediates. In a dynamic ecological context, co-inheritance of gene clusters may favor maintenance of adaptive chemical defense polymorphisms in natural populations subjected to opposing selection pressures (see Section 24.19).

24.8.2 Metabolon formation helps regulate cyanogenic glycoside synthesis

The enzymes of cyanogenic glycoside biosynthesis are organized within a dynamic **metabolon** (macromolecular enzyme complex) (Fig. 24.22) (see Sections 24.12.4 and 24.18.4). There is precedence for metabolon participation in primary metabolism, for example in glycolysis, the tricarboxylic acid cycle, and fatty acid biosynthesis.

Metabolon formation facilitates channeling of toxic and labile intermediates (see Fig. 24.20) toward formation of the final product. The E-oxime formed by the first P450 enzyme is reactive and must be efficiently converted into the Z-isomer by the second P450 before the dehydration reaction and further conversion can take place. Likewise, rapid glycosylation of the last intermediate in the pathway, the labile α -hydroxynitrile, is required to prevent its dissociation into HCN and an aldehyde. The metabolon controls the number of products formed and protects the cell from autotoxicity.

FIGURE 24.22 Metabolon formation in cyanogenic glycoside synthesis. The two cytochrome P450 enzymes (CYP79A1 and CYP71E1) and UDP-glucosyltransferase (UGT85B1) interact to channel intermediates in the biosynthetic pathway directly into formation of dhurrin.

Metabolon formation in cyanogenic glycoside synthesis is a dynamic process mediated by weak protein–protein interactions or controlled by the composition of the lipids in the endoplasmic reticulum interacting with the P450s. The transient nature of the metabolon affords metabolic flexibility and

enables interaction with other primary and secondary metabolic processes. For example, the second P450 in the pathway is highly sensitive to oxygen, so fungal attack followed by oxygen burst may inactivate this P450 and result in the release of oximes with antifungal effects. In a similar manner, the small

**BOX
24.5**

Sequestering and de novo biosynthesis of cyanogenic glucosides in insects

Some specialized herbivores, especially insects, preferentially feed on cyanogenic plants. The larvae of such herbivores have acquired the ability to either metabolize cyanogenic glucosides without release of HCN or to sequester them for use in their own defense against predators.

Larvae of the burnet moth (*Zygaena filipendulae*) not only sequester the cyanogenic glucosides linamarin and lotaustralin (see Fig. 24.18) from their food plants (Fabaceae), they are able to carry out de novo synthesis of the same compounds. The larvae store these cyanogenic glucosides in cuticular cavities and secrete them upon stimulation as sticky droplets to deter potential predators. The ratio and content of cyanogenic glucosides are tightly regulated in the different stages of the *Z. filipendulae* life cycle, and the compounds play other roles in addition to defense. The transfer of a nuptial

gift of cyanogenic glucosides during mating, for example, may explain why females prefer to mate with males carrying high amounts of cyanogenic glucosides. The reduced nitrogen contained in cyanogenic glucosides may be remobilized into primary nitrogen metabolism.

Linamarin and lotaustralin biosynthesis in *Z. filipendulae* share the same unusual biosynthetic intermediates as in plants. Three genes (*CYP405A2*, *CYP332A3*, and *UGT33A1*) encode the entire biosynthetic pathway. As in plants, the insect P450 enzymes are multifunctional. Phylogenetic analyses demonstrated that the ability to synthesize cyanogenic glucosides has evolved in plants and insects by convergent evolution, not from horizontal gene transfer or divergent evolution. Thus, plants and insects have independently found a way to package a cyanide time bomb to fend off herbivores and predators.

Larvae of *Zygaena filipendulae* sequester the cyanogenic glucosides linamarin and lotaustralin present in their host plant *Lotus corniculatus* or synthesize the same compounds de novo from their parent amino acids. When irritated, cyanogenic glucoside-loaded defense droplets are exuded and visible on top of the black patches of the integument. When the female imago is ready to mate, she prefers males with high cyanogenic glucoside content. During the mating process, the male transfers cyanogenic glucosides to the female.

family of CYP79-encoding genes found in many plant species not accumulating cyanogenic glycosides may be involved in controlling the release of volatile oximes or corresponding nitriles. Diurnal variations in CYP79 expression or metabolism formation may also enable release of volatile oximes. The function of volatile oximes as insect attractants has been documented in a number of moth-pollinated night-scented orchids, in which they increase the likelihood of pollination.

24.9 Functions of cyanogenic glycosides

24.9.1 Cyanogenic glycosides act as plant defense compounds

One of the most notable functions of cyanogenic glycosides in plants depends on their activation by β -glycosidases to release toxic volatile HCN, as well as a ketone or aldehyde, to fend off herbivores and pathogens (see Fig. 24.17). This is a classic example of how plant defense compounds may be stored in a nontoxic form that, upon attack, is activated to provide an immediate chemical defense response. However, whether such a defense system is able to successfully fend off an attack depends on the actual cyanogenic glycoside level and whether the rate of HCN release is high enough to block the mitochondrial electron transport chain in the attacking organism at the oxygen-binding site of cytochrome *c* oxidase. The bitterness of the cyanogenic glycoside and hydrolysis products may also prevent feeding.

Natural populations of cyanogenic plants vary greatly in their content of cyanogenic glycosides, and variation is also pronounced with respect to plant ontogeny, leaf age, and environmental conditions. Biosynthesis of cyanogenic glycosides primarily occurs in young and developing tissues, and the levels found in older plant parts generally decrease, as *de novo* biosynthesis proceeds at a low rate or does not keep up with the net gain in total biomass. Environmental stresses such as drought may induce cyanogenic glycoside production. This signifies that a plant that is harmless to an herbivore when grown under one set of conditions may be toxic or lethal under another. Thus, in many cases cyanogenesis provides an effective general defense system.

Cyanogenesis-based plant defense systems are estimated to be 400 million years old (see Fig. 24.19). Some fungi and herbivores have co-evolved and counteract and exploit cyanogenesis-based defenses for their own benefits. Fungal pathogens of cyanogenic plants may tolerate HCN based on their use of cyanide-resistant alternative oxidases and efficient metabolism of HCN into formamide in a reaction catalyzed by formamide hydrolyase. Hydrolysis of formamide provides the fungus with ammonia as a source of reduced nitrogen.

Some highly cyanogenic plant species are more susceptible to fungal infection than are varieties with reduced cyanide

potential. This applies to the interaction between the rubber tree (*Hevea brasiliensis*) and the causative agent of rubber tree leaf blight, the fungus *Microcyclus ulei*. The main cyanogenic glycoside found in the rubber tree is linamarin (see Fig. 24.18), and *M. ulei* is tolerant of the levels of HCN released during disease development. In the highly cyanogenic rubber tree varieties, the accumulated levels of free HCN in the leaves impairs overall plant defense by inhibiting formation of the phytoalexin scopoletin and most likely also by inhibiting the activity of peroxidases and polyphenoloxidases. This illustrates that the versatile batteries of chemical plant defenses within a single plant species in some cases do not act synergistically but may be trade-offs against each other due to negative interactions at the biochemical level.

Some arthropods are also able to cope with and in some cases benefit from or even depend on the presence of cyanogenic glycosides in their host plant. Sequestration of the plant-derived cyanogenic glycosides in the arthropod or *de novo* synthesis of the same compounds provides the arthropod with a defense system against its own predators (see Box 24.5).

24.9.2 Cyanogenic glycosides play other roles in plants

In addition to serving as defense compounds, cyanogenic glycosides serve many other functions that afford an advantage at certain developmental stages or following specific environmental challenges.

The total cyanogenic glycoside content of a plant typically shows diurnal changes. In leaves of the rubber tree (*Hevea brasiliensis*) and in cassava, the cyanogenic glycosides are constantly degraded and resynthesized: The levels are highest at dawn, decrease rapidly upon exposure to sunlight, and are re-established after sunset and during the night. This observation prompted investigations into the operation of an endogenous turnover pathway for cyanogenic glycosides that is not accompanied by HCN release (Fig. 24.23). Using sorghum (*Sorghum bicolor*) as an experimental system, the turnover pathway was found to proceed with conversion of dhurrin to *p*-hydroxyphenylacetonitrile. The action of a heteromeric complex of nitrilases (NIT4A/B2) then catalyzes the conversion of the nitrile into *p*-hydroxyphenylacetic acid and ammonia. Hydrogen cyanide released by the classic β -glycosidase catalyzed hydrolysis of cyanogenic glycosides is converted into β -cyanoalanine by the action of β -cyanoalanine synthase with a stoichiometric consumption of cysteine. NIT4A/B1 and/or NIT4A/B2 complete the cyanide detoxification reaction by converting β -cyanoalanine into asparagine and aspartic acid.

The ability to turnover cyanogenic glycosides without release of toxic constituents provides an avenue for their use as long- and short-distance transporters of reduced nitrogen and glucose. This was first demonstrated in studies with the rubber tree (*H. brasiliensis*), where cyanogenic glycoside

FIGURE 24.23 Endogenous turnover pathways of the cyanogenic glycoside *dhurrin* in sorghum. *Dhurrin* can be metabolized in the plant either through wounding (i.e., herbivory) or in a diurnal rhythm. This exemplifies its role as both a defense compound, and as a transportable source of reduced nitrogen and glucose.

transport buffers nitrogen and glucose supplies during seedling development and for the latex regeneration process following bark tapping.

In some cyanogenic plant species like white clover (*Trifolium repens*), natural variants exist that are not cyanogenic (acyanogenic), either because they cannot synthesize cyanogenic glycosides *de novo* or because they cannot degrade them. The cyanogenic and acyanogenic plants coexist, but with a shift in prevalence from year to year that reflects fluctuations in the main environmental challenges. In general, cyanogenic plants dominate in seasons with heavy attack by generalist herbivores (e.g., snails) that avoid eating them, and acyanogenic plants dominate in cooler climates and profit from resource allocation trade-offs when herbivore attack is minimal. Thus, the presence of cyanogenic glycosides offers additional possibilities for fine-tuning plant metabolism and adapting to environmental stress.

24.10 Glucosinolates

24.10.1 Glucosinolates also derive their biological activity following hydrolysis

Glucosinolates are sulfur-rich, anionic β -thioglycosides. They contain a central carbon atom that is bound by a sulfur to a glycone group, and by a nitrogen to a sulfonated oxime

group. In addition, the central carbon is bound to a side group (Fig. 24.24A). Different glucosinolates have different side groups as defined by the amino acids from which they are derived. The amino acid precursors include alanine, valine, isoleucine, leucine, methionine, phenylalanine, tyrosine, and tryptophan, and chain-elongated forms of methionine and phenylalanine.

Glucosinolates constitute a small class of specialty compounds that obtain their biological activity following hydrolysis by β -thioglucosidases, also known as myrosinases. The labile aglycon that is formed may rearrange in different ways to produce isothiocyanates, nitriles, epithionitriles, oxazolidine-2-thiones, and thiocyanate (Fig. 24.24B). The profile of bioactive products obtained is shaped by the glucosinolate side chain structure and the presence of modifying protein partners or specifier proteins, the presence of ferrous ions, and pH.

To prevent damage to the plant, myrosinase and glucosinolates are stored in separate subcellular compartments and come together only under conditions of stress or injury (e.g., cell disruption due to biting or chewing by herbivores). The hydrolysis products produced as a result of cell disruption are referred to as the **mustard oil bomb** and provide defense against generalist herbivores.

The natural occurrence of glucosinolates is largely restricted to the Brassicales order, including oil seed rape (*Brassica napus*), cabbage and broccoli (*Brassica oleracea*), radish (*Raphanus sativus*), horseradish (*Armoracia rusticana*), and *Arabidopsis thaliana*. Besides the structural variation

FIGURE 24.24 (A) Core structure of a glucosinolate. Every glucosinolate contains a central carbon atom, which is bound through a sulfur linkage to the glycone group, and through a nitrogen linkage to a sulfonated oxime group. The central carbon is also bound to a side group (R); different glucosinolates have different side groups. (B) The possible products formed following hydrolysis of the thioglucosidic linkage. ESP, epithiospecifier protein.

offered by different degrees of chain elongation of mainly Met- and Phe-derived glucosinolates, the core structure may be further modified by the activity of flavin monooxygenases and 2-oxoglutarate-dependent dioxygenases.

24.10.2 Biosynthesis of glucosinolates

Glucosinolate biosynthesis, like cyanogenic glycoside biosynthesis, begins with the conversion of the parent amino acid into an E-oxime in a reaction catalyzed by cytochrome

P450 enzymes belonging to the CYP79 family (Fig. 24.25). In a second set of reactions catalyzed by cytochrome P450 enzymes belonging to the CYP83 family, the E-oxime is hydroxylated to a labile *aci*-nitro compound or nitrile oxide that is conjugated to glutathione. The conjugation reaction may proceed nonenzymatically. The GSH conjugate is then cleaved by a cytosolic γ -glutamyl peptidase, resulting in the formation of a Cys-Gly conjugate. The Gly may subsequently be removed by the action of a carboxypeptidase; alternatively, the C-S lyase SUPERROOT 1 may be able to cleave the Cys-Gly as well as the Cys conjugate to afford a thiohydroxamic acid. S-glucosylation by the action of a UDPG-glucosyltransferase belonging to the UGT74 family converts the thiohydroxamic acid into a desulfoglucosinolate that is converted into the glucosinolate by sulfotransferases (SOT16, 17, 18).

Structural diversity of glucosinolates also arises from the ability of some CYP79 enzymes to use chain-elongated forms of Met and Phe as substrates (see Box 24.6).

24.11 Alkaloids

24.11.1 Alkaloids have a 3,000-year history of human use

For much of human history, **alkaloid**-containing plant extracts have been used as ingredients in potions and poisons. In the eastern Mediterranean, use of the latex of the opium poppy (*Papaver somniferum*; Fig. 24.26) can be traced back at least to 1400–1200 BC. The Sarpagandha root (*Rauwolfia serpentina*) has been used in India since approximately 1000 BC. Ancient people used medicinal plant extracts as purgatives, antitussives, sedatives, and treatments for a wide range of ailments, including snakebite, fever, and insanity.

As the use of medicinal plants spread westward across Arabia and Europe, new infusions and decoctions played a role in famous events. During his execution in 399 BC, the philosopher Socrates drank an extract of coniine-containing hemlock (*Conium maculatum*; Fig. 24.27). In the last century BC, Queen Cleopatra used extracts of henbane (*Hyoscyamus*), which contains atropine (Fig. 24.28), to dilate her pupils and appear more alluring to her male political rivals. Over the centuries, however, the king of all medicinals has been opium, which was widely consumed in the form of Theriak, a concoction consisting mainly of opium, dried snake meat, and wine (see Box 24.7). Analysis of the individual components of opium led to the identification of morphine (Fig. 24.29A), named for Morpheus, the god of dreams in Greek mythology. The isolation of morphine in 1806 gave rise to the study of alkaloids.

The term alkaloid, coined in 1819 in Halle (Saale) Germany, finds its origin in the Arabic name *al-qali*, the plant from which soda was first isolated. Alkaloids were originally

defined as pharmacologically active, nitrogen-containing basic compounds of plant origin. After 200 years of alkaloid research, this definition no longer encompasses the entire alkaloid field, but in many cases it is still appropriate. Alkaloids are not unique to plants. They have also been isolated from numerous animal sources (see Box 24.8); the alkaloid morphine, for example, has been detected in mammals and is synthesized *de novo* in mouse (see Box 24.9). Many of the alkaloids that have been discovered are not pharmacologically active in mammals, and some are neutral rather than basic in character, despite the presence of a nitrogen atom in the molecule.

24.11.2 Alkaloid-containing plants were mankind's original "materia medica"

Alkaloid-containing plants were mankind's original "materia medica," and many are still in use today as prescription drugs (Table 24.1). One of the best-known prescription alkaloids is the antitussive and analgesic codeine from the opium poppy, *Papaver somniferum* (Fig. 24.29). Plant alkaloids have also served as models for modern synthetic drugs, such as the tropane alkaloid atropine (see Fig. 24.28) for tropicamide used to dilate the pupil during eye examinations and the indole-derived antimalarial alkaloid quinine for chloroquine (Fig. 24.30).

FIGURE 24.25 Biosynthesis of glucosinolates. Cleavage of the glutathione (GSH) conjugate may be achieved by multiple routes, including action of a carboxypeptidase or the C-S lyase SUPERROOT 1 to produce the thiohydroxamic acid.

BOX 24.6

Amino acid chain elongation is a key part of glucosinolate biosynthesis

A unique and integral part of glucosinolate biosynthesis is the side chain elongation of the precursor amino acids. This is the prerequisite for much of the structural diversity within the glucosinolate family. Special enzymes are responsible for catalyzing the synthesis of different side chains of the various glucosinolates. The enzyme methylthioalkylmalate (MAM) synthase, which elongates the side chain of methionine, resembles the enzyme isopropylmalate synthase (IPMS) of the biosynthesis of the amino acid L-leucine (see Chapter 7). There are two major structural differences between MAM synthase and IPMS: the last 120 amino acids at the carboxy terminus of IPMS

are absent in MAM synthase; in the active sites of the enzymes, two amino acids have been exchanged.

The evolution of MAM synthase has been a major driver in the amino acid chain elongation process in glucosinolate metabolism and illustrates how changes at the protein level may lead to the recruitment of an enzyme from primary metabolism (IPMS) to serve an important new function (MAM synthase) in the synthesis of secondary metabolites, providing yet another example of the role of gene duplication and diversification in the evolution of natural product biosynthetic pathways (see Sections 24.8.2 and 24.19).

The amino acid chain elongation reactions in glucosinolate synthesis. (1) Condensation of the 2-oxo acid and acetyl-CoA is catalyzed by MAM synthase. This condensation step followed by (2) isomerization of the 2-malate derivative to the 3-malate derivative and (3) oxidative decarboxylation of the 3-malate derivative to the 2-oxo acid now elongated by one methylene ($-\text{CH}_2-$) group forms the elongation cycle. The elongation cycle can be repeated two to six times.

In addition to having a major impact on modern medicine, alkaloids have also influenced world geopolitics. Notorious examples include the Opium Wars between China and Britain (1839–1859) and the efforts currently underway in various countries to eradicate illicit production of heroin, a semi-synthetic compound derived by acetylation of morphine (see Fig. 24.29C), and cocaine, a naturally occurring alkaloid of the coca plant (Fig. 24.31). Because of their various pharmacological activities, alkaloids have influenced human history profoundly, both for good and ill. Of interest to plant biologists, however, is the evolutionary process in plants that has caused alkaloids to evolve and the role in communication of the plant with the environment in which these molecules participate.

24.11.3 Physiologically active alkaloids participate in plant chemical defenses

More than 20,000 alkaloids have been isolated from various organisms since the discovery of morphine. It is estimated that the number of plant genera is greater than 20,000. Approximately

9% of plant genera have alkaloid-accumulating species, and these plants occur most abundantly in genera belonging to angiosperms (flowering plants). Each species that accumulates alkaloids does so in a unique, defined pattern. Some plants, such as the periwinkle (*Catharanthus roseus*) contain more than 100 different monoterpenoid indole alkaloids. Certain alkaloids are restricted to a single species, such as (+)-tubocurarine in the liana *Chondrodendron tomentosum*, whereas other alkaloids are more widely distributed among plant families.

Why should a plant invest so much nitrogen into synthesizing alkaloids of such diverse structure? How does only one plant species evolve to produce a particular alkaloid? The role of alkaloids in plants and their evolution have been long-standing questions, but a picture is emerging that supports an ecochemical function for these compounds.

The role of chemical defense for alkaloids in plants is supported by their wide range of physiological effects on animals and by the antibiotic activities many alkaloids possess. Various alkaloids are also toxic to insects or function as feeding deterrents. For example, nicotine, found in tobacco (*Nicotiana* sp.), was one of the first insecticides used by humans and remains

one of the most effective (Fig. 24.32). Herbivory stimulates nicotine biosynthesis in wild tobacco plants. Another effective insect toxin is caffeine (Fig. 24.33), found in seeds and leaves of cocoa (*Theobroma cacao*), coffee (*Coffea arabica*), cola (family Malvaceae), maté (*Ilex paraguariensis*), and tea (*Camellia sinensis*). At a dietary concentration well below that

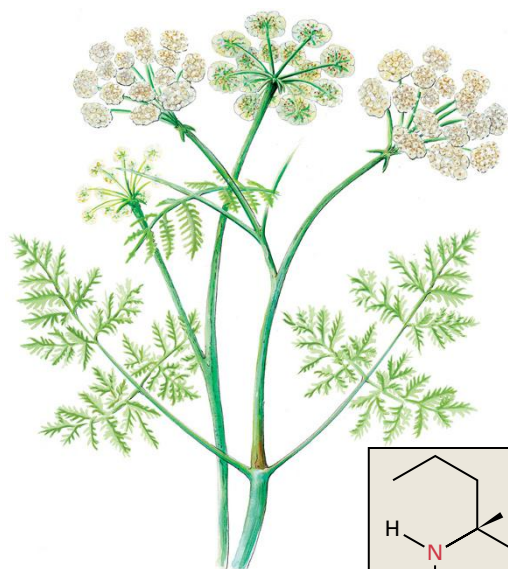

FIGURE 24.26 (A) Maturing capsule of the opium poppy *Papaver somniferum*. When the capsule is wounded, a white, milky latex is exuded. Poppy latex contains morphine and related alkaloids, such as codeine. When the exuded latex is allowed to dry, a hard, brown substance called opium is formed. (B) Statuette from Gazi of a goddess of sleep crowned with capsules of the opium poppy (1250–1200 BC). Source: (A) Kutchan, Liebnitz Institut für Pflanzenbiochemie, Halle, Germany; previously unpublished; (B) Ministry of Culture Archaeological Receipts Fund, Athens, Greece.

found in fresh coffee beans or tea leaves, caffeine kills nearly all larvae of the tobacco hornworm (*Manduca sexta*) within 24 hours, primarily by inhibiting the phosphodiesterase that hydrolyzes cAMP. The steroid alkaloid α -solanine, a cholinesterase inhibitor found in potato tuber (*Solanum tuberosum*, Fig. 24.34), is the trace toxic constituent thought to be responsible for the teratogenicity of sprouting potatoes.

Two groups of alkaloids that have been well studied with respect to ecochemical function are the pyrrolizidine and quinolizidine alkaloids (Fig. 24.35). Pyrrolizidine alkaloids, frequently found in members of the tribe Senecioneae (Asteraceae) and in the Boraginaceae, render most of these plants toxic to mammals. In *Senecio* species, senecionine N-oxide is synthesized in roots and translocated throughout the plant. In species such as *Senecio vulgaris* and *S. vernalis*, 60–80% of the pyrrolizidine alkaloids accumulate in the inflorescences. Members of the *Senecio* genus are responsible for livestock poisonings and also represent a potential health hazard for humans.

Naturally occurring pyrrolizidine alkaloids are harmless but become highly toxic when transformed by cytochrome P450 monooxygenases in the liver. On the other hand, several insect species have adapted to the pyrrolizidine alkaloids that accumulate in plants and have evolved mechanisms for using these alkaloids to their own benefit. Some insects can feed on pyrrolizidine alkaloid-producing plants and effectively and efficiently eliminate the alkaloids after enzymatic modification, such as formation of N-oxide derivatives. Other insects not only feed on these plants, but also store the pyrrolizidine alkaloids for their own defense or convert the ingested pyrrolizidine alkaloids to pheromones that attract prospective mates (see Box 24.8).

The quinolizidine alkaloids occur primarily in the genus *Lupinus* and are frequently referred to as lupine alkaloids

Conium maculatum

FIGURE 24.27 (A) The piperidine alkaloid coniine, the first alkaloid to be synthesized, is extremely toxic, causing paralysis of motor nerve endings. (B) In 399 BC, the philosopher Socrates was executed by consuming an extract of coniine-containing poisonous hemlock. This depiction of the event, “The Death of Socrates,” was painted by Jacques-Louis David in 1787. Source: (B) The Metropolitan Museum of Art, New York, NY.

(Fig. 24.35B); they are toxic to grazing animals, particularly to sheep. The highest incidence of livestock losses attributable to lupine alkaloid poisoning occurs in autumn during the seed-bearing stage of the plant life cycle—the seeds being the plant parts that accumulate the greatest quantities of these alkaloids. Because of their bitter taste, lupine alkaloids can also function as feeding deterrents. Given a mixed population of sweet and bitter lupines, rabbits and hares readily eat the alkaloid-free sweet variety and avoid the lupine alkaloid-accumulating bitter variety, indicating that lupine alkaloids can reduce herbivory by functioning both as bitter-tasting deterrents and toxins. Given this collection of examples, alkaloids can be viewed as a part of the chemical defense system of the plant that evolved under the selection pressure of predation.

24.7

Theriak, an ancient antipoisoning nostrum containing opium, wine, and snake meat, is still used today in rare instances

One of the oldest and most long-lived medications in the history of mankind is Theriak. Originating in Greco-Roman culture, Theriak consists of mainly opium and wine with a variety of plant, animal, and mineral constituents. Panel A of the figure shows a recipe for Theriak from the French Pharmacopée Royale in 1676.

Theriak was developed as an antidote against poisoning, snake and spider bites, and scorpion stings. History has it that the Roman Emperor Nero contracted the Greek physician Andromachus to discover a medicine that was effective against all diseases and poisons. Andromachus improved the then-existing recipe to include, in addition to opium, five other plant poisons and 64 plant drugs. Another

crucial component was dried snake meat, believed to act against snakebite by neutralizing the venom.

Today, Theriak is still prescribed in rare cases in Europe for pain and other ailments. Panel B shows a valuable Theriak-holding vessel made of Nymphenburg porcelain (in about 1820), which is on display in the Residenz Pharmacy in Munich, Germany.

24.11.4 Typically considered constitutive defense compounds, some alkaloids are synthesized in response to plant tissue damage

Alkaloids are thought to be part of the direct chemical defense system of many plants, and in some cases, such as that of nicotine in tobacco (*Nicotiana tabacum*), convincing evidence has been presented that an alkaloid is involved in induced chemical defense.

Wild species of tobacco are highly toxic to the hornworm *Manduca sexta*, a tobacco-adapted species. Feeding by larvae of *M. sexta* on its host plant *Nicotiana attenuata* elicits responses from the plant that are distinguishable from mechanical simulation of the damage that results from feeding. Mechanical damage induces accumulation of the plant hormone jasmonic acid (see Chapter 17) in the wounded leaf, and that systemically results in an accumulation of nicotine in the whole plant. Feeding by the tobacco hornworm results in higher leaf jasmonic acid levels than mechanical wounding, but whole plant nicotine levels do not surpass those achieved with mechanical damage. Hornworm feeding, in particular chemicals present in hornworm regurgitant, interferes with whole plant accumulation of nicotine, and it appears that the plant hormone ethylene (see Chapter 17) is specifically elicited by hornworm herbivory. The interplay between jasmonic acid and ethylene regulates nicotine biosynthesis and accumulation that results from insect attack of the tobacco plant.

To determine whether nicotine actually functions in defense required down regulating the nicotine biosynthesis gene that encodes putrescine *N*-methyl transferase in *N. attenuata* using RNA interference (RNAi) technology. This reduced constitutive and inducible nicotine levels by greater than 95% in the transgenic plants. Larvae of the tobacco hornworm (Fig. 24.36) grew faster and preferred transgenic plants with reduced nicotine in choice tests. When planted in their native habitat, the low nicotine, transgenic plants were attacked more frequently and lost more leaf area to a variety of native herbivores compared to wild-type plants that contained normal levels of nicotine. Nicotine down-regulated plants were also used to demonstrate a role for this alkaloid in reproductive fitness of *Nicotiana* flowers (Box 24.10).

24.12 Alkaloid biosynthesis

24.12.1 Alkaloid biosynthesis research has been aided by the development of techniques for high-throughput sequencing of transcriptomes

Many alkaloids have complex chemical structures and contain multiple asymmetric centers. This complicates structure elucidation and has made the study of alkaloid biosynthesis

BOX
24.8

Some butterflies and moths use alkaloids for sexual signaling or for protection against predators

Alkaloid-bearing species have been found in nearly all classes of organisms, including frogs, ants, butterflies, bacteria, sponges, fungi, spiders, beetles, and mammals. Alkaloids of various structures have been isolated from a variety of marine creatures. Some animals, such as amphibians, produce an array of either toxic or noxious alkaloids in the skin or the secretory glands. Others, such as the insects described below, use plant alkaloids as a source of attractants, pheromones, and defense substances.

Some butterflies gather alkaloidal precursors from plants that are not their food sources and convert these compounds into pheromones and defense compounds. Larvae of the cinnabar moth (*Tyria jacobaea*) continuously graze their plant host *Senecio jacobaea* until the plant is completely defoliated (A). The alkaloids thus obtained by the larvae are retained throughout metamorphosis. Male Asian and American arctiid moths incorporate pyrrolizidine alkaloids into their reproductive biology by sequestering these alkaloids in abdominal scent organs called coremata, which are everted in the final stages of their courtship to release the pheromones necessary to gain acceptance by a female. The coremata of a male Asian arctiid moth (*Cretonotos transiens*) is directly proportional in size to the pyrrolizidine alkaloid content of its diet during the larval stage (B). The courtship success of these male butterflies, therefore, depends on their ingesting alkaloids from higher plants.

The larvae of a second insect group, the Ithomiine butterflies, feed on solanaceous plants and sequester the plant toxins, including tropane alkaloids and steroidal glycoalkaloids. Adult Ithomiinae, however, do not contain tropane and steroid alkaloids; they prefer to ingest plants that produce pyrrolizidine alkaloids, sequestering these bitter substances as N-oxides and monoesters. The pyrrolizidine alkaloid derivatives protect Ithomiinae butterflies from an abundant predator, the giant tropical orb spider. The spider will release a field-caught butterfly from its web, but will readily eat a freshly emerged adult that has not yet had an opportunity to feed on the preferred host plant. When palatable butterflies were painted externally with a solution of pyrrolizidine alkaloids, the spider released them from its web. In contrast, palatable butterflies treated the same way with Solanaceae alkaloids were devoured. In general, mostly male butterflies are found feeding on the pyrrolizidine alkaloid-accumulating plants; up to 50% of the pyrrolizidine alkaloids present in these males is sequestered in the spermatophores and transferred to females at mating. In some butterfly species, the protective alkaloids are then transferred on to the eggs.

B

quite difficult. For example, although nicotine (one asymmetric center; see Fig. 24.32) was discovered in 1828, its structure was not known until it was synthesized in 1904. In addition, the structure of morphine (five asymmetric centers; see Fig. 24.29A) was not elucidated until 1952, almost 150 years

after its isolation, and the enzymes involved in its biosynthesis were identified more than 200 years after it was first isolated.

Why has it been so difficult to elucidate alkaloid biosynthetic pathways? Plants synthesize natural products at a

BOX
24.9

Morphine, the opiate analgesic formed in opium poppy, is synthesized de novo in mouse

Morphine has been detected in animal tissues, such as in skin of the frog *Bufo marinus* (Fig. 24.29B), but whether the alkaloid is formed de novo in frog has not been clarified. Humans also excrete a small amount of morphine in urine, but it is not yet clear whether this morphine is of dietary or endogenous origin. The simple isoquinoline alkaloid tetrahydropapaveroline is found in human and rodent brain as well as in human urine. The structural elements suggested a potential biogenetic

relationship between tetrahydropapaveroline and morphine. Studies using high-resolution mass spectrometry have shown that mice have the biosynthetic capability to convert tetrahydropapaveroline, a normal constituent of rodents, into morphine. In fact, the morphine detected in mouse urine results from de novo biosynthesis, and the medical implications of the plant alkaloid morphine also being synthesized in animals may be significant to pain research.

relatively sluggish rate, so steady-state concentrations of the alkaloid biosynthetic enzymes can be low. In addition, the large amounts of tannins and other phenolics that accumulate in plants interfere with extraction of active enzymes. Even when plants are treated with radiolabeled precursors and the resulting radioactive alkaloids are chemically degraded to identify the position of the label, the low rate of natural product metabolism can prevent the high rates of incorporation required to yield clear results. The use of polyvinylpyrrolidone and Dowex-1 in preparing protein extracts from plant tissues has helped overcome the enzyme inactivation by phenolic compounds, but isolation of the enzymes involved in natural product synthesis has had only limited success because of their very low concentrations in the plant.

Next-generation sequencing technologies (Fig. 24.37) have enhanced the study of alkaloid biosynthesis by generating

deep transcriptome datasets of a rapidly increasing number of plant species. From a comparative expression analysis of transcript, either between tissues of one plant or between plant species, candidate biosynthetic genes can be selected and recombinant enzymes experimentally verified. This new transcriptomic approach circumvents problems previously encountered with whole-plant studies, such as year-round availability of plant material, and the inability of dedifferentiated plant cell cultures to synthesize certain alkaloids to any appreciable extent due to tissue-specific expression of alkaloid biosynthesis genes. An example of an alkaloid biosynthetic pathway that has been largely elucidated within a short period of time from a transcriptome dataset is that of the terpenoid-isoquinoline alkaloid emetine (Fig. 24.38), an orally active emetic and amoebicide from the Central American plant *Psychotria ipecacuanha*.

TABLE 24.1 Physiologically active alkaloids used in modern medicine.

Alkaloid	Plant source	Use
Ajmaline	<i>Rauwolfia serpentina</i>	Antiarrhythmic that functions by inhibiting glucose uptake by heart tissue mitochondria
Atropine, (±)hyoscyamine	<i>Hyoscyamus niger</i>	Anticholinergic, bronchodilator
Caffeine	<i>Coffea arabica</i>	Widely used central nervous system stimulant
Camptothecin	<i>Camptotheca acuminata</i>	Potent anticancer agent
Cocaine	<i>Erythroxylon coca</i>	Topical anesthetic, potent central nervous system stimulant, and adrenergic blocking agent; drug of abuse
Codeine	<i>Papaver somniferum</i>	Relatively nonaddictive analgesic and antitussive
Coniine	<i>Conium maculatum</i>	First alkaloid to be synthesized; extremely toxic, causes paralysis of motor nerve endings, used in homeopathy in small doses
Emetine	<i>Uragoga ipecacuanha</i>	Orally active emetic, amoebicide
Morphine	<i>Papaver somniferum</i>	Powerful narcotic analgesic, addictive drug of abuse
Nicotine	<i>Nicotiana tabacum</i>	Highly toxic, causes respiratory paralysis, horticultural insecticide; drug of abuse
Pilocarpine	<i>Pilocarpus jaborandi</i>	Peripheral stimulant of the parasympathetic system, used to treat glaucoma
Quinine	<i>Cinchona officinalis</i>	Traditional antimalarial, important in treating <i>Plasmodium falciparum</i> strains that are resistant to other antimalarials
Sanguinarine	<i>Eschscholzia californica</i>	Antibacterial showing antiplaque activity, used in toothpastes and oral rinses
Scopolamine	<i>Hyoscyamus niger</i>	Anticholinergic, effective against motion sickness
Strychnine	<i>Strychnos nux-vomica</i>	Violent tetanic poison, rat poison, used in homeopathy
(+)-Tubocurarine	<i>Chondrodendron tomentosum</i>	Nondepolarizing muscle relaxant producing paralysis, used as an adjuvant to anesthesia
Vincristine	<i>Catharanthus roseus</i>	Antineoplastic used to treat childhood leukemia and other cancers.

24.12.2 Plants synthesize alkaloids from simple precursors, using unique enzymes

Until the mid-20th century, our view of plant alkaloid biosynthesis was based on biogenic hypotheses. Pathways suggested by illustrious natural product chemists were based on projections considered feasible within the realm of organic chemistry. In the 1950s, however, alkaloid biosynthesis became an experimental science, as radioactively labeled organic molecules became available for testing hypotheses. These early precursor-feeding experiments established that alkaloids are, in most cases, formed from L-amino acids (e.g., tryptophan, tyrosine, phenylalanine, lysine, and arginine), either alone or in combination with a steroidal, secoiridoid (e.g., secologanin) or other terpenoid-type moiety. One or two transformations

can convert these ubiquitous amino acids from primary metabolites to substrates for species-specific alkaloid metabolism. Although we do not thoroughly understand how most alkaloids are made by plants, several systems can serve as

examples of the types of building blocks and enzymatic transformations that have evolved in alkaloid biosynthesis.

Ajmalicine (Fig. 24.39), an L-tryptophan-derived monoterpene indole alkaloid, was the first alkaloid for which biosynthesis was clarified at the enzyme level. In plants, the biosynthesis of ajmalicine and more than 1800 other monoterpene indole alkaloids begins with the decarboxylation of the L-amino acid tryptophan by tryptophan decarboxylase to form tryptamine. Then tryptamine, by action of strictosidine synthase, is stereospecifically condensed with the secoiridoid secologanin (derived in multiple enzymatic steps from geraniol) to form 3 α (S)-strictosidine. Strictosidine can then be enzymatically permuted in a species-specific manner to form a multitude of diverse structures (Fig. 24.39). The elucidation of the enzymatic formation of ajmalicine laid the groundwork for analysis of more complex biosynthetic pathways, such as those leading to two other L-tryptophan-derived monoterpene indole alkaloids, ajmaline (Fig. 24.40) and vindoline.

24.12.3 The berberine synthesis pathway has been defined completely at the enzyme and gene levels

The first alkaloid for which each biosynthetic enzyme and corresponding cDNA were identified, isolated, and characterized is the antimicrobial benzylisoquinoline alkaloid, berberine, in *Berberis* (barberry). This pathway exemplifies the role of substrate-specific enzymes and compartmentalization in alkaloid biosynthesis.

The biosynthesis of tetrahydrobenzylisoquinoline alkaloids in plants begins in the cytosol with a matrix of reactions that generates the first tetrahydrobenzylisoquinoline alkaloid, (S)-norcoclaurine (Fig. 24.41) from two molecules of

BOX
24.10Nicotine has a role in reproductive fitness of *Nicotiana attenuata* flowers

Flowers produce distinctive combinations (bouquets) of volatile secondary metabolites that aid reproduction by attracting pollinators. Another familiar example of a floral reproductive aid is flower color, which can attract specific pollinators, such as hummingbirds or bees. Flowers face a diverse challenge in that they must attract a pollinator, but must also repel florivores and nectar thieves, which do not contribute to pollen transfer.

The combination of the secondary metabolites nicotine and benzylacetone in flowers of *Nicotiana attenuata*, a tobacco species native to western North America, optimizes reproductive fitness. *N. attenuata* flowers attract the moth *Hyles lineata* (A) and the hummingbird *Archilochus alexandri* (B) as pollinators. Using genetic engineering, *N. attenuata* plants have been

designed to lack nicotine, benzylacetone, or both nicotine and benzylacetone. When these metabolically tailored plants were tested in the wild for fitness, the plants that contained both nicotine and benzylacetone in their floral blend sired more seeds on other plants and produced larger seed capsules themselves. Benzylacetone attracts visitors to a flower, while nicotine prevents visitors from loitering while also deterring florivory by caterpillars and nectar robbing by carpenter bees. Combinations of attractants and repellents can help flowers to attract mates while avoiding predators, a pull and push strategy that optimizes a visitor's behavior.

A

B

L-tyrosine. One tyrosine is decarboxylated to form tyramine or is acted on by a phenol oxidase to form L-dopa. Dopamine can then be formed by decarboxylation of L-dopa or by the action of a phenol oxidase on tyramine. Determining which of these two pathways dominates in a plant is difficult because all of the enzyme activities are present in protein extracts and *Berberis* species are not yet genetically tractable.

The benzyl moiety of (S)-norcoclaurine is formed by transamination of the second L-tyrosine molecule to form *p*-hydroxyphenylpyruvate, which is then decarboxylated to *p*-hydroxyphenylacetaldehyde. Dopamine and *p*-hydroxyphenylacetaldehyde are then stereoselectively condensed to form (S)-norcoclaurine. A series of methylation and oxidation reactions yield the branchpoint intermediate, (S)-reticuline (Fig. 24.42).

In *Berberis*, the *N*-methyl group of (S)-reticuline is oxidized to form the berberine bridge carbon C-8 of (S)-scoulerine (see Fig. 24.41). The specific pathway from (S)-scoulerine that leads to berberine proceeds with O-methylation to (S)-tetrahydrocolumbamine. The 3-*O*-methyl moiety of tetrahydrocolumbamine is converted to the methylenedioxy bridge of canadine by canadine synthase, a cytochrome P450 enzyme. The final step in the biosynthesis of berberine is catalyzed by (S)-tetrahydroprotoberberine oxidase, an enzyme with a covalently bound flavin.

The berberine bridge enzyme and (S)-tetrahydroprotoberberine oxidase each consumes 1 mol of O₂ and produces 1 mol of H₂O₂ per mol of berberine formed. Overall, the course of reactions from 2 mol of L-tyrosine to 1 mol of berberine consumes 4 mol of S-adenosylmethionine and 2 mol of NADPH.

24.12.4 Enzymes of alkaloid biosynthesis are localized to specific subcellular compartments and cell types

Alkaloid biosynthetic enzymes can be localized within a cell to different compartments. The cytochrome P450 enzymes of alkaloid biosynthesis, for example, are associated with the endoplasmic reticulum, whereas methyltransferases are found mainly in the cytosol. Strictosidine synthase of monoterpene indole alkaloid biosynthesis is contained within the vacuole, and the berberine bridge enzyme and (S)-tetrahydroprotoberberine oxidase of berberine biosynthesis are compartmentalized in vesicles thought to be derived from the smooth endoplasmic reticulum; berberine accumulates in the central vacuole of the *Berberis* cell.

Another aspect of the structural organization of an alkaloid biosynthetic pathway is the formation of a metabolon, as evidenced in morphine biosynthesis (Fig. 24.43) with the physical interaction of salutaridine reductase and salutaridinol acetyltransferase. As with cyanogenic glycoside biosynthesis (see Section 24.8.2) and the core phenylpropanoid pathway (see Section 24.18.4), the metabolon facilitates the channeling of substrates, confers protection of chemically labile intermediates, regulates flux through a pathway, and interacts with a cellular structural element or organelle (to control the localization of the biosynthetic machinery).

Alkaloids are synthesized and accumulate in specialized cell types. Knowledge gained on enzymes and genes of alkaloid formation enabled analyses of the tissue and cell types involved for several classes of alkaloid, including monoterpene indole and morphinan alkaloids. Multiple cell types, including leaf epidermal cells, are necessary for the formation and storage of, for example, vindoline and catharanthine in *Catharanthus roseus* (Fig. 24.44). These cell types are not adjacent, implying transport of biosynthetic intermediates. This suggests that several levels of posttranslational regulation may control alkaloid formation. For example, biosynthetic enzymes may have to associate to form a multienzyme complex; intermediates may have to be transported between cell types, in some cases over long distances within a tissue.

The development of technologies for the analysis and quantitation of the contents of single cell types has aided elucidation of alkaloid biosynthetic pathways. Laser capture microdissection, a technique by which single cells are excised under a microscope with a laser and then captured in a microtube, greatly aided the discovery of genes of alkaloid biosynthesis in *C. roseus*. The captured cells can be extracted and analyzed for natural products by mass spectrometry, or the RNA in the cells can be sequenced using next-generation sequencing to yield gene expression profiles. Even more promising and exciting in metabolite analysis of single plant cells is MALDI imaging of intact tissue. This technology uses matrix-assisted laser desorption ionization (MALDI) mass spectrometry to scan tissue in two dimensions as the mass spectrum is recorded. Current laser resolution is approximately the diameter of a plant cell, allowing for cell specific metabolite analysis across tissues.

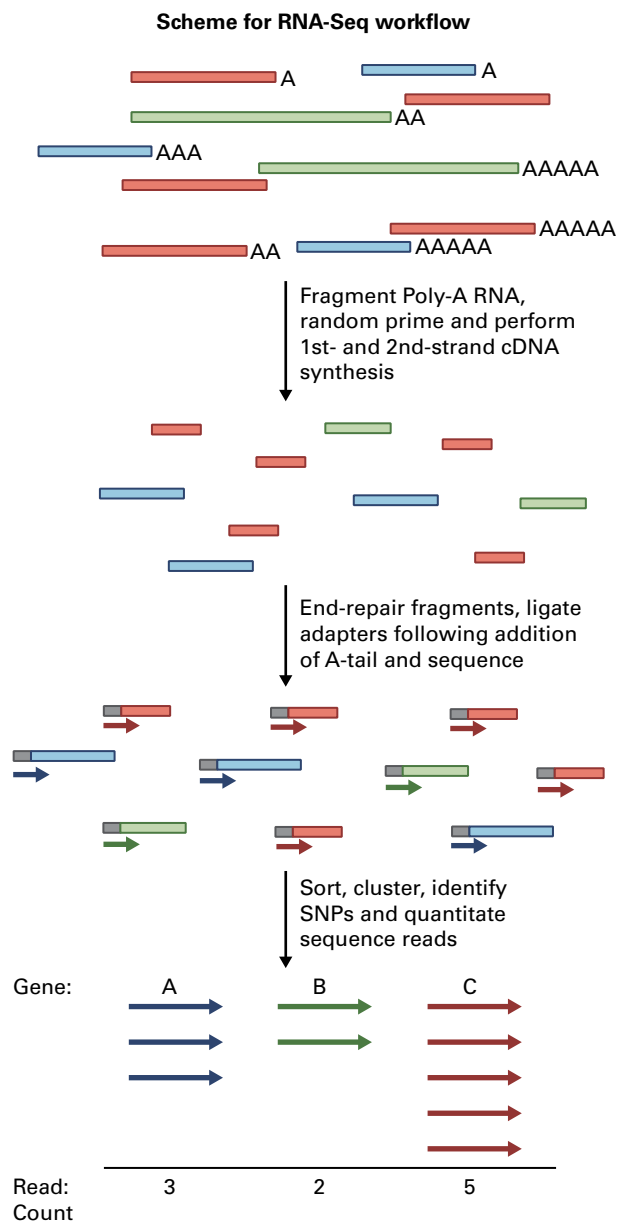

FIGURE 24.37 Deep transcriptome sequencing using next-generation sequencing technologies yields transcript sequences and quantitation of sequence reads that provide information on differential gene expression.

24.13 Biotechnological application of alkaloid biosynthesis research

24.13.1 Biochemical and molecular genetic techniques facilitate identification, purification, and production of useful alkaloids

The current status of the alkaloid branch of the field of natural products reflects the many advances in analytical chemistry, enzymology, and pharmacology. Only minimal quantities of a

FIGURE 24.38 Emetine formation was not well studied until the advent of transcriptome sequencing of plants. In a relatively short time, emetine biosynthesis has been nearly completely elucidated at the enzyme and cDNA levels, beginning with knowledge of the transcriptome. A hallmark of emetine formation is that permissive O-methyltransferases act at multiple positions along the biosynthetic pathway.

pure alkaloid are now necessary for elucidation of a complete structure by mass spectrometric and NMR spectroscopic analyses. Absolute stereochemistry can be assigned by determining the crystal structure. The pharmacological activities of crude plant extracts or pure substances are determined by fully automated systems, such that millions of data points are collected each year in industrial screening programs. The factor that limits the number of biological activities for which we can test is the number of available target enzymes and receptors. As more of the underlying biochemical bases for diseases continue to be discovered, the number of test systems will increase.

When a small quantity of an alkaloid of complex chemical structure from a rare plant is found to be physiologically active, it must first pass animal and clinical trials. If these are successful, enough material will be needed to satisfy market demand. The following studies demonstrate how alkaloid biosynthesis has been engineered to quantitatively and qualitatively alter alkaloid accumulation.

24.13.2 Atomic structures of alkaloid biosynthetic enzymes yield information on their reaction mechanisms

The first alkaloid biosynthetic enzyme for which the atomic structure was solved was strictosidine synthase (Fig. 24.45), which is active in monoterpene indole alkaloid formation and initiates the biosynthetic pathways that lead to approximately 2,000 plant compounds. Synthases are a heterogeneous class of enzymes that catalyze a wide variety of reactions; strictosidine synthase stereospecifically condenses an amine and aldehyde to form a Schiff base that cyclizes to a nitrogen heterocycle in a reaction called a Pictet–Spengler reaction.

The crystal structure of strictosidine synthase in complex with its natural substrates tryptamine and secologanin represents a novel six-bladed β -propeller fold in plant proteins (Fig. 24.45). A common repetitive motif of three hydrophobic

FIGURE 24.39 Strictosidine, the product of tryptamine and secologanin, is the precursor for many species-specific alkaloids.

residues followed by a small residue and a hydrophilic residue indicated by the structure-based sequence comparison suggests a possible evolutionary relationship between strictosidine synthase and several sequence-unrelated six-bladed β -propeller structures. The crystal structure of strictosidine in complex with its substrates has enabled the rational design of the enzyme to generate mutants that expand the natural

substrate specificity. This has resulted in the production of novel derivatives of monoterpene indole alkaloids produced by the native enzyme.

Since the crystallization of strictosidine synthase, a number of additional alkaloid biosynthetic enzymes have had their atomic structures solved. These include strictosidine glucosidase, vinorine synthase, raucaffricine glucosidase,

FIGURE 24.40 The biosynthesis of the antiarrhythmic monoterpene indole alkaloid ajmaline in *Rauwolfia serpentina* from tryptamine and secologanin is one of the best-understood alkaloid biosynthetic pathways. Several of the enzymes have been crystallized, and their atomic structures have been determined (Section 24.13.2).

perakine reductase, polyneuridine aldehyde esterase, and the first enzyme of morphine biosynthesis in the opium poppy to be crystallized, salutaridine reductase (Fig. 24.46).

24.13.3 Metabolic engineering of natural product pathways is the future of plant pharmaceutical biotechnology

Opium, known and used for its medicinal properties, is the air-dried latex (milky exudate) obtained by excision of *Papaver somniferum* capsules after petal fall while the capsules are still unripe (see Fig. 24.26). The exuded latex turns brown due to oxidation and can be scraped off the capsule and formed into a block of crude opium. Opium has been used for thousands of years as an analgesic, a narcotic, and a cough suppressant and has also been smoked for pleasure. Opium contains the morphinan class of alkaloids, which include the analgesic, antitussive drugs morphine and codeine (see Fig. 24.29).

In modern medicine, morphinan alkaloids, of which morphine is the main component, are purified from opium for the pharmaceutical industry. Owing to the commercial

importance of morphine and the opium poppy, the biosynthesis of morphine and the ability to metabolically engineer opium poppy have been intensely investigated. Morphine biosynthesis is completely understood at the enzyme level and nearly clarified at the gene level. Opium poppy has been transformed with a number of morphine biosynthetic genes, and regenerated plants have been tested in field trials in Tasmania, a major producer of opium poppy for the pharmaceutical industry.

Synthetic biology is a new area of biological research that combines science and engineering. Although many different definitions exist, synthetic biology is seen as the design and construction of new biological functions and systems not found in nature. It has been applied to the production of isoquinoline alkaloids in bacteria and yeast. Biosynthetic pathways that lead to the central isoquinoline alkaloid biosynthetic precursor, reticuline, have been constructed in *Escherichia coli* and *Saccharomyces cerevisiae* (Fig. 24.47). Genes specific to selected classes of isoquinoline alkaloids, such as the protoberberines, benzo[*c*]phenanthridines, and morphinans, were expressed in these systems and resulted in the accumulation of specific biosynthetic precursors of berberine, sanguinarine, and morphine. Yeast has also been engineered to convert thebaine into morphine and commercially relevant derivatives.

FIGURE 24.41 Biosynthesis of berberine from two molecules of L-tyrosine. SAM, S-adenosylmethionine; SAH, S-adenosylhomocysteine. (S)-reticuline functions as a branchpoint intermediate in the biosynthesis of tetrahydrobenzylisoquinoline-derived alkaloids (see Fig. 24.42).

FIGURE 24.42 (S)-Reticuline has been called the chemical chameleon. Depending on how the molecule is twisted and turned before undergoing enzymatic oxidation, a vast array of tetrahydrobenzylisoquinoline-derived alkaloids of remarkably different structures can be formed.

Synthetic biology is certain to play an important role in the production of commercially important alkaloids in the future.

The monoterpenoid indole alkaloid family is a structurally diverse group with established therapeutic importance and complex biosynthesis. The chemotherapeutic bisindole alkaloids vinblastine and vincristine of the Madagascar periwinkle (*Catharanthus roseus*) have been targets of biosynthetic and synthetic biology studies. Many of the enzymes and genes of vinblastine and vincristine biosynthesis have been identified and characterized. Using information provided by the atomic structure of strictosidine synthase, an enzyme was engineered to accept unnatural halogenated substrates and produce halogenated monoterpenoid indole alkaloids in transgenic *Catharanthus roseus* hairy root cultures. Bacterial

halogenases have been introduced into *Catharanthus roseus* cell- and hairy root cultures together with the modified strictosidine synthase to generate a synthetic system that accumulates halogenated monoterpenoid indole alkaloids of complex structure, such as 10-chloro-ajmalicine, 10-chloro-catharanthine and 15-chloro-tabersonine (Fig. 24.48).

The design of these alternative systems and optimized plants requires molecular manipulation, which in turn requires knowledge of alkaloid biosynthetic pathways at the enzyme level. Much progress has been made with selected alkaloids, but much remains to be discovered about the enzymatic synthesis of pharmaceutically important alkaloids such as camptothecin, colchicine, and quinine to name only a few examples. With the advent of next generation sequencing

FIGURE 24.43 The isolation and characterization of all of the enzymes of morphine biosynthesis is complete more than 200 years after the discovery of the alkaloid. Most of the cDNAs that encode enzymes of morphine biosynthesis have also been characterized. The discovery that mammals can also synthesize morphine has tremendous implications concerning the evolutionary development of the opiate receptor in animals and humans (see Box 24.9). Enzymes are color-coded to indicate that they can act at two points in the pathway, resulting in a metabolic grid between thebaine and morphine.

FIGURE 24.44 The biosynthesis of monoterpenoid indole alkaloids in the Madagascar periwinkle (*Catharanthus roseus*) involves multiple subcellular compartments and cell types. The cytochrome P450-dependent enzymes in the pathway (G10H, SLS, T16H) are associated with the endoplasmic reticulum. Strictosidine synthase (STR1) is vacuolar. O-Methyltransferases (such as LAMT and 16OMT) are typically localized to the cytosol, as are the acetyltransferase DAT and the oxoglutarate dependent dioxygenase D4H. The terpenoid biosynthetic intermediate geraniol is formed in the chloroplast, and the N-methyltransferase (NMT) is localized to the plastid. The biosynthetic pathway that leads to 10-hydroxygeraniol occurs in phloem parenchyma, while subsequent steps that lead to catharanthine and 16-methoxytabersonine are localized to leaf epidermal cells. Catharanthine is then transported to the cell surface by the ABC transporter CrTPT2, while 16-methoxytabersonine is transported to the mesophyll, where it is further modified and eventually transported into idioblast and laticifer cells, the sites of vindoline accumulation. The bisindole alkaloid vinblastine, which is formed by oxidative coupling of catharanthine and vindoline, is formed upon injury of leaf tissue by wounding or herbivory. G10H, geraniol 10-hydroxylase; LAMT, loganic acid O-methyltransferase; TDC, tryptophan decarboxylase; STR1, strictosidine synthase; SLS, secologanin synthase; SGD, strictosidine glucosidase; T16H, tabersonine 16-hydroxylase; 16OMT, 16-hydroxytabersonine 16-O-methyltransferase; NMT, 16-methoxytabersonine N-methyltransferase; DAT, deacetylvindoline O-acetyltransferase; D4H, desacetoxyvindoline 4-hydroxylase; ABC transporter, ATP-binding cassette transporter.

(Fig. 24.37) and single-cell analytics, the rate at which new biosynthetic genes are identified is certain to increase in the coming years.

As genes are isolated, we can anticipate that heterologous expression systems will continue to be developed in plant, bacterial, yeast, and insect cell culture systems to allow production of single enzymes and pathways for biomimetic syntheses of alkaloids. Our understanding of how the expression of alkaloid biosynthesis genes is regulated by elicitors or in specific tissues will also improve as the promoters of alkaloid biosynthetic genes are analyzed. The future will bring more genetically engineered microorganisms and eukaryotic cell cultures that produce alkaloids, metabolically engineered

plants with tailored alkaloid spectra and enzymatic synthesis of novel alkaloids through combinatorial biochemistry.

24.14 Phenolic compounds

24.14.1 Plants contain a remarkably diverse array of phenolic compounds

The transition of early vascular plants to a terrestrial habitat was successful in large part because of the development and elaboration of a diverse group of compounds known generally

FIGURE 24.45 The structure of strictosidine synthase (β -propeller fold) is shown in complex with strictosidine in stick presentation (gray). The six blades of the propeller are indicated by numerals, the four β -sheets of a blade by A, B, C, D, and the N- and C-termini by nitrogen and carbon. Structure-based sequence alignment reveals a common repetitive sequence motif that suggests an evolutionary relationship between strictosidine synthase and several sequence- and functionally unrelated six-bladed β -propeller structures that include diisopropylfluorophosphatase from *Loligo vulgaris*, brain tumor NHL domain, serum paraoxonase, and the low-density lipoprotein receptor YWTD domain.

as “phenolics.” Although the majority of phenolics are structural components of cell walls, a vast array are the toxins and antifedants of plant defense, coloring agents of flowers and fruits, aroma complement of plant organs (such as flower scents and fruit flavors), and antioxidants of wood, bark, and seeds. These and other functions performed by plant phenolics are essential for the continued survival of vascular plants.

Plant phenolics vary greatly in size and complexity, but all generally possess (or are derived from compounds that once possessed) an aromatic arene (phenyl) ring with at least one hydroxyl group attached (Fig. 24.49). The phenolic hydroxyl group is acidic compared to other hydroxyl groups because it resides on an arene ring, which can readily stabilize a deprotonated oxygen substituent. As a result, plant phenolics are reactive and well suited to being the building blocks of large polymers, such as lignins or suberins, and in the generation of a large number of compounds that play important roles in many aspects of plant biology.

Phenolic compounds can be classified in various ways, for example according to the functional groups attached to the phenol, or based on the number of phenol units in the molecule. Major subclasses of phenolic compounds include the flavonoids, anthocyanidins, isoflavones, chalcones, stilbenes, coumarins and furanocoumarins, monolignols and lignans, naphtha- and anthraquinones, and diarylheptanoids.

FIGURE 24.46 The core salutaridine reductase structure is highly homologous to other members of the short chain dehydrogenase/reductase family. The major difference is that the cofactor NADPH and the substrate-binding pocket are covered by a loop, on top of which lies a large “flap”-like domain. This configuration appears to be a combination of the two common structural themes found in other members of the short chain dehydrogenase/reductase family. The ribbon, colored from blue to red, indicates the progression of the amino acid chain from the N- to the C-terminus. The bound NADPH is represented by a stick figure. (1) The cofactor NADPH binds to the enzyme, (2) the flap over the catalytic site changes the conformation of the enzyme, and (3) the substrate salutaridine then enters the active site and reduction of the carbonyl moiety to a hydroxyl group occurs.

24.14.2 Evolution of phenolics helped plants overcome the challenges of a terrestrial environment

Phenolic compounds account for approximately 40% of organic carbon in plants and are derived primarily from **phenylpropanoid** and **phenylpropanoid-acetate** backbones (Fig. 24.50), although related biochemical pathways, such as those leading to “hydrolyzable” tannins, also contribute. The phenylpropanoid and phenylpropanoid-acetate pathways, discussed in more detail later in this chapter, produce products that ameliorate the challenges that faced early land plants. These challenges persist and provide selection pressure to maintain the phenylpropanoid pathway in plants (Table 24.2).

Evolution of the phenylpropanoid-acetate pathway, present in the most primitive of land plants as well as in many algae, helped overcome the first of these challenges, damaging UV irradiation, which was faced by plants even before they left the water. This pathway leads to production of a large and diverse class of compounds called **flavonoids**, which has more than 5,000 members. Flavonoids, such as quercetin

FIGURE 24.47 Bacteria and yeast have been engineered with a combination of plant and animal genes to produce isoquinoline alkaloids, such as the protoberberine alkaloid berberine and the aporphine alkaloid magnoflorine. Microbial production of the morphine precursor thebaine has not yet been achieved, but this is an attractive target due to commercial importance in the synthesis of pharmaceutically relevant opiates. Yeast has been engineered, however, to produce morphine from thebaine. MAO, Monoamine oxidase; NCS, norcoclaurine synthase; 6OMT, norcoclaurine 6-O-methyltransferase; NMT, coclaurine N-methyltransferase; 4' OMT, 3'-hydroxy-N-methylcoclaurine 4'-O-methyltransferase; BBE, berberine bridge enzyme; CYP719A1, canadine synthase; STOX, (S)-tetrahydroprotoberberine oxidase; CYP80G2, corytuberine synthase; CYP719B1, salutaridine synthase; SalR, salutaridine reductase; SalAT, salutaridine acetyltransferase. Single batch biosynthesis here means a co-culture of yeast and the bacterium *Escherichia coli*.

FIGURE 24.48 The product of the gene *rebH* from the antitumor agent rebeccamycin biosynthetic cluster in the soil bacterium *Lechevalieria aerocolonigenes* incorporates halogen in the conversion of *L*-tryptophan into 7-chlorotryptophan. *rebH* was introduced into root cultures of the medicinal plant *Catharanthus roseus* and resulted in the generation of novel halogenated monoterpene indole alkaloids. Source: O'Connor, John Innes Centre, Norwich, UK.

(Fig. 24.50), consist of a basic three-ring core structure that is modified to produce subclasses (Fig. 24.51), such as the anthocyanins (pigments), proanthocyanidins or condensed tannins (feeding deterrents and wood protectants), isoflavonoids (active in plant defensive and signaling), and flavones and flavonols (anti-inflammatory agents in animals). The most basic flavonoids—the flavones, flavonols, and flavanones—are widespread in the plant kingdom and typically absorb damaging UV rays.

The second challenge was a desiccating environment. This was overcome not only by development of cutin and the cuticle on the epidermis (derived from fatty acid pathways, see

FIGURE 24.49 Structure of phenol.

Chapter 9), but also by the advent of the phenylpropanoid pathway and development of a class of compounds known as **suberins** (see Chapter 8), which are mixed polymers of phenolic (more hydrophilic) and aliphatic (hydrophobic) moieties. Suberin plays a critical role in the periderm of roots and in bark by providing a hydrophobic barrier to prevent water loss. A major component of cork, it also provides a physical barrier that inhibits attack by pathogens.

The third challenge, the opposing forces of gravity and the need to grow taller to outcompete competitors for sunlight, was overcome by further elaboration of the phenylpropanoid pathway and development of **lignin** (see Chapter 2). Lignin is a crosslinked macromolecule made up of monolignol monomers (see Section 24.17). It provides the "cement" to cellulose's rod-like structure in specialized cell walls, such as fibers, tracheids, and vessels to enable plants to support their weight on land and transport water and minerals from roots to leaves, even in the tallest of trees.

Another challenge that plants continue to face is the need to deter herbivores and pathogens while maintaining a sessile growth habit. This has been achieved by elaboration of several other subclasses of compounds that provide a chemical defense by being antiherbivory, insecticidal, antifungal, bactericidal

FIGURE 24.50 Phenylpropanoid and phenylpropanoid-acetate skeletons and representative plant compounds based on those structures. Flavonoids, such as quercetin, typically have three interconnected rings at their core, the A, B, and C rings. Modifications to the C ring are responsible for creation of new classes of compounds, whereas modifications to the A and B rings lead to diversification within the compound class.

TABLE 24.2 Roles of phenolics against environmental challenges.

Challenge	Phenolic compounds	Pathway
UV irradiation	Flavonoids (anthocyanins, proanthocyanidins, condensed tannins, isoflavonoids, flavones, flavonols, etc.)	Phenylpropanoid-acetate
Desiccation	Suberins	Phenylpropanoid-fatty acid
Gravity	Lignins	Phenylpropanoid
Herbivores/pathogens	Stilbenes, coumarins, furanocoumarins	Phenylpropanoid-acetate
	Diarylheptanoids, gingerols, phenylphalenones, lignans, volatile aromatics	Phenylpropanoid-acetate
	Hydrolyzable tannins	Shikimate

FIGURE 24.51 Basic structures of phenylpropanoid-acetate-derived subclasses of flavonoids.

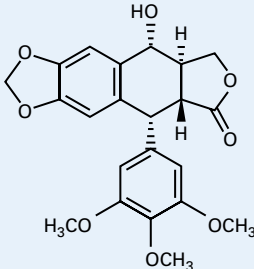

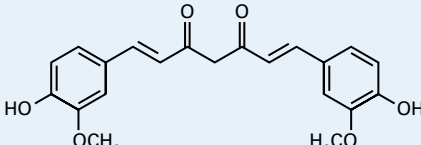

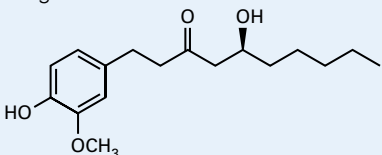

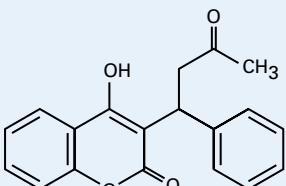

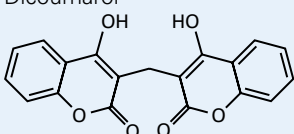

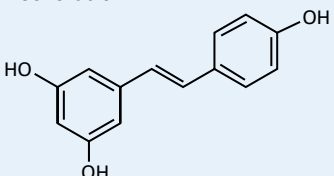

and bacteriostatic, allelopathic, or otherwise toxic in nature. As examples, the **stilbenes**, **coumarins**, and **furanocoumarins** are phenylpropanoid-acetate-derived compounds that discourage herbivory, inhibit seed germination, or deter bacterial or fungal pathogens. Some, such as resveratrol, also have important human health-enhancing properties (see Section 24.14.3).

Other phenylpropanoid-derived compounds, such as the **diarylheptanoids** and allies such as **gingerols** and **phenylphalenones**, impart colors, organoleptic properties, and medicinal value to humans (see Section 24.14.3), but also play defensive roles or act as pollinator or seed disperser attractants in diverse

groups of plants. **Lignans**, the dimers or higher order oligomers of monolignols, are not believed to share the extensive polymerization that occurs in lignins and suberins, are widespread throughout the vascular plants and serve mainly defensive roles by protecting against pathogens or acting as antioxidants in all plant tissues. **Volatile aromatics** derived from the phenylpropanoid pathway, such as phenylacetaldehyde and eugenol, function in pollinator attraction, seed dispersal, and protection from herbivory and pathogen attack. Such compounds also contribute to the aromas and flavors that make spices such highly prized plant products the world over.

TABLE 24.3 Societal uses of plant phenolics.

Phenolic compound	Plant source	Use
Lignans		
<p>Podophyllotoxin</p> 	May apple (<i>Podophyllum peltatum</i>)	Derivatized to form cancer-treating drugs
Diarylheptanoids		
<p>Curcumin</p> 	Turmeric rhizome (<i>Curcuma longa</i>)	Anti-inflammatory, pungent component of turmeric
<p>Gingerol</p> 	Ginger rhizome (<i>Zingiber officinale</i>)	Anti-inflammatory, pungent component of ginger
Coumarins		
<p>Warfarin</p> 	Synthetic derivative of dicoumarol	Anticoagulant
<p>Dicoumarol</p> 	Sweet clover (<i>Melilotus</i> sp.)	Anticoagulant produced by fermentation of sweet clover
Stilbenes		
<p>Resveratrol</p> 	Skins of red grapes (<i>Vitis</i> sp.)	Improves heart health, deters cancer development

*A large class of diverse polymeric compounds that are characterized by more than two carbonyl groups connected by single intervening carbon atoms.		

24.14.3 Phenolics are beneficial to humans

Human societies would not exist in their present form without the properties imparted by phenolic compounds (Table 24.3). Leather, which throughout early human history enabled more rapid transportation and thereby better trade (and war), has been produced for millennia by treating raw animal hides with “tannins,” either **gallate esters** or **condensed tannins** (see Section 24.16.2). The wheel was perfected because of the properties of wood, the strength and durability of which can be attributed to the lignin polymers and lignans, flavonoids, and hydrolyzable tannins. Much of the world relies on wood for building as well as a fuel to provide warmth; we are now turning to wood products as a source of lignocellulosic materials for biofuel production. As alternatives to dwindling natural resources are sought, plants, based in part on the phenolics that they contain, are among the best choices for renewable industrial feedstocks and materials.

Human health is also intimately tied to this class of compounds, as many medicinal compounds are derived or inspired by plant phenolics. Examples include the lignan **podophyllotoxin** from May apple (*Podophyllum peltatum*), which is derivatized to form teniposide, etoposide, and etophos, used to treat a number of cancers; the diarylheptanoid **curcumin** from turmeric (the curry spice), which has potent anti-inflammatory properties and is used worldwide to treat arthritis and other inflammatory diseases; and the stilbene **resveratrol** from red grapes and wine, which has been demonstrated to improve heart health and deter cancer development. The world is a healthier, more colorful, tasty, and fragrant place because of the phenolics that plants produce.

24.15 Phenolic biosynthesis

24.15.1 The phenylpropanoid and phenylpropanoid-acetate pathways share a common core phenylpropanoid pathway

As mentioned in the previous section, most phenolics originate from the phenylpropanoid and the phenylpropanoid-acetate pathways. Both the phenylpropanoid and phenylpropanoid-acetate pathways share the first three biochemical steps, the core **phenylpropanoid pathway** (Fig. 24.52). These steps begin with an L-phenylalanine precursor and end with the formation of 4-coumaroyl CoA, a reactive compound that can participate in further reactions that lead to the wealth of compounds that are the plant phenolics.

24.15.2 L-Phenylalanine is the precursor for most plant phenolics

The obvious choices for primary metabolites that might lead into these pathways are L-phenylalanine (Phe) and L-tyrosine (Tyr) (Fig. 24.53). Decades of research have established that L-Tyr, although it has a 4-hydroxyl group, is not the precursor of most plant phenolics. Numerous labeling studies, in which radiolabeled or stable isotopically labeled compounds were “fed” to plants to monitor formation of phenolics and incorporation rates of the labeled compounds, have shown that L-Phe is the preferred precursor in most cases. L-Phenylalanine is synthesized through the shikimate pathway (see Chapter 7).

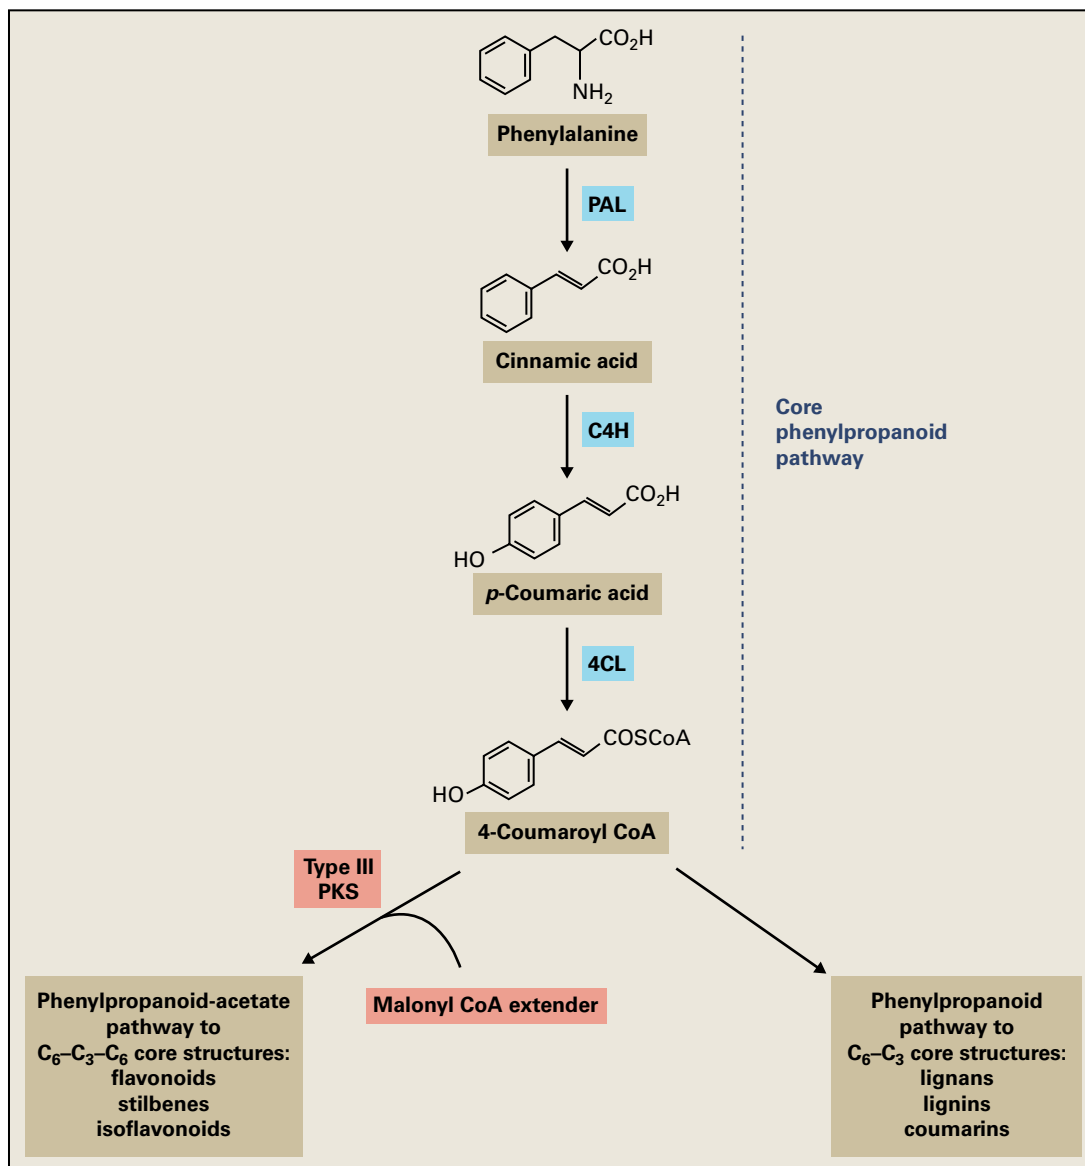

FIGURE 24.52 Overview of the biosynthetic pathways contributing to the production of several of the major subclasses of phenolic compounds in plants. Synthesis begins with L-phenylalanine and diverges into the phenylpropanoid-acetate and phenylpropanoid pathways. Both pathways share the first three steps, the core phenylpropanoid pathway, which ends with the formation of 4-coumaroyl CoA.

FIGURE 24.53 The aromatic amino acids phenylalanine and tyrosine are derivatives of the shikimic–chorismic acid pathway (see Chapter 7).

24.15.3 Phenylalanine ammonia lyase is the entry point enzyme to most plant phenolics

Phenylalanine ammonia lyase (PAL) catalyzes the first step in phenylpropanoid metabolism in which L-Phe undergoes deamination to yield *trans*-cinnamate and ammonia. The ammonia generated by PAL spontaneously becomes protonated in the cytosol to form NH_4^+ (Fig. 24.54).

PAL was one of the first enzymes identified, and is one of the best-studied in phenylpropanoid metabolism. The elucidation of the crystal structure of the PAL from parsley (*Petroselinum crispum*) has helped elucidate the function and regulation of this protein. A cytosolic protein, PAL belongs to

FIGURE 24.54 The nitrogen cycle present in cells is actively engaged in phenylpropanoid-acetate/phenylpropanoid metabolism. It prevents accumulation of ammonia and eliminates the requirement for N during phenolic synthesis. GOGAT, glutamine: α -ketoglutarate aminotransferase; L-Gln, glutamine; L-Glu, glutamate; α -KG, α -ketoglutarate; Fdx_{red} , reduced ferredoxin; Fdx_{ox} , oxidized ferredoxin.

the histidine ammonia lyase (HAL) gene family, which is widespread in plants, fungi, microbes, and animals. The enzymes in this family consist mostly of α -helices, exist as tetramers in solution, and require no exogenous cofactors.

Most PAL isoforms do not efficiently utilize any substrate other than L-Phe, supporting the role of L-Phe as the general precursor for the phenylpropanoid and phenylpropanoid-acetate pathways. Most plants have several PAL genes, ranging from four in *Arabidopsis thaliana* to close to two dozen in some rare instances, such as cultivated tomato (*Solanum lycopersicum*). These genes exist as a small gene family and are differentially expressed throughout plant development, leading to specific roles for specific PAL isoforms. In most plants, as in *Arabidopsis thaliana* and poplar (*Populus* sp.), all PAL isoforms utilize L-Phe almost exclusively, with L-Tyr being either a very poor substrate, or not a substrate. Different isoforms or gene family members appear to play different roles in the plant. For example, although PAL1, PAL2, and PAL4 from *A. thaliana* are believed to be involved in lignin biosynthesis, only PAL1 and PAL2 are thought to play a role in providing precursors for flavonoid and sinapate ester biosynthesis. PAL4 has no role in flavonoid biosynthesis; PAL3 has poor activity, and its actual role in the plant has not been established. PAL1 and PAL2 may act redundantly, or may play distinct roles under normal conditions, but they can substitute

for each other when either is mutated. Single knockout mutations in either have no apparent phenotype, but a double *pal1/pal2* mutation causes severe growth defects and dramatic reduction in lignin, flavonoid, and sinapate ester formation.

24.15.4 Conversion of L-Phe into cinnamate requires a subcellular nitrogen cycle

The availability of L-Phe can determine flux into the phenylpropanoid and phenylpropanoid-acetate pathways. The phenylpropanoid pathway contributes to the deposition of a large amount of organic carbon produced from the conversion of the amino acid L-Phe into cinnamate. An equimolar amount of nitrogen is released by PAL in the form of NH_4^+ (Fig. 24.54), which is toxic at high concentrations. Moreover, production of polymers such as lignin requires a very high demand for nitrogen. A nitrogen cycle within plant cells that utilizes glutamine synthetase and glutamate synthetase (GS and GOGAT; see Chapter 7) to produce glutamate ensures that sufficient flux through L-Phe is possible.

Glutamate is the amino donor in the reaction that forms aroenate from prephenate (Fig. 24.54). NH_4^+ is released by PAL in

the cytosol, but formation of aroenate occurs in the plastid, so transport of NH_4^+ is a critical component of this cycle; the transporter involved, however, has not yet been characterized.

24.15.5 Cinnamate-4-hydroxylase (C4H) is a membrane-bound cytochrome P450 monooxygenase that produces *p*-coumarate

The second enzyme in the core phenylpropanoid pathway is cinnamate 4-hydroxylase (C4H) (see Fig. 24.52), an ER membrane-bound cytochrome P450 monooxygenase that produces 4-coumarate (***p*-coumarate**). C4H, which belongs to the CYP73A class of P450 enzymes, typically exists as a single gene in most angiosperms, although some plants have one to three additional C4H-like enzymes. *Arabidopsis* has only one C4H, whereas the moss *Physcomitrella patens* has four CYP73A genes. C4H requires molecular oxygen and a cytochrome P450 reductase for activity, and is specific for *trans*-cinnamate. C4H is regiospecific as well, with hydroxylation only occurring at the 4-position (or *para* position) on the aromatic ring.

Because the carboxylate functional groups of both cinnamate and *p*-coumarate have a pKa value of 4, these two critical pathway intermediates exist as deprotonated forms under physiological conditions (hence use of the names cinnamate and *p*-coumarate instead of cinnamic acid and *p*-coumaric acid); because they are negatively charged under physiological conditions, these otherwise hydrophobic molecules remain soluble in the aqueous environment of the cell (solubilities of ≈ 3 mM and 165 mM, respectively, in water), making it possible for them to accumulate to high concentrations. However, both metabolomics based and targeted metabolite analyses have demonstrated that these molecules do not accumulate in most plant tissues and, if detectable, are found only at low concentration.

C4H has a high affinity towards *trans*-cinnamate (K_m of ≈ 10 μM). Other enzymes that utilize this substrate have a much higher K_m , such as cinnamate carboxymethyl transferase (125–200 μM). This differential substrate affinity effectively shunts metabolite flux toward *p*-coumarate unless or until C4H activity is reduced, thereby allowing for formation of alternative products. This type of regulation appears to be active in formation of volatile phenylpropanoids versus phenylpropanoid-acetate derived flavonoids in specific cell types, such as some glandular trichome secretory cells.

24.15.6 Coumarate CoA ligase (4CL) activates *p*-coumarate

The third enzyme of the core phenylpropanoid pathway, 4-coumarate CoA ligase (4CL, see Fig. 24.52), utilizes *p*-coumarate, ATP, and coenzyme A to form the CoA thioester

derivative, ***p*-coumaroyl-CoA**, a highly activated molecule that resides at a critical position in the greater plant metabolic network (Fig. 24.55). *p*-Coumaroyl-CoA is the substrate for chalcone synthase (CHS), the first committed step in the phenylpropanoid-acetate pathway, and for hydroxycinnamoyl transferase (HCT), the first committed step in the phenylpropanoid pathway to G lignin, S lignin, selected lignans, and volatile phenylpropenes. *p*-Coumaroyl-CoA is also precursor to a suite of other phenolic compounds that result from branches of the greater network, including the diarylheptanoids, phenylphalenones, hydroxycinnamyl amides, and coumarins (see Fig. 24.52).

Availability and competition for *p*-coumaroyl-CoA determine the abundance of entire classes of phenolic compounds. Thus, *p*-coumaroyl-CoA serves the function of a metabolic hub (see Section 24.18.4). The phenylpropanoid pathway, in fact, diverges from the phenylpropanoid-acetate pathway by differential utilization of the common hub intermediate, *p*-coumaroyl-CoA (see Section 24.16).

Plants contain a small family of 4CL genes; for example, *Arabidopsis* has seven 4CL and 4CL-like genes. Depending on the species, the corresponding enzymes have various substrate selectivities. The best-studied 4CL enzymes are from tobacco (*Nicotiana tabacum*), which has uncharacterized 4CL-like genes and four known 4CL genes, with slightly differing substrate selectivity.

24.16 The phenylpropanoid-acetate pathway

The phenylpropanoid-acetate and phenylpropanoid pathways diverge through differential utilization of *p*-coumaroyl-CoA (see Fig. 24.52 and Fig. 24.55). The phenylpropanoid pathway culminates in formation of compounds with a $\text{C}_6\text{-C}_3$ core, hence the term phenylpropanoid (see Fig. 24.50). These compounds include the monolignols, which are then used in the synthesis of lignins and the structurally and biosynthetically related lignans (see Section 24.17). The phenylpropanoid-acetate pathway, on the other hand, culminates in the formation of products that are built up of a $\text{C}_6\text{-C}_3\text{-C}_6$ core structure and include the flavonoids and diarylheptanoids (Fig. 24.56). Flavonoids were most likely the first complex phenolic compounds produced by plants; the monolignols, lignans, and lignins likely evolved later.

24.16.1 Products of the phenylpropanoid-acetate pathway are called polyketides, and plant polyketide synthases (PKSs) are the catalysts of polyketide diversity

Products of the phenylpropanoid-acetate pathway are called polyketides because of the manner in which they are synthesized. The pathway originated when type-III polyketide

FIGURE 24.55 *p*-Coumaroyl-CoA plays a central role in phenylpropanoid-acetate/phenylpropanoid metabolism, as illustrated by the great diversity of phenolic compounds to which it gives rise.

synthases (PKS) related to ketoacyl-ACP III (KAS III) of fatty acid synthesis (see Chapter 8) developed the ability to utilize a hydroxycinnamoyl-CoA ester molecule instead of acetyl-CoA. This CoA ester condensed with one or more molecules of malonyl-CoA, resulting in polyketides, which were then converted into chalcones and, ultimately, to more complex polyphenolic compounds, such as flavonoids and diarylheptanoids (see Section 24.16.2).

PKSs still utilize malonyl-CoA for elongation, as does the fatty acid synthesis pathway. The evolution of this one function, the ability to condense polyketides with an aromatic starter molecule, led to development of the UV and desiccation protection needed for plants to survive on land, and

indicates how even a minor mutation can have long-reaching effects on the biosphere.

In contrast to fatty acid synthases like KAS III (see Section 8.4.4), plant type-III PKSs are relatively small homodimeric enzymes (≈ 42 kDa per subunit) that utilize acyl-CoA esters instead of acyl-ACPs as substrates. Plant type III PKSs are typically named for the class of compounds that they produce. Chalcone synthase (CHS) (Figs. 24.56 and 24.57) and stilbene synthase (STS) (Fig. 24.57) are the best understood, with the former likely the first type-III PKS activity to evolve in plants.

All plant lineages can produce at least the most basic of flavonoid classes, the chalcones and flavanones (Figs. 24.51 and 24.56). Although the direct synthesis of chalcones

FIGURE 24.56 Biosynthetic pathways of specific flavonoid subclasses, including the chalcones, aurones, flavanones, and isoflavones (isoflavonoids). The enzymes involved (and their cofactors) are as follows: CHI, chalcone isomerase; AUS, aurone synthase; IFS, 2-hydroxyisoflavanone synthase (O_2 , cyt. P450, NADPH); IFD, 2-hydroxyisoflavanone dehydratase.

typically does not involve modification by other enzymes, some chalcone derivatives are reduced at specific positions in the synthesized aromatic ring (loss of hydroxyl groups), leading to deoxychalcones. In some plant groups, the coordinated action of CHS and an NADPH-dependent reductase generates a 6-deoxychalcone (**isoliquiritigenin**) as opposed to **naringenin chalcone**, which is the product of CHS working alone (Fig. 24.56). It is not known how or even if CHS and the reductase interact. Both isoliquiritigenin and naringenin chalcone can then be converted by aurone synthase, a polyphenol oxidase homolog, into **aurones**, such as **hispidol** and **areusidin**, a subclass of flavonoids that, as their name suggests, are bright yellow in color (Fig. 24.56).

While most type-III PKSs have CHS activity, a growing number of different activities (Box 24.11) produce di-, penta-, and heptaketides and an array of compound classes such as benzalacetones, stilbene carboxylates, pyrones, chromones, C-methylated chalcones, acridone alkaloids, diarylheptanoids, and gingerol-related compounds, as well as others (Fig. 24.57).

Subsequent to polyketide formation, diverse enzymes modify the core polyketide to produce the large array of compounds derived from the phenylpropanoid-acetate pathway.

These enzymes include NADPH-dependent reductases, prenyltransferases, and glycosyltransferases. The substrate specificity, with appropriate tissue-specific expression of these various enzymes, leads to the great diversity of species- and tissue-specific polyketides observed in the plant kingdom.

24.16.2 The phenylpropanoid-acetate pathway leads to synthesis of flavonoids, stilbenes, isoflavonoids, and coumarins

The flavonoids (including the isoflavonoids, catechins, condensed tannins, and other derivatives) are perhaps the best-studied group of phenylpropanoid-acetate derived compounds. They are also, along with the lignans, responsible for much of the diversity observed in compounds derived from L-Phe in the plant kingdom. Major classes of flavonoids include flavanones, flavones, isoflavones, isoflavanones, pterocarpan, dihydroflavonols, flavonols, leucoanthocyanidins (flavan-3,4-diols), anthocyanins, proanthocyanidins (including condensed tannins), phlobaphenes, and catechins (flavan-3-ols).

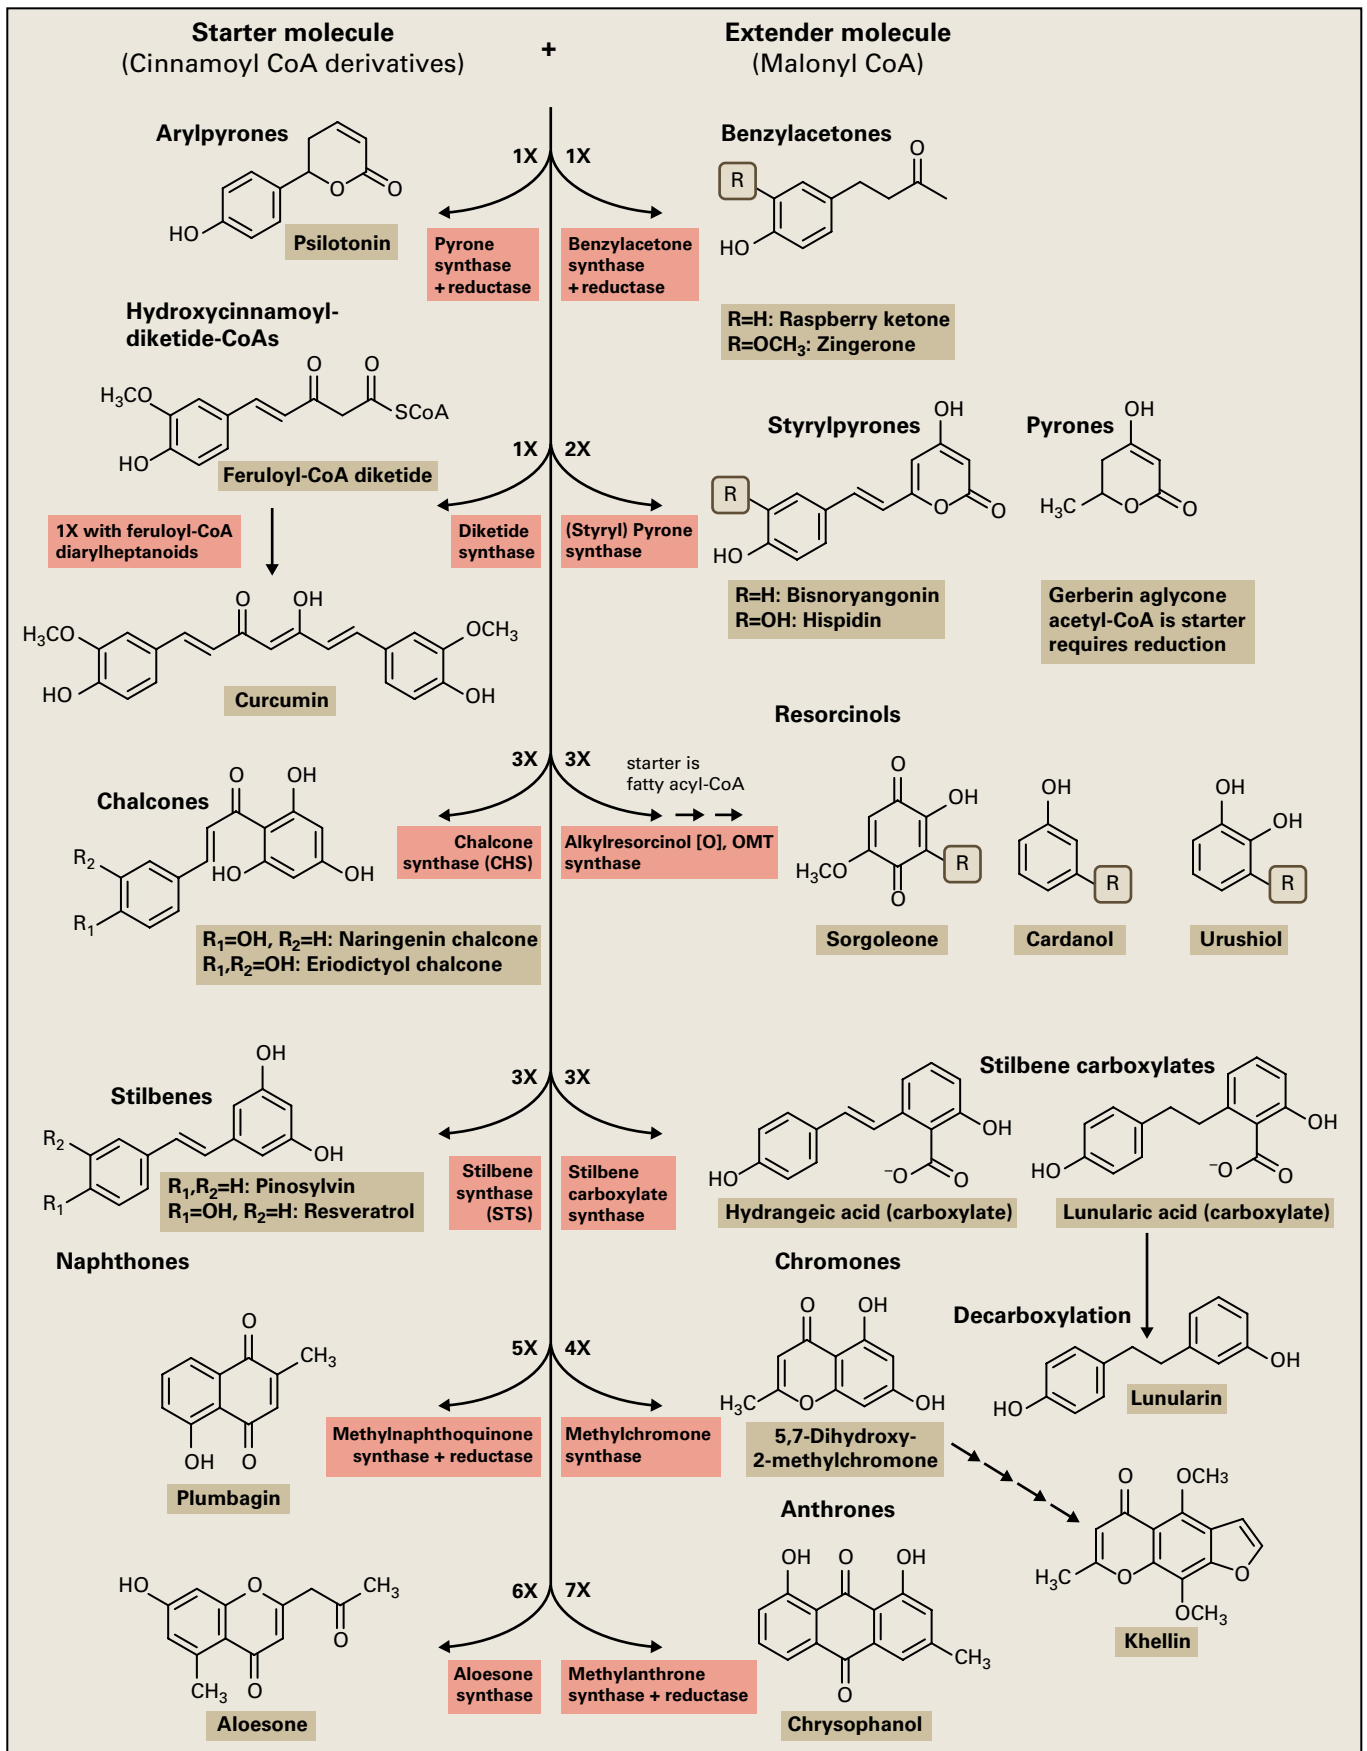

FIGURE 24.57 Biosynthesis of polyketide classes in plants, including benzylacetones and arylpyrones, methylpyrones and styrylpyrones, stilbene carboxylates, resorcylic acids, anacardic acids, resorcinols, urushiols, and cardanols, chromones, naphthoquinones, and anthrones. The designation 1X, 2X, 3X etc., refers to the number of molar equivalents of malonyl-CoA required. Some classes utilize acetyl-CoA or fatty acyl-CoA instead of hydroxycinnamoyl-CoAs as starter molecules, but still produce phenolic products.

BOX
24.11

Exotic polyketides result from a variety of starter molecules and condensations

Other polyketide-derived compounds are produced by type III PKS enzymes that belong to the CHS/STS family, but that differ from canonical CHS/STS enzymes in starter substrate or in the number of condensation reactions with malonyl-CoA (see Fig. 24.57). Additional modifications (such as methylations and glycosylations) lead to compound diversification within a class. Examples are given for the following classes with corresponding number of condensations: the benzylacetones and arylpyrones (e.g., **raspberry ketone**, **zingerone**, and **psilotonin**), one condensation; the methylpyrones and styrylpyrones (e.g., **gerberin aglycone**, and **hispidin**), two condensations; the stilbene carboxylates, resorcylic acids, anacardic acids, resorcinols, urushiols, and cardanols (e.g., **hydrangeic** and **lunularic acids**, **olive-tolic acid**, **6-nonadecyl salicylic acid**, **sorgoleone**, **pentadecylcatechol**, and **lunularin**), three condensations; chromones (e.g., **khellin**), four condensations; possibly

methylnaphthoquinones (e.g., **plumbagin**), five condensations; acetyl-methylchromones (e.g., **aloesone**), six condensations; and anthrones (e.g., **chrysophanol**), seven condensations.

Many products of the alternative PKS pathways are physiologically active. The anacardic and resorcylic acids, urushiols, and cardanols all have allergenic properties and are the active components responsible for the contact dermatitis caused by members of the Anacardiaceae (poison ivy, poison oak and poison sumac, all *Toxicodendron* species). Such compounds are also present at high levels in the sap of the lacquer tree (*Toxicodendron vernicifluum*), which oxidizes and polymerizes in the presence of moisture to form lacquer, used to form traditional Asian lacquer wares. Some alkylresorcinols, such as sorgoleone secreted from sorghum roots, possess potent allelopathic properties.

Flavonoids typically have three interconnected rings at their core (see Fig. 24.50). The A ring is derived from a hydroxycinnamoyl-CoA precursor (typically *p*-coumaroyl-CoA) (Fig. 24.58), and the B ring is formed by the condensation reactions involving malonyl-CoA in the active site of CHS. The C ring is formed by closure of the chalcone, leading to formation of flavanones. This latter reaction occurs spontaneously in aqueous solution, but is relatively slow and produces products that are racemic at C2. Most flavanones isolated from plants, on the other hand, possess the *S* configuration at C2. Chalcone isomerase (CHI) catalyzes the rapid and stereospecific formation of *S* flavanones (see Fig. 24.56), which are important branchpoint intermediates in the flavonoid pathway. Modifications to the C ring are responsible for creation of new classes of compounds, whereas modifications to the A and B rings lead to diversification within compound class. Thus, enzymes that modify the C ring are the most important for generation of diversity within the flavonoid class. This trend is repeated in the lignans, diarylheptanoids, and other phenolic classes.

After the core flavanone structure (such as naringenin) is formed by CHS and the C ring is closed by CHI, several important modifications can take place that lead to great structural diversity. Entry into the isoflavonoid pathway occurs by action of two enzymes (see Fig. 24.56). The first is a cytochrome P450, isoflavone synthase (IFS), which catalyzes an oxygenation and an unusual C-2 to C-3 aryl migration to yield the 2-hydroxyisoflavanones. Dehydration of the 2-hydroxyisoflavanones by the second enzyme, 2-hydroxyisoflavanone dehydratase (IFD), leads to the isoflavones, such as **genistein** and **daidzein**. The isoflavones can be further metabolized, primarily in the Fabaceae, to yield isoflavanones, such as (–)-**vestitone**, pterocarpan phytoalexins, such as (–)-**medicarpin** in alfalfa

(*Medicago sativa*) (Fig. 24.59), or rotenoids (e.g., **9-demethylmunduserone** from *Amorpha fruticosa*).

In a second major conversion, the flavanone C ring can be aromatized by the 2-oxoglutarate-dependent flavone synthase (FNS), to form an achiral class of compounds, the flavones (see Fig. 24.58). These are among the most primitive of the flavonoids, along with the dihydroflavonols and flavonols, and are found in the earliest vascular plants as well as nonvascular plants.

Another modification of flavanones involves oxygenation at position 3 (on the C ring) by a 2-oxoglutarate-dependent flavanone 3-hydroxylase (F3H) to form dihydroflavonols, such as dihydrokaempferol. The A ring can be further oxygenated by F3'5'H/CYP75A or F3'H/CYP75B to form compounds with higher orders of hydroxylation within this class (see Fig. 24.58). The C-ring keto group can be reduced by dihydroflavonol reductase (DFR) to form the leucoanthocyanidin class, which sits at another important branch point in the greater flavonoid biosynthetic network.

Leucoanthocyanidins (flavan-3,4-diols) are precursors for anthocyanins, flavan-3-ols (catechins), and condensed tannins (proanthocyanidins) (see Fig. 24.58). Anthocyanidin synthase (ANS), also called leucoanthocyanidin dioxygenase (LDOX), is a 2-oxoglutarate-dependent dioxygenase that catalyzes the formation of anthocyanidins, such as cyanidin, pelargonidin, and delphinidin (Fig. 24.60), from their leucoanthocyanidin analogs. A UDP-glucose dependent glucosyltransferase (UGT) then catalyzes the formation of the anthocyanins, colored compounds that are important constituents of flower petals, leaves, stems, and fruits and play roles in pollinator or seed disperser attraction.

In contrast to the brightly hued anthocyanins, the catechins (flavan-3-ols, see Fig. 24.58) are colorless. These compounds are thought to have human health benefits, and

FIGURE 24.58 The core flavonoid pathway includes two important “hub” metabolites, naringenin and apigenin, which lead to production of thousands of other metabolites in the flavone and other branches of flavonoid metabolism. Major enzymes (and their cofactors) are indicated that lead to compound class formation: FNS, flavone synthase (FNS I: 2-oxoglutarate, O_2 ; FNS II: O_2 , cytochrome P450, NADPH); F3H, flavanone 3-hydroxylase (α -ketoglutarate, O_2 , ascorbate, Fe(II)); FLS, flavonol synthase (α -ketoglutarate, O_2 , ascorbate, Fe(II)); DFR, dihydroflavonol 4-reductase (NADPH); ANS, anthocyanidin synthase (α -ketoglutarate, O_2 , ascorbate, Fe(II)); ANR, anthocyanidin reductase (NADPH); LAR, leucoanthocyanidin reductase (NADPH); UGT, UDP-glucose:flavonoid glucosyltransferase (UDP-glucose); OMTs, O-methyltransferases (AdoMet); BAHD-ATs, BAHD family acyltransferases. The A, B, and C rings of the flavonoid skeleton are indicated on naringenin, as is a standard numbering system.

FIGURE 24.59 Flavonoids perform diverse functions in alfalfa (*Medicago sativa*). The flavonoids apigenin and luteolin function as signaling molecules that induce *Nod* gene expression in compatible *Rhizobium* bacteria, facilitating the development of nitrogen-fixing root nodules (see Chapter 16). The phytoalexin isoflavonoid pterocarpin medicarpin participates in inducible plant defense.

FIGURE 24.60 Selected anthocyanin pigments: pelargonidin, cyanidin, and delphinidin from geranium, rose, and larkspur, respectively.

to have a role in plant defense. Especially well known are *epi*-gallocatechin 3-gallate (EGCG) from green tea and *epi*-catechin from cocoa, which impart strong antioxidant properties. Leucoanthocyanidin reductase (LAR) catalyzes the conversion of 2,3-*trans*-3,4-*cis*-leucocyanidins into (+)-flavan-3-ols, such as (+)-2,3-*trans*-catechin ((+)-catechin).

The catechins then serve as building blocks of the proanthocyanidins, along with the *epi*-catechins, which are formed from anthocyanidins by anthocyanidin reductase (ANR, see Fig. 24.58). The actual mechanism is yet to be determined whereby these compounds are polymerized to form the colored proanthocyanidins (condensed tannins, Fig. 24.61).

FIGURE 24.61 Red sorghum produces proanthocyanidin antifeedant compounds (condensed tannins) in its seed coat, which deter birds from feeding on the seed. White sorghum, which is deficient in these compounds, is rapidly consumed by birds. Similar compounds are present in many species.

Coumarins (e.g., coumarin; see Table 24.3) belong to a widespread family of plant metabolites called the benzopyranones, with more than 1,500 representatives in more than 800 plant species. Their roles in plants appear to be mainly defense-related, given their UV-screening-, germination inhibitory-, antimicrobial-, and antifeedant properties. The structures of representative simple coumarins, umbelliferone and scopoletin, are shown in Fig. 24.62. Additional families of plant coumarins (Fig. 24.63) include linear furanocoumarins (e.g., psoralen), angular furanocoumarins (e.g., angelicin), pyranocoumarins (e.g., seselin), and pyrone-substituted coumarins (e.g., 4-hydroxycoumarin). The carbons destined to form the furano- and pyrano- groups originate from a prenyl group that is attached to the simple coumarin core structure after the latter is produced from *p*-coumaroyl-CoA or feruloyl-CoA by the 2-oxoglutarate dependent dioxygenase, *p*-coumaroyl-CoA 2-hydroxylase (C2H). Again, *p*-coumaroyl-CoA serves as precursor to yet another large class of plant phenolics. Other modifications to coumarins are catalyzed by prenyltransferases, oxidases, and *O*-methyltransferases.

Coumarins present serious health threats and benefits. Ingesting coumarins from plants such as clover can cause massive internal bleeding in mammals. This discovery ultimately led to the development of the rodenticide, Warfarin (see Table 24.3) and to the use of related compounds (blood thinners) to treat and prevent stroke. These planar UV-absorbing molecules can intercalate into DNA helices, causing chromosomal breakages upon UV light activation, ultimately leading to cell death. In this manner, compounds such as the photosensitizing compound 8-methoxypsoralen, present in leaf tissue of *Heracleum mantegazzianum* (giant hogweed), can cause severe phytophotodermatitis (Fig. 24.64). Psoralen (see Fig. 24.63), on the other hand, is successfully used to treat various skin disorders (e.g., eczema and psoriasis) by combination of oral ingestion and UV-A treatment.

24.17 The phenylpropanoid pathway

The phenylpropanoid pathway diverges from the phenylpropanoid-acetate pathway by differential utilization of *p*-coumaroyl-CoA. It culminates in formation of monolignols, which are then used as intermediates in the synthesis of lignin and the structurally and biosynthetically related lignans (Fig. 24.65).

After cellulose, lignin is the most abundant biopolymer on Earth and accounts for roughly 20–30% or more of the carbon that is fixed by a plant. Lignin is a structural component of the plant cell wall. It appears that production of monolignols evolved later than phenolic compounds, produced by the phenylpropanoid-acetate pathway, as monolignols are not present in nonvascular plants.

Most plants produce only two hydroxycinnamates, *trans*-cinnamate and *p*-coumarate. It was originally believed that caffeate and ferulate were intermediates in the pathway that led to the monolignols. Caffeate and ferulate are, however, not core pathway intermediates—they are unusual phenylpropanoids that are only produced or accumulate in specific plant species, such as the mint family and the grasses, respectively.

24.17.1 The phenylpropanoid pathway culminates in formation of the monolignols

A *p*-coumaroyl-CoA molecule, destined for incorporation into compound classes such as lignins, lignans, and volatile phenylpropenes, is converted by cinnamoyl-CoA:NADPH oxidoreductase (CCR) to form *p*-coumaryl aldehyde. The latter is then transformed by cinnamyl alcohol dehydrogenase (CAD) into the monolignol, *p*-coumaryl alcohol, the precursor of H lignins, a large number of lignans, and certain volatile aromatics such as *t*-**anol**, **anethole**, and **methylechavicol** (see Section 24.17.3). CCR is a type B reductase that abstracts the pro-*S* hydride from behind the nicotinamide plane of NADPH during reduction; CAD, on the other hand, is a type A reductase that abstracts the pro-*R* hydride from in front of the nicotinamide plane (Fig. 24.66).

When other monolignols (such as **caffeyl alcohol**, **coniferyl alcohol**, **5-hydroxyconiferyl alcohol**, or **sinapyl alcohol**) are required, *p*-coumaroyl units are first transferred from *p*-coumaroyl-CoA to shikimate by hydroxycinnamoyl-CoA:shikimate hydroxycinnamoyltransferase (HCT) to form the ester, ***p*-coumaroyl-5-*O*-shikimate** (see Fig. 24.65). This is a regiospecific reaction, with only the 5-*O*-shikimate product being enzymatically formed.

HCT belongs to a subclade of the BAHD family of plant acyltransferases that includes several other hydroxycinnamoyl transferases involved in the production of secondary metabolites, such as **chlorogenic acid**, which is an ester of caffeic acid and quinate (see Fig. 24.65). Hydroxycinnamoyl-quinic acid transferase (HQT) functions as the chlorogenic acid synthase in plants such as apple and artichoke.

FIGURE 24.62 Most coumarins are produced from either *p*-coumaroyl-CoA or feruloyl-CoA (although some such as coumarin are produced from cinnamoyl-CoA). Conversion of the hydroxylated product of the coumarin synthase reaction (CoA ester or carboxylate) to the coumarin is spontaneous in aqueous solution. Major enzymes (and their cofactors) are indicated: F6H, feruloyl-CoA 6-hydroxylase/coumarin synthase [α -ketoglutarate, O_2 , ascorbate, Fe(II)]; C2H, *p*-coumaroyl-CoA 2-hydroxylase/coumarin synthase [α -ketoglutarate, O_2 , ascorbate, Fe(II)]; PT, dimethylallyl prenyltransferase; MS, marmesin synthase (O_2 , cytochrome P450, NADPH); PS, psoralen synthase (O_2 , cytochrome P450, NADPH); BS, bergaptol synthase (O_2 , cytochrome P450, NADPH); XS, xanthotoxol synthase (O_2 , cytochrome P450, NADPH); BOMT, bergaptol O-methyltransferase (AdoMet); CS, columbianetin synthase (O_2 , cytochrome P450, NADPH); and AS, angelican synthase (O_2 , cytochrome P450, NADPH).

Source: Photographs: Towers, University of British Columbia, Vancouver, Canada; previously unpublished.

The next reaction in the pathway to the monolignols is also highly substrate selective and is catalyzed by a cytochrome P450 enzyme of the CYP98A class called *p*-coumaroyl-5-*O*-shikimate 3'-hydroxylase (C3'H, see Fig. 24.65). Genetic experiments with the *ref8* mutation (defective in the *CYP98A3* gene) and detailed characterization of the *CYP98A3* gene product from *Arabidopsis thaliana* validated involvement in production of caffeoyl-5-*O*-shikimate. HCT (or a similar acyltransferase) then transfers the caffeoyl group back to CoASH. Thus, HCT appears to play two roles in the pathway. It is curious that plants would form the unusual shikimate ester as a transient intermediate in the pathway, only to return the more oxygenated hydroxycinnamoyl moiety back to CoASH for the next step in the pathway.

24.17.2 Monolignols are primarily converted into lignans and lignins

Monolignols are primarily converted into two distinct classes of plant metabolites, the lignans (dimers formed by phenolic oxidative coupling of coniferyl alcohol monomers) and the lignins (polymers formed by phenolic oxidative coupling of hydroxycinnamyl alcohol monomers; see Chapter 2),

although other products, such as volatile phenylpropenes (propenylphenols, allylphenols, and derivatives), are also derived from these intermediates. Most flux through the phenylpropanoid pathway in plants is directed to the production of lignins, which are structural components of cell walls. Free radicals participate in the reactions that produce both di- and oligomeric lignans and lignins as well as related complex plant polymers, such as those in suberized tissue.

Lignan dimers are found in ferns, gymnosperms, and angiosperms; higher oligomeric forms also occur. Lignans have a likely role in plant defense. Plicatic acid (Fig. 24.67), for example, is deposited in large quantity during heartwood formation in Western red cedar (*Thuja plicata*), thereby contributing to the color, quality and durability of this highly valued heartwood. Lignans are also used in human medicine. For example, podophyllotoxin (Fig. 24.67) is used to treat venereal warts, and its semisynthetic derivatives, teniposide, etoposide, and etophos are used in chemotherapy to treat a variety of cancers. Lignan formation favors *E*-coniferyl alcohol as the initial substrate, although other monolignols, allylphenols, and phenylpropanoid monomers can be used to a lesser extent.

Although the term **lignan** was initially coined to describe a class of dimeric phenylpropanoid (C_6C_3 - C_6C_3) metabolites linked by their 8-8' bonds, this definition has been expanded

FIGURE 24.65 Phenylpropanoid metabolism leading to production of the monolignols, p-coumaryl, coniferyl, and sinapyl alcohols, as well as to other (sub)classes of plant phenolics. Considerable revision of this network has taken place in the last 20 years. Instead of being a completely interconnected grid, it appears that only specific routes are available in most plant cells. Pathways not shaded are not universal, but can contribute to significant flux in certain species. Enzymes (and their cofactors) are as follows: PAL, phenylalanine ammonia lyase (MIO); cinnamate-4-hydroxylase (O_2 , cytochrome P450, NADPH); 4CL, 4-hydroxycinnamoyl-CoA ligase (ATP, coenzyme A [CoASH]); HCT, hydroxycinnamoyl-CoA:shikimate hydroxycinnamoyl transferase (shikimate); C3'H, p-coumaroyl-5-O-shikimate 3'-hydroxylase (O_2 , cytochrome P450, NADPH); CCoAOMT, caffeoyl-CoA O-methyl transferase (AdoMet); CCR, (hydroxy)cinnamoyl-CoA reductase (NADPH); CAldH, coniferylaldehyde 5-hydroxylase (O_2 , cytochrome P450, NADPH); CAD, (hydroxy)cinnamyl alcohol dehydrogenase (NAD^+); Hcaldh, hydroxycinnamaldehyde dehydrogenase (NAD^+); COMT, "caffeic acid" O-methyltransferase (AdoMet); ODD, 2-oxoglutarate-dependent dioxygenase (α -ketoglutarate, Fe(II), ascorbate); HQT, chlorogenic acid synthase/hydroxycinnamoyl-CoA:quinic acid hydroxycinnamoyl transferase (quinic acid); CYP98A class, cytochrome P450 involved in production of chlorogenic acid, related to C3'H; SmF5H and SmCOMT, multifunctional P450 and OMT, respectively, involved in monolignol formation in the moss *Selaginella moellendorffii*, not found yet in other plants.

FIGURE 24.66 The stereospecificity of a type B oxidoreductase, NADPH-dependent cinnamoyl-CoA reductase (CCR), and a type A oxidoreductase, cinnamyl alcohol dehydrogenase (CAD). H_A , pro-R (the hydrogen projecting upwards from the A-face of the nicotinamide ring, that is, out from the plane of the page); H_B , pro-S (the hydrogen projecting upwards from the B-face of the nicotinamide ring, i.e., behind the plane of the page). R, adenine nucleotide diphosphate.

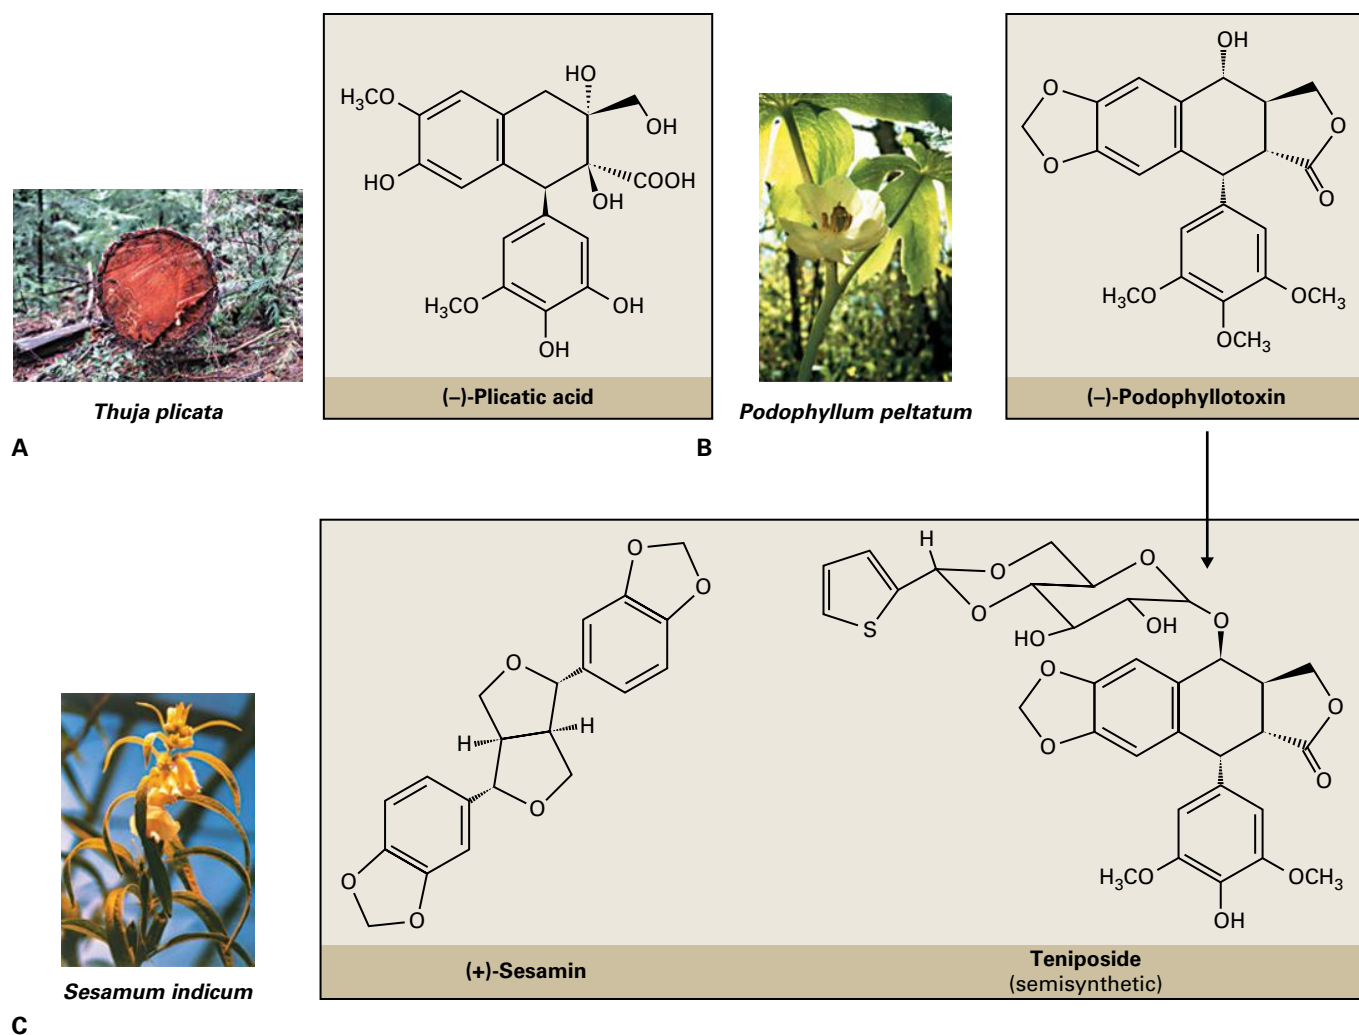

FIGURE 24.67 Examples of 8-8'-linked lignans. (A) Plicatic acid accumulates to 3% of the dry weight of the heartwood in western red cedar. This and related compounds enable such species to survive for more than 3,000 years. (B) Podophyllotoxin, from *Podophyllum* species, such as the may apple. The teniposide, etoposide, and etophos derivatives of this compound are used in treatment of certain cancers. (C) Sesamin, from sesame seed, has antioxidant properties that prevent sesame oil from turning rancid during storage.

FIGURE 24.69 Isoeugenol, an allylphenol.

to include all monolignol-derived dimers and higher order oligomers, regardless of linkage type (e.g., 8-O-4'-linked, 8-5'-linked and 8-1'-linked dimers, Fig. 24.68) that do not serve the structural role of the lignins. Subclasses of lignans, called **neolignans**, have similar linkages, but are derived from allylphenol compounds, such as isoeugenol (Fig. 24.69). **Norlignans** ($C_6C_3-C_6C_2$) are thought to be derived from coupling of a hydroxycinnamic acid to either a monolignol or an allylphenol, with subsequent loss of the carboxyl group during coupling. Although several thousand lignans, neolignans, and norlignans are known in nature, relatively few coupling modes have been encountered.

Lignans are most often found in enantiomerically pure or enriched form in plants. The dimers are produced in plants when two monolignol radicals formed by proteins such as laccases or peroxidases are brought into close proximity in

the “active site” of a directing or **dirigent protein**, which has no catalytic activity of its own, but directs the orientation of the reacting monolignol (most commonly *E*-coniferyl alcohol) radicals in a stereoselective manner so that only one enantiomeric product is typically formed (Fig. 24.70). For example, the particular optical form of pinoresinol that is formed varies with the plant species in question: whereas forsythia (*Forsythia* sp.) stem produces (+)-pinoresinol, flax (*Linum* sp.) seed produces (–)-pinoresinol. Once formed, pinoresinol can then undergo a variety of conversions, depending on the plant species (Fig. 24.71). The *Arabidopsis* genome encodes about a dozen dirigent proteins, some of which are involved in lignan production.

24.17.3 Plant volatiles are derived from the phenylpropanoid pathway

Four groups of related volatile compounds of particular interest are derived from phenylpropanoid-pathway intermediates. These are represented by compounds such as the benzoates benzylbenzoate, benzylacetate, and methylbenzoate; the phenylpropenes derived from eugenol, methyleugenol, methylchavicol, isoeugenol, *t*-anol and anethole (also referred to as allylphenol- and propenylphenol-derived compounds, see Table 24.3); cinnamaldehyde and methylcinnamate; and vanillin. All are important components of floral scents and/or of important spices such as cloves, cinnamon, anise, sweet basil, and vanilla bean.

These volatile compounds are derived from intermediates in the core phenylpropanoid or phenylpropanoid pathways

FIGURE 24.70 Proposed biochemical mechanism accounting for stereoselective control (regio- and stereochemistry) of E-coniferyl alcohol coupling in *Forsythia* species. The particular enantiomer of pinoresinol formed can vary with plant species.

Source: Photograph: L.B. Davin, Washington State University, Pullman; previously unpublished.

(Fig. 24.72). The benzonates are derived from cinnamyl-CoA esters and the monolignol pathway (Fig. 24.72). Methylcinnamate is derived directly from cinnamate via the action of a SABATH carboxymethyltransferase called CCMT. The phenylpropenes are derived from the monolignols via action of a BAHD acyltransferase (CCAT/CFAT) that yields

the corresponding acetyl ester, which is then reduced by a member of IFR/PLR family of NADPH-dependent reductases (EGS or IGS) to yield eugenol, chavicol, isoeugenol or *t*-anol. These are further modified by cytochrome P450 enzymes and *O*-methyltransferases to a variety of structures (such as safrole, isosafrole, and myristicin; Fig. 24.72).

FIGURE 24.71 Proposed biochemical pathway to the various 8-8'-linked lignan classes in Forsythia, western red cedar (*Thuja plicata*), and *Podophyllum* species. Similar pathways exist in many other species.

24.18 Universal features of phenolic biosynthesis

24.18.1 Phenolic biosynthesis requires significant methylation

Despite being called phenolics or even polyphenolics, which implies the presence of free hydroxyl groups on aromatic rings, most compounds produced by the combined phenylpropanoid/phenylpropanoid-acetate pathways contain methylated hydroxyl groups (methoxy groups), and some contain methylated carboxyl groups (methyl esters). Indeed, some compound classes, such as lignans and flavonoids, are highly methoxylated, with methyl groups accounting for up to one fourth of the carbon in some molecules. As a result, the cells

that produce such compounds have a very high demand for the general enzyme cofactor for methylation, *S*-adenosylmethionine (see Chapter 7).

Production of methylated phenolics requires the availability of enzymes catalyzing their formation. A large superfamily of methyltransferases has been characterized in detail; specific subfamilies are involved in methylation of specific types of functional groups. Most members of what has been called the SABATH family of carboxymethyltransferases (named after the first three enzymes identified in the gene family, salicylic acid, benzoic acid, and theobromine methyltransferases) typically methylate carboxyl groups to produce methyl esters. The majority of methylation reactions involved in formation of plant phenolics, however, are catalyzed by *O*-methyltransferases (OMTs). Most OMTs have limited substrate selectivities, although some enzymes, such as COMT ("caffeic acid" OMT), are promiscuous, which can lead to difficulties delineating biosynthetic pathways.

FIGURE 24.72 *Trans*-cinnamate, a monolignol derived from the core phenylpropanoid pathway (Fig. 24.52), is converted to a large number of volatile phenolics.

24.18.2 Phenolic biosynthesis has a high demand for sugar moieties

Many or most of the naturally occurring plant phenolics are also modified by addition of saccharide (sugar) moieties. Many flavonoids are highly glycosylated, with the number of carbon atoms in the sugar additions often outnumbering the carbon atoms in the flavonoid core. The same is likely true for compounds of the lignan class. In contrast, the hydrolyzable tannins (see Fig. 24.73)

have sugar moieties as their core, with addition of gallate or other modified benzoates to increase diversity of structure.

The sugar moieties often impart important properties to these molecules. For example, glycosylated flavonoids are more soluble in an aqueous environment than their aglycone counterparts, and it is the former that accumulate to high levels in plant vacuoles. In addition, the bitterness associated with compounds such as **naringin** (see Fig. 24.74) is eliminated when its sugar moieties are removed, leaving an aglycone with essentially no organoleptic effect.

FIGURE 24.73 The shikimate-derived skeleton (A) forms the core of gallic acid (B), a component of hydrolysable tannins, including castalagin, the core sugar moiety of which is shaded (C), from chestnut (*Castanea sp.*, D).

Source: (D) Davin, Washington State University, Pullman; previously unpublished.

FIGURE 24.74 The flavonone glycoside naringin. In grapefruit (*Citrus x paradisi*), this flavonoid gives the juice its bitter taste.

24.18.3 Oligomers and mixed molecules are common

Lignins and suberins are not the only plant phenolics that are polymerized. Condensed tannins and oligolignans have various solubilities due to their variable states of polymerization. Proanthocyanidins with polymerization numbers in the 20s are common, as are oligolignans with varying degrees of polymerization. Other polyflavonoids are common, as are

mixed flavonoid/lignan dimers/oligomers. In many instances, these compounds are again of specific absolute configurations, not being found in racemic form; a whole suite of enzymes that are involved in such dimer-/polymerization reactions are yet to be discovered.

24.18.4 Metabolons, modularity and metabolic bowties have a role in the biosynthesis of phenolics

It has long been debated whether the first three enzymes in the core phenylpropanoid pathway are associated in a metabolon (see Sections 24.8.2 and 24.12.4). Evidence for metabolon formation in the early steps of the phenylpropanoid pathway includes colocalization of PAL and 4CL on the ER in apparent close proximity to C₄H, as well as measurements of flux through these early steps in some cell systems that exceed what would be expected based on the catalytic properties and diffusion rates of the enzymes and intermediates measured in a cell-free system. Assembly of the enzymes

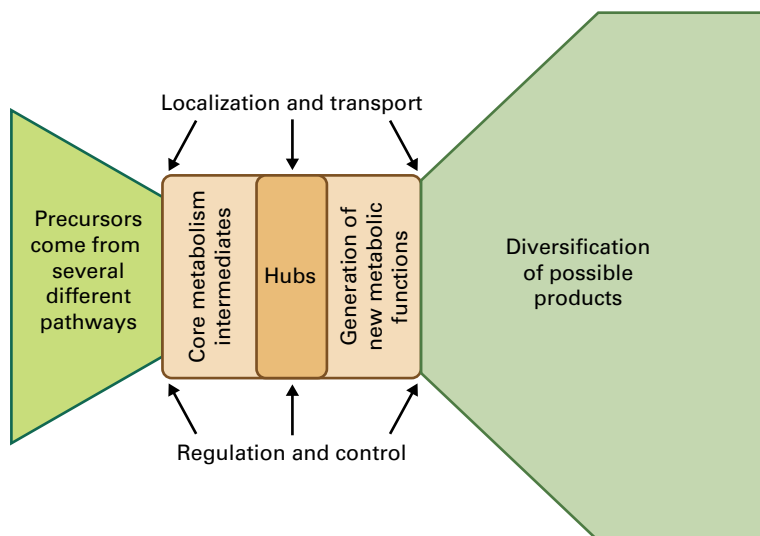

FIGURE 24.75 Modularity and bowties are organizational features in plant specialized metabolism that include central hub metabolites, such as *p*-coumaroyl-CoA.

of the core phenylpropanoid pathway could explain how individual plant cells differentially regulate the production of lignin precursors while simultaneously producing flavonoids under different regulatory regimes.

Another organizational principle recognized in plant metabolism in recent years, which appears to be a contributing factor in the phenylpropanoid-acetate/phenylpropanoid metabolic network, is modularity. Modularity occurs when metabolism is organized into a system that resembles “bow-ties.” In such a system, selected intermediates act as hubs to connect one part of metabolism to another, and allow for great diversification in biochemical capacity (Fig. 24.75). In the phenylpropanoid-acetate and phenylpropanoid pathways, several hub molecules are clearly indicated, including *p*-coumaroyl-CoA, naringenin chalcone (flavanone), apigenin (flavone), and the monolignols (especially coniferyl alcohol). These compounds occupy key branch points that allow partitioning of one metabolite into multiple downstream pathways as a result of the action of multiple enzymes on each individual hub intermediate.

In this system, the entire phenolic biosynthetic system in plants is highly modular. Different metabolic outcomes occur in particular cells by different pathways “plugging in” to the greater phenylpropanoid/phenylpropanoid-acetate network at specific points. Partitioning between these pathways is controlled by the kinetic parameters of the enzyme that acts on the hub intermediate. Modularity thus allows for regulation of phenolic biosynthesis in a given cell, tissue, or plant.

24.19 Evolution of secondary pathways

Plants adapt to the environment by diversifying in various ways. This diversification can be reflected at the chemical level in the plethora of natural products that are produced in a species-specific manner. Selected examples of this chemical diversity have been presented in detail in the preceding

sections of this chapter. Plant speciation is also linked to chemical diversification.

How do new metabolic pathways in plants evolve? As we understand more about the genes of natural product biosynthesis, a common theme has arisen that is centered on gene duplication and diversification. Those duplication and diversification events that impart fitness are then maintained through natural selection, and genes for a given secondary pathway can be either distributed throughout the plant genome or clustered. An insufficient number of plant genome sequences has been determined to date to know which of these two pathway organizations occurs most frequently.

Clustering of pathway genes may allow inheritance of the defense trait as a single functional unit. In pathways with toxic intermediates, clustering would reduce the likelihood of its disruption by segregation. At the chromatin level, clustering may also allow coordinated expression of all pathway genes. Recent advances in plant genomics and systems biology have yielded the first insights into pathway evolution in plant metabolism.

There are multiple examples of clustering of secondary pathway genes in plants. Unlike clustered microbial secondary pathways, these plant counterparts are not located in operons, but rather each gene is associated with a unique promoter. The first example of plant secondary pathway gene clustering was discovered in maize (*Zea mays*). The clustered biochemical pathway that leads to the benzoxazinones in maize was viewed as unusual at the time, but as more draft genomes are assembled, examples emerge of clustered pathways that lead to triterpenes in oat (*Avena sativa*), triterpenes in *Arabidopsis*, diterpenes in rice (*Oryza sativa*), cyanogenic glucosides in lotus (*Lotus* sp.), cassava (*Manihot esculenta*), and sorghum (*Sorghum* sp.), alkaloids in opium poppy (*Papaver somniferum*) and steroid alkaloids in tomato (*Solanum lycopersicum*). In addition, preliminary analyses of other genomes suggest that gene clusters may be present in moss, rice, and cucumber (*Cucumis sativus*). Clustering will facilitate both pathway elucidation based on signature genes and the discovery of novel plant natural products.

Summary

One of nature's greatest assets is the diversity of life forms. Although we have cataloged a large number of plant species in herbaria, we have only just begun to analyze and understand the wealth of chemical diversity that these plants produce and utilize. These chemicals constitute a largely untapped reservoir of biologically active molecules that have potential application in the emerging bioeconomy in agriculture, human health, and as renewable bioproducts for energy and manufacturing.

Although there are approximately 400,000 species of flowering plants on our planet, mankind derives 95% of food and energy needs from only 30 of these species. During human history, however, 7,000 plant species have been cultivated for consumption. A larger number, some 20,000, have been used as medicines, attesting to the unique chemical composition of plants. Plant chemicals did not, however, evolve to meet human needs. These chemicals have roles in the communication of the plant with the environment, as well as functions in plant physiology. They contribute to the fitness of the plant under varying biotic and abiotic conditions. Many answers to

current, and future, societal challenges will be found in plant chemical diversity. We need only to better understand the composition of that chemical diversity, the environmental conditions that regulate it, the role played in plant fitness, and the collection of genes that underlie formation and storage of this veritable treasure trove.

Advances made in the field of plant natural products in the past decade have led to a better understanding of the intricate roles played in plant function and the interaction with the environment. We now appreciate more the *raison d'être* of plant natural products, however, we need to better understand how and where they are made and stored, why and how this biosynthesis is regulated, to fully exploit these molecules. We need more detailed knowledge of the repertoire of natural products in the plant kingdom in varying environments. With robotics and bioinformatics, the next decade of plant science will surely bring rapid advances to our understanding of how plants react to and interact with their environment. An important part of these interactions will certainly involve plant natural products.
