Library of Congress Cataloging-in-Publication Data are available.

Paperback ISBN: 9780470714218

Hardback ISBN: 9780470714225

A catalogue record for this book is available from the British Library.

Wiley also publishes its books in a variety of electronic formats. Some content that appears in print may not be available in electronic books.

Cover image: The illustration on the cover shows a fluorescence image of an *Arabidopsis* epidermal cell depicting the localization of cellulose synthase (CESA, green) and microtubules (red). The overlying graphic shows how the synthesis of a cellulose microfibril (yellow) is related to the CESA complex, portrayed as a rosette of six light green particles embedded in the plasma membrane that are attached to a microtubule by a purple linker protein (CS11). Fluorescent image courtesy of Chris Somerville and Trevor Yeats, Energy Biosciences Institute, University of California, Berkeley.

Cover design by Dan Jubb.

Complex illustrations by Debbie Maizels, Zoobotanica Scientific Illustration.

Set in 10/12pt Minion by SPi Global, Pondicherry, India

BRIEF CONTENTS

I COMPARTMENTS

- 1 Membrane Structure and Membranous Organelles 2
- 2 The Cell Wall 45
- 3 Membrane Transport 111
- 4 Protein Sorting and Vesicle Traffic 151
- 5 The Cytoskeleton 191

II CELL REPRODUCTION

- 6 Nucleic Acids 240
- 7 Amino Acids 289
- 8 Lipids 337
- 9 Genome Structure and Organization 401
- 10 Protein Synthesis, Folding, and Degradation 438
- 11 Cell Division 476

III ENERGY FLOW

- 12 Photosynthesis 508
- 13 Carbohydrate Metabolism 567
- 14 Respiration and Photorespiration 610

IV METABOLIC AND DEVELOPMENTAL INTEGRATION

- 15 Long-Distance Transport 658
- 16 Nitrogen and Sulfur 711
- 17 Biosynthesis of Hormones 769
- 18 Signal Transduction 834
- 19 Molecular Regulation of Reproductive Development 872
- 20 Senescence and Cell Death 925

V PLANT ENVIRONMENT AND AGRICULTURE

- 21 Responses to Plant Pathogens 984
- 22 Responses to Abiotic Stress 1051
- 23 Mineral Nutrient Acquisition, Transport, and Utilization 1101
- 24 Natural Products 1132

About the Companion Website xvi

I COMPARTMENTS

1 Membrane Structure and Membranous Organelles 2

Introduction 2

- 1.1 Common properties and inheritance of cell membranes 2
 - 1.2 The fluid-mosaic membrane model 4
 - 1.3 Plasma membrane 10
 - 1.4 Endoplasmic reticulum 13
 - 1.5 Golgi apparatus 18
 - 1.6 Exocytosis and endocytosis 23
 - 1.7 Vacuoles 27
 - 1.8 The nucleus 28
 - 1.9 Peroxisomes 31
 - 1.10 Plastids 32
 - 1.11 Mitochondria 39
- Summary 44

2 The Cell Wall 45

Introduction 45

- 2.1 Sugars are building blocks of the cell wall 45
 - 2.2 Macromolecules of the cell wall 51
 - 2.3 Cell wall architecture 73
 - 2.4 Cell wall biosynthesis and assembly 80
 - 2.5 Growth and cell walls 90
 - 2.6 Cell differentiation 99
 - 2.7 Cell walls as sources of food, feed, fiber, and fuel, and their genetic improvement 108
- Summary 110

3 Membrane Transport 111

Introduction 111

- 3.1 Overview of plant membrane transport systems 111
 - 3.2 Pumps 120
 - 3.3 Ion channels 128
 - 3.4 Cotransporters 142
 - 3.5 Water transport through aquaporins 146
- Summary 148

4 Protein Sorting and Vesicle Traffic 151

Introduction 151

- 4.1 The cellular machinery of protein sorting 151
 - 4.2 Targeting proteins to the plastids 153
 - 4.3 Targeting proteins to mitochondria 157
 - 4.4 Targeting proteins to peroxisomes 159
 - 4.5 Transport in and out of the nucleus 160
 - 4.6 ER is the secretory pathway port of entry and a protein nursery 161
 - 4.7 Protein traffic and sorting in the secretory pathway: the ER 175
 - 4.8 Protein traffic and sorting in the secretory pathway: the Golgi apparatus and beyond 182
 - 4.9 Endocytosis and endosomal compartments 188
- Summary 189

5 The Cytoskeleton 191

Introduction 191

- 5.1 Introduction to the cytoskeleton 191
 - 5.2 Actin and tubulin gene families 194
 - 5.3 Characteristics of actin filaments and microtubules 196
 - 5.4 Cytoskeletal accessory proteins 202
 - 5.5 Observing the cytoskeleton: Statics and dynamics 207
 - 5.6 Role of actin filaments in directed intracellular movement 210
 - 5.7 Cortical microtubules and expansion 216
 - 5.8 The cytoskeleton and signal transduction 219
 - 5.9 Mitosis and cytokinesis 222
- Summary 238

CELL REPRODUCTION

6 Nucleic Acids 240

Introduction 240

- 6.1 Composition of nucleic acids and synthesis of nucleotides 240
- 6.2 Replication of nuclear DNA 245
- 6.3 DNA repair 250
- 6.4 DNA recombination 255
- 6.5 Organellar DNA 260
- 6.6 DNA transcription 268
- 6.7 Characteristics and functions of RNA 270
- 6.8 RNA processing 278

Summary 288

7 Amino Acids 289

Introduction 289

- 7.1 Amino acid biosynthesis in plants: research and prospects 289
- 7.2 Assimilation of inorganic nitrogen into N-transport amino acids 292
- 7.3 Aromatic amino acids 302
- 7.4 Aspartate-derived amino acids 318
- 7.5 Branched-chain amino acids 326
- 7.6 Glutamate-derived amino acids 330
- 7.7 Histidine 333

Summary 336

8 Lipids 337

Introduction 337

- 8.1 Structure and function of lipids 337
- 8.2 Fatty acid biosynthesis 344
- 8.3 Acetyl-CoA carboxylase 348
- 8.4 Fatty acid synthase 350
- 8.5 Desaturation and elongation of C_{16} and C_{18} fatty acids 352
- 8.6 Synthesis of unusual fatty acids 360
- 8.7 Synthesis of membrane lipids 365
- 8.8 Function of membrane lipids 373
- 8.9 Synthesis and function of extracellular lipids 382
- 8.10 Synthesis and catabolism of storage lipids 389
- 8.11 Genetic engineering of lipids 395

Summary 400

9 Genome Structure and Organization 401

Introduction 401

- 9.1 Genome structure: a 21st-century perspective 401
- 9.2 Genome organization 404
- 9.3 Transposable elements 416
- 9.4 Gene expression 422
- 9.5 Chromatin and the epigenetic regulation of gene expression 430

Summary 436

10 Protein Synthesis, Folding, and Degradation 438

Introduction 438

- 10.1 Organellar compartmentalization of protein synthesis 438
- 10.2 From RNA to protein 439
- 10.3 Mechanisms of plant viral translation 447
- 10.4 Protein synthesis in plastids 450
- 10.5 Post-translational modification of proteins 457
- 10.6 Protein degradation 463

Summary 475

11 Cell Division 476

Introduction 476

- 11.1 Animal and plant cell cycles 476
- 11.2 Historical perspective on cell cycle research 477
- 11.3 Mechanisms of cell cycle control 482
- 11.4 The cell cycle in action 488
- 11.5 Cell cycle control during development 497

Summary 506

ENERGY FLOW

12 Photosynthesis 508

Introduction 508

- 12.1 Overview of photosynthesis 508
- 12.2 Light absorption and energy conversion 511
- 12.3 Photosystem structure and function 519
- 12.4 Electron transport pathways in chloroplast membranes 529
- 12.5 ATP synthesis in chloroplasts 537
- 12.6 Organization and regulation of photosynthetic complexes 540
- 12.7 Carbon reactions: the Calvin–Benson cycle 542

- 12.8 Rubisco 548
- 12.9 Regulation of the Calvin–Benson cycle by light 551
- 12.10 Variations in mechanisms of CO₂ fixation 557
- Summary 565

13 Carbohydrate Metabolism 567

- Introduction 567
- 13.1 The concept of metabolite pools 570
- 13.2 The hexose phosphate pool: a major crossroads in plant metabolism 571
- 13.3 Sucrose biosynthesis 573
- 13.4 Sucrose metabolism 577
- 13.5 Starch biosynthesis 580
- 13.6 Partitioning of photoassimilates between sucrose and starch 587
- 13.7 Starch degradation 593
- 13.8 The pentose phosphate/triose phosphate pool 597
- 13.9 Energy and reducing power for biosynthesis 601
- 13.10 Sugar-regulated gene expression 606
- Summary 608

14 Respiration and Photorespiration 610

- Introduction 610
- 14.1 Overview of respiration 610
- 14.2 Citric acid cycle 613
- 14.3 Plant mitochondrial electron transport 620
- 14.4 Plant mitochondrial ATP synthesis 632
- 14.5 Regulation of the citric acid cycle and the cytochrome pathway 634
- 14.6 Integration of the cytochrome pathway and nonphosphorylating pathways 635
- 14.7 Interactions between mitochondria and other cellular compartments 639
- 14.8 Biochemical basis of photorespiration 646
- 14.9 The photorespiratory pathway 648
- 14.10 Role of photorespiration in plants 652
- Summary 655

IV

METABOLIC AND DEVELOPMENTAL INTEGRATION

15 Long-Distance Transport 658

- Introduction 658
- 15.1 Selection pressures and long-distance transport systems 658

- 15.2 Cell biology of transport modules 664
- 15.3 Short-distance transport events between xylem and nonvascular cells 668
- 15.4 Short-distance transport events between phloem and nonvascular cells 673
- 15.5 Whole-plant organization of xylem transport 691
- 15.6 Whole-plant organization of phloem transport 696
- 15.7 Communication and regulation controlling phloem transport events 705
- Summary 710

16 Nitrogen and Sulfur 711

- Introduction 711
- 16.1 Overview of nitrogen in the biosphere and in plants 711
- 16.2 Overview of biological nitrogen fixation 715
- 16.3 Enzymology of nitrogen fixation 715
- 16.4 Symbiotic nitrogen fixation 718
- 16.5 Ammonia uptake and transport 735
- 16.6 Nitrate uptake and transport 735
- 16.7 Nitrate reduction 739
- 16.8 Nitrite reduction 744
- 16.9 Nitrate signaling 745
- 16.10 Interaction between nitrate assimilation and carbon metabolism 745
- 16.11 Overview of sulfur in the biosphere and plants 746
- 16.12 Sulfur chemistry and function 747
- 16.13 Sulfate uptake and transport 750
- 16.14 The reductive sulfate assimilation pathway 752
- 16.15 Cysteine synthesis 755
- 16.16 Synthesis and function of glutathione and its derivatives 758
- 16.17 Sulfated compounds 763
- 16.18 Regulation of sulfate assimilation and interaction with nitrogen and carbon metabolism 764
- Summary 767

17 Biosynthesis of Hormones 769

- Introduction 769
- 17.1 Gibberellins 769
- 17.2 Abscisic acid 777
- 17.3 Cytokinins 785
- 17.4 Auxins 795
- 17.5 Ethylene 806
- 17.6 Brassinosteroids 810
- 17.7 Polyamines 818
- 17.8 Jasmonic acid 821
- 17.9 Salicylic acid 826

17.10 Strigolactones 830

Summary 833

18 Signal Transduction 834

Introduction 834

- 18.1 Characteristics of signal perception, transduction, and integration in plants 834
 - 18.2 Overview of signal perception at the plasma membrane 838
 - 18.3 Intracellular signal transduction, amplification, and integration via second messengers and MAPK cascades 843
 - 18.4 Ethylene signal transduction 847
 - 18.5 Cytokinin signal transduction 850
 - 18.6 Integration of auxin signaling and transport 852
 - 18.7 Signal transduction from phytochromes 857
 - 18.8 Gibberellin signal transduction and its integration with phytochrome signaling during seedling development 861
 - 18.9 Integration of light, ABA, and CO₂ signals in the regulation of stomatal aperture 866
 - 18.10 Prospects 870
- Summary 870

19 Molecular Regulation of Reproductive Development 872

Introduction 872

- 19.1 The transition from vegetative to reproductive development 872
 - 19.2 The molecular basis of flower development 881
 - 19.3 The formation of male gametes 889
 - 19.4 The formation of female gametes 897
 - 19.5 Pollination and fertilization 902
 - 19.6 The molecular basis of self-incompatibility 908
 - 19.7 Seed development 913
- Summary 923

20 Senescence and Cell Death 925

Introduction 925

- 20.1 Types of cell death 925
- 20.2 PCD during seed development and germination 930
- 20.3 Cell death during the development of secretory bodies, defensive structures and organ shapes 932
- 20.4 PCD during reproductive development 937
- 20.5 Senescence and PCD in the terminal development of leaves and other lateral organs 940
- 20.6 Pigment metabolism in senescence 948

- 20.7 Macromolecule breakdown and salvage of nutrients in senescence 951
 - 20.8 Energy and oxidative metabolism during senescence 957
 - 20.9 Environmental influences on senescence and cell death I: Abiotic interactions 961
 - 20.10 Environmental influences on senescence and cell death II: PCD responses to pathogen attack 964
 - 20.11 Plant hormones in senescence and defense-related PCD 974
- Summary 982

**PLANT ENVIRONMENT AND AGRICULTURE****21 Responses to Plant Pathogens** 984

Introduction 984

- 21.1 Pathogens, pests, and disease 984
 - 21.2 An overview of immunity and defense 985
 - 21.3 How pathogens and pests cause disease 989
 - 21.4 Preformed defenses 1009
 - 21.5 Induced defense 1012
 - 21.6 Effector-triggered immunity, a second level of induced defense 1022
 - 21.7 Other sources of genetic variation for resistance 1032
 - 21.8 Local and systemic defense signaling 1033
 - 21.9 Plant gene silencing confers virus resistance, tolerance, and attenuation 1042
 - 21.10 Control of plant pathogens by genetic engineering 1044
- Summary 1050

22 Responses to Abiotic Stress 1051

Introduction 1051

- 22.1 Plant responses to abiotic stress 1051
 - 22.2 Physiological and cellular responses to water deficit 1054
 - 22.3 Gene expression and signal transduction in response to dehydration 1061
 - 22.4 Freezing and chilling stress 1068
 - 22.5 Flooding and oxygen deficit 1076
 - 22.6 Oxidative stress 1085
 - 22.7 Heat stress 1094
 - 22.8 Crosstalk in stress responses 1097
- Summary 1099

23 Mineral Nutrient Acquisition, Transport, and Utilization 1101

Introduction 1101

23.1 Overview of essential mineral elements 1102

23.2 Mechanisms and regulation of plant K⁺ transport 1103

23.3 Phosphorus nutrition and transport 1113

23.4 The molecular physiology of micronutrient acquisition 1118

23.5 Plant responses to mineral toxicity 1127

Summary 1131

24 Natural Products 1132

Introduction 1132

24.1 Terpenoids 1133

24.2 Biosynthesis of the basic five-carbon unit 1135

24.3 Repetitive additions of C₅ units 1138

24.4 Formation of parent carbon skeletons 1141

24.5 Modification of terpenoid skeletons 1143

24.6 Metabolic engineering of terpenoid production 1145

24.7 Cyanogenic glycosides 1146

24.8 Cyanogenic glycoside biosynthesis 1152

24.9 Functions of cyanogenic glycosides 1157

24.10 Glucosinolates 1158

24.11 Alkaloids 1159

24.12 Alkaloid biosynthesis 1164

24.13 Biotechnological application of alkaloid biosynthesis research 1171

24.14 Phenolic compounds 1178

24.15 Phenolic biosynthesis 1185

24.16 The phenylpropanoid-acetate pathway 1188

24.17 The phenylpropanoid pathway 1195

24.18 Universal features of phenolic biosynthesis 1202

24.19 Evolution of secondary pathways 1205

Summary 1206

THE EDITORS

Bob B. Buchanan

A native Virginian, Bob B. Buchanan obtained his PhD in microbiology at Duke University and did postdoctoral research at the University of California at Berkeley. In 1963, he joined the Berkeley faculty and is currently a professor emeritus in the Department of Plant and Microbial Biology. He has taught general biology and biochemistry to undergraduate students and graduate-level courses in plant biochemistry and photosynthesis. Initially focused on pathways and regulatory mechanisms in photosynthesis, his research has more recently dealt with the regulatory role of thioredoxin in seeds, plant mitochondria and methane-producing archaea. The work on seeds is finding application in several areas. Bob has served as department chair at UC Berkeley and was president of the American Society of Plant Physiologists from 1995 to 1996. A former Guggenheim Fellow, he is a member of the National Academy of Sciences and the Japanese Society of Plant Physiologists (honorary). He is a fellow of the American Academy of Arts and Sciences, the American Society of Microbiology, the American Society of Plant Biologists, and the American Association for the Advancement of Science. His other honors include the Bessenyei Medal from the Hungarian Ministry of Education, the Kettering Award for Excellence in Photosynthesis, and the Stephen Hales Prize from the American Society of Plant Physiologists, a Research Award from the Alexander von Humboldt Foundation, the Distinguished Achievement Award from his undergraduate alma mater, Emory and Henry College, and the Berkeley Citation.

Wilhelm Gruissem

Wilhelm Gruissem was born in Germany where he studied biology and chemistry. After obtaining his PhD in 1979 at the University of Bonn in Germany and postdoctoral research at the University of Marburg in Germany and the University of Colorado in Boulder, he was appointed as Professor of Plant Biology at the University of California at Berkeley in 1983. He was Chair of the Department of Plant and Microbial Biology at UC Berkeley from 1993 to 1998, and from 1998 to 2000 he was Director of a collaborative research program between the Department and the Novartis Agricultural Discovery Institute in San Diego. In 2000 he joined the ETH Zurich (Swiss Federal Institute of Technology) as Professor of Plant Biotechnology in the Department of Biology and the Institute

of Agricultural Sciences. Since 2001 he has been Co-Director of the Functional Genomics Center Zurich. From 2006 to 2010 he served as President of the European Plant Science Organization (EPSO) and since 2011 as Chair of the Global Plant Council. From 2009 to 2011 he also served as Chair of the Department of Biology at ETH Zurich. In addition to his research on systems approaches to understand pathways and molecules involved in plant growth control, he directs a biotechnology program on trait improvement in cassava, rice, and wheat. In 2008 he founded Nebion, a bioinformatics company building the internationally successful Geneinvestigator database. He is an elected fellow of the American Association for the Advancement of Sciences (AAAS) and the American Society of Plant Biologists, he is Editor of *Plant Molecular Biology*, and he serves on the editorial boards of several journals and on advisory boards for various research institutions. He has received several prestigious awards, including a prize from the Fiat Panis Foundation in Germany and the Shang-Fa Yang award of Academia Sinica in Taiwan for his trait improvement work in cassava and rice. In 2007 he was elected lifetime foreign member of the American Society of Plant Biologists.

Russell L. Jones

Russell L. Jones was born in Wales and completed his BSc and PhD degrees at the University of Wales, Aberystwyth. He spent 1 year as a postdoctoral fellow at the Michigan State University Department of Energy Plant Research Laboratory with Anton Lang before being appointed to the faculty of the Department of Botany at the University of California at Berkeley in 1966. As Professor of Plant Biology at UC Berkeley he taught undergraduate classes in general biology and graduate courses in plant physiology and cell biology for over 45 years. He is now Professor Emeritus, Department of Plant and Microbial Biology at UC Berkeley. His research focuses on hormonal regulation in plants using the cereal aleurone as a model system, with approaches that exploit the techniques of biochemistry, biophysics, and cell and molecular biology. Russell was president of the American Society of Plant Physiologists from 1993 to 1994. He was a Guggenheim Fellow at the University of Nottingham in 1972, a Miller Professor at UC Berkeley in 1976, a Humboldt Prize Winner at the University of Göttingen in 1986, and a RIKEN Eminent Scientist, RIKEN, Japan, in 1996.

PREFACE

The second edition of the *Biochemistry & Molecular Biology of Plants* retains the overall format of the first edition in response to the enthusiastic feedback we received from users of the book. The first edition was organized into five sections dealing with organization and functioning of the cell (Compartments), the cell's ability to replicate (Cell Reproduction), generation of energy (Energy Flow), regulation of development (Metabolism and Developmental Regulation), and the impact of fundamental discoveries in plant biology (Plant, Environment, and Agriculture). Although the section organization of the second edition remains unchanged, many of the chapters have been written by new teams of authors, reflecting the retirement of some of our colleagues, but also the dynamic development of plant biology during the last 20 years that was driven by a cohort of younger investigators, many of whom have contributed to this second edition.

Changes in chapter authorship also reflect the impact that molecular genetics had on our field, and three chapters stand out in this regard: Chapter 9 on Genome Structure and Organization, Chapter 18 on Signal Transduction, and Chapter 19 on Molecular Regulation of Reproductive Development. Advances resulting from molecular genetics have been particularly dramatic in the field of plant hormones and other signaling molecules where the receptors for all of the major hormones and their complex signaling pathways have now been described in detail.

Soon after publication of the first edition, *Biochemistry & Molecular Biology of Plants* was translated into Chinese, Italian, and Japanese, and a special low-priced English-language version of the book was published in India. In this version the entire book was published in black and white, illustrating the costs involved in producing four-color versions of textbooks.

Another change that accompanied the writing and production of this second edition was the involvement of the publisher John Wiley and our interaction with the Editorial

Office in the United Kingdom. Wiley had entered into an agreement with the American Society of Plant Biologists to lead the publication of books written by ASPB members. The second edition of *Biochemistry & Molecular Biology of Plants* is one of the first of hopefully many books that will be published jointly by ASPB and Wiley.

Production of this book required input from many talented people. First and foremost the authors, who patiently, in some cases very patiently, worked with the editors and developmental editors to produce chapters of remarkably high quality. The two excellent developmental editors, Justine Walsh and Yolanda Kowalewski, worked to produce a collection of chapters that read seamlessly; the artist Debbie Maizels produced figures of exceptional technical and artistic quality; the staff at John Wiley, who worked tirelessly on this project; and Dr Nik Prowse, freelance project manager, who efficiently handled the chapter editing and management during the production phase of the book. Special thanks go to Celia Carden whose support, enthusiasm, and management across two continents have gone a long way to making this book successful. The support of ASPB's leadership and staff, notably Executive Director Crispin Taylor and Publications Manager Nancy Winchester, are gratefully acknowledged. We also appreciate the continuing/ongoing support that we received from ASPB as this book was being developed. The contributing authors thank reviewers for commenting on their chapters.

Most important, we want to express appreciation to our wives, Melinda, Barbara, and Frances, who during the past few years again tolerated and accepted the textbook as a demanding family member.

Note: Following the common publishing convention, species names that appear in the italicized figure legends have been set in standard roman typeface so that they are easily identifiable.

ABOUT THE COMPANION WEBSITE

This book is accompanied by a companion website:

www.wiley.com/go/buchanan/biochem

This website includes:

- PowerPoint slides of all the figures from the book, to download;
- PDF files of all the tables from the book, to download.

COMPARTMENTS

Membrane Structure and Membranous Organelles

L. Andrew Staehelin

Introduction

Cells, the basic units of life, require **membranes** for their existence. Foremost among these is the plasma membrane, which defines each cell's boundary and helps create and maintain electrochemically distinct environments within and outside the cell. Other membranes enclose eukaryotic organelles such as the nucleus, chloroplasts, and mitochondria. Membranes also form internal compartments, such as the endoplasmic reticulum (ER) in the cytoplasm and thylakoids in the chloroplast (Fig. 1.1).

The principal function of membranes is to serve as a barrier to diffusion of most water-soluble molecules. Cellular compartments delimited by membranes can differ in chemical composition from their surroundings and be optimized for a particular activity. Membranes also serve as scaffolding for certain proteins. As membrane components, proteins perform a wide array of functions: transporting molecules and transmitting signals across the membrane, processing lipids enzymatically, assembling glycoproteins and polysaccharides, and providing mechanical links between cytosolic and cell wall molecules.

This chapter is divided into two parts. The first is devoted to the general features and molecular organization of membranes. The second provides an introduction to the architecture and functions of the different membranous organelles of plant cells. Many later chapters of this book focus on metabolic events that involve these organelles.

1.1 Common properties and inheritance of cell membranes

1.1.1 Cell membranes possess common structural and functional properties

All cell membranes consist of a bilayer of polar lipid molecules and associated proteins. In an aqueous environment, membrane lipids self-assemble with their hydrocarbon tails clustered together, protected from contact with water (Fig. 1.2). Besides mediating the formation of bilayers, this property causes membranes to form closed compartments. As a result, every membrane is an asymmetrical structure, with one side exposed to the contents inside the compartment and the other side in contact with the external solution.

The lipid bilayer serves as a general permeability barrier because most water-soluble (polar) molecules cannot readily traverse its nonpolar interior. Proteins perform most of the other membrane functions and thereby define the specificity of each membrane system. Virtually all membrane molecules are able to diffuse freely within the plane of the membrane, permitting membranes to change shape and membrane molecules to rearrange rapidly.

1.1.2 All basic types of cell membranes are inherited

Plant cells contain approximately 20 different membrane systems. The exact number depends on how sets of related membranes are counted (Table 1.1). From the moment they are formed, cells must maintain the integrity of all their membrane-bounded compartments to survive, so all membrane systems must be passed from one generation of cells to

the next in a functionally active form. Membrane inheritance follows certain rules:

- Daughter cells inherit a complete set of membrane types from their mother.
- Each potential mother cell maintains a complete set of membranes.
- New membranes arise by growth and fission of existing membranes.

FIGURE 1.2 Cross-sectional views of a lipid micelle and a lipid bilayer in aqueous solution.

1.2 The fluid-mosaic membrane model

The **fluid-mosaic membrane model** describes the molecular organization of lipids and proteins in cellular membranes and illustrates how a membrane's mechanical and physiological traits are defined by the physicochemical characteristics of its various molecular components. This model integrates much of what we know about the molecular properties of membrane lipids, their assembly into bilayers, the regulation of membrane fluidity, and the different mechanisms by which membrane proteins associate with lipid bilayers.

1.2.1 The amphipathic nature of membrane lipids allows for the spontaneous assembly of bilayers

In most cell membranes, lipids and glycoproteins make roughly equal contributions to the membrane's mass. Lipids belong to several classes, including phospholipids,

glucocerebrosides, galactosylglycerides, and sterols (Figs. 1.3 and 1.4). These molecules share an important physicochemical property: they are **amphipathic**, containing both **hydrophilic** (“water-loving”) and **hydrophobic** (“water-fearing”) domains. When brought into contact with water, these molecules spontaneously self-assemble into higher-order structures. The hydrophilic head groups maximize their interactions with water molecules, whereas hydrophobic tails interact with each other, minimizing their exposure to the aqueous phase (see Fig. 1.2). The geometry of the resulting lipid assemblies is governed by the shape of the amphipathic molecules and the balance between hydrophilic and hydrophobic domains. For most membrane lipids, the bilayer configuration is the minimum-energy self-assembly structure, that is, the structure that takes the least amount of energy to form in the presence of water (Fig. 1.5). In this configuration, the polar groups form the interface to the bulk water, and the hydrophobic groups become sequestered in the interior.

Phospholipids, the most common type of membrane lipid, have a charged, phosphate-containing polar head group and two hydrophobic hydrocarbon tails. Fatty acid tails contain between 14 and 24 carbon atoms, and at least one tail has one or more *cis* double bonds (Fig. 1.6). The kinks introduced by these double bonds influence the packing of the molecules in the lipid bilayer, and the packing, in turn, affects the overall fluidity of the membrane.

FIGURE 1.3 Plant membrane lipids.

FIGURE 1.4 Sterols found in plant plasma membranes.

1.2.2 Phospholipids move rapidly in the plane of the membrane but very slowly from one side of the bilayer to the other

Because individual lipid molecules in a bilayer are not bonded to each other covalently, they are free to move. Within the plane of the bilayer, molecules can slide past each other freely. A membrane can assume any shape without disrupting the hydrophobic interactions that stabilize its structure. Aiding this general flexibility is the ability of lipid bilayers to close on themselves to form discrete compartments, a property that also enables them to seal damaged membranes.

Studies of the movement of phospholipids in bilayers have revealed that these molecules can diffuse laterally, rotate, flex their tails, bob up and down, and flip-flop (Fig. 1.7). The exact mechanism of lateral diffusion is unknown. One theory suggests that individual molecules hop into vacancies (“holes”) that form transiently as the lipid molecules within each monolayer exhibit thermal motions. Such vacancies arise in a fluid bilayer at high frequencies, and the average molecule hops $\sim 10^7$ times per second, which translates to a diffusional distance of $\sim 1 \mu\text{m}$ traversed in a second. Both rotation of individual molecules around their long axes and up-and-down bobbing are also very rapid events. Superimposed on these motions is a constant flexing of the hydrocarbon tails. Because this flexing

FIGURE 1.5 Organization of amphipathic lipid molecules in a bilayer.

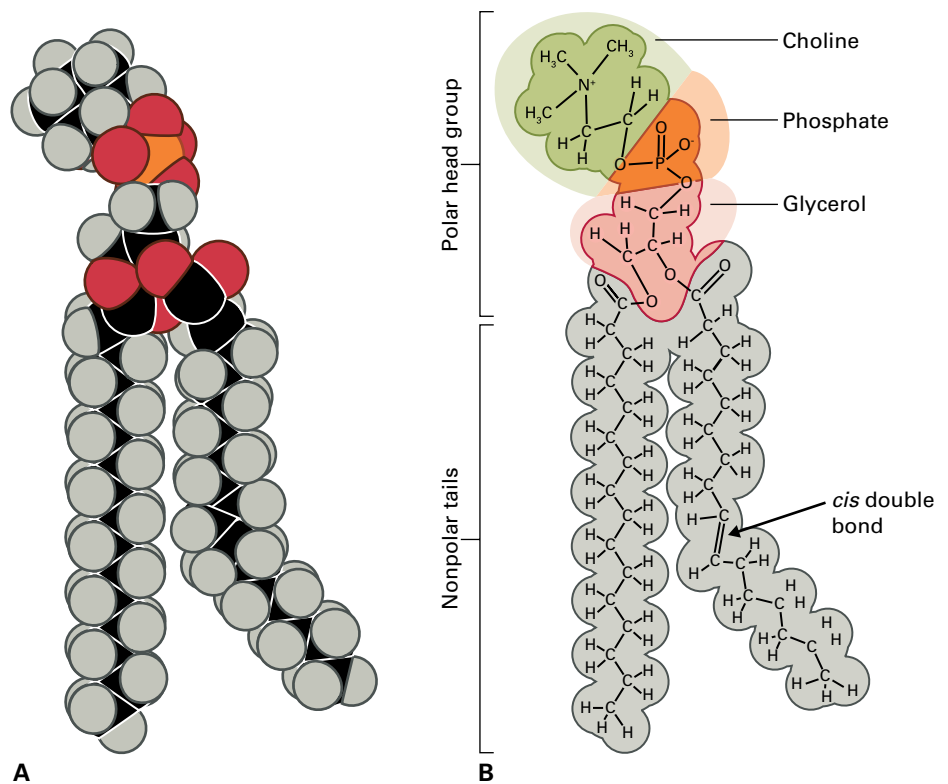

FIGURE 1.6 (A) Space-filling model of a phosphatidylcholine molecule. (B) Diagram defining the functional groups of a phosphatidylcholine molecule.

increases towards the ends of the tails, the center of the bilayer has the greatest degree of fluidity.

In contrast, spontaneous transfer of phospholipids across the bilayer, called flipping, rarely occurs. A flip would require the polar head to migrate through the nonpolar interior of the bilayer, an energetically unfavorable event. Some membranes contain “flippase” enzymes, which mediate movement of

newly synthesized lipids across the bilayer (Fig. 1.8). Different flippases specifically catalyze translocation of particular lipid types and thus can flip their lipid substrates in only one direction. The energy barrier to spontaneous flipping and flippase specificity, together with the specific orientation of the lipid-synthesizing enzymes in the membranes, result in an asymmetrical distribution of lipid types across membrane bilayers.

FIGURE 1.7 Mobility of phospholipid molecules in a lipid bilayer.

Membrane sterols in lipid bilayers behave somewhat differently from phospholipids, primarily because the hydrophobic domain of a sterol molecule is much larger than the uncharged polar head group (see Fig. 1.4). Thus, membrane sterols are not only able to diffuse rapidly in the plane of the bilayer, they can also flip-flop without enzymatic assistance at a higher rate than phospholipids.

1.2.3 Cells optimize the fluidity of their membranes by controlling lipid composition

Like all fatty substances, membrane lipids exist in two different physical states, as a semicrystalline gel and as a fluid. Any given lipid, or mixture of lipids, can be melted—converted from gel to fluid—by a temperature increase. This change in state is known as **phase transition**, and for every lipid this transition occurs at a precise temperature, called the temperature of melting (T_m , see Table 1.2). Gelling brings most membrane activities to a standstill and increases permeability. At high temperatures, on the other hand, lipids can become too fluid to maintain the permeability barrier. Nonetheless, some organisms live happily in frigid conditions, whereas others thrive in boiling hot springs and thermal vents. Many plants survive daily temperature fluctuations of 30°C. How do organisms adapt the fluidity of their membranes to suit their mutable growth environments?

To cope successfully with the problem of temperature-dependent changes in membrane fluidity, virtually all poikilothermic organisms—those whose temperatures fluctuate with the environment—can alter the composition of their membranes to optimize fluidity for a given temperature. Mechanisms exploited to compensate for low temperatures include shortening of fatty acid tails, increasing the number of double bonds, and increasing the size or charge of head groups. Changes in sterol composition can also alter membrane responses to temperature. Membrane sterols serve as membrane fluidity

FIGURE 1.8 Mechanism of action of a “flippase,” a phospholipid translocator.

“buffers,” increasing the fluidity at lower temperatures by disrupting the gelling of phospholipids, and decreasing fluidity at high temperatures by interfering with the flexing motions of the fatty acid tails. Because each lipid has a different T_m , lowering the temperature can induce one type of lipid to undergo a fluid-to-gel transition and form semicrystalline patches, whereas other lipids remain in the fluid state. Like all cellular molecules, membrane lipids have a finite life span and are turned over on a regular basis. This turnover enables plant cells to adjust the lipid composition of their membranes in response to seasonal changes in ambient temperature.

1.2.4 Membrane proteins associate with lipid bilayers in many different ways

The different ways in which membrane-bound proteins associate with lipid bilayers reflect the diversity of enzymatic and structural functions they perform. The original fluid-mosaic membrane model included two basic types of membrane proteins: peripheral and integral (Fig. 1.9). More recent

research has led to the discovery of three additional classes of membrane proteins—**fatty acid-linked**, **prenyl group-linked**, and **phosphatidylinositol-anchored**—all of which are attached to the bilayer by lipid tails (Fig. 1.10).

By definition, **peripheral proteins** are water-soluble and can be removed by washing membranes in water or in salt or acid solutions that do not disrupt the lipid bilayer. Peripheral proteins bind either to integral proteins or to lipids through

TABLE 1.2 The effects of fatty acid chain length and double bonds on the temperature of melting (T_m) of some defined phospholipids.

Types of chains*	T_m (°C)		
	Phosphatidylcholine	Phosphatidyl-ethanolamine	Phosphatidic acid
Two C _{14:0}	24	51	
Two C _{16:0}	42	63	67
Two C _{18:0}	55	82	
Two C _{18:1} (<i>cis</i>)	-22	15	8

*The shorthand nomenclature for the fatty acyl chains denotes how many carbon atoms (first number) and double bonds (second number) they contain.

FIGURE 1.9 A modern version of the fluid-mosaic membrane model, depicting integral, peripheral, and lipid-anchored membrane proteins. Not drawn to scale.

FIGURE 1.10 Fatty acid-anchored, prenyl lipid-anchored, and glycosylphosphatidylinositol (GPI)-anchored proteins.

salt bridges, electrostatic interactions, hydrogen bonds, or some combination of these, but they do not penetrate the lipid bilayer. Some peripheral proteins also provide links between membranes and cytoskeletal systems. In contrast, the amphipathic, transmembrane or partly embedded **integral proteins** are insoluble in water. Because the hydrophobic domains are sequestered in the hydrophobic interior of the bilayer, an integral protein can be removed and solubilized only with the help of detergents or organic solvents, which degrade the bilayer.

Both the fatty acid-linked and the prenyl group-linked proteins bind reversibly to the cytoplasmic surfaces of membranes to help regulate membrane activities. Cycling between

the membrane-bound and free states is mediated in most cases by phosphorylation/dephosphorylation or by GTP/GDP binding cycles. The fatty acid-linked proteins are attached either to a myristic acid (C₁₄), by way of an amide linkage to an amino terminal glycine, or to one or more palmitic acid (C₁₆) residues, by way of thioester linkages to cysteines near the carboxyl terminus. Prenyl lipid-anchored proteins are attached to one or more molecules of farnesyl (C₁₅; 3 isoprene units) or geranylgeranyl (C₂₀; 4 isoprene units), which are also coupled to cysteine residues in carboxyl-terminal CXXX, CXC, and XCC motifs (Fig. 1.10).

In contrast to the fatty acid- and the prenyl group-linked proteins, the phosphatidylinositol-anchored proteins are

bound to the luminal/extracellular surfaces of membranes (Fig. 1.10). Interestingly, these proteins are first produced as larger, integral proteins with one transmembrane domain. Enzymatic cleavage between the transmembrane domain and the globular surface domain produces a new C terminus on the globular domain, to which the lipid is coupled by ER-based enzymes (see Chapter 4, Section 4.6.4). The remaining transmembrane domain is then degraded by proteases. Many arabinogalactan proteins (AGPs) appear to be linked to the plasma membrane via a glycosylphosphatidylinositol (GPI) anchor. These molecules can be enzymatically released from the cell surface by phospholipase C.

1.2.5 The fluid-mosaic membrane model predicts structural and dynamic properties of cell membranes

Although the original fluid-mosaic membrane model was developed at a time when membrane researchers knew only of peripheral and integral proteins, slight modifications to its basic premises have accommodated more recent discoveries, including lipid-anchored proteins and membrane protein-cytoskeletal interactions.

Membrane fluidity involves the movement not only of lipid molecules, but also of integral proteins that span the bilayer and of the different types of surface-associated membrane proteins. This ability of membrane proteins to diffuse laterally in the plane of the membrane is crucial to the functioning of most membranes: Collisional interactions are essential for the transfer of substrate molecules between many membrane-bound enzymes and of electrons between the electron transfer chain components of chloroplasts and mitochondria (see Chapters 12 and 14). Such movements are also critical for the assembly of multiprotein membrane complexes. In addition, many signaling pathways depend on transient interactions among defined sets of integral membrane proteins and peripheral or lipid-anchored proteins.

Tethering structures regulate and restrict the movement of membrane proteins, often limiting their distribution to defined membrane domains. This tethering can involve connections to the cytoskeleton and the cell wall, bridges between related integral proteins, or junction-type interactions between proteins in adjacent membranes. A particularly striking example of the latter type of interaction occurs in the grana stacks of chloroplast membranes (see Section 1.10.4). Grana stack formation has been shown to affect the lateral distribution of all major protein complexes in thylakoid membranes and to regulate the functional activity of the photosynthetic reaction centers and other components of the photosynthetic electron transport chain.

Another mechanism for generating transient membrane microdomains of different composition involves membrane lipids organized in the form of **lipid rafts**. GPI-anchored proteins are typically associated with such membrane domains, which have been defined by cell biologists as membrane

domains that are resistant to certain types of detergents. Biochemical analyses of these detergent-resistant membrane fractions have shown that they contain over 100 proteins and are enriched for phytosterols, and that the degree of fatty acid unsaturation affects their stability. However, due to their transient nature, there is no consensus on their *in vivo* size and composition. Indirect evidence suggests that lipid rafts participate in membrane sorting and signaling functions.

1.3 Plasma membrane

The plasma membrane forms the outermost boundary of the living cell and functions as an active interface between the cell and its environment (Fig. 1.11). In this capacity it controls the transport of molecules into and out of the cell, transmits signals from the environment to the cell interior, participates in the synthesis and assembly of cell wall molecules, and provides physical links between elements of the cytoskeleton and the extracellular matrix. In conjunction with specialized domains of the ER, the plasma membrane produces **plasmodesmata**, membrane tubes that cross cell walls and provide direct channels of communication between adjacent cells (Fig. 1.12). As a result of these plasmodesmal connections, almost all the living cells of an individual plant share a physically continuous plasma membrane. This contrasts sharply with the situation in animals, where virtually every

FIGURE 1.11 The plasma membrane (PM) of a turgid plant cell is pressed tightly against a cell wall (CW). These adjacent cryofixed plant cells have been processed by techniques that preserve the close physical relationship between plasma membrane and cell wall. Cells preserved with chemical fixatives for observation under an electron microscope often demonstrate artifacts of specimen preparation, such as a wavy conformation of the plasma membrane and a gap between the membrane and the cell wall. Microtubule (MT).

Source: TEM by A. Lacey Samuels, University of British Columbia, Vancouver, Canada.

FIGURE 1.12 Longitudinal section through a plasmodesma. Plasma membrane (PM), endoplasmic reticulum (ER), cell wall (CW). Source: TEM by Lewis Tilney, from Tilney et al. (1991). *J Cell Biol* 112: 739–747.

cell has a separate plasma membrane, and cell-to-cell communication occurs instead through protein channels known as gap junctions.

Yet another important difference between plants and animals is that plant cells are normally under turgor pressure, whereas animal cells are isoosmotic with their environments. Turgor pressure forces the plasma membrane tightly against the cell wall (see Fig. 1.11).

1.3.1 The lipid composition of plasma membranes is highly variable

Plasma membranes of plant cells consist of lipids, proteins, and carbohydrates in a molecular ratio of ~40:40:20. The lipid mixture contains phospholipids, glycolipids, and sterols, the same classes found in animal plasma membranes. In plant plasma membranes, the ratio of lipid classes varies remarkably

among the different organs in a given plant and among identical organs in different plants—in contrast to the far more constant ratios in animal cells. Barley (*Hordeum vulgare*) root cell plasma membranes, for example, contain more than twice as many free sterol molecules as phospholipids (Table 1.3). In leaf tissues this ratio is generally reversed, but varies: In barley leaf plasma membranes, the phospholipid to free sterol ratio is 1.3:1, whereas in spinach (*Spinacia oleracea*) it is 9:1.

This striking variability, which continues to puzzle researchers, indicates that ubiquitous plasma membrane enzymes can function in widely different lipid environments. These results have led to the suggestion that the lipid composition of plant plasma membranes may have little bearing on their functional properties and that the only important lipid parameter is membrane fluidity. If this were true, it would mean that virtually all lipid classes are interchangeable so long as a given combination of lipids yields a bilayer of desired fluidity at a particular temperature. This provocative idea may well be an overstatement, reflecting our ignorance about the functional roles of specific lipid types; moreover, it seems to be contradicted by the finding that the activity of proton-translocating ATPase (H^+ -ATPase) molecules from corn (*Zea mays*) root reconstituted into artificial membranes can be modulated by changes in sterol composition. More research is needed to clarify how different lipid classes contribute to plasma membrane function.

The most common free **sterols** of plant plasma membranes are campesterol, sitosterol, and stigmasterol (see Fig. 1.4). Cholesterol, the principal free sterol of mammalian plasma membranes, is a minor component in the vast majority of plant species analyzed to date, oat (*Avena sativa*) being a notable exception to this trend. Sterol esters, sterol glycosides, and acylated sterol glycosides are more abundant in plants than in animals. Sterol glycosylation, a reaction catalyzed by UDP-glucose:sterol glycosyltransferase, has been exploited as a marker for isolated plant plasma membranes. Sphingomyelin, another major type of lipid formed in mammalian plasma membranes, has yet to be found in plants. Interesting differences in the fatty acid tails of plant and mammalian plasma membrane **glycerolipids** have also been reported. Whereas plants principally utilize palmitic ($C_{16:0}$), linoleic ($C_{18:2}$), and linolenic ($C_{18:3}$) acids, mammals use palmitic ($C_{16:0}$), stearic ($C_{18:0}$), and arachidonic ($C_{20:4}$) acids.

TABLE 1.3 Lipid composition of plasma membranes from various non-cold-acclimated species and tissues (mole %).

Lipid type	Barley root	Barley leaf	<i>Arabidopsis</i> leaf	Spinach leaf
Phospholipids	26	44	47	64
Free sterols	57	35	38	7
Steryl glucosides	7	–	5	–
Acylated steryl glucosides	–	–	3	13
Glucocerebrosides	9	16	7	14

1.3.2 Cold acclimation leads to characteristic changes in plasma membrane lipid composition

Low temperature is one of the most important factors limiting the productivity and distribution of plants. All plants able to withstand freezing temperatures possess the ability to freeze-proof their cells by a process known as **cold acclimation** (see Chapter 22). This metabolic process involves altering the composition and physical properties of membranes, cytoplasm, and cell walls so that they can withstand not only freezing temperatures but also freeze-induced dehydration. One of the most cold-hardy woody species is the mulberry tree (*Morus bombycis* Koidz). After cold acclimation in midwinter, these trees can withstand freezing below -40°C , but in midsummer, when they are not cold-acclimated, they can be injured by a freeze below -3°C .

Among the most pronounced and critical alterations that occur during cold acclimation are changes in lipid composition of plasma membranes. One might expect cold acclimation-induced lipid changes to vary among species, given the differences in plasma membrane lipid composition already noted (Table 1.3). However, in all cold-hardy herbaceous and woody species studied to date, cold acclimation has been reported to cause an increase in the proportion of phospholipids and a decrease in the proportion of glucocerebrosides. In addition, the mole percent of phospholipids carrying two unsaturated tails increases. Species in which the cold-acclimated plasma membranes contain the highest proportion of diunsaturated phospholipids and the lowest proportion of glucocerebrosides tend to be the most cold hardy.

1.3.3 Plasma membrane proteins serve a variety of functions

Among the prominent classes of proteins present in the plasma membrane are transporters, signal receptors, and proteins that function in cell wall interactions and synthesis. Most plasma membrane proteins involved in these transmembrane activities are of the integral type. However, these proteins often form larger complexes with peripheral proteins. The extracellular domains of many integral proteins are glycosylated, bearing N- and O-linked oligosaccharides.

The plasma membrane H^+ -ATPase (P-type H^+ -ATPase) couples ATP hydrolysis to the transmembrane transport of protons from the cytosol to the extracellular space. This proton pumping has two effects. First, it acidifies cell walls and alkalizes the cytosol, thereby affecting cell growth and expansion (see Chapter 2) as well as many other cellular activities. Second, it produces an electrochemical potential gradient across the plasma membrane that can drive the transport of ions and solutes against their respective concentration gradients (see Chapters 3 and 23). The plasma membrane also contains specialized water-conducting channels known as aquaporins (see Chapter 3).

In plants, transmembrane signaling receptors (see Chapter 18) are essential for cell communication and for mediating interactions with the environment. They also play important roles in development and in orchestrating diverse defense responses. Receptors capable of responding to many types of signaling molecules, including hormones, oligosaccharins, proteins, peptides, and toxins have been identified, but only a small number of these have been characterized to date.

Plasma membrane proteins participate in a variety of interactions with the cell wall, including formation of physical links to cell wall molecules, synthesis and assembly of cell wall polymers, and creation of a highly hydrated, tissue-specific interfacial domain. The presence of physical connections between the plasma membrane and the cell wall was first deduced from the presence of thread-like strands connecting the protoplasts of plasmolyzed cells to the cell wall (Fig. 1.13). These strands are known as **Hechtian strands** in honor of Kurt Hecht, who is credited with their discovery in 1912. During cold acclimation, the number of Hechtian strands increases, suggesting that increasing the strength of the protoplast–cell wall interactions helps protect protoplasts from the stress of freeze-induced dehydration. Electron microscopic analysis has shown that these strands are thin

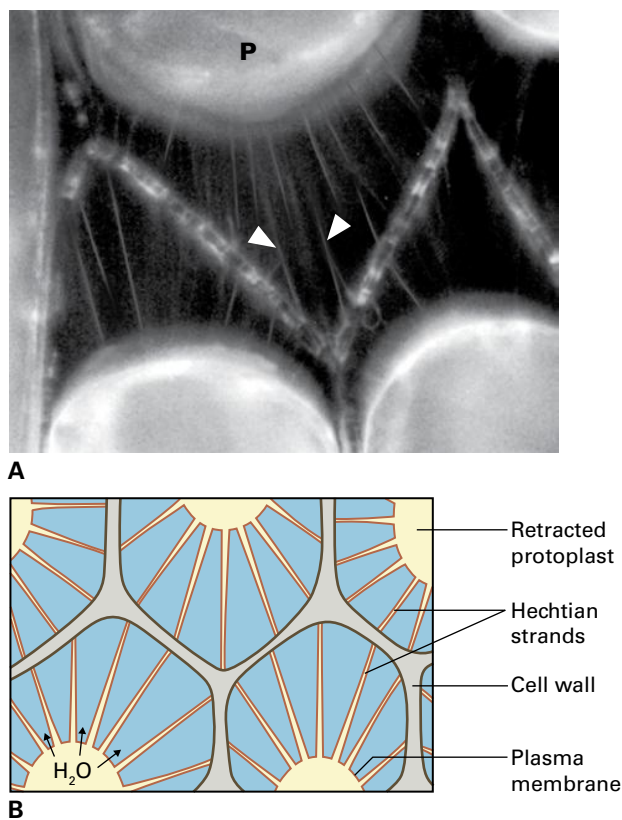

FIGURE 1.13 (A) Light micrograph of plasmolyzed onion epidermal cells. Hechtian strands (“arrowheads”) connect the protoplasts (P) to the cell walls (CW). (B) Diagram illustrating features of plasmolyzed plant cells.

Source: TEM by Karl Oparka, from Oparka et al. (1994). *Plant Cell Environ* 17: 163–171.

tubes of cytoplasm delineated by a plasma membrane that retains tight contacts with the cell wall. These strands remain continuous with the plasma membrane. Although the molecules that link the plasma membrane to the cell wall have not yet been identified, indirect studies suggest they may be integrin-type receptors that recognize the amino acid sequence Arg-Gly-Asp (RGD) in cell wall constituents. A protein known as WAK1, a plasma membrane receptor with kinase activity, is another candidate protein.

AGPs, another class of cell surface proteins, are highly glycosylated proteoglycans that derive >90% of their mass from sugar. Classical-type AGPs appear to be anchored to the external surface of the plasma membrane by means of GPI lipid anchors (see Section 1.2.4), providing a carbohydrate-rich interface between the cell wall and the plasma membrane. The fact that AGPs are expressed in a tissue- and developmental stage-specific manner suggests they may play a role in differentiation. Additional plasma membrane proteins, the cellulose synthase and callose synthase complexes, extrude cellulose (β -1,4-linked glucose) and callose (β -1,3-linked glucose), respectively, directly into the cell walls (see Chapter 2).

1.4 Endoplasmic reticulum

The ER is the most extensive, versatile, and adaptable organelle in eukaryotic cells. It consists of a three-dimensional (3D) network of continuous tubules and flattened sacs that underlie the plasma membrane, course through the cytoplasm, and connect to the nuclear envelope but remain distinct from the plasma membrane. In plants, the principal functions of ER include synthesizing, processing, and sorting proteins targeted to membranes, vacuoles, or the secretory pathway as well as adding N-linked glycans to many of these proteins and synthesizing a diverse array of lipid molecules. The ER also provides anchoring sites for the actin filament bundles that drive cytoplasmic streaming, and plays a critical role in regulating the cytosolic concentrations of calcium (Ca^{2+}), which influence many other cellular activities.

The classical literature distinguishes three types of ER membranes: **rough ER**, **smooth ER**, and **nuclear envelope**. However, researchers now recognize many more morphologically distinct subdomains that perform a variety of different functions (Fig. 1.14). Despite this functional diversity, virtually all ER membranes are physically linked and enclose a single, continuous lumen that extends beyond the boundaries of individual cells via the plasmodesmata.

1.4.1 The ER gives rise to the endomembrane system

The **endomembrane system** includes membranous organelles that exchange membrane molecules, either by lateral diffusion through continuous membrane or by transport vesicles that bud from one type of membrane and fuse

with another (Fig. 1.15). The principal membrane systems connected in this manner include the nuclear envelope, membranes of the secretory pathway (ER, Golgi, *trans*-Golgi network, multivesicular body, plasma membrane, vacuole, and different types of transport/secretory vesicles), and membranes associated with the endocytic pathway (plasma membrane, clathrin-coated endocytic vesicles, *trans*-Golgi network/early endosome/recycling endosome, multivesicular body/late endosome, vacuole, and transport vesicles). Extensive traffic between these compartments not only transports secreted molecules to the cell surface and vacuolar proteins to the vacuoles, but also distributes membrane proteins and membrane lipids from their sites of synthesis, the ER and Golgi cisternae, to their sites of action, all of the endomembrane organelles. A plethora of sorting, targeting, and retrieval systems regulate traffic between the different compartments, ensuring delivery of molecules to the correct membranes and the maintenance of organelle identity (see Chapter 4).

All membranes of the endomembrane system are connected by both **anterograde** (forward) and **retrograde** (backward) **traffic** (Fig. 1.15). The anterograde pathway usually delivers newly synthesized molecules to their destination. In the retrograde pathway, membrane molecules dispersed by transport processes are recycled to their sites of origin, and “escaped” molecules are returned to their normal site of action. Because the volume of membrane traffic is large and the accuracy of sorting is <100%, a certain percentage of mislocalized proteins remain in all endomembrane systems. This normal “contamination” of endomembranes provides a never-ending challenge for biochemists interested in obtaining “pure” membrane fractions.

1.4.2 The ER forms a dynamic network, the organization of which changes during the cell cycle and development

In living plant cells, the spatial organization and kinetic behavior of ER membranes can be visualized by means of the lipophilic fluorescent stain DiOC₆ (3,3'-dihexyloxycarbocyanine iodide). Light microscopic images of such cells show a lace-like network of lamellar and tubular cisternae that continuously undergo architectural rearrangements (Fig. 1.16). Electron microscopic studies have shown that the lamellar regions correspond to sheets of polysome-bearing rough ER membranes (Fig. 1.17; see also domain 5 in Fig. 1.14), and the tubular regions to smooth ER membranes (Fig. 1.18; see also domain 6 in Fig. 1.14) that possess fewer or, in specialized tissues, no bound ribosomes. New tubules can grow from existing membranes and then fuse with other ER cisternae to create new network polygons while other tubules rupture and are reabsorbed into the network.

In interphase cells, the ER underlying the plasma membrane, called the cortical ER, is highly developed, and because of its links to the plasma membrane and to plasmodesmata, is less dynamic than the ER cisternae that pass through the cell

FIGURE 1.14 Diagram illustrating 18 functional domains of the plant ER system.

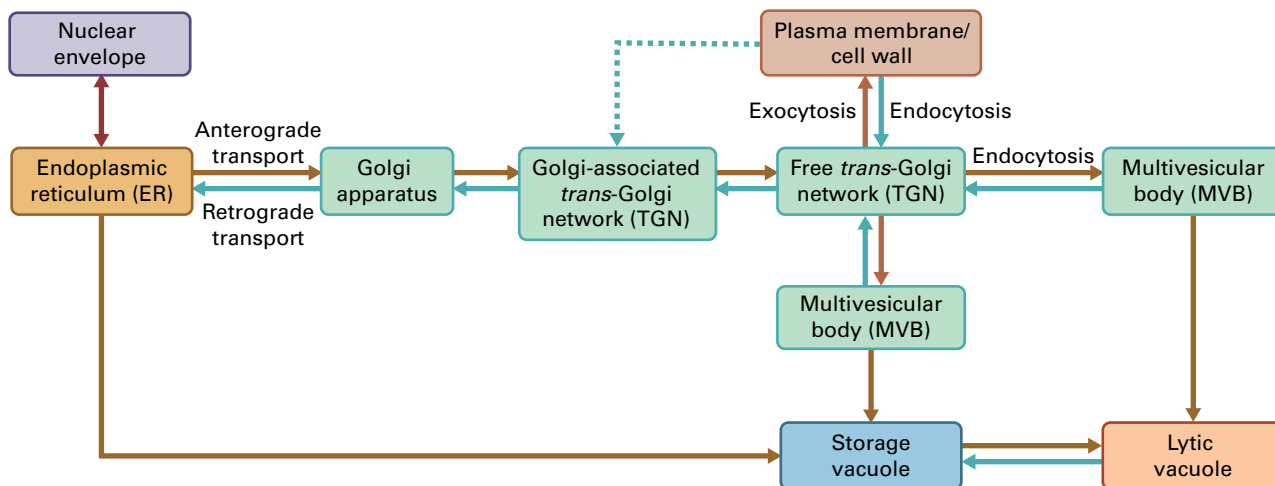

FIGURE 1.15 Diagrammatic overview of the major membrane compartments of the endomembrane system and the directions of membrane trafficking between these compartments. Single-headed arrows represent anterograde and retrograde vesicle traffic. Double-headed arrows connected by a single line indicate that membrane components and lumen contents can diffuse laterally between these compartments (nuclear envelope and ER). Double-headed arrow connected by two lines signals interconversion between vacuole types.

interior. Indeed, the cortical ER often serves as a semi-immobile platform to which the actin filament bundles involved in cytoplasmic streaming are bound (Fig. 1.19; see also domain 16 in Fig. 1.14). During mitosis, the ER undergoes a series of characteristic rearrangements consistent with the idea that it might regulate spindle activities and cell plate assembly by controlling local Ca²⁺ concentrations. In gravity-sensing columella cells of root tips, ER membranes are confined to the cell cortex in a dense network, leaving the central cytoplasm free of ER cisternae to allow specialized amyloplasts (statoliths) to sediment freely (see Section 1.10.7). Gravitropic signaling appears to involve deformation of cortical ER membranes by the heavy statoliths and production of a Ca²⁺ flux. In seeds, extensive arrays of rough ER develop in storage cells during the accumulation of storage proteins. In contrast, intricate networks of smooth ER tubes are a characteristic feature of

oil gland cells (see Fig. 1.18) that synthesize and secrete significant amounts of lipophilic substances such as volatile alcohols, terpenes, and flavonoids (see Chapter 24).

1.4.3 Oil bodies and some types of protein bodies are formed by specialized ER domains

Two important agricultural products, vegetable oils and dietary seed proteins, are produced by enzymes associated with the ER. The storage oils of seeds—triacylglycerols—provide energy and membrane lipid building blocks during early stages of seedling growth. During their synthesis by ER enzymes, triacylglycerols partition into the interior of the ER bilayer and then accumulate at sites defined by molecules known as oleosins. Oleosins have a thumbtack-like architecture, with the “shaft” portion consisting of hydrophobic amino acids and the head exhibiting an amphipathic structure. As the newly synthesized triacylglyceride molecules accumulate between the bilayer leaflets at the oleosin sites, they give rise to spherical **oil bodies** (Fig. 1.20; see also domain 9 in Fig. 1.14). The surface layer of each oil body consists of a phospholipid monolayer, embedded oleosins, and other proteins (see Chapter 8).

Seed storage proteins are synthesized during seed development and serve as the principal source of amino acids for germination and seedling growth. Cereal plants produce two classes of storage proteins, the water-soluble **globulin** proteins and the more hydrophobic, alcohol-soluble **prolamins**. Globulin proteins are synthesized by rough ER polysomes and subsequently accumulate in storage vacuoles (see Chapters 4 and 19). In contrast, prolamins assemble into disulfide-linked polymers, while still residing in the ER, giving rise to spherical structures known as **protein bodies** (Fig. 1.21; see also domain 8 in Fig. 1.14). **ER bodies** (Fig. 1.22;

see also domain 18 in Fig. 1.14) resemble protein bodies but possess a more lens-shaped architecture and do not accumulate storage proteins. Some native ER bodies contain aggregated β -glucosidases, enzymes involved in pathogen defenses. However, ER bodies can also be induced to form in transgenic plants by the expression of green fluorescent protein (GFP) containing a signal peptide and an ER retention signal.

1.4.4 Transport vesicles mediate the transfer of newly synthesized secretory/storage/membrane proteins from the ER to the Golgi apparatus

COPII vesicles bud from specialized ER membrane domains and mediate ER-to-Golgi transport of soluble proteins destined for the cell surface and vacuoles, and membrane proteins for the different compartments of the endomembrane system (Fig. 1.23). ER domains that produce **COPII vesicles** are known as **ER export sites** (see domain 7 in Fig. 1.14). At these sites secretory proteins are separated from resident ER proteins and selectively packaged into the forming COPII vesicles for trafficking to *cis*-Golgi cisternae. In higher plants, budding COPII vesicles are unstable structures with a half-life of ~ 10 s, and they can only be observed in electron micrographs of cells preserved by high-pressure freezing. Furthermore, the identification of an ER export site, as defined by a localized ER region producing several budding COPII vesicles together with an associated Golgi stack with its *cis*-side facing this site, is often complicated by the 3D architecture of the ER membranes. Thus, the site often consists of budding COPII vesicles that are being formed on several adjacent tubular ER domains.

1.4.5 ER attachment domains appear to mediate non-vesicular lipid transport between the ER and other membrane systems

ER membranes possess several types of membrane attachment domains where the ER forms appositional contacts with other membrane systems. Such contact sites have been observed between ER and plasma membrane, cell plate membrane, mitochondria, plastids, peroxisomes, and vacuoles (see domains 10–15 in Fig. 1.14). In such regions, ER membranes approach these other membranes to within ~ 10 nm,

FIGURE 1.19 TEM showing sites where an actin filament (AF) attaches to cortical ER (arrows). See domain 16 in Figure 1.14. Source: Micrograph by Irene Lichtscheidl, from Lichtscheidl et al. (1990). *Protoplasma* 155: 116–126.

FIGURE 1.20 (A) Triacylglycerides accumulate between the two lipid monolayers of a smooth ER membrane and bud off as oil bodies at sites defined by oleosin molecules. (B) TEM of oil bodies (OB) budding from an ER membrane into the cytoplasm. See domain 9 in Figure 1.14.

and in electron tomographic images the adjacent membranes can be seen to be connected through discrete bridging structures (Fig. 1.24A).

Preliminary evidence suggests that such attachment sites may serve as sites of calcium transport via calcium channels (for example, between plasma membrane and ER) and/or mediate non-vesicular, intermembrane lipid transport. Higher plants contain two distinct pathways for membrane lipid synthesis (see Chapter 8), and the enzymes of these pathways are located both in plastids (the **prokaryotic pathway**) and ER (the **eukaryotic pathway**). The prokaryotic

FIGURE 1.21 (A) Prolamin storage proteins (e.g., zein) aggregate in protein bodies that bud from specialized rough ER. (B) TEM of protein bodies (PB) forming in maize endosperm. Polysomes (arrows) are attached to the delimiting ER membrane. See domain 8 in Fig. 1.14.

pathway produces C_{16} and C_{18} fatty acids, and a significant fraction of these fatty acids are exported to the ER for synthesis of phospholipids, some of which are exported back to plastids. ER-plastid lipid trafficking occurs via lipid-transfer proteins, which are most likely concentrated in the ER-plastid attachment sites (Fig. 1.24B; see also domain 11 in Fig. 1.14). The ER-mitochondria contact sites most likely mediate transfer of phosphatidylserine from ER to mitochondria for the production of phosphatidylethanolamine, a major component of mitochondrial membranes. Molecular lipid recycling has also been shown to occur between the plasma membrane and ER (see Section 1.6.1 and domains 13 and 15 in Fig. 1.14). No information is available on the functional roles of ER-vacuole and ER-peroxisome attachment sites.

1.5 Golgi apparatus

The term Golgi apparatus refers to the complement of **Golgi stacks** and associated **trans-Golgi networks** (TGNs) within a given cell. The Golgi apparatus occupies a central position in the secretory pathway, receiving newly synthesized proteins and lipids from the ER and directing them to either the cell surface or vacuoles (see Fig. 1.15). In plants, the Golgi apparatus is involved in assembling complex polysaccharides of the cell wall matrix, synthesizing and processing O- and N-linked oligosaccharide side chains of membrane, cell wall, and vacuolar glycoproteins, and producing glycolipids for the plasma and tonoplast membranes.

The glycosyltransferases and glycosidases that carry out these reactions are integral proteins. Most of these enzymes possess an active site that faces the interior space of the flattened Golgi cisternae. However, some of the enzymes that produce polysaccharide backbones have a transmembrane disposition with an active site on the cytosolic side of the membrane and a channel for transferring the growing polysaccharide chain across the membrane and into the cisternal lumen (see Chapter 2). Sugar nucleotides are used as substrates by the glycosyltransferases that synthesize the different carbohydrate products.

1.5.1 The plant Golgi apparatus consists of dispersed Golgi stack-Golgi associated TGN units that exhibit a polar cisternal organization

The functional unit of the plant Golgi apparatus is the Golgi stack, its associated Golgi-associated (early) TGN, and the **Golgi scaffold (Golgi matrix)**, which encompasses both structures (Figs. 1.25, 1.26, and 1.28–1.30). Unlike in animal cells, where the Golgi apparatus occupies a position close to

the cell center, the Golgi stack–Golgi-associated TGN units of plants are always dispersed throughout the cytoplasm, either as individual units or in small clusters (Fig. 1.27). This dispersed organization, together with the fact that the stacks can travel along actin filaments by means of myosin motors, ensures that secretory products reach their destinations even in large, vacuolated cells. The number of Golgi stack–TGN units per cell varies widely, depending on species, size, and developmental stage of the cell and the volume and type of secretory/storage materials produced. For example, small shoot apical meristem cells of *Arabidopsis thaliana* contain

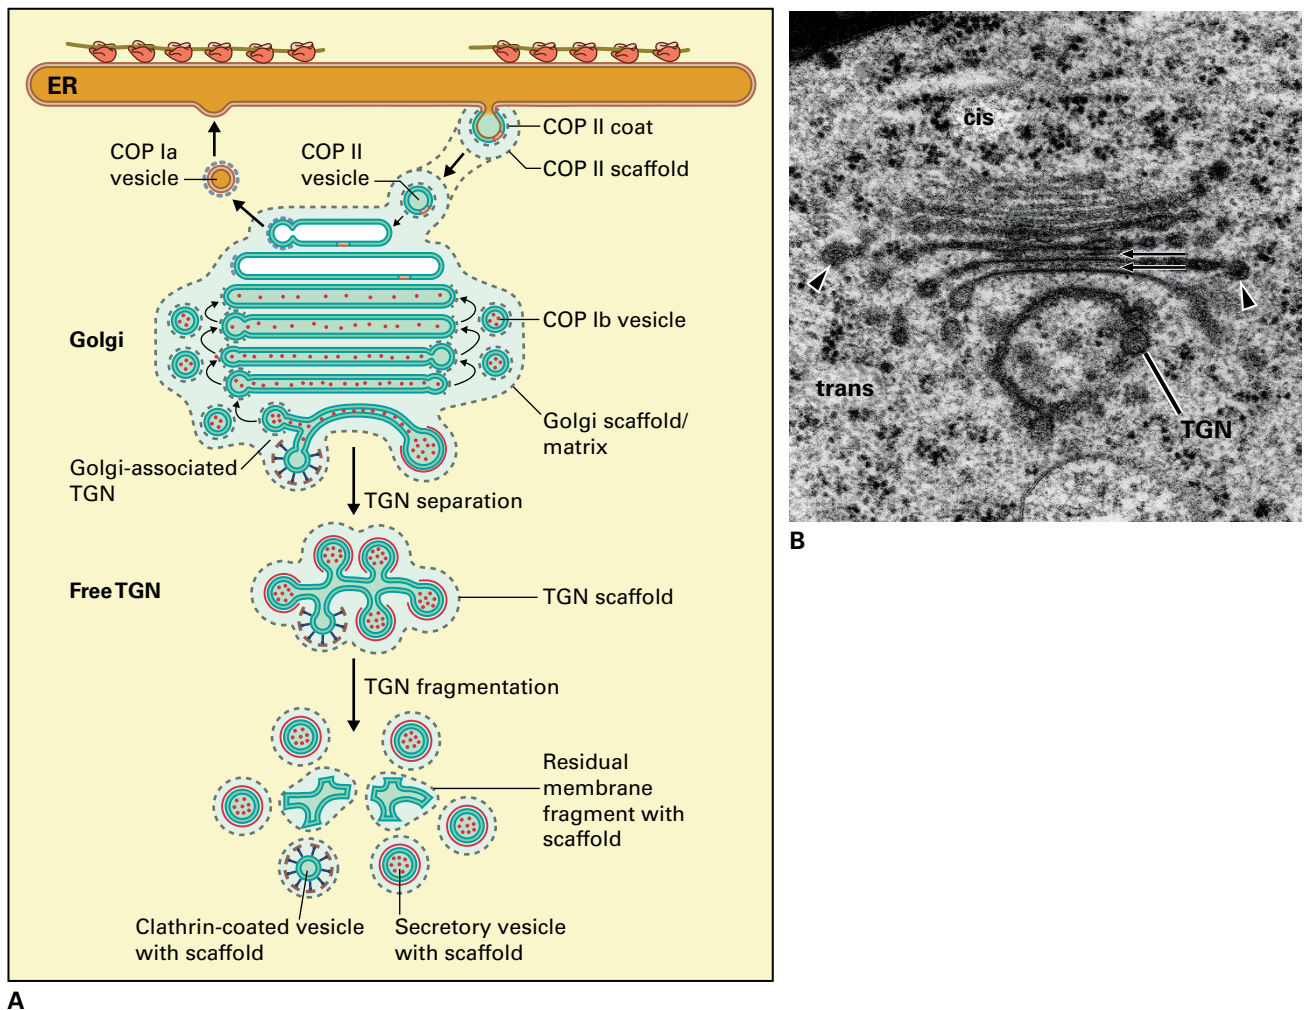

FIGURE 1.25 (A) Schematic diagram illustrating the sites of origin and the trafficking routes of five types of ER/Golgi/TGN-associated vesicles. COPII-type vesicles bud from the ER and transport cargo molecules and membrane to the cis-Golgi cisternae. COPIa-type vesicles bud from cis-Golgi cisternae and recycle ER proteins back to ER. COPIb-type vesicles are produced by cisternae of the medial and trans Golgi and Golgi-associated TGN and recycle molecules between those compartments. Secretory and clathrin-coated vesicles are formed on TGN cisternae to transport the final products to their ultimate destinations: plasma membrane/cell wall and vacuoles. Cisternal fragmentation releases the latter vesicles and gives rise to residual cisternal membrane fragments. Note that the Golgi stack, the TGN cisternae and associated vesicles are all encased by protein scaffolds (matrices). (B) TEM of a cross-sectioned Golgi stack from a root cap columella cell. The cisternae exhibit a distinct cis-to-trans polarity with the luminal contents of the trans side cisternae staining more densely. ~35 Golgi stacks, suspension-cultured tobacco (*Nicotiana tabacum*) BY-2 cells up to 800, and giant fiber cells of cotton >10,000.

Each Golgi stack-TGN unit consists of a set of five to eight flattened **Golgi cisternae** that exhibit a distinct morphological polarity and possess fenestrated and bulbous margins, and a Golgi-associated TGN cisterna on the *trans*-side of the stack (see Figs. 1.25, 1.26, and 1.28). Three types of Golgi cisternae, *cis*, medial, and *trans*, can be distinguished based on their position in a stack, their staining properties, the types of vesicles that bud from their rims, and their biosynthetic functions. According to the **cisternal progression** model of Golgi trafficking, COPII vesicles from the ER are assembled into new cisternae on the *cis*-side of the stack (Figs. 1.25 and 1.28), and the *trans*-most cisternae are converted to Golgi-associated TGN cisternae before they are shed to become free TGN cisternae. This process leads to a net displacement of cargo-laden cisternae across the stack as new cisternae are added

and old cisternae are shed. During their assembly the *cis*-Golgi cisternae remain biochemically inactive. Most of the biosynthetic activities are confined to the medial and *trans*-Golgi cisternae and to a lesser extent to the Golgi-associated TGN compartments.

To maintain the characteristic enzymatic properties of the different cisternal types during translocation of cisternae across the stack, the cisternae bud recycling vesicles that

transport membrane proteins in a retrograde direction. These vesicles are known as **COPI vesicles** (see Fig. 1.25A). In plants, two types of COPI vesicles have been characterized: **COPIa vesicles** that recycle escaped ER proteins from *cis*-Golgi cisternae back to the ER, and **COPIb vesicles** that bud from medial- and *trans*-Golgi and Golgi-associated TGN cisternae and transport cisternal membrane proteins in a retrograde direction. This latter transport is responsible for maintaining the steady-state distribution of enzymes within Golgi stacks.

Intercisternal elements are another type of *trans*-Golgi cisterna-associated structure (see Fig. 1.25B). These parallel protein fibers lie sandwiched between cisternae and may serve as anchors for the glycosyltransferases involved in synthesis of large polysaccharide slime molecules, such as those secreted by the outermost cells of root caps.

1.5.2 The *trans*-most Golgi cisternae give rise to TGN cisternae that sort and package Golgi products

The function of the TGN is to sort and to package the products of the Golgi stacks into **secretory vesicles** and **clathrin-coated vesicles**. Secretory vesicles transport membrane and cargo molecules to the plasma membrane and cell wall, whereas clathrin-coated vesicles produced by the TGN deliver membrane and soluble molecules to multivesicular bodies and vacuoles. The TGN cisternae arise from the *trans*-most Golgi cisternae by a cisternal peeling process that yields free, independent TGN compartments (see Fig. 1.25). TGN cisternae in the process of peeling are called Golgi-associated or **early TGN cisternae**, and those that have become physically separated from the originating Golgi stack, **free** or **late TGN cisternae**. During cisternal peeling, the cisternae undergo multiple changes in architecture, including a 30–35% decrease in cisternal membrane surface area, most likely due to the removal of membrane by COPIb-type recycling vesicles. Concomitantly, the flattened cisternae are converted into grape-like membrane compartments as the number of budding secretory and clathrin-coated vesicles increases. This maturation process continues until all products have been sorted and packaged. Once this has happened, the fully matured free TGN cisterna breaks up, yielding free secretory and clathrin-coated vesicles together with small residual fragments of the cisternal membranes (see Fig. 1.25A). The fate of the residual membrane fragments is unknown.

The ratio of secretory to clathrin-coated vesicles budding from free TGN cisternae is highly variable, but typically secretory vesicles are more numerous. Even in a single root apical meristem cell, the ratio can vary from 5:1 to 1:3 on free TGN cisternae derived from adjacent Golgi stacks. This variability most likely reflects the composition of mRNAs (coding for secretory versus vacuolar proteins) that were translated by ER-bound polysomes close to a given ER export site. Upon transfer of each batch of locally produced

proteins to a forming *cis*-Golgi cisterna of an individual Golgi stack, and after passing through the stack, the biased set of vacuolar or secretory proteins reaches the TGN. There, the ratio of secretory to clathrin-coated vesicles formed is adjusted to the ratio of products in the cisternal lumen. This variability reflects the inherent flexibility of the sorting and packaging systems of the TGN cisternae. Free TGN compartments with a high ratio of clathrin-coated vesicles were given the name “partially coated reticulum” by early electron microscopists, but in light of the new findings, this name has outlived its usefulness and should be abandoned. *Trans*-Golgi and TGN cisternae are the most acidic compartments of the Golgi apparatus. They are acidified by vacuolar (V-type) H⁺-ATPases (see Chapter 3). The low pH environment of the cisternal lumen appears to regulate enzyme activities and cause an osmotic collapse of the lumen, which is of critical importance for the sorting and packaging of the Golgi products.

1.5.3 The Golgi scaffold/matrix originates on COPII buds and mediates ER-to-Golgi COPII vesicle transport

The Golgi matrix is a fine, filamentous, cage-like structure that completely surrounds all Golgi and TGN cisternae and is comprised of long coiled-coil scaffolding proteins, hence the more recent name Golgi scaffold. This scaffold/matrix excludes ribosomes from the immediate vicinity of Golgi and TGN cisternae, thereby facilitating its visualization in electron micrographs of ribosome-rich cell types (Fig. 1.29). It also appears to prevent COPI-type intercisternal recycling vesicles from escaping from the immediate surroundings of the Golgi stack and helps maintain structural integrity of Golgi stacks and associated TGN cisternae as they move along actin filaments through the cytoplasm.

Analysis of Golgi stack dynamics has shown that stacks move in a stop-and-go manner. This has led to the hypothesis that stacks may pause at ER export sites to pick up cargo for processing by Golgi enzymes. The mechanism responsible for inducing Golgi stacks to pause at ER export sites has puzzled cell biologists for many years. It now appears that the Golgi scaffold/matrix is intimately engaged in this process (see Figs. 1.25 and 1.30). In particular, recent studies have shown that COPII vesicles originate with a ~40-nm-wide external layer of long, scaffold-type proteins, termed **COPII scaffold**. As illustrated in the “dock, pluck and go model” of ER-to-Golgi trafficking (Fig. 1.31), the scaffold layer of budding COPII vesicles appears to capture passing Golgi stacks by binding to the *cis*-side of the Golgi scaffold/matrix. Once bound to a COPII vesicle, the wiggling motion of the Golgi stack appears to provide the force needed to pluck the budding vesicle from the ER export site. The plucked COPII vesicle together with its scaffold layer is then transferred to the *cis*-side of the Golgi scaffold/matrix where it contributes to the assembly of a new *cis*-Golgi cisterna.

1.5.4 The sugar-containing molecules produced in Golgi cisternae serve diverse functions

The Golgi apparatus is involved in assembling the **N-linked** and **O-linked glycans** of glycoproteins and proteoglycans and in synthesizing complex polysaccharides (see Chapters 2 and 4). One of the principal functions of glycosylation is to protect proteins against proteolysis, thereby increasing their life span. Sugar groups increase protein solubility and may specify plasma membrane–cell wall interactions, prevent premature activation of lectins (highly specific sugar-binding proteins), and contribute to protein folding or assembly of multiprotein complexes. Most proteins subject to N-linked glycosylation perform enzymatic functions, whereas O-glycosylated proteins often serve structural roles. For example, the O-glycosylation of extensin molecules (see Chapter 2) is responsible for their rod-shaped architecture. Both N- and O-linked glycan side chains are present in many highly glycosylated AGPs that, at >90% sugars, are classified as proteoglycans. The complex cell wall polysaccharides produced by the Golgi apparatus perform structural functions and can bind water and heavy metals. In addition, these polysaccharides contain cryptic regulatory oligosaccharide domains that can be released by specific enzymes to yield regulatory molecules known as oligosaccharins.

1.5.5 The Golgi apparatus is a carbohydrate factory

The synthesis of N-linked glycans starts in the ER with assembly of a 14-sugar oligosaccharide on a molecule of **dolichol**, a large lipid composed of 14–24 isoprene units. Once complete, this oligosaccharide is transferred by oligosaccharyl transferase to selected asparagine residues in nascent polypeptide chains. Most of the subsequent processing of the oligosaccharide occurs in the Golgi, including systematic removal of mannose residues and the addition of other types of sugars (see Chapter 4). The enzymes involved in these reactions are not randomly distributed among Golgi cisternae but become localized to medial, or *trans* cisternae, depending on which sequential step they catalyze as a given N-linked glycan moves through the stack from *cis* to *trans*. For example, the native enzyme mannosidase I, which mediates the first step of N-glycan processing in the Golgi is localized in medial Golgi cisternae. However, when this enzyme is expressed in transgenic plant cells as a mannosidase I-GFP fusion protein, the fusion protein is also seen in *cis*-Golgi cisternae and even in the ER. Apparently, when too many Golgi membrane enzymes of a given type are produced, they pile up in upstream compartments of the secretory pathway. For this reason, localizing Golgi membrane proteins by means of GFP fusion proteins yields unreliable results.

O-linked glycans are important components of hydroxyproline-rich glycoproteins and AGPs, many of which serve structural

FIGURE 1.31 Dock, pluck, and go model of ER-to-Golgi vesicle trafficking. (A) Go-phase: Golgi stacks travel along actin filaments propelled by myosin motors. (B) Dock-and-pluck phase: The scaffold of a budding COPII vesicle attaches to the cis-side of the Golgi scaffold/matrix of a passing Golgi stack and pulls the Golgi off the actin track. Once the COPII scaffold binds to the Golgi matrix, the wiggling motion of the Golgi stack facilitates the release of the COPII vesicle from the ER by a “plucking” mechanism. Once it has harvested the COPII vesicle from the ER export site, the Golgi is free to resume its movement along the actin track.

Source: Adapted from Staehelin, L.A. and Kang, B.-H. (2008). *Plant Physiol.* 147: 1454–1468.

roles. The sugars, mostly arabinose and galactose, are attached to amino acids that contain hydroxyl groups, such as hydroxyproline, serine, and threonine. Very little is known about the synthesis of O-linked glycans. On newly synthesized proteins destined for O-glycosylation, selected proline residues are converted to hydroxyproline in the ER, but where the enzymes are located that add the first arabinose sugars to those hydroxyprolines remains to be determined.

The matrix polysaccharides of plant cell walls are structurally complex molecules that play a central role in determining cell size and shape (see Chapter 2). Defined fragments of such molecules also function as signaling molecules in pathways that control plant growth, organogenesis, and the elicitation of defense responses. Unlike the linear polymers cellulose and callose, all branched cell-wall polysaccharides are synthesized by enzymes in Golgi and Golgi-associated TGN cisternae. The molecular details of the assembly pathways have yet to be elucidated. However, an outline of the spatial organization of the xyloglucan and pectic polysaccharide pathways in the Golgi stacks has been developed by using immunolocalization to

track in which cisternae specific carbohydrate groups are added. Probably the most striking result of these studies is that assembly of pectic polysaccharides appears to involve enzymes localized in medial and *trans*-Golgi and possibly Golgi-associated TGN cisternae, whereas enzymes that produce xyloglucan appear to be confined to *trans*-Golgi and Golgi-associated TGN cisternae. To date, very few native enzymes and nucleotide sugar transporters involved in complex polysaccharide biosynthesis have been immunolocalized to specific types of Golgi cisternae.

1.6 Exocytosis and endocytosis

Exocytosis is the process by which secretory vesicles derived from the TGN fuse with the plasma membrane, releasing their contents into the extracellular space (Fig. 1.32A). In growing cells, this process delivers proteins and lipids needed

FIGURE 1.32 Cross-sectional images of secretory vesicles. (A) TEM of a secretory vesicle in the process of initiating membrane fusion with the plasma membrane (PM). (B) TEM of a secretory vesicle that has fused with the plasma membrane and discharged its contents. The disc-shaped infolding of the membrane shown here is observed only in turgid cells.

for expansion of the plasma membrane as well as complex polysaccharides, glycoproteins, and proteoglycans required for cell wall growth. Because of the large surface-to-volume ratio of secretory vesicles, exocytosis delivers more membrane to the cell surface than is needed for expansion of the plasma membrane. Excess plasma membrane molecules are returned to the cytoplasm by two mechanisms: (1) **endocytosis** mediated by clathrin-coated vesicles (Fig. 1.33) that contain membrane proteins and lipids, and (2) non-vesicular, intermembrane lipid transport at plasma membrane–ER interaction sites associated with fused vesicle membrane domains (see domain 15 in Fig. 1.14). Endocytosis is also used to turn over plasma membrane molecules and remove activated receptors from the cell surface. A **recycling pathway** allows endocytosed, but still functional plasma membrane proteins to be recycled back to the plasma membrane. In animal cells, endocytosis plays a major role in the uptake of nutrient molecules, but little evidence suggests such a role in plants.

1.6.1 In plants, turgor pressure affects membrane events associated with exocytosis, endocytosis and membrane recycling

When a secretory vesicle in an animal cell fuses with the plasma membrane, its contents are expelled to the extracellular space and the vesicle membrane becomes part of the plasma membrane. As this occurs, the plasma membrane is expanded slightly, an expansion that can be readily accommodated by changes in surface architecture of the animal cell. Turgor pressure prevents this from happening in plant cells. In turgid plant cells, the plasma membrane is pressed tightly against the cell wall (see Fig. 1.11) and cannot expand unless the cell wall expands as well. When a spherical secretory vesicle fuses with the plasma membrane of a turgid cell, turgor pressure not only forces the vesicle contents into the cell wall, but also flattens the vesicle into a disc-shaped infolding of the

FIGURE 1.34 Three mechanisms for removing excess membrane from a plasma membrane infolding generated by the fusion of a secretory vesicle with the plasma membrane (see Fig. 1.32B) of a turgid plant cell: 1. cell expansion; 2. formation of clathrin-coated endocytic vesicles (CCV); 3. direct transfer of lipid molecules from the plasma membrane to adjacent ER membrane via lipid transfer proteins.

Source: Adapted from Staehelin, L.A. and Chapman, R.L. (1987). *Planta* 171: 43–57.

plasma membrane (Fig. 1.32B). Because the plasma membrane cannot expand, the infolding remains in place until excess membrane is removed.

How then is excess membrane removed from plant plasma membranes? Plants, like animal cells, can recycle excess membrane from the plasma membrane via endocytosis of clathrin-coated vesicles (Fig. 1.34 and Section 1.6.2). However, endocytosis demands much more energy in plants than in animal cells because sizable hydrostatic pressure forces must be overcome to form plasma membrane invaginations. In contrast, retrieval of lipid molecules from the plasma membrane via non-vesicular, intermembrane lipid transport—lipid “hopping”—mediated by lipid transfer proteins (Fig. 1.34) circumvents this energy problem, and reduces the number of endocytotic vesicles needed for the removal of excess plasma membrane material.

Evidence for lipid hopping has come from both lipid uptake research and electron microscopic studies of ultra-rapidly frozen cells. To investigate lipid uptake, a fluorescent analog of the membrane lipid phosphatidylcholine was added to the outer surface of the plasma membrane. This molecular marker was quickly translocated to peripheral ER cisternae with no evidence of vesicular intermediates. However, this uptake required that an extracellular enzyme convert phosphatidylcholine to diacylglycerol, a membrane lipid that lacks a large, polar headgroup and can readily flip-flop across the plasma membrane before being transferred to the ER. Electron micrographs of cryofixed cells suggest that this rapid lipid transfer is mediated by unique ER membrane extensions that form tight caps over the plasma membrane appendages left behind by the fused secretory vesicles (Figs. 1.34 and 1.35; see also domain 15 in Fig. 1.14). During this process the disc-shaped appendages tip over to form characteristic horseshoe-shaped plasma membrane invaginations. Once capped by an ER extension, the invagination

FIGURE 1.35 TEM showing lipid-recycling ER domains. The ER cisterna has characteristic extensions that form specialized contact sites (arrows) with freshly fused and collapsed secretory vesicles in the plasma membrane (PM) of a cryofixed pea root tip cell. These structures correspond to domain 15 in Figure 1.14.

Source: Micrograph by Stuart Craig, from Craig, S. and Staehelin, L.A. (1988). *Eur J Cell Biol* 46: 81–93.

shrinks until excess membrane is gone. The ER then retracts from the plasma membrane.

1.6.2 The membrane compartments associated with endocytosis can be identified by following the uptake of tracer molecules

The process of endocytosis can be visualized by exposing cells to tracer molecules that are internalized by clathrin-coated endocytic vesicles. Two classes of molecular markers have been used in such investigations. Compounds in one group serve as membrane markers and bind to the plasma membrane (e.g., cationized ferritin); members of the other class, known as fluid-phase markers, are internalized with the aqueous phase (e.g., lanthanum nitrate). The widely used fluorescent endocytosis marker FM4-64 is generally portrayed as a membrane marker, but based on published micrographs it also appears to bind to cell-wall components. Compared to the vast literature on endocytosis in animal systems, the number of comparable plant studies remains remarkably small. Two factors have contributed to the slow development of the field: (1) the low level of endocytic activity of plant cells, and (2) the presence of cell walls that greatly impede access of tracer molecules to the plasma membranes, making experimentation more difficult. Protoplasts can be used for tracer uptake studies, but the concentrated sucrose medium that protects protoplasts from bursting also affects cell function, yielding results that may not be representative of what occurs in healthy turgid cells.

A schematic model of our current understanding of the endocytic pathway in plants is depicted in Figure 1.36. Much

FIGURE 1.36 Schematic diagram of the endocytic pathway of plant cells. Plasma membrane material internalized via clathrin-coated vesicles is delivered to compartments called early endosomes, most of which appear to correspond to free TGN cisternae (see Fig. 1.25A) where the different types of proteins are sorted and packaged into either secretory vesicles (SV) that recycle materials back to the plasma membrane or clathrin-coated vesicles (CCV) that deliver molecules to multivesicular bodies (MVBs), which serve as late endosomes. Some MVBs deliver molecules to lytic vacuoles, whereas others send materials to protein storage vacuoles.

of the recent progress in plant endocytosis research has resulted from following the uptake of fluorescent tracer molecules into cells. The first compartments to receive endocytosed molecules are known as **early endosomes** and/or **recycling endosomes**, and those that receive the molecules later as **late endosomes**. In plants, the early endosomes correspond to TGN cisternae, and the late endosomes to **multivesicular bodies (MVBs)**. As discussed above, TGN cisternae serve as sorting and packaging compartments in the secretory pathway. The endocytosis pathway makes use of these capabilities to sort recyclable molecules from the plasma membrane into secretory vesicles so that they can be returned to the plasma membrane, and molecules destined for destruction into clathrin-coated vesicles for transport to MVBs and ultimately to lytic vacuoles. MVBs are spherical membrane compartments that contain distinct internal vesicles (Fig. 1.37A). Two types of vesicles bud from the boundary membrane of MVBs. Those that bud towards the cytoplasm and recycle membrane proteins back to the TGN are known as **retromer vesicles**. In contrast, budding of the boundary membrane into the MVB lumen gives rise to the **internal vesicles**. This latter process is employed to sequester membrane proteins—most notably activated, internalized plasma membrane receptors—into the interior of MVBs so that they can be functionally silenced and subsequently degraded by lytic vacuolar enzymes. Delivery of the vesicular contents of MVBs to storage or lytic vacuoles occurs by fusion of the MVBs with the vacuolar membranes (Fig. 1.37B).

Two types of structurally similar MVBs can be distinguished based on their cellular location and functional attributes. One type is seen in close proximity to the TGN, with both types of membrane compartments encompassed by a continuous TGN/MVB scaffold system. In developing *Arabidopsis* embryo cells the proteolytic processing of seed storage proteins starts in these TGN-associated MVBs, which

FIGURE 1.37 (A) TEM of one large and one small multivesicular body in the cytoplasm of a tobacco cell cultured in suspension. (B) Multivesicular body (MVB) that has just fused with a vacuole (V) and is in the process of delivering its internal vesicles to the vacuolar lumen. Source: (A) Micrograph by L. Andrew Staehelin. (B) Micrograph by Byung-Ho Kang, University of Florida, Gainesville, FL.

deliver the processed storage proteins to the protein storage vacuoles. MVBs that contain cargo molecules destined for vacuoles have also been called prevacuolar compartments, but because the definition of MVBs is more precise, the prevacuolar compartment nomenclature is now being phased out. MVBs not contained within the TGN/MVB scaffold system are capable of moving around cells in an independent manner and do not appear to process storage proteins. These independent MVBs, which receive endocytosed molecules, are also surrounded by a scaffold system, and deliver their contents to lytic vacuoles.

1.7 Vacuoles

Vacuoles, fluid-filled compartments encompassed by a **tonoplast membrane**, are conspicuous organelles of most plant cells: They typically occupy ~30% of the cell volume (Fig. 1.38), but in some cells, the space occupied by the vacuolar compartment(s) can approach 90%, with most of the cytoplasm confined to a thin peripheral layer connected to the nuclear region by transvacuolar strands of cytoplasm. During the cell cycle (see Chapter 11), vacuoles of apical meristem cells undergo major changes in shape and size. During interphase (G1 phase of the cell cycle), numerous small vacuoles are dispersed throughout the cytoplasm (see Fig. 1.1B). These vacuoles fuse into larger units during S and G2 phases and prometaphase. Coinciding with formation of the phragmoplast during cell plate formation, vacuolar volume shrinks by up to 80% and vacuoles assume a tubular configuration. This

FIGURE 1.38 TEM showing a cross-sectional view of spongy mesophyll cells in a bean leaf illustrating the large amount of cell volume occupied by the central vacuoles (V). Chloroplasts (C). Source: Micrograph by L. Andrew Staehelin.

shrunken state persists until cytokinesis is complete and the two daughter cells enter the G1 phase. It has been postulated that the transient reduction in vacuole volume during early telophase provides a means for increasing the volume of the cytosol to accommodate the forming phragmoplast microtubule arrays and associated cell plate-forming structures.

1.7.1 Plants use vacuoles to produce large cells cheaply

One of the major challenges faced by plants during evolution was to produce large solar collectors at a metabolic cost that could be recovered by the energy trapped and utilized by chloroplasts in a growing season. This problem was solved by increasing the volume of the vacuolar compartment to drive cell enlargement while keeping the amount of nitrogen-rich cytoplasm constant. This latter point is particularly important for plants, whose growth is often limited by N availability. By filling a large volume of the cell with “inexpensive” vacuolar contents, mostly water and minerals, plants are able to drastically reduce the cost of making expanded structures such as leaves, which are essentially throwaway solar collectors.

Plant cell expansion is driven by a combination of osmotic uptake of water into the vacuoles and altered cell wall extensibility. The water taken into vacuoles generates turgor pressure which expands the primary cell wall and creates stiff, load-bearing structures in conjunction with the walls. This exploitation of internal hydrostatic pressure to stiffen thin primary cell walls resembles the use of air pressure in an inner tube to convert a pliable, flat bicycle tire into a stiff circle capable of supporting heavy loads. Wilting and the associated softening of plant organs are caused by the loss of water from the vacuoles.

To maintain turgor pressure of continuously expanding cells, solutes must be actively transported into the growing vacuole to maintain its osmolarity. An electrochemical potential gradient across the tonoplast membrane provides the driving force for uptake of solutes. The gradient, in turn, is produced and maintained by two electrogenic proton pumps: V-type H^+ -ATPase and vacuolar H^+ -pyrophosphatase (H^+ -PPase). The principal solutes in vacuoles include the ions K^+ , Na^+ , Ca^{2+} , Mg^{2+} , Cl^- , SO_4^{2-} , PO_4^{3-} , and NO_3^- , and primary metabolites such as amino acids, organic acids, and sugars. Movement of water across the tonoplast membrane is mediated by aquaporin channels (see Chapter 3).

1.7.2 Plant vacuoles are multifunctional compartments

Vacuoles play several metabolic roles in addition to promoting cell expansion.

Storage: In addition to the solutes and primary metabolites mentioned above, plants also store large amounts of proteins in their vacuoles, especially in seeds. Stored reserves

can be retrieved from vacuoles and used in metabolic pathways to sustain growth. Interestingly, most of the flavors of fruits and vegetables can be traced to compounds that are stored in vacuoles.

Digestion: Vacuoles have been shown to contain the same types of acid hydrolases found in animal cell lysosomes. These enzymes, which include proteases, nucleases, glycosidases, and lipases, together allow for the breakdown and recycling of nearly all cellular components. Such recycling is needed not only for the normal turnover of cellular structures, but also for the retrieval of valuable nutrients during programmed cell death associated with development and senescence (see Chapter 20).

pH and ionic homeostasis: Large vacuoles serve as reservoirs of protons and metabolically important ions, such as Ca^{2+} . Typically, plant vacuoles have a pH between 5.0 and 5.5, but the range extends from ~ 2.5 in vacuoles of lemon (*Citrus limon*) fruit to >7.0 in unactivated protein storage vacuoles. By controlling the release of protons and other ions into the cytosol, cells can regulate not only cytosolic pH but also the activity of enzymes, the assembly of cytoskeletal structures, and membrane fusion events.

Defense against microbial pathogens and herbivores: Plant cells accumulate an amazing variety of toxic compounds in their vacuoles, both to reduce feeding by herbivores and to destroy microbial pathogens. These compounds include:

- phenolic compounds, alkaloids, cyanogenic glycosides, and protease inhibitors to discourage insect and animal herbivores
- cell wall-degrading enzymes such as chitinase and glucanase, and defense molecules such as saponins to destroy pathogenic fungi and bacteria
- latexes, wound-clogging emulsions of hydrophobic polymers that possess insecticidal and fungicidal properties and also serve as antiherbivory agents

Sequestration of toxic compounds: Plants cannot escape from toxic sites. Nor can they efficiently excrete toxic elements (e.g., heavy metals) and metabolites (e.g., oxalate). Instead, plants sequester these compounds into vacuoles. For example, to remove oxalate, specific cells develop vacuoles containing an organic matrix within which oxalate is allowed to react with Ca^{2+} to form calcium oxalate crystals. In other plant cell types, members of the **ABC family of transporters** (see Chapter 3) are used to transport **xenobiotics** (foreign compounds) from the cytoplasm into vacuoles. Accumulation of toxic compounds in leaf vacuoles is one reason leaves are shed on a regular basis.

Pigmentation: Vacuoles that contain anthocyanin pigments are found in many types of plant cells. Pigmented flower petals and fruits are used to attract pollinators and seed dispersers, respectively. In leaves, some vacuolar pigments screen out UV and visible light, helping prevent photo-oxidative damage to the photosynthetic apparatus.

1.7.3 Plants generate different types of vacuoles by means of vacuole transformation pathways

A fundamental question in plant vacuole research is whether plant cells produce multiple populations of functionally different types of vacuoles (multiple vacuole hypothesis), or if they produce one basic type of vacuole system that becomes specialized in response to developmental and/or physiological signals. Until recently, most researchers subscribed to the multiple vacuole hypothesis, which postulates that the large central vacuoles in root tip cells arise from the fusion of protein storage vacuoles and pre-existing lytic vacuoles. However, several recent investigations have yielded data that contradict this hypothesis. In particular, these new studies have demonstrated that the root tip cells of freshly germinated seedlings contain only protein storage vacuoles, which provide nutrients to the growing cells. As these nutrients are released from the vacuoles, the protein storage-type vacuoles are gradually converted into lytic vacuoles by means of cell type-specific transformation pathways. The transformation process includes changes in vacuole architecture as well as changes in composition of the vacuole membrane. Most notably, the protein storage vacuole marker protein α -TIP, an aquaporin-type protein, is replaced by the lytic vacuole aquaporin homolog, γ -TIP. Formation and maintenance of the different vacuole types also involves different types of vacuole targeting signals (see Chapter 4).

Senescing leaves of *Arabidopsis* and soybean (*Glycine max*) have been shown to produce two types of acidic vacuole systems in mesophyll and guard cells, a large central vacuole system with lytic properties, and smaller senescence-associated vacuoles. These latter vacuoles are more acidic than the central vacuole, accumulate a senescence-specific cysteine protease, and lack the γ -TIP of the central vacuole. Yet to be determined is whether these vacuoles arise *de novo*, or if they originate by budding from the central vacuole.

Autophagic vacuoles, also known as **autophagosomes**, are transient, large, double membrane vesicles responsible for delivering cytoplasmic materials to lytic vacuoles/lysosomes for degradation. The process begins with the entrapment of a targeted region of cytoplasm, including whole organelles, by cisterna-like membranes derived from collapsed vacuolar membranes and possibly ER membranes, followed by fusion with a lytic vacuole or lysosome. Autophagic vacuole formation is used to recycle old or damaged organelles, to provide nutrients during starvation, to generate large central vacuoles in root tip cells during germination, and to mobilize the cytoplasm during programmed cell death (Fig. 1.39).

1.8 The nucleus

The nucleus contains most of the cell's genetic information and serves as the center of regulatory activity (Fig. 1.40). Although the DNA-protein complexes that make up chromosomes are

FIGURE 1.39 Light micrograph of an aleurone protoplast stained with a fluorescent dye. Two types of vacuoles are depicted: large protein storage vacuoles (V_1) and smaller lytic/autophagic-type vacuoles (V_2) that may be involved in autophagy-associated programmed cell death.

Source: Micrograph by Paul C. Bethke, University of Wisconsin, Madison, WI.

evident only as an irregular network of chromatin during interphase, individual chromosomes nevertheless occupy discrete domains within the nucleus throughout this part of the cell cycle. Interphase is the most important stage of the cell cycle for gene expression because during this period chromosomes are actively transcribed.

A typical interphase plant cell nucleus also contains one to several **nucleoli** (singular: nucleolus) lying free in the nuclear matrix, or **nucleoplasm**. These prominent, densely staining, often spherical bodies house the cytoplasmic ribosome manufacturing machinery. A brief introduction is given below to the ultrastructure and activities of the nucleolus as well as to the structure of nuclear pores, through which nucleolar products must move to reach the cytoplasm.

1.8.1 The nuclear envelope is a dynamic structure with many functions

The **nuclear envelope** forms the outer boundary of the nucleus. It consists of two concentric membranes, the **inner nuclear membrane** and the **outer nuclear membrane**, separated by the **perinuclear space** (Fig. 1.41). The two principal functions of the nuclear envelope are to separate the genetic material in the nuclear compartment from the enzyme systems in the cytoplasm, and to regulate the exchange of molecules that traffic between the two compartments via the **nuclear pores** (Figs. 1.41 and 1.42). The inner and outer envelope membranes

Source: Micrograph by L. Andrew Staehelin.

are connected to each other via the bridging bilayer regions of the pores. The outer membrane of the nuclear envelope is continuous with membranes of the ER through narrow (~20 nm in diameter) connections (see domain 3 in Fig. 1.14) and

B

FIGURE 1.42 (A) Diagram of a nuclear pore complex in a nuclear membrane. (B) TEM showing a tangential thin section through nuclear pore complexes of a tobacco root tip cell. resembles the ER in having functional ribosomes on its cytoplasmic face. The perinuclear space is therefore continuous with the ER lumen. A meshwork of 10-nm-diameter filaments, called the **nuclear lamina**, underlies the inner envelope membrane (see domain 1 in Fig. 1.14). The lamina links the nuclear pore complexes and anchors and organizes the interphase chromatin at the nuclear periphery.

1.8.2 Nuclear pore complexes function as both molecular sieves and as active transporters

The density of nuclear pores embedded in the envelope varies considerably, depending on the type of cell. In plant cells, pores occupy from 8% to 20% of the envelope surface, at a pore density of 6–25 μm^{-2} . The pattern of pore distribution over the envelope varies in different organisms and cell types.

Each pore consists of an elaborate macromolecular assemblage known as the **nuclear pore complex** (Fig. 1.42). Nuclear pore complexes have an octagonal symmetry and appear similar in size and architecture throughout the plant and animal kingdoms. A nuclear pore complex is ~50 nm in diameter, has an estimated molecular mass of 125 MDa, and is composed of multiple copies of at least 30 different proteins, **nucleoporins**.

Nuclear pore complexes regulate trafficking between cytoplasm and nucleus. They permit rapid diffusion of small (<1 kDa), water-soluble molecules. Larger molecules (<40 kDa) can also diffuse across the pores, but more slowly. Proteins and protein–RNA complexes >40 kDa require an active

transport system as do some smaller proteins such as histones. In electron micrographs the central pore region stains more darkly (Fig. 1.42), most likely due to the presence of translocating proteins.

Proteins translated in the cytoplasm can be targeted to the nucleus by a **nuclear localization signal** sequence of amino acids (see Chapter 4). Recognition of this signal by the nuclear import receptors causes the opening of the central channel region of the pore. An additional signal facilitates exit from the nucleus. Most imported proteins remain in the nucleus, even if they are in soluble form and can move freely in the nucleoplasm. However, some proteins are known to move back and forth between nucleus and cytoplasm. Energy in the form of ATP is required to transport larger proteins or particles through the pore in either direction. Hydrolysis of ATP probably leads to a conformational change in transporters that causes pores to open.

1.8.3 The nucleolus is the ribosome factory of the cell

Although the **nucleolus** is not membrane-bounded, it is a distinct organelle within the nucleus (Fig. 1.43). It consists of a large aggregate of macromolecules, including rRNA genes, precursor and mature rRNAs, RNA processing enzymes, snoRNPs (small nucleolar ribonuclear proteins), ribosomal proteins and partially assembled ribosomes. Its main function is to transcribe ribosomal DNA, which loops through the nucleolus, and to assemble the ribosomal RNAs and imported ribosomal proteins into ribonucleoprotein subunits

FIGURE 1.43 TEM of a nucleolus within the nucleus of a carnation (*Dianthus caryophyllus*) cell. Note the three characteristic subdomains: fibrillar center, where ribosomal transcription takes place; surrounding dense fibrillar domain, where the rRNA transcripts are processed; and outermost granular layer that surrounds the whole structure.

Source: Micrograph by Eldon Newcomb.

for transport to the cytoplasm. The size of the nucleolus is highly variable and reflects the number of ribosomes the cell is producing. Three types of subdomains can be identified by electron microscopy:

- one or more fibrillar centers, in which ribosomal transcription takes place,
- dense fibrillar components surrounding the centers, where ribosomal RNA transcripts are processed, and
- granular component that encompasses the fibrillar region.

The granular component consists of preribosomal particles and ribosomal subunits 15–20 nm in diameter. These are in various stages of assembly and are smaller than fully developed ribosomes in the cytoplasm. On maturation they are exported from the nucleus through the central channel of the nuclear pore. The nucleolus breaks down at the beginning of prophase and reforms when ribosomal genes of the chromosomal nucleolar organizing region become active in the young daughter nuclei during telophase.

1.8.4 During mitosis, the nuclear envelope disassembles into cisternal fragments that initiate the formation of new envelopes around the daughter nuclei

At the onset of mitosis (see Chapter 11), nuclear pore complexes disassemble, leaving holes in the envelope membranes before the envelope itself breaks down at the start of prometaphase.

A cyclin-dependent protein kinase plays a central role in regulating disassembly and reassembly of the envelope during mitosis. Phosphorylation of the nuclear lamins on the inner surface of the envelope correlates with breakdown of the nuclear lamina and envelope and is also believed to play a part in assembly and disassembly of the pore complex. When the nuclear envelope breaks down, the membranes are converted into cisterna-like membrane compartments of the ER. After prometaphase, these nuclear envelope remnants are partitioned into the two halves of the dividing cell. During early telophase, dephosphorylation of nuclear lamins and other proteins triggers reassembly of the nuclear envelope on the surface of chromosomes in a process that excludes cytoplasmic proteins. This is followed by reassembly of the nuclear pore complexes between the borders of neighboring membrane compartments and completion of the nuclear envelope by membrane growth and coalescence.

1.9 Peroxisomes

Peroxisomes are structurally simple organelles composed of a single membrane that surrounds the finely granular peroxisome matrix (Fig. 1.44). Most peroxisomes are roughly spherical, with diameters ranging from 0.2 to 1.7 μm . The number of peroxisomes per cell is highly variable, as is their enzyme composition, which can change within a given cell during development and in response to environmental challenges. Peroxisomes contain over 300 nucleus-encoded proteins that function in fatty acid oxidation, metabolism of reactive oxygen species, photorespiration, and triglyceride metabolism. Catalase is present in all peroxisomes and used as a marker enzyme for the organelle (Fig. 1.44B). The concentration of enzymes in the peroxisome matrix is very high as evidenced by their high density (1.23 g cm^{-3} , compared to 1.18 g cm^{-3} for mitochondria), and the formation of strikingly beautiful catalase crystals in leaf peroxisomes (Fig. 1.45). In living cells of transgenic *Arabidopsis* plants in which GFP is fused to a peroxisome targeting signal, peroxisomes are seen to give rise to new peroxisomes via budding, and to translocate along actin filaments at peak velocities of 10 μm per second.

1.9.1 The role of peroxisomes depends on the organ or tissue in which they occur

In leaves of C_3 plants (plants that produce the three-carbon compound 3-phosphoglycerate as the first stable photosynthetic intermediate), peroxisomes play a key role in **photorespiration** (see Chapter 14), a light-dependent uptake of O_2 and release of CO_2 that arises from the dual function of the Calvin-Benson-Bassham cycle enzyme Rubisco (ribulose-1,5-bisphosphate carboxylase/oxygenase; see Chapter 12). Although Rubisco has much higher substrate affinity for CO_2 , which it joins to ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate, the enzyme also combines abundant

FIGURE 1.44 (A) TEM showing three roundish, unspecialized peroxisomes closely associated with ER cisternae in a bean root cell. (B) TEM of a tobacco leaf peroxisome stained with diaminobenzidine and osmium to demonstrate the presence of catalase in the organelle.

atmospheric O_2 with ribulose 1,5-bisphosphate to form one molecule of 3-phosphoglycerate and one molecule of 2-phosphoglycolate. The photorespiratory carbon oxidation cycle salvages this 2-phosphoglycolate by converting it to 3-phosphoglycerate, returning to the Calvin–Benson–Bassham cycle up to 75% of the reduced carbon in 2-phosphoglycolate and releasing the remainder as CO_2 .

The photorespiratory cycle involves interactions between a chloroplast, a leaf peroxisome, and a mitochondrion. Electron micrographs of leaf tissues in C_3 plants show that these three organelles are always closely associated physically and are often appressed to one another (Fig. 1.45). Recently, a protein called PEX10 has been shown to mediate attachment of peroxisomes to chloroplasts.

Because photorespiration is an inevitable accompaniment of C_3 photosynthesis, peroxisomes are large and abundant in the mesophyll tissues of C_3 plants. In C_4 plants, for which the first stable photosynthetic intermediate is a four-carbon organic acid, the Calvin–Benson–Bassham cycle occurs not in the mesophyll but in vascular bundle sheath cells (see Chapter 12), where the oxygenase activity of Rubisco is

FIGURE 1.46 TEM of glyoxysomes (G) surrounding oil bodies (OB) in a cotyledon of a germinating tomato seed.

Source: Micrograph by Sue E. Frederick, Mount Holyoke College, South Hadley, MA.

decreased because CO_2 concentration is much higher than in the ambient atmosphere. Leaf peroxisomes of C_4 plants are concentrated in bundle sheath cells, being smaller and relatively scarce in mesophyll cells. Specialized peroxisomes termed **glyoxysomes** participate in the mobilization of lipids in germinating oil seeds (Fig. 1.46; see also Chapter 8) and the breakdown and recycling of membranes during senescence (see Chapter 20). In some legume root nodules, peroxisomes are involved in the conversion of fixed N_2 into nitrogen-rich organic compounds (see Chapter 16).

1.10 Plastids

Plastids are major organelles found only in plant cells. They carry out photosynthesis, synthesize and store starch and oils, and contribute products to other biosynthetic pathways.

FIGURE 1.47 Diagram illustrating the developmental relationships between the major types of plastids. All plastids in plants are derived from proplastids, which are passed on to the next generation in eggs and sperm, and are maintained in the meristems. Single arrows with solid lines depict normal steps of plastid development; dashed arrows show conversions that occur under special circumstances.

Their outer boundary is formed by an envelope consisting of a pair of concentric membranes (Fig. 1.47). Plastids are semiautonomous and contain the genetic machinery required to synthesize some of their own proteins. The numbers of plastids per cell is highly variable and can change during development. They reproduce by division.

As is implied in the name (from the Greek *plastikos*: molded), plastids vary in size, shape, content, and function. Interest in this morphological plasticity was rekindled by studies of transgenic plant cells expressing GFP fused to a chloroplast stroma localization signal. Such GFP probes can be used to follow rapid changes in plastid shape, particularly the formation and retraction of 0.35 to 0.85- μm -wide tubular extensions known as **stromules** (stroma-filled tubules, Fig. 1.48). Stromules not only have the ability to grow and contract, they can also attach to each other and to other plastids, but they do not form tubular bridges that allow for the exchange of molecules.

Plastids also possess a remarkable capacity to differentiate, dedifferentiate, and redifferentiate (Fig. 1.47), and this plasticity has led to some confusion in plastid nomenclature. Most notably, the term leucoplast has been used in three different ways, as a generic term for some/all types of non-pigmented plastids, as a name for a postulated precursor type of plastid that gives rise to certain types of non-pigmented plastids, and as a name for non-pigmented plastids that

produce essential oils (see below). In this chapter, we use the term leucoplast to describe essential oil-producing plastids. Using the term leucoplast as a generic name for some/all types of uncolored plastids no longer serves a useful purpose and should therefore be discontinued.

1.10.1 The outer and inner membranes of the plastid envelope differ in composition, structure, and transport functions

Plastid envelope membranes mediate bidirectional metabolic traffic flows between the interior of plastids and the surrounding cytosol. Unlike other membranes of most eukaryotic cells, the envelope and thylakoid membranes of the chloroplast are poor in phospholipids and rich in galactolipids, a difference that some investigators believe might reflect the evolution of plants in a marine environment, where phosphorus is a limiting element (see Chapter 8).

The **outer envelope membrane** contains a non-specific pore protein that freely permits water and a variety of ions and metabolites (<10 kDa) to pass into the **intermembrane space**, the aqueous compartment between the membranes. The outer membrane is smooth and never becomes confluent

FIGURE 1.48 Light micrograph of two fluorescently labeled plastids with thin, tubular stromule extensions that contact each other at their ends. Both plastids contain the same photoconvertible type of GFP, but the plastid on the left was irradiated to convert its fluorescent molecules from green to red. The lack of conversion of the green fluorescence on the right demonstrates that the stromules are not fused and do not exchange proteins. Micrograph courtesy of Jaideep Mathur, University of Guelph, Canada.

with the inner membrane at any point. Electron microscopic studies, however, have revealed contact sites where proteins connecting the membranes mediate the transfer of nuclear-encoded chloroplast proteins from the cytosol to the chloroplast stroma (see Chapter 4). Among the polypeptides localized to the outer membrane are enzymes involved in galactolipid metabolism, some of which participate in cold acclimation.

The **inner envelope membrane** is freely permeable to small, uncharged molecules, including O_2 and NH_3 , and to low-molecular-mass, undissociated monocarboxylic acids. Most metabolites, however, cross the inner membrane with the aid of specific transporters. The inner envelope membrane also contains enzymes involved in the assembly of thylakoid membrane lipids.

1.10.2 All types of plastids are developmentally related to proplastids

Proplastids are the precursors of all types of plastids (Fig. 1.47). They are the plastids that are passed on to the next plant generation in eggs and sperm, and are a characteristic feature of meristematic cells. Angiosperm meristem cells contain 10–20 spherical or ovoid proplastids with diameters from ~0.2 to 1.0 μm (Fig. 1.49). The internal milieu of the proplastid, called the **stroma**, appears uniformly dense and finely granular and contains fewer ribosomes than do the more highly differentiated etioplasts and chloroplasts. In chemically fixed cells one or more nucleoids are sometimes identifiable in the stroma as electron-lucent regions containing fine (3-nm-diameter) DNA fibrils. The internal membrane system remains poorly developed, consisting of a few invaginations of the inner membrane and a small number of flattened sacs called **lamellae** with associated plastoglobules (see Section 1.10.5). The proplastid

FIGURE 1.49 TEM showing a proplastid (left) adjacent to a mitochondrion in a bean root cell. Note that ribosomes in the two organelles (small arrows) are smaller than cytoplasmic ribosomes (large arrows). The large electron-dense particles in the proplastid are plastoglobules, and the large round structure in the middle is a protein deposit.

stroma frequently contains starch granules, and occasionally deposits of phytoferritin (Fig. 1.50), a storage form of iron similar to the ferritin of animal cells. Such deposits are most frequently observed in the plastids of storage organs.

1.10.3 Chloroplasts house the photosynthetic machinery

Chloroplasts (Fig. 1.51), the green photosynthetic plastids responsible for energy capture, are commonly hemispherical or lens-shaped in vascular plants but vary considerably in

shape in mosses and algae. Plant chloroplasts commonly measure ~5–8 μm long and 3–4 μm thick. The photosynthetic apparatus of chloroplasts is contained within the expansive **thylakoid** membrane system (see Section 1.10.4).

The number of chloroplasts present in photosynthetic cells varies by cell type and species. In a leaf of the castor bean plant (*Ricinus communis*), a palisade mesophyll cell contains ~36 chloroplasts, but a spongy mesophyll cell only ~20. Of the ~500,000 chloroplasts per square millimeter of castor leaf, 82% occur in palisade mesophyll cells. Chloroplasts frequently store starch in quantities that vary according to the balance between sugar synthesis and sugar export. Developing chloroplasts in young leaves also possess many plastoglobules, thylakoid-associated lipid bodies (Figs. 1.51 and 1.57; see Section 1.10.5).

Etioplasts (Fig. 1.52A) are plastids for which the development from proplastids to chloroplasts has been arrested by the absence of light or by very low light conditions. They do not represent an intermediate stage in the normal, light-induced proplastid to chloroplast development. Instead, they

FIGURE 1.51 TEM of a developing tobacco chloroplast. Two envelope membranes (EM) delineate the chloroplast stroma (S) within which stacked grana thylakoids (GT) and non-stacked stroma thylakoids (ST) are seen. The dark granules are plastoglobuli (PG). The arrows point to lightly stained DNA-containing regions of the stroma. Source: Micrograph by L. Andrew Staehelin, University of Colorado, Boulder, CO.

constitute a special kind of plastid found only in white or pale-yellow etiolated tissues kept in the dark. Etioplasts lack the green, light-harvesting pigment **chlorophyll**, but accumulate large amounts of the colorless chlorophyll precursor called protochlorophyllide.

Etioplasts store membrane lipids in the form of a prominent, quasicrystalline membranous structure called the **prolamellar body** (Fig. 1.52A). This structure forms when membrane lipid synthesis continues in the absence of corresponding amounts of thylakoid protein synthesis, which requires light. The high concentration of lipids in prolamellar bodies (~75%) results in the formation of lipid tubes that branch in three dimensions to form a semi-crystalline lattice (Fig. 1.52B–D). When etioplasts are illuminated, they begin to develop into chloroplasts. Light triggers synthesis of chlorophyll from protochlorophyllide as well as the assembly of stable chlorophyll–protein complexes, resulting in the outgrowth of thylakoid membranes from the prolamellar body.

1.10.4 The photosynthetic grana and stroma thylakoid membranes form a physically continuous three-dimensional network

As illuminated proplastids differentiate into chloroplasts, a highly complex thylakoid membrane system develops in the stroma (Figs. 1.51 and 1.53). The electron transfer chain of the thylakoid membranes harnesses light energy to generate NADPH and a transmembrane proton gradient that drives ATP synthesis (see Chapters 3 and 12). The NADPH and ATP, in turn, power photosynthetic carbon fixation in the stroma (see Chapter 12).

Within each chloroplast, two distinct types of internal membrane domains—stacks of thylakoids, called **grana** (singular: granum), and non-stacked **stroma thylakoids**—form a continuous network that encloses a single anastomosing (branching and reconnecting) chamber, the thylakoid lumen (Figs. 1.53, 1.54, and 1.55). In young developing chloroplasts,

the initial thylakoids are unstacked and highly perforated. During chloroplast development, stacked grana arise from tongue-like outgrowths in the margins of the perforations of the originating thylakoids. As each outgrowth expands into a flattened sac, it contributes to the stacked grana membrane domain. As this process repeats, the grana stacks increase in height and differentiate further into intricate 3D thylakoid networks. The number of thylakoids in the grana of a mature chloroplast may vary from several to 40 or more, depending on the species and environmental conditions. In general, plants

grown in the shade have more numerous and thicker grana than individuals of the same species growing in bright light.

Membranes of non-stacked, stroma and stacked, grana thylakoids differ in important ways from one another. For example, photosystem I and ATP synthase complexes reside exclusively in stroma thylakoids and unappressed regions of the grana stacks. Photosystem II and light harvesting complex II, on the other hand, are located in the appressed regions of grana stacks. This segregation of protein complexes between appressed grana thylakoids and unappressed stroma thylakoids is known as **lateral heterogeneity** of the photosynthetic membrane system (see Chapter 12). In the freeze-fracture

electron micrograph shown in Figure 1.56, this lateral heterogeneity is evidenced by nonrandom distribution of membrane particles (protein complexes) between grana and stroma membranes. Thylakoid stacking is ubiquitous in green plants and is believed to be involved in regulating the distribution of absorbed energy between photosystem I and photosystem II during photosynthesis.

1.10.5 Plastoglobules are thylakoid-associated lipoprotein bodies that contain structural proteins and enzymes involved in the synthesis and storage of lipid molecules

Plastoglobules (Figs. 1.51 and 1.57A) are lipoprotein bodies encompassed by a monolayer of polar lipids that is contiguous with the stroma-side leaflet of the thylakoid membrane (Fig. 1.57B). The lipid core contains several types of prenylquinones, (α -tocopherol [vitamin E], phyloquinone [vitamin K1], plastoquinone, and menaquinones), as well as carotenoids, neutral lipids, and breakdown products of chlorophylls. The boundary layer consists of a monolayer of galactosylglycerides, structural proteins called plastoglobulins and enzymes involved in the synthesis and metabolism of the core lipids. Plastoglobules vary in size and number during plastid development and differentiation, becoming more abundant in response to environmental stresses (e.g., high light levels, drought, high salinity, and exposure to ozone) and during senescence. During chromoplast development, accumulation of carotenoids in plastoglobules confers color to fruits and petals.

1.10.6 Chromoplasts and gerontoplasts derive their color from carotene and xanthophyll pigments

Chromoplasts (Fig. 1.58) are yellow, orange, or red, depending on the particular combination of carotenes and xanthophylls present. These pigments are produced during chromoplast differentiation, and are deposited in plastoglobules as well as in lycopene crystals within residual thylakoid membranes. Chromoplasts are responsible for the colors of many fruits (e.g., tomato [*Lycopersicon esculentum*], orange [*Citrus sinensis*]), flowers (e.g., buttercup [*Ranunculus* spp.], marigold [*Tagetes* spp.]), and roots (e.g., carrot [*Daucus carota*], sweet potato [*Ipomoea batatas*]). Chromoplasts can develop directly from proplastids or by the dedifferentiation of chloroplasts (Fig. 1.47), as happens in ripening tomato fruits. Occasionally chromoplasts will redifferentiate into chloroplasts, as they do in some yellow and orange citrus fruits that regreen under the appropriate conditions or in light-exposed surfaces of carrot roots.

(B) Diagram of a plastoglobule attached to a thylakoid membrane. The lipid monolayer that surrounds the plastoglobule is contiguous with the outer leaflet of the thylakoid membrane and is studded with structural and enzymatic proteins. The functional domains of these latter proteins are located mostly in the plastoglobule interior.

Source: (A) Tomographic model by Jotham R. Austin II, from Austin, J.R., II, et al. (2006). *Plant Cell* 18:1693–1703. (B) Adapted from Austin, J.R., II, et al. (2006). *Plant Cell* 18: 1693–1703.

Chromoplast development is accompanied by a massive induction of enzymes that catalyze carotenoid biosynthesis. Although inactive forms of these enzymes occur in the stroma, active forms occur only in plastid membranes, where the highly lipophilic precursors of carotenes, as well as carotenes themselves, are localized. The great variation in composition of large carotenoid deposits results in major differences in the size and shape of the internal structures of chromoplasts.

Gerontoplasts are formed from chloroplasts during senescence of foliar tissues. Chloroplast senescence involves a controlled dismantling of the photosynthetic apparatus including the thylakoid membranes, and the accumulation of massive amounts of plastoglobules that can become very large. The

FIGURE 1.58 TEM of a developing chromoplast in a ripening tomato. The relatively early stage of this chloroplast to chromoplast transformation (see Fig. 1.47) is evidenced by the presence of small grana thylakoid stacks, which later disappear. Mature chromoplasts only contain plastoglobules (PG) and crystals (*) of lycopene within residual membrane sacs.

degraded thylakoid and stroma proteins provide a significant source of amino acids and nitrogen for the plant. In contrast, neither lipids nor pigments are recycled.

1.10.7 Different classes of colorless plastids synthesize and store starch and oils

Amyloplasts (Fig. 1.59) are unpigmented plastids that resemble proplastids but contain starch granules. Amyloplasts are especially common organelles in storage organs such as potato (*Solanum tuberosum*) tubers. Starch grains, which can be quite massive, occur free in the stroma together with a few flattened membrane sacs that line the inner envelope membrane. In gravity-sensing columella cells of root caps, amyloplasts serve as statoliths, sedimenting in response to gravity and thereby triggering the gravitropic response.

Elaioplasts are small, round plastids that store oil in the form of membrane-associated oil droplets. The oils contain triglycerides and sterol esters, and the droplets are delineated by a monolayer of polar lipids and proteins as in plastoglobules. Elaioplasts are produced in tapetal cells that surround developing pollen. When the tapetal cells lyse during the final stage of pollen maturation, the released sterol esters and oils become incorporated into the outer exine layer of the pollen wall.

Leucoplasts (Fig. 1.60), as defined in this chapter (see Section 1.10 introduction), are colorless plastids involved in synthesis of monoterpenes, and other volatile compounds contained in essential oils. Many of these compounds such as menthol, a derivative of mint oil, are exploited by humans as flavors or pharmacological agents. Their synthesis is carried out by specialized secretory gland cells associated with leaf and stem trichomes or within the secretory cavities of citrus peel. They possess a dense stroma, few internal membranes and ribosomes,

FIGURE 1.59 TEM of an amyloplast with many starch granules (S) and flattened membrane sacs (arrow) that underlie the inner envelope membrane in an *Arabidopsis columella* cell. Columella cell amyloplasts serve as statoliths of the gravity-sensing apparatus of root tips. Amyloplasts also store starch in potato tubers.

and the essential oil-containing plastoglobules that stain darkly with osmium. Leucoplasts are typically surrounded by an extensive network of tubular smooth ER membranes, which also participate in the synthesis of lipid molecules.

1.10.8 Plastids are partially autonomous, encoding and synthesizing some of their own proteins

Chloroplasts contain double-stranded, circular chromosomes and protein-synthesis machinery that accounts for as much as 50% of the total ribosomal complement of photosynthetic cells. Given that most chloroplast polypeptides are synthesized on cytoplasmic ribosomes, clearly the development of chloroplasts requires the integrated activities of both chloroplast and nuclear genomes.

Rubisco, the key enzyme in photosynthesis and photorespiration, serves as a good example. Although the small subunit of this enzyme is encoded in nuclear DNA and translated on cytoplasmic ribosomes, the large subunit is encoded in chloroplast DNA and translated on chloroplast ribosomes. Because the enzyme makes up ~50% of the total soluble protein in leaves and may be the most abundant protein in nature, the pattern of its continual breakdown and replacement helps explain the large number of ribosomes present in chloroplasts.

1.10.9 Plastids reproduce by division of existing plastids

Plastids arise from the binary fission of existing plastids. Division of proplastids, etioplasts, and young chloroplasts is most common, but even fully developed chloroplasts can divide. In meristematic cells, plastid division occurs during the G₂ phase of the cell cycle (see Chapter 11), thereby enabling daughter cells to inherit the same number of plastids as parent cells. The number of plastids in interphase shoot apical meristem cells of *Arabidopsis* is ~11. During cell expansion, the number of plastids per cell can increase several-fold.

Plastid division is first made evident by a constriction in the center of the plastid (Fig. 1.61). The constriction deepens and tightens, creating an extremely narrow isthmus before the two daughter plastids separate completely. The division machinery includes two contractile ring systems, an internal ring located

FIGURE 1.61 TEM of a dividing etioplast in an etiolated leaf of a bean seedling. Note the central constriction.

Source: Micrograph by Peter J. Gruber, Mount Holyoke College, South Hadley, MA.

on the stromal side of the inner envelope membrane, and an external ring that forms on the cytosolic side of the outer envelope membrane. The inner ring subunits have been shown to be homologs of the *FtsZ* proteins that function in the cell division of cyanobacteria, the endosymbiotic precursors of chloroplasts (see Box 1.1). The outer ring contains a polysaccharide ring composed of polyglucan chains and associated dynamin proteins. Dynamin proteins are mechanoproteins that also form the contractile rings involved in budding of clathrin-coated vesicles (see Fig. 1.33A), and the dumbbell-shaped vesicles involved in cell plate assembly. Chloroplast division starts with the formation of the *FtsZ* ring, which recruits cytosolic glucosyltransferases to the site of constriction to produce the polyglucan molecules that form the polysaccharide ring. The polysaccharide ring, in turn, appears to serve as a template for the contractile force-generating dynamin molecules.

1.10.10 Plastids are inherited maternally in most flowering plants but paternally in gymnosperms

Cytoplasmic organelles can be passed from one generation to the next by way of the egg (maternal inheritance), sperm (paternal inheritance), or both (biparental inheritance). Genetic evidence indicates that in most angiosperms, plastids (and mitochondria) are inherited maternally. These organelles from the male are either excluded from sperm cells or degraded during male gametophyte development or double fertilization. Whether from egg or sperm, plastids are in the proplastid stage of development at the time they are inherited.

Biparental inheritance of plastids and mitochondria has been documented both cytologically and genetically in a few flowering plant genera, including *Pelargonium* (geranium), *Plumbago* (leadwort), and *Oenothera* (evening primrose). In *Pelargonium*, male plastids and mitochondria differ ultrastructurally from those of the female, making it possible to establish that organelles from both are present in the developing embryo. *Plumbago*, a model of particular interest, has dimorphic sperm—one of the male gametes is rich in mitochondria, the other in plastids—and exhibits preferential fertilization, the plastid-rich sperm fusing with the egg most commonly and the mitochondrion-rich sperm doing so only rarely. Gymnosperms differ strikingly from angiosperms in their mode of plastid inheritance, with plastids typically passed to the next generation through sperm.

1.11 Mitochondria

Mitochondria (singular: mitochondrion) are organelles that house enzymes and electron transfer chain components that produce ATP by ways of the citric acid cycle, respiration, and ATP synthase (see Chapter 14). In addition, mitochondria

BOX
1.1

Plastids and mitochondria evolved from endosymbiotic bacteria

Plastids and mitochondria are widely thought to have arisen from eubacteria that invaded or were engulfed by protoeukaryotic cells during the origin of the eukaryotic lineage. These organelles retain the genetic capacity to make some of their own proteins, but most of their genes have been transferred to the nucleus over time in what appears to be an ongoing process. Genes are first translocated from organelle to nucleus, so that they coexist for a time in both, before being gradually lost from the organelle. As a result of this gene loss, mitochondria and plastids now require nuclear gene products for function and replication.

Evidence for the endosymbiosis theory includes cellular and molecular traits that plastids and mitochondria share with free-living eubacteria. Similar to the genomes of eubacteria and unlike the nuclear genomes of eukaryotes, the DNA that remains within the organelles is predominantly circular and does not form extensive supramolecular complexes with proteins. In

eubacteria, the DNA is organized in the form of a nucleoid that is attached to a specific region of the plasma membrane, but it is not segregated from the other cellular constituents by a membrane. Similarly, the DNA of chloroplasts and mitochondria is organized in the form of nucleoids that are attached to thylakoids and the inner membrane, respectively. Mitochondrial and plastid ribosomes are smaller than cytoplasmic ribosomes (see Figs. 1.49 and 1.62) and resemble those of eubacteria in shape and size, appearing in electron micrographs as electron-opaque particles ~15 nm in diameter. The organellar ribosomes, like those of eubacteria, are sensitive to certain antibiotics that are ineffective against cytoplasmic ribosomes (e.g., chloramphenicol). Comparison of ribosomal RNA (rRNA) sequences from organelles and certain free-living eubacteria suggests that plastids share a common ancestor with modern cyanobacteria and mitochondria with modern proteobacteria.

Synechococcus lividus

Rickettsiella popilliae

Evidence indicates that plants and other eukaryotic organisms evolved from endosymbiotic associations between different eubacteria. A comparison of ribosomal RNA sequences suggests that plant plastids share a common ancestor with modern cyanobacteria, such as the free-living organism *Synechococcus lividus*. Mitochondrial rRNA sequences of extant eukaryotes share greatest homology with members of the α -group of the proteobacteria, which includes several genera of intracellular parasites (e.g., *Agrobacterium*, *Rhizobium*, and *Rickettsia*). The electron micrograph at lower right shows cells of *Rickettsiella popilliae* within a blood cell of its insect host.

produce organic acids and amino acids that are used in biosynthetic and multiorganelle metabolic pathways such as photorespiration (see Chapter 14), C_4 photosynthesis and Crassulacean acid metabolism (see Chapter 12), and gluconeogenesis (see Chapters 8 and 20). The two principal waste products of mitochondria are CO_2 and H_2O .

FIGURE 1.62 Thin-section TEM of a mitochondrion in a eucalyptus root tip cell. A crista-forming infolding of the inner membrane is marked by the open arrow. Small eubacteria type ribosomes, ~15 nm in diameter (arrows), and hints of fibrous DNA strands are seen within the mitochondrial matrix.

1.11.1 Mitochondria comprise two membranes and two membrane-bounded compartments

Mitochondria are composed of two membranes and two membrane-bounded compartments: the **outer membrane**, the **inner membrane**, the **intermembrane space**, and the large internal space called **matrix** (Figs. 1.62 and 1.63). Most of the functional activities of mitochondria are located in the inner membrane and the matrix (see Chapter 14). The inner membrane can be divided into two subdomains, the **inner boundary membrane**, which is closely apposed to the outer membrane, and the **cristae membranes**, which give rise to the membrane infoldings, **cristae** that protrude into the matrix. Connecting these two inner membrane domains are the narrow **cristae junctions** located at the base of the cristae.

A defining feature of the outer membrane are proteins called **porins**, large, integral membrane proteins that form channels and enable molecules up to 10 kDa to diffuse freely into and out of the intermembrane space. Molecules capable of diffusing across these pores include ions, sugars, amino acids as well as ADP and ATP, but not proteins. The outer membrane also contains enzymes involved in the conversion of phosphatidylserine into phosphatidylethanolamine, but most of the lipids needed for mitochondrial membrane synthesis are produced by the ER and imported without modification.

The inner membrane has a high protein/lipid ratio (~75:25) and houses the protein complexes of the electron transport chain, which together with the ATP synthases, comprise ~80% of the membrane proteins. Mitochondrial ATP synthases, like

FIGURE 1.63 Diagram depicting the 3D organization of mitochondrial cristae and the distribution, within its membranes, of associated protein complexes.

those in chloroplasts, are driven by a transmembrane proton gradient produced by the action of the electron transfer chain (see Chapters 3 and 14). Recent studies have shown that these latter proteins are located preferentially in the cristae membrane domains of the inner membrane. In contrast, the inner boundary membrane domains are significantly enriched in protein translocation proteins and carriers that facilitate the movement of metabolites between the cytosol and intermembrane space and the mitochondrial matrix. The cristae junctions are, in part, responsible for the non-random distribution of these different types of proteins between the two inner membrane domains.

In dormant seeds, the **promitochondria of the embryo** are largely devoid of cristae and possess a matrix with a low

FIGURE 1.64 Structure of cardiolipin, an unusual phospholipid component of the inner mitochondrial membrane.

protein content. During imbibition, new cristae are formed following the activation of the protein synthesis machinery and the assembly of new respiratory chain and ATP synthase complexes in the inner membrane. Simultaneously, the accumulation of citric acid cycle and biosynthetic enzymes increases the protein content of the matrix. When the demand for ATP increases, the number and size of the mitochondrial cristae can grow further to accommodate the additional electron transfer chain and ATP synthase proteins.

The inner membrane also contains a unique type of “double” phospholipid, **cardiolipin**, which has four fatty acid tails (Fig. 1.64). Cardiolipin binds to the transmembrane domains of the ATP synthase rotor proteins. In damaged mitochondria, it translocates to the outer membrane where it triggers autophagy.

The matrix is comprised of hundreds of soluble enzymes that metabolize pyruvate and fatty acids to acetyl-CoA and oxidize the acetyl-CoA via the citric acid cycle to produce NADH for the electron transfer chain. Other matrix components include multiple copies of the mitochondrial genome, mitochondrial ribosomes, tRNAs and various proteins required for the expression of mitochondrial genes.

1.11.2 Shoot apical meristem cells are unique in that they contain two structurally distinct types of mitochondria

Until recently, plant mitochondria have been portrayed as being small, round to sausage-like organelles measuring 0.5–1 μm in diameter and 1–3 μm in length (Fig. 1.65A). This description appears to be correct for all cells of intact higher plants except for shoot apical meristem (SAM) cells, which

FIGURE 1.65 (A) 3D reconstruction of the mitochondria and nucleus of an epidermal cell in *Arabidopsis* based on serial confocal microscopy sections. Typical of cells in most plant organs, the mitochondria (M, green) are small and dispersed throughout the cytoplasm. n, nucleus. (B) 3D reconstruction of an *Arabidopsis* shoot apical meristem cell based on serial thin-section TEMs. In this mitotic cell most of the mitochondria (M, green and light blue) are organized into a large, cage-like structure with only a few small, individual mitochondria seen in the cell cortex. n, nucleus.

Source: Models by Jose-Maria Segui-Simarro, Universidad Politécnic de Valencia, Spain.

possess both the characteristic small mitochondria in the cell cortex as well as a large, central, reticulate mitochondrion (Fig. 1.65B) that undergoes characteristic cell cycle-dependent changes.

In living plant cells, the small mitochondria are seen to be highly dynamic organelles that can slide to different cellular locations and frequently undergo fission and fusion and occasional branching changes. The number of mitochondria per cell varies from fewer than 50 to several thousand depending on cell type and cell size. However, for a given type of cell the cytoplasmic volume occupied by mitochondria is fairly stable. For example, in SAM cells mitochondria make up ~10% of cell volume whereas in cell types with high energy requirements such as transfer cells (see Chapter 15) they make up to 20%. Mitochondria congregate around cellular areas with high energy needs; in plant cells their movements are mediated by the actin–myosin cytoskeletal system.

The large, central mitochondrion of *Arabidopsis* SAM cells varies in shape from tentaculate to cage-like during the cell cycle (Fig. 1.66). The tentaculate mitochondrial form, which wraps around one nuclear pole, is seen during the G1 and S phases of the cell cycle, where it contributes 40% of the mitochondrial volume. The remaining small mitochondria are scattered throughout the cortical cytoplasm. In G2, the tentaculate mitochondrion extends around the nucleus to produce a second cap-like domain on the opposite side of the nucleus. During this expansion, ~60% of the smaller mitochondria fuse with the large mitochondrion, whose volume increases to 80% of the total mitochondrial volume. The cage-like mitochondrion is formed during mitosis. It completely encompasses the mitotic spindle and the early phragmoplast. During late cytokinesis the cage-like mitochondrion divides into two tentaculate mitochondria that wrap around the opposite poles of the daughter nuclei, while simultaneously budding off new small mitochondria by fission. It has been postulated that the tentaculate/cage-like mitochondrion of SAM cells provides an efficient means for recombining the mitochondrial DNA during vegetative life prior to gamete production, thereby preventing speciation.

1.11.3 Like plastids, mitochondria are semiautonomous and possess the genetic machinery to make some of their own proteins

Plant mitochondria, like the mitochondria of all eukaryotes, contain genomes that encode ribosomal RNAs (rRNAs), transfer RNAs (tRNAs), and a few proteins. However, enzymes concerned with DNA replication, transcription and processing, and translation are apparently all encoded in the nucleus. Among the distinctive features of plant mitochondrial genomes are their large size and complexity in comparison with mitochondria of other organisms (see Chapter 6). For example, whereas mammalian mtDNAs are 15,000–18,000

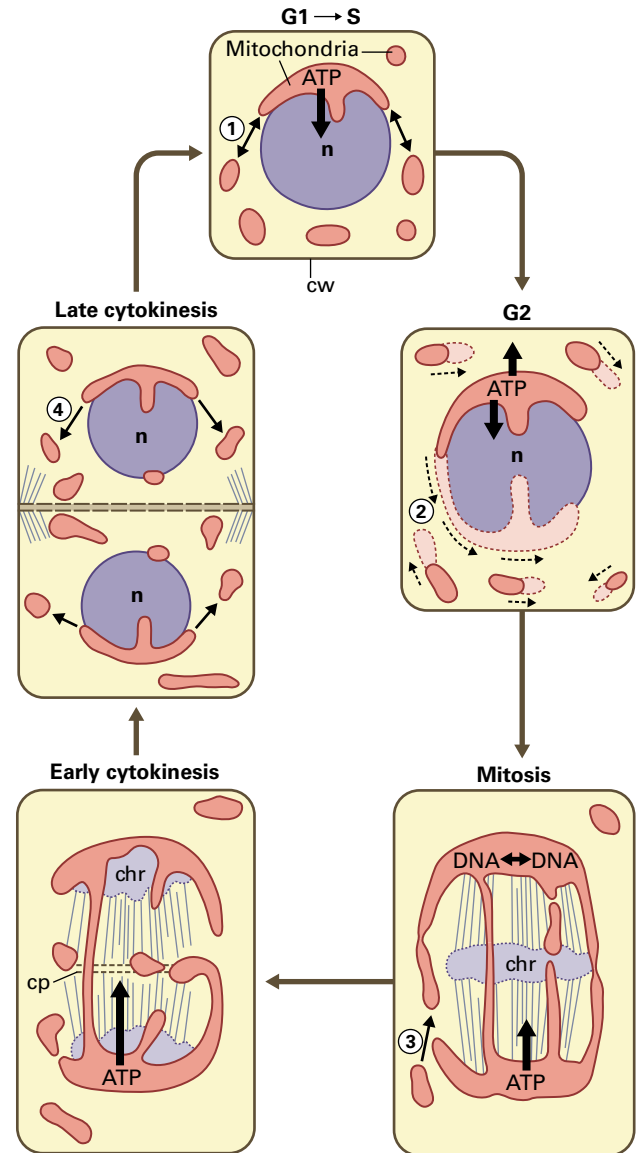

FIGURE 1.66 Model of cell cycle-dependent changes in mitochondrial architecture in *Arabidopsis* shoot apical meristem cells and their potential functional roles. The model postulates that the large, tentacular/cage-like mitochondria provide a structural framework that enables mtDNA intermixing for mtDNA recombination prior to cytokinesis. (1) fusion/fission equilibrium; (2) net mitochondrial growth; (3) fusion during mitosis. n, nucleus; chr, chromosomes; cp, cell plate; cw, cell wall; G1, G2, and S, cell cycle stages. Source: Adapted from Segui-Simarro, J.M., Coronado, M.J. and Staehelin, L.A. (2008). *Plant Physiol* 148: 1380–1393.

nucleotides long, plant mtDNAs range in size from ~200,000 nucleotides in some crucifers to a remarkable 2,500,000 nucleotides in watermelon (*Citrullus lanatus*). Related to this wide range in nucleotide number is variability in the sizes of mtDNA molecules. Mitochondrial genomes take the form of either a single large, circular chromosome or one large, circular molecule and several smaller circular molecules (representing recombination between repeated sequences), depending on species.

Another notable feature of plant mitochondrial genomes is that they do not contain a complete set of tRNA genes but encode only ~16 tRNAs, specific for 12–14 amino acids. Twenty tRNAs, at least one for each of 20 common amino acids, are generally necessary for protein synthesis. How, then, can plant mitochondria synthesize any proteins at all? The best evidence to date is that the “missing” tRNAs are encoded by nuclear genes and imported into mitochondria from the cytosol.

Still another special feature of plant mitochondria is the presence of some plastid DNA sequences in their genomes. These sequences, some of which are tRNA genes, represent

DNA transferred from plastids and incorporated into the mtDNA during the course of evolution. Most of them are not functional in the mitochondria.

Plant mitochondria probably contain several hundred different proteins. Only a very few of these, some 15 or 20, are encoded and synthesized in mitochondria. Of these few, most are components of the electron transfer chain or part of the ATP synthase complex in the mitochondrial inner membrane. All remaining mitochondrial proteins must be encoded by nuclear genes, synthesized on ribosomes in the cytosol, and imported into the mitochondria.

Summary

This chapter provides an introduction to cell membranes and the endomembrane system with an emphasis on structural aspects.

Cell membranes are inherited structures that serve as barriers to the diffusion of most water-soluble molecules and enable cells to create compartments in which chemical composition can differ from the surroundings. Membranes are composed of polar lipids that form a bilayer continuum and proteins that are responsible for most membrane functions. The plasma membrane serves as the diffusional boundary of individual cells and controls the transport of molecules into and out of cells. The endomembrane system forms a dynamic network that permeates all regions of the cytosol and gives rise to specialized membranous organelles. Together, the components of the endomembrane system are involved in many important cellular processes, including transport and secretion, protein modification, and metabolic reactions. Vacuoles are organelles that enable plant cells to grow

rapidly with the expenditure of minimal amounts of energy and proteins. They perform a multitude of functions, including storage, digestion, ionic homeostasis, defense against pathogens and herbivores, and sequestration of toxic compounds.

Plastids are members of a family of organelles specific to plants and algae. The principal types of plastids are the photosynthetic chloroplasts, starch-storing amyloplasts, carotenoid-forming and colorful chromoplasts, and essential oil-producing leucoplasts. All plastids are semi-autonomous organelles, that is, they are capable of producing some but not all of their proteins, with the rest being imported from the cytoplasm.

Mitochondria are organelles in which the process of aerobic respiration produces ATP mostly from sugars and fatty acids. They also provide metabolic intermediates that serve as substrates for the synthesis of other molecules. Like plastids, they are semiautonomous organelles.

The Cell Wall

Nicholas C. Carpita, John Ralph,
and Maureen C. McCann

Introduction

The shape of a plant cell is constrained by its cell wall. When a living plant cell is treated with cell wall-degrading enzymes, the resulting membrane-bound **protoplast** is spherical (Fig. 2.1). The cell wall limits the rate and direction of cell growth, exerting a profound influence on plant development and morphology. In certain cell types, walls are elaborated to carry out specialized functions, and in some, including tracheary elements and some trichomes, the protoplast disintegrates during development and the mature cell consists entirely of cell wall (Fig. 2.2).

The plant cell wall is a dynamic compartment, changing throughout the life of the cell. When cells of the meristem enlarge and elongate, new material is continuously integrated into the **primary cell wall**, which expands and increases in surface area, in some cases over a 1,000-fold. New walls are born in the **cell plate** during cell division and fuse with the existing side walls (Fig. 2.3). A **middle lamella** forms the interface between the primary walls of neighboring cells, and material is also added to this interface as their primary walls increase in area (Fig. 2.4). In older cells, the pectin-rich material in the cell corners is sometimes digested by hydrolytic enzymes, and an air space forms (Fig. 2.4). Finally, at differentiation, many cells, such as tracheids and fibers, elaborate within the primary wall a distinct **secondary cell wall**, building complex structures uniquely suited to the cell's function (Fig. 2.5).

The plant cell wall is a highly organized composite of many different polysaccharides, proteins, and aromatic substances. Some structural molecules act as fibers, others as a crosslinked matrix analogous to the glass fibers and plastic matrix in

fiberglass. The molecular composition and arrangements of wall polymers differ among species, tissues of a single species, individual cells, and even regions of the wall around a single protoplast (Fig. 2.6).

Not all specialized functions of cell walls are structural. Some cell walls contain molecules that affect patterns of development and mark a cell's position within the plant. Walls contain signaling molecules that participate in cell–cell and wall–nucleus communication. Fragments of wall polysaccharides may elicit secretion of defense molecules, and the wall may become impregnated with protein and lignin to armor it against invading fungal and bacterial pathogens (Fig. 2.7). Cell wall surface molecules also allow plant cells to recognize their own kind in pollen–style interactions (Fig. 2.8).

2.1 Sugars are building blocks of the cell wall

Polysaccharides, polymers of sugars, are the principal components of the cell wall and form its main structural framework. Polysaccharides are long chains of sugar molecules covalently linked at various positions, and some are decorated with side-chains of various lengths. Familiarity with the chemistry and nomenclature of sugars greatly facilitates understanding of the many biological functions of polysaccharides.

Sugars are polyhydroxy aldehydes (**aldoses**) and ketones (**ketoses**) that can be grouped according to their chemical formula, configuration, and stereochemical conformation. Almost

all cell wall sugars are aldoses. Many sugars have the empirical formula $(\text{CH}_2\text{O})_n$, from which the term **carbohydrate** is derived.

Numerical prefixes define how many carbons a sugar contains. For example, a triose has three carbon atoms, a pentose five, and a hexose six. All sugars can exist in a straight-chain conformation, and sugar molecules with four carbons or more can

FIGURE 2.1 Without their cell walls, protoplasts adopt a spherical form.
Source: N. J. Stacey, John Innes Centre, Norwich, UK.

also rearrange to form heterocyclic rings (Fig. 2.9). Sugars that adopt a five-membered ring configuration (four carbons and an oxygen) are called **furanoses**, and those forming six-membered rings (five carbons and an oxygen) are **pyranoses**. The ring conformation a sugar adopts is not defined by the number of carbons: both pentoses and hexoses can occur in either ring form.

Pyranose and furanose rings can be diagrammed using either flat **Haworth projections** or conformational models (Fig. 2.9). The pyranose sugars assume the so-called “chair” conformation, whereas the furanose sugars are a “puckered” five-membered ring. The five tetrahedral carbon atoms forming a pyranose ring project the hydrogen and hydroxyl groups either in **equatorial** positions away from the ring or in **axial** positions above and below the ring. Pyranoses adopt one of two possible “chair” forms to accommodate as many hydroxyl or other bulky groups as possible in the equatorial position. For common cell wall D-sugars, such as D-glucose, the ${}^4\text{C}_1$ -chair conformation is the most energetically favorable, but for the deoxy-sugars L-fucose and L-rhamnose, the ${}^1\text{C}_4$ -chair is the more favorable conformation (Fig. 2.10).

In aldoses, including the hexose glucose and the pentose arabinose, the C-1 is the **anomeric carbon**, the only carbon bound to two oxygen atoms. The other carbons are numbered sequentially around the ring. The hydroxyl group of the anomeric carbon can be in α or β position. In solution,

FIGURE 2.2 A developing cell constructs its wall architecture to provide characteristic shapes. (A) The spongy parenchyma of a *Zinnia elegans* leaf minimizes cell contact and maximizes cell surface for gas exchange. Note how water droplets bead on the waxy lower epidermis but not on the spongy mesophyll cells. (B) An *Arabidopsis* trichome is an exquisitely branched, modified epidermal cell. (C) The thickened and elaborated inner wall of a guard-cell pair (G) provides the physical form needed to control aperture size of a stoma. The cuticle (Cu), a special wall outgrowth of waxy and phenolic substances, minimizes evaporative loss of water from the exterior surface. (D) Transfer cells elaborate a highly fenestrated wall to enhance surface area of the plasma membrane for sugar transport. (E) The end wall (sieve plate) of the sieve element is perforated with many canals as a result of selective wall hydrolysis. (F) The specialized shapes of these epidermal cells reflect light to enrich the colors of a snapdragon (*Antirrhinum* sp.) petal. (G) Pollen grains elaborate outer walls of many forms.

FIGURE 2.3 Formation of the cell plate during cell division of a *Tradescantia* staminal hair cell. The cell plate forms during cytokinesis and undulates until it contacts the mother wall. Coincident with partitioning of the mother cell into two daughter cells, the cell plate changes from a wavy appearance to a firm, flattened wall. Values in the corners of each plate are minutes from the onset of prophase. Source: P. Hepler in Gunning & Steer. (1996). *Plant Cell Biology*. Jones and Bartlett, London.

FIGURE 2.4 Primary walls of cells are capable of expansion. Adhesion between certain cells is maintained by the middle lamella, and the cell corners are often filled with pectin-rich polysaccharides. The middle lamella forms during cell division and grows coordinately with the primary walls.

Source: M. Bush, John Innes Centre, UK.

FIGURE 2.5 When they have achieved their final size and shape, some cells elaborate a multilayered secondary wall within the primary wall. In this example of a fiber cell from a young stem of a locust (*Robinia* spp.) tree (A), three distinct layers of secondary wall (S1–S3) within the primary wall (CW1) and middle lamella (ML) are visualized in the electron microscope (B). Many fibers contain “warts” (W), which are a last stage of wall thickening before the protoplast disintegrates. Subfunctionalization is inherent in the pattern of the thickenings, from the netted appearance of stem tracheids that resist torsional strain (C) compared to the radially oriented thickenings of petiole tracheids that provide more flexibility (D). Source: (B, C) Maureen McCann, Purdue University.

FIGURE 2.6 Production of complex, chemically diverse molecules of cell walls is developmentally regulated. (A) Staining walls of *Arabidopsis* root with six monoclonal antibodies against cell-wall polysaccharides demonstrates they occur in specific cell and tissue types. JIM7 recognizes methyl-esterified homogalacturonan and stains all cells; CCRC-M2, which recognizes an epitope of sycamore maple rhamnogalacturonan I (RG I), stains epidermal and cortical cells, whereas CCRC-M39 recognizes fucosylated xyloglucans (and RG I), and stains only the outward facing wall of the epidermis; JIM13 recognizes an arabinogalactan-protein epitope in the stele; LM11 recognizes arabino-4-O-methyl glucurono-xylans and stains fiber cells of the stele, whereas CCRC-M36, which recognizes unbranched backbones of RG I, stains primarily cortical cells. (B) Cross-section of an *Arabidopsis* stem showing domains enriched in methyl-esterified pectin are labeled in green. De-esterified pectins, shown in yellow, are found in specialized cells, such as the outer epidermal wall (oe), fiber cells of phloem (pf), some cell corners and cross-walls, and tracheary elements of the xylem (te). Lignin autofluorescence is shown in red. Source: (A) Glenn Freshour & Michael Hahn, CCRC, University of Georgia. (B) Paul Linstead, John Innes Centre, UK.

FIGURE 2.7 Cells often alter their cell wall in response to environmental stimuli and potential pathogens and symbionts. (A) In response to attempted invasion by fungal hyphae of *Colletotrichum* (stained with lactophenol-cotton blue), a maize (*Zea mays*) cell produces a wall apposition called a papilla. Largely composed of callose, the papilla also accumulates lignin, as shown by staining with phloroglucinol (B) and by staining with syringaldehyde stain for laccase activity (C). (D) In its response to *Colletotrichum* invasion, an infected cell of sorghum (*Sorghum bicolor*) accumulates phytoalexins in inclusion bodies (IB), and neighboring cells armor their walls with reddish phenylpropanoids (arrowheads). Source: R. L. Nicholson, Purdue University.

the hydroxyl group of the anomeric carbon **mutarotates**, flip-flopping between α and β configurations as the ring spontaneously opens and closes. However, the hydroxyl is locked into a specific configuration when the anomeric carbon becomes linked to another molecule.

The designation **D** or **L** should accompany any reference to an α or β configuration. The **D** or **L** designation refers to the position of the hydroxyl group on the asymmetric (**chiral**) carbon farthest from the C-1 (i.e., C-5 of hexoses and C-4 of pentoses). An asymmetric carbon is one in which all four substituent groups are different, so that **enantiomers** (mirror images) of the structures cannot be superimposed. In the **D**-configuration, when viewed in a **ball-and-stick model**, the three larger groups of the last asymmetric carbon increase in size clockwise; in the **L**-configuration, they increase in size counterclockwise (see Fig. 2.9). **D** and **L** are not related to the (+) or (-) designations for **dextrorotatory** or **laevorotatory** optical rotation, which define as clockwise or counterclockwise, respectively, the direction in which a chemical species rotates plane-polarized light.

2.1.1 Monosaccharides linked into cell wall polymers are derived from glucose

D-Mannose (Man) and **D-galactose** (Gal) are **epimers** of **D-glucose** (Glc) made by converting the C-2 and C-4 hydroxyl groups, respectively, from the equatorial to the axial positions

FIGURE 2.8 In a self-incompatibility response, growth of pollen tubes is terminated coincident with swelling of pollen tube tips and formation of callose plugs, as observed here by staining with aniline blue. Source: Image by R. Cotter provided by Sheila McCormick, USDA-Albany, CA.

(Fig. 2.10). Replacement of the C-6 primary alcohols by carboxylic acid groups gives **D-mannuronic acid** (ManA), **D-galacturonic acid** (GalA), or **D-glucuronic acid** (GlcA). Removal of the carboxyl group from D-glucuronic acid forms the pentapyranose, **D-xylose** (Xyl), a sugar in which all of the carbons are in the heterocyclic ring. A rare branched sugar, **D-apiose** (Api), is also formed from D-GlcA. The C-4 epimer of D-xylose is **L-arabinose** (Ara). The D to L conversion occurs because, in this instance, epimerization occurs at C-4, the last asymmetric carbon. By convention, this places the C-1 hydroxyls of α -D-pyranoses in the axial position, and those of α -L-pyranoses in the equatorial position.

The C-6 of some hexapyranoses can also be dehydrated to methyl groups to create deoxysugars. In plants, the two major cell wall deoxysugars are 6-deoxy-L-mannose, called **L-rhamnose** (Rha), and 6-deoxy-L-galactose, called **L-fucose** (Fuc). This spontaneously changes the conformation of L-Rha and L-Fuc from the 4C_1 -chair conformation to the more favorable 1C_4 -chair conformation, which allows more hydroxyl groups to be in the equatorial rather than axial position (Fig. 2.10). Cell wall sugars are interconverted via nucleotide-sugar intermediates by reactions that take place largely at the endoplasmic reticulum (ER) and Golgi apparatus (see Section 2.4.3).

FIGURE 2.9 Sugar nomenclature. Both D-glucose and L-arabinose are shown (from left to right) in straight-chain, ball-and-stick, and conformational models and as Haworth projections. The ball-and-stick model demonstrates the convention whereby the last asymmetric carbon (marked by asterisk) is oriented with the single hydrogen group in the rear. The three asymmetric groups are labeled numerically, with 1 being the smallest and 3 the largest. The size of the three asymmetric groups increases clockwise for D-sugars and counterclockwise for L-sugars. The conformational model distinguishes the relative axial and equatorial positions of the hydroxyl groups around the ring structure of pyranoses. α -D-Glucose is the most stable of the hexoses because every hydroxyl group of the ring and the C-6 primary alcohol group are in the equatorial position, which is energetically more favorable than any other orientation. By convention, the α -configuration of L-arabinofuranose is in the "up" equatorial position.

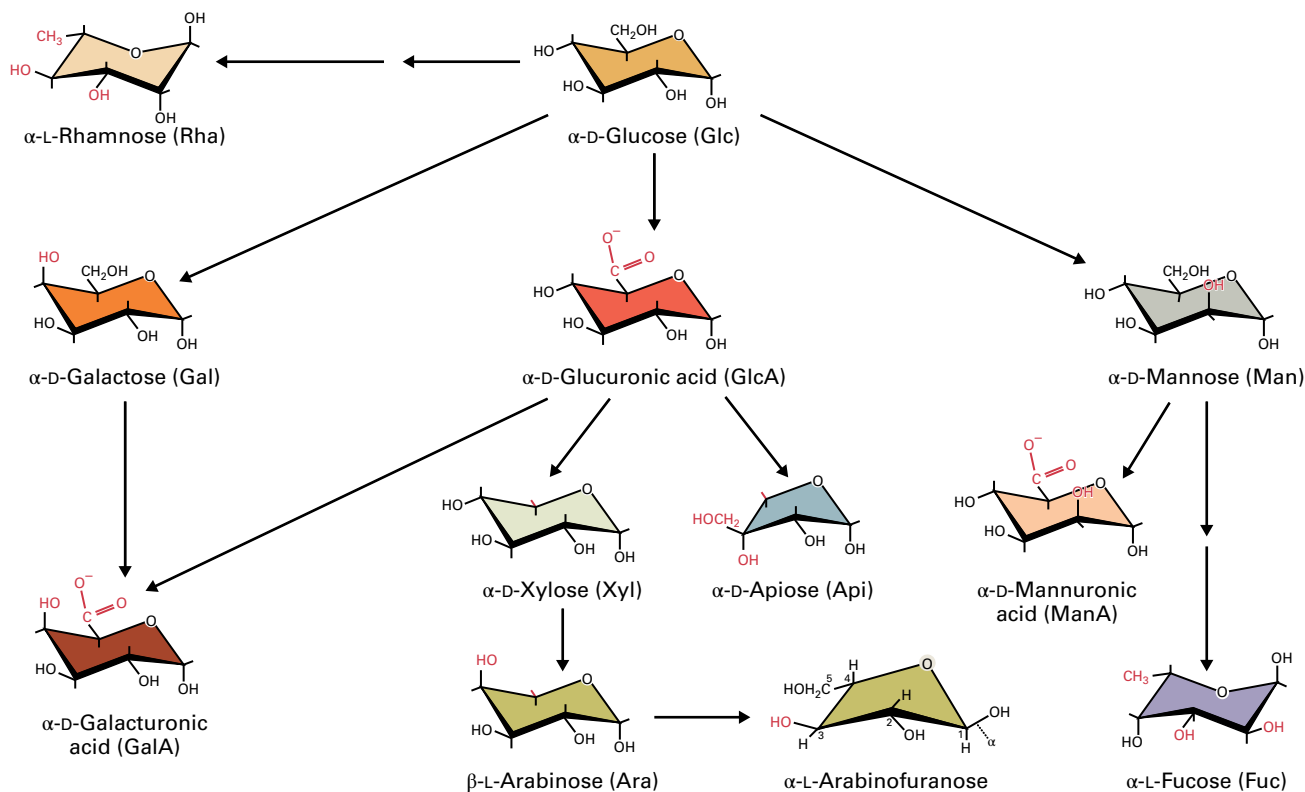

FIGURE 2.10 Common sugars of plant cell walls and their interconversion. Modifications needed to convert D-glucose into other sugars are shown in red. For pyranoses, ring conformations can also spontaneously invert into two chair conformations—the ${}^4\text{C}_1$ -chair or ${}^1\text{C}_4$ -chair conformations—which switches equatorial groups to axial groups and vice versa at each position. The lowest energy conformation is one that places as many bulky hydroxyls in the equatorial position as possible. For most pyranoses, the ${}^4\text{C}_1$ -chair is thus the preferred conformation, but by activity of a 3,5-epimerase, the ${}^1\text{C}_4$ -chair becomes the preferred conformation for L-Rha and L-Fuc. The abbreviations of each of these sugars are specified by IUPAC-IUBMB convention and should be used exclusively. Note that L-Ara can assume both the α -furanose conformation shown in Figure 2.8 and the β -pyranose conformation shown here.

2.1.2 Polymers of specific sugars are further characterized by their linkage types and configuration of their anomeric carbons

Sugars in polymers are always locked in pyranose or furanose rings. During sugar polymerization, the anomeric carbon of one sugar molecule is joined to the hydroxyl group of another sugar, sugar alcohol, hydroxylamino acid, or phenylpropanoid compound in a **glycosidic linkage**. A sugar can be attached to D-glucose at O-2, O-3, O-4, or O-6, that is, to the hydroxyl oxygens on C-2, C-3, C-4 or C-6. Only the O-5 position is unavailable, as it constitutes part of the ring structure.

A disaccharide can be described with respect to both linkage and anomeric configuration. For example, cellobiose is β -D-glucose-(1 \rightarrow 4)-D-glucose: The anomeric linkage forms when the C-1 of one D-glucose residue is replaced by the equatorial hydroxyl at the C-4 position of another D-glucose (Fig. 2.11). Only one D-glucose is locked in the β -configuration; the other D-glucose is undesignated because its anomeric hydroxyl group is free to mutarotate in solution. Because the aldehyde of this sugar is able to reduce copper

under alkaline conditions, it is classically described as a **reducing sugar**, and this end of even a very long polymer is called the **reducing end**. In branched polysaccharides there will be a nonreducing sugar at the end of each side-chain and at the terminus of the backbone, but there will only be a single reducing end.

In cellobiose, the anomeric carbon of one glucose is linked to the hydroxyl group farthest away from the anomeric carbon of the other glucose (Fig. 2.11). For the β -linkage to occur with the C-4 equatorial hydroxyl group, sugars to be linked must be inverted almost 180° relative to each other, and iteration of this linkage produces a nearly linear molecule. In contrast, the units of laminaribiose, or β -D-glucose-(1 \rightarrow 3)-D-glucose, are linked somewhat askew (Fig. 2.11), and iteration of this linkage produces a helical polymer.

Polysaccharides are named after the principal sugars that constitute them. Most polysaccharides have a backbone structure, and the composition of this structure is indicated by the last sugar in the polymer's name. For example, xyloglucan is a backbone of (1 \rightarrow 4)- β -D-glucosyl residues with xylosyl units attached, glucuronarabinoxylan is a backbone of (1 \rightarrow 4)- β -D-xylosyl residues with glucosyluronic acid and arabinosyl units attached to it, and so forth.

FIGURE 2.11 Linkage structures of cellobiose and laminaribiose. The (1→4)- β -D-linkage of cellobiose inverts the glucosyl unit about 180° with respect to each other, whereas the (1→3)- β -D-linkage is only slightly askew. (Shading of the glucose units illustrates the 180° inversion.)

2.1.3 Polymer branching produces great structural diversity

What makes sugar subunits such versatile building materials is their ability to form linkages at multiple positions. With 11 different sugars commonly found in plant cell walls (see Fig. 2.10), four different linkage positions, and two configurations with respect to the oxygen atom, the permutations of pentasaccharide structure zoom to over 5 billion! Glucose alone can form almost 15,000 different pentameric structures. Multiple bonding positions also make possible the formation of branched polysaccharides, enormously increasing the number of possible structures. Fortunately for cell wall researchers, the structures of some of the major wall components are relatively conserved among species.

The two major tools that carbohydrate chemists use to elucidate the structure of highly complex polysaccharides are methylation analysis (Box 2.1) and nuclear magnetic resonance (NMR) spectroscopy (Box 2.2). NMR spectroscopy is particularly useful for examining polysaccharides and aromatic molecules in the underivatized state.

2.2 Macromolecules of the cell wall

2.2.1 Cellulose is the principal scaffolding component of all plant cell walls

Cellulose is the most abundant plant polysaccharide, accounting for 15–30% of the dry mass of all primary cell walls and a much larger percentage of secondary walls. Cellulose exists in the form of **microfibrils**, which are *para*-crystalline assemblies of several dozen (1→4)- β -D-glucan chains hydrogen bonded to one another along their length (Fig. 2.12). In vascular plants, each microfibril consists of a crystalline core of about 24 chains coated with 12 more that can interact with other glycans and water. Microfibrils of 36 glucan chains have a theoretical diameter of 3.8 nm, but X-ray diffraction shows some microfibrils could be as small as 3.3 nm, or about 24 chains. Microfibrils of angiosperms have been measured to be between 5 and 12 nm wide in the electron microscope, but

this estimate includes noncellulosic polymers tightly bound onto the surface. Microfibrils of algae can form either large, round cables or flattened ribbons of several hundreds of chains. Each (1→4)- β -D-glucan chain may be just several thousand units (≈ 2 – $3 \mu\text{m}$ long), but individual chains begin and end at different places within the microfibril to allow a microfibril to reach lengths of hundreds of micrometers and contain thousands of individual glucan chains. This structure is analogous to a spool of thread that comprises thousands of individual cotton fibers, each about 2–3 cm long.

From electron diffraction it can be seen that the (1→4)- β -D-glucan chains of cellulose are arranged parallel to one another, that is, all of the reducing ends of the chains point in the same direction. Bacterial cellulose is synthesized at the nonreducing ends of the glucan chains.

Callose differs from cellulose in consisting of (1→3)- β -D-glucan chains, which can form helical duplexes and triplexes. Callose is made by a few cell types at specific stages of wall development, such as growing pollen tubes and in the cell plates of dividing cells. Callose is also made in response to wounding or attempted penetration by invading fungal hyphae (see Fig. 2.7).

2.2.2 Crosslinking glycans interlock the cellulosic scaffold

Crosslinking glycans are a class of polysaccharides that can hydrogen bond to cellulose microfibrils: they may coat microfibrils, but are also long enough to span the distance between microfibrils and link them together to form a network. Crosslinking glycans are often called “hemicelluloses,” a widely used term for all materials extracted from the cell wall with molar concentrations of alkali, regardless of structure.

The two major crosslinking glycans of all primary cell walls of flowering plants are **xyloglucans** (XyGs) and **glucuronarabinoxylans** (GAXs) (Fig. 2.13). The XyGs crosslink the walls of all eudicots and about one-half of the monocots, but in the cell walls of the “commelinid” line of monocots, which includes bromeliads, palms, ginger, sedges, and grasses, the major crosslinking glycan is GAX (Fig. 2.13).

Most XyGs consist of linear chains of (1→4)- β -D-glucan with two or three contiguous α -D-Xyl units linked to the O-6 position of the Glc units between unbranched Glc residues.

Certain xylosyl units are substituted further with other monosaccharides, typically α -L-Ara, or β -D-Gal, to improve water solubility and possible recognition by wall-modifying enzymes, and sometimes the Gal is substituted further with α -L-Fuc (Fig. 2.13). Sequence-dependent hydrolases are used

to elucidate the fine structure of XyGs by cleaving them at specific sites along the glucan backbone into fragments that are small enough to characterize fully (Boxes 2.3 and 2.4). A convention has been adopted to describe certain ubiquitous side-chains of XyG in which the entire subtending side-chain

BOX 2.1

Methylation analysis determines carbohydrate linkage structure

Strong acids can break the glycosidic linkages of polysaccharides to release individual monosaccharides. The monosaccharides can then be chemically reduced with borohydride and acetylated with acetic anhydride to make **alditol acetates**. For example, the complex xyloglucan shown in (A) is hydrolyzed to its four major sugar components. The alditol acetates derived from different sugars are volatile at different temperatures and can be separated on that basis using **gas-liquid chromatography**. The derivatives are injected onto a thin capillary column coated with a highly polar waxy liquid phase to which they adhere. The temperature is then raised to the point at which the interaction with the wax is broken, and the derivatives are swept out of the column by an inert carrier gas to a detector. If a temperature gradient is applied, different sugars will elute at different times and be resolved in a chromatogram (B). By comparing these results with the behavior of similarly treated standards, one can determine the molar ratio of each sugar in the original sample. Frequently, the types of sugars present in the sample and their molar ratios will be indicative of a specific polysaccharide.

However, complex polysaccharides cannot be identified from their sugar composition alone. Polymer backbones are built from unit structures of one to a few repeated sugars and linkages, but are frequently substituted with appendant sugar units and side-chains that can themselves be further branched. Linkage structure of polysaccharides can be deduced indirectly by methylation analysis (C), a method in which polysaccharides are chemically methylated with methyl iodide at every free hydroxyl group. Carbon atoms that participate in glycosidic linkages and in the ring do not have a free hydroxyl group and so are not methylated. The methylated polysaccharide is hydrolyzed to its components of partly methylated monosaccharides, and these components are reduced and acetylated as before. However, because linkage analyses of certain derivatives depend upon the ability to differentiate the top (C-1 containing) of the molecule or molecular fragment from its bottom (C-5 or C-6 containing), the reducing agent borodeuteride is used to label the C-1 alcohol, thereby marking its position for further analyses. These partly methylated alditol acetates are resolved by gas-liquid chromatography. The xyloglucan methylated before hydrolysis yields an array of derivatives

(C), the nature of which depends on the number and positions of the acetyl groups, which in turn indicate the positions of which another sugar was attached (see arrows). The *t*- designation refers to a nonreducing terminal sugar in a side-chain.

Unequivocal determination of the structure is made by **electron-impact mass spectrometry (EIMS)**. As the partly methylated alditol acetate derivatives exit the gas chromatography column, an electron beam breaks each derivative into fragments. The bonds in each derivative have different susceptibilities to breakage, so the molecule breaks into a characteristic set of fragments, which are like the pieces of a jigsaw puzzle. The larger fragments are more diagnostic, but each of these may be broken into smaller fragments that can be used to confirm the deduced structures. The relative abundance of the mass of each fragment in combination with the spectrum of masses for a particular derivative is diagnostic of its structure. Identification of the one or two extra acetyl groups instead of methyl groups indicates which carbons were participating in glycosidic bonds. For example (D), a 4-linked glucose unit in xyloglucan gives characteristic mass/charge ratios (*m/z* values) of 118 and 233, and the latter fragment indicates the acetyl group at the O-4 position, which was protected from methylation by the linkage of a sugar. Likewise, the 4,6-linked glucose branch point contains yet another acetyl group, increasing the mass of this fragment to *m/z* 261. Note the presence of the deuterium atom at C-1 is essential for discriminating between 2-Xyl and 4-Xyl, which are symmetrical derivatives. The major fragments from the 2-Xyl derivative are *m/z* 190 and *m/z* 117, whereas those from 4-Xyl are *m/z* 118 and *m/z* 189; without the deuterium at the C-1, both 2- and 4-Xyl would give *m/z* 117 and *m/z* 189, making them indistinguishable.

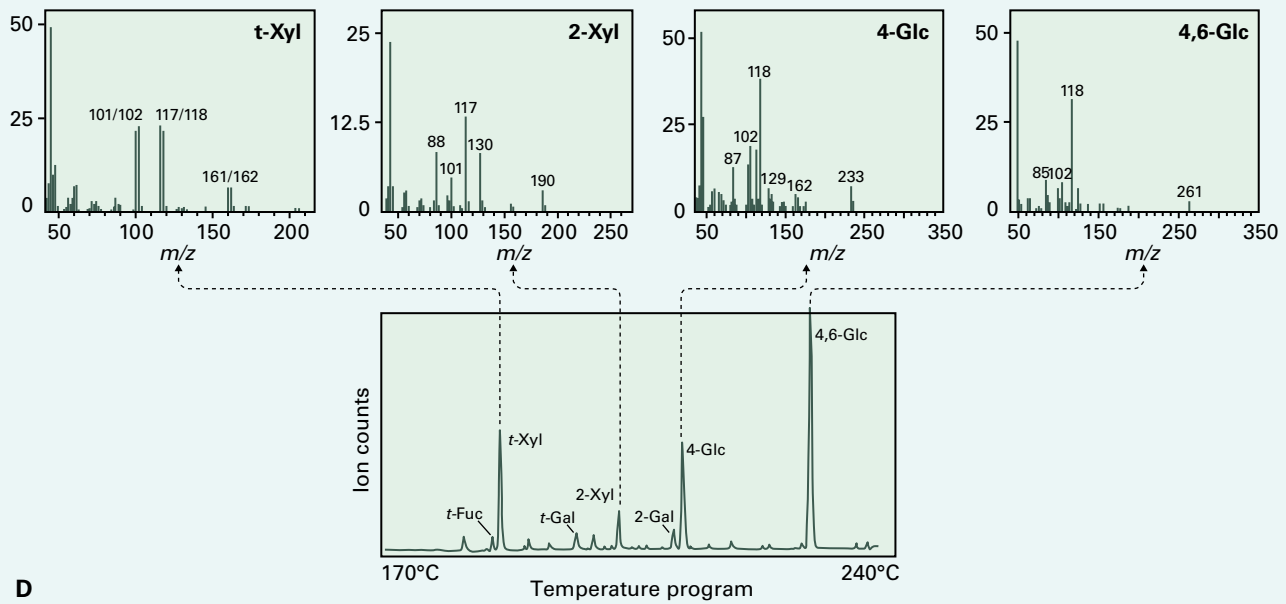

Uronic acids, such as the galactosyluronic acid of pectins, can be converted to their respective neutral sugars after coupling the carboxyl group with a water-soluble diimide and reducing it with sodium borodeuteride (NaBD₄). This reaction introduces two deuterium atoms onto the C-6 of the sugar, and the proportion of uronic acid originally present is inferred as a relative proportion of the corresponding neutral sugar. In (E), 4-Gal and 4-GalA are differentiated by the 2 amu shift in *m/z* 233 to give *m/z* 235.

BOX
2.2

Polymer composition and structure can be determined by nuclear magnetic resonance (NMR) spectroscopy

NMR spectroscopy is a nondestructive method that can provide information about the chemical structure and composition of polysaccharides and lignins, their relative orientations, their mobilities, and the nature of their interactions. An NMR spectrometer consists of a powerful magnet and electronic circuitry designed to measure the magnetic properties of the atomic nuclei contained in a sample. Asymmetric atomic nuclei – those with an odd number of protons and neutrons, such as ^1H and ^{13}C – have an intrinsic angular momentum, sometimes called the **nuclear spin**, which generates a magnetic field (A). When a magnetic nucleus is placed in the spectrometer magnetic field, a force is exerted that tends to line up its nuclear spin with the applied magnetic field. However, the rules of quantum mechanics do not allow a nucleus to arbitrarily adopt any orientation. That is, its angular momentum (or spin) is **quantized** (i.e., limited to a few well-defined values). For ^1H and ^{13}C nuclei, there are two spin states, often conceptualized as ‘spin-up’ and ‘spin-down’, or aligned with vs. against the magnetic field direction. The interplay of the quantized angular momentum and the magnetic force causes the nucleus to precess the way a spinning top does under the influence of gravity, wobbling as it spins (B). This precessive motion has a characteristic **resonance frequency** (frequency of the spin) that depends on the strength of the magnetic field, the magnetic properties of the nucleus, and its closest atomic neighbors. It is those interactions with its closest neighbors that give the most information about the nucleus of interest.

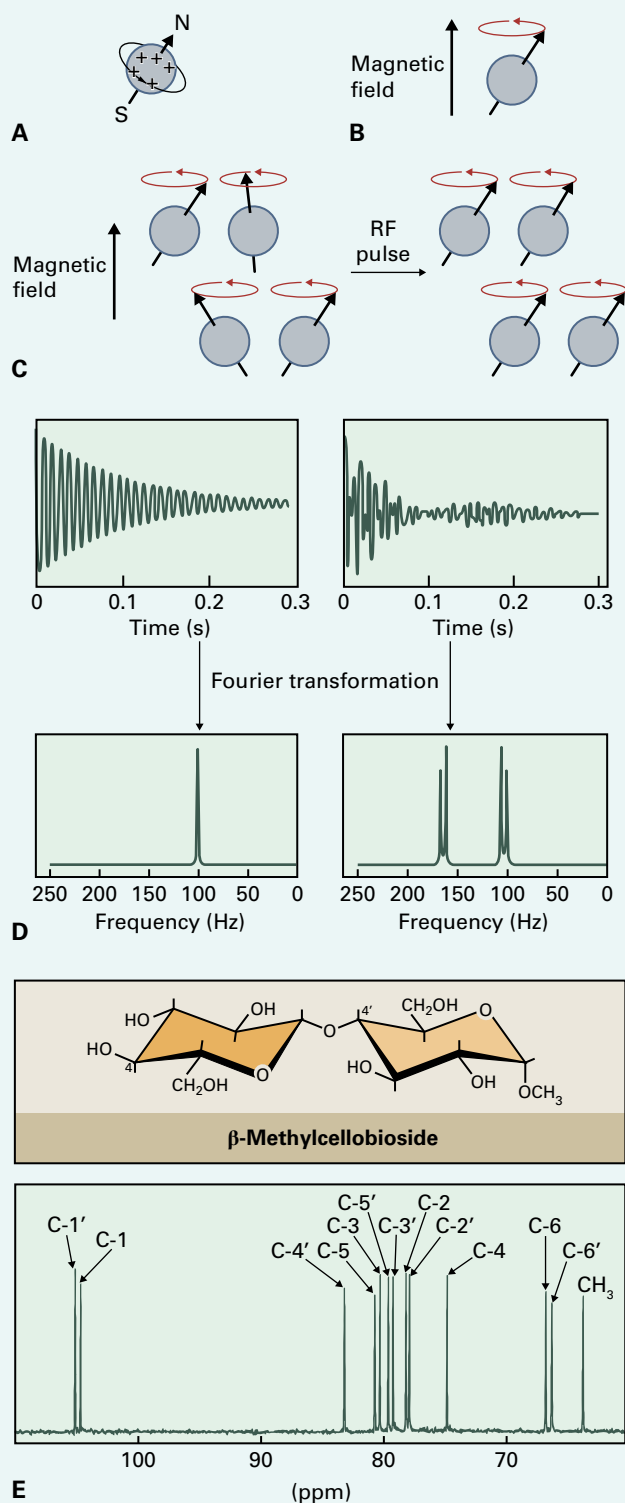

In an NMR experiment, populations of nuclei, rather than individual nuclei, are observed. Under most conditions, the precession of a population of nuclei is not coherent; that is, the individual nuclear spins in the sample tilt in different directions so the precession cannot be detected (C left). To be observed by NMR, a sample is subjected to a brief magnetic pulse, called a radio frequency (RF)-pulse, that oscillates at the nuclear resonance frequency delivered by small coils close to the sample. This redistributes the nuclear spin orientations so they become partially aligned and the precessing components of nuclear spin can be observed from the population of nuclei (C right).

The signal observed as a result of the RF-pulse is usually composed of a range of slightly different resonance frequencies. The RF-pulse itself comprises a range of frequencies, and is thus analogous to striking a bell simultaneously to produce a mixture of different audio frequencies. Just as we hear all of the frequencies of the ringing bell simultaneously, all the frequencies

returning from the sample are picked up in the same RF coils and are recorded simultaneously. A mathematical operation called **Fourier transformation** is used to convert the time-domain (amplitude vs time) NMR response into a frequency-domain (amplitude vs frequency) spectrum that makes it easier to distinguish and tabulate signals with different frequencies (D).

Nuclei connected by three or fewer molecular bonds often exhibit an interaction called **scalar coupling**. The molecular geometry of this coupling leads to the splitting of signals that is a characteristic feature of ^1H -NMR spectra. The anomeric (H-1) resonance of a typical sugar is split into a doublet by scalar coupling with H-2—the larger the dihedral angle, the larger the frequency difference. For a β -linked glucosyl residue (as in cellobiose), the dihedral angle H1–C1–C2–H2 is approximately 180° , which results in a relatively large H1–H2 scalar coupling of 8 Hz, whereas the dihedral angle for an α -linked glucosyl residue (as in maltose) is only 60° , which results in a relatively small H-1–H-2 scalar coupling of 3.6 Hz. Thus, the anomeric configuration of a glucosyl residue can be unambiguously determined simply by measuring the distance (in Hz) between the two components of the anomeric proton doublet.

The different frequencies in the NMR spectrum arise because the electron cloud surrounding each nucleus shields it from the applied magnetic field. Neighboring atoms with differing degrees of electronegativity surrounding the nucleus being observed produce a change in its resonance frequency called the **chemical shift**. This chemical shift, which is measured in parts per million (ppm) relative to the resonance frequency of a nucleus in a standard compound such as tetramethylsilane (TMS), provides information about the chemical environment of the nucleus within the molecule. For example, the electron-withdrawing oxygen attached to C-6 of glucose decreases the electronic shielding for this nucleus, resulting in a chemical shift of approximately 60 ppm. On the other hand, two electron-withdrawing oxygen atoms are attached to the anomeric carbon (C-1) of glucose, which is thus much less shielded than C-6, and has a chemical shift of approximately 100 ppm. Chemical shifts can provide structural information, as illustrated in the ^{13}C -NMR spectrum of β -methyl cellobioside (E). Here, the glycosidic bond between two glucosyl residues causes the chemical shift (80.2 ppm) of C-4' (at the point of attachment) to be substantially greater than the chemical shift (71.0 ppm) of C-4. This difference is called a glycosylation effect, and is often used to establish the specific point at which two sugars are joined by a glycosidic bond.

The ^1H - and ^{13}C -NMR spectra of complex molecules are much more complicated, and multi-dimensional NMR, where more than a single NMR parameter is presented in a spectrum, has greatly improved structural analyses, such as **two-dimensional (2D) NMR**, **heteronuclear multiple-quantum coherence (HMQC)**,

heteronuclear single-quantum correlation (HSQC), and **three-dimensional (3D) NMR**. **Correlation spectroscopy (COSY)** is a type of 2D NMR where a proton's chemical shift in one dimension is correlated with the proton to which it is scalar-coupled in the second dimension (^1H - ^1H COSY). **Total correlation spectroscopy (TOCSY)** experiments are particularly useful for identifying the side-chains in various lignin structures, or for identifying resonances in an individual saccharide unit of a polysaccharide — an example is given below. **Solid-state NMR** techniques can distinguish regions of a polysaccharide that differ in their mobility or conformation, facilitating the development of models for assembly of polysaccharides to form complex, dynamic structures within the cell wall.

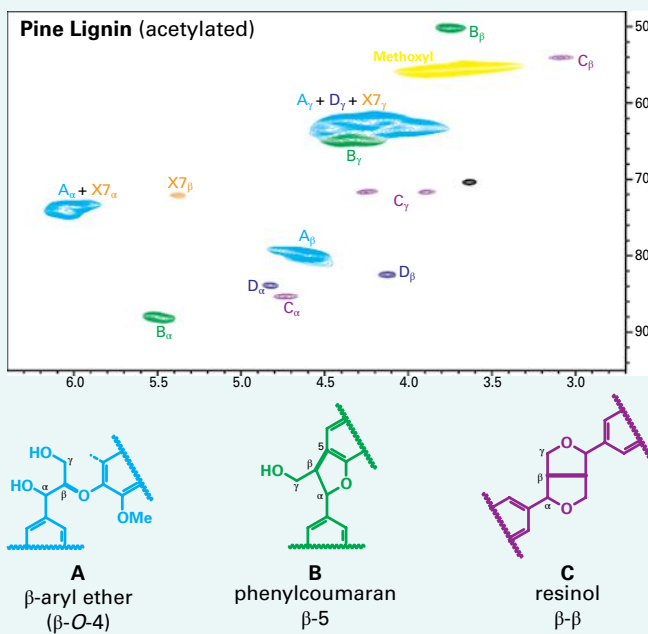

An example of the characterization of a complex structure containing both carbohydrate and phenolic structures is the di-arabinosyl β -*O*-4-dehydrodiferulate from grass walls, formed by radical-coupling of two ferulates 5-linked to two arabinosyl units of two GAX polymers (Fig. 2.13) after hydrolysis from the xylan backbone. Simple inspection of the structure suggests that there should be two different arabinosyl moieties, and the NMR spectra resolve both the α - or β -orientation anomeric configurations of each arabinosyl moiety (F). The arabinosyl region of the proton-NMR spectrum, colored for clarity, show splitting patterns arising from scalar coupling between protons on neighboring carbons. Anomeric H-1 protons are each simple doublets, from coupling with their respective H-2 protons, but H-2 protons are more complex (basically doublets of doublets) because of coupling with both H-1 and H-3 protons (with different scalar coupling constants). Sub-spectra for each of the four arabinosyl moieties can be accurately calculated and plotted by computer simulation using the actual spectrum as input, and the correct chemical shifts and coupling constants are then revealed. The nonanomeric protons are found by tracing the coupling network in a 2D ^1H - ^1H COSY experiment, starting from the easily identified anomeric H-1 with H-2, then H-2 with H-3 (and H-1), H-3 with H-4 (and H-2), and H-4 with the two H-5 protons (and vice versa) (F).

In an HMQC or HSQC 2D ^{13}C - ^1H correlation experiment, protons at the chemical shifts centered on the contours in the horizontal (^1H) direction are directly attached to their respective carbons with the chemical shift given on the vertical (^{13}C) axis. Much of the power of these data comes from the dispersion created, that is, by the way signals from protons are resolved because of the differing chemical shifts of their attached carbons and, conversely, by the way the carbons are resolved by the chemical shifts of their attached protons. In this example, four complex 5-proton pairs are all clearly separated.

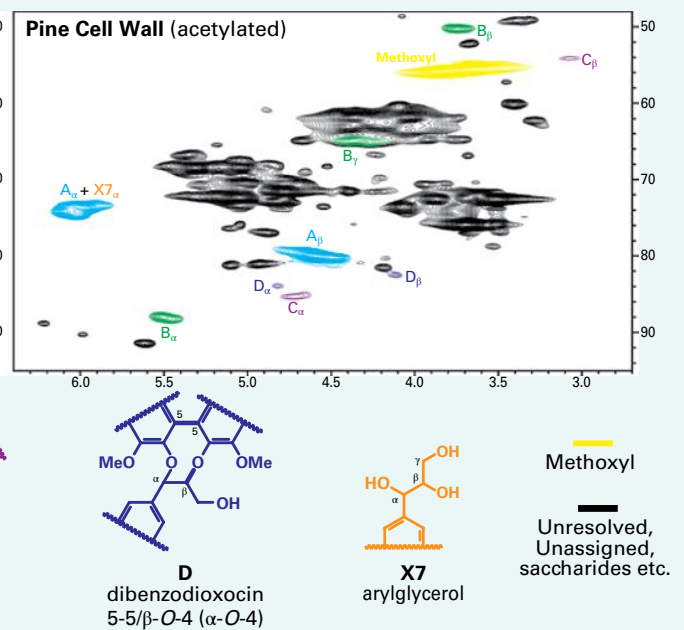

F ^1H NMR, Arabinosyl region

G

H

As a second example, we show a partial 2D NMR spectrum of a lignin isolated from pine (G). Lignins are more complex in that they are created from combinatorial free-radical coupling reactions in which the coupling can take several pathways (see Fig. 2.22) and produce chains with random sequence. It is possible to readily discern the types and distribution of interunit linkages from 2D ^{13}C - ^1H correlation

experiments, as shown in G. Because of the excellent dispersion in this experiment, many of the correlations in the same type of spectrum run on whole (unfractionated) cell wall (H), despite the dominance of the polysaccharide components.

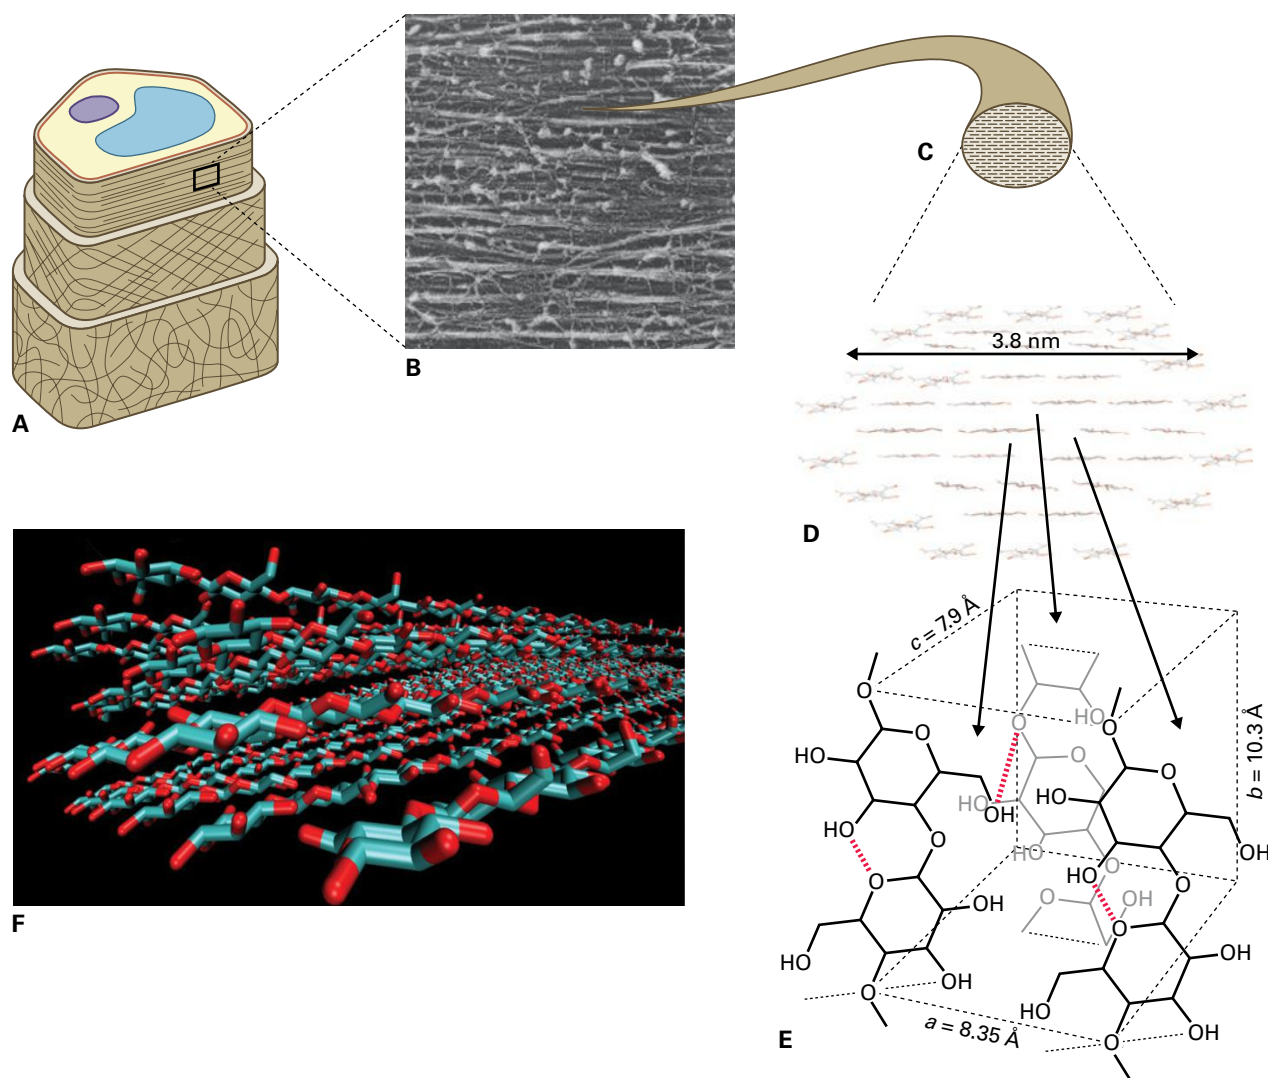

FIGURE 2.12 Cellulose microfibrils are para-crystalline arrays of several dozen (1 \rightarrow 4)- β -D-glucan chains that tightly hydrogen bond to each other, both side-to-side and top-to-bottom. The microfibrils can spool randomly around a spherical meristematic or a cell expanding isodiametrically (i.e., in all directions equally). However, in elongating cells (A), microfibrils wind around the cell in slightly helical arrays nearly transverse to the long axis of the cell, and can be seen in freeze-fracture replica of an elongating maize root cell wall (B). A single microfibril (C) is shown in cross-section (D). From solid-state NMR spectroscopy studies, glucan chains at the surface of the microfibril are thought to adopt a slightly different alignment. A microfibril of 36 chains in this arrangement is predicted to be 3.8 nm in diameter. The 18–24 glucan chains in the core of the microfibril have a precise spacing, representing a diameter of 2.6–3.0 nm. The arrangement of atoms in the unit structure of the microfibril core has been determined by X-ray diffraction (E). Molecular modeling of a cellulose microfibril predicts a slight right-handed twist from 180° (F).

Oligosaccharide unit structure can be determined by sequence-specific glycanases and high-performance anion exchange chromatography (HPAEC)

A direct method to determine the sequence of sugars in a complex carbohydrate is not presently available. However, much like the restriction endonucleases that recognize and cleave specific sequences of DNA, **sequence-dependent glycanases** that cleave polysaccharides at specific glycosidic linkages can be used to generate small oligosaccharides, the structure of which can be determined.

Sequence-dependent glycanases obtained from microbes either require or are restricted by structural features of the polysaccharide in addition to a specific sugar linkage. Several of these enzymes have been used to yield oligomers characteristic of repeating unit structures, indicating the characteristic unit composition of very large polymers. For example, a *Bacillus subtilis* endoglucanase cleaves a (1→4)-β-D-glucosyl linkage only if preceded by a (1→3)-β-D-linkage, and a *B. subtilis* glucuronoxylanase C cleaves (1→4)-β-D-xylosyl linkages only at sites with appendant glucuronic acid units. The activity of an endo-β-D-glucanase from the fungus *Trichoderma viride* is blocked by appendant groups of the glucan chain; the enzyme can only hydrolyze unsubstituted (1→4)-β-D-glucosyl linkages. This feature makes the enzyme useful in determining the frequency of contiguous attachment of xylosyl units onto the (1→4)-β-D-glucan chain of xyloglucan. For most flowering plants, the basic unit of structure of xyloglucan comprises glucose residues, three of which are substituted with three xylosyl groups. The first two xyloses can be decorated by galactose, and a fucose can be added to the first galactose to generate six characteristic oligomers (Table 2.1).

Conventional anion-exchange chromatography is a convenient method to separate uronic acid-containing

polymers (A), but in general, neutral sugars and oligosaccharides are not well resolved by conventional **high-performance liquid chromatography (HPLC)**. However, special alkali-resistant HPLC apparatus can support **HPAEC**, a useful tool for analyzing oligosaccharide products of sequence-dependent glycanases. The hydroxyl groups of sugars are weak acids and become negatively charged at high pH. This property may be exploited since the relative retention on an anion-exchange column depends on the number, position, and degrees of freedom of the hydroxyl groups of the oligomer. The oligosaccharides become charged when introduced into a stream of up to 0.5 M NaOH. The anionic oligosaccharides bind to the column and are then eluted in a gradient of increasing sodium acetate in NaOH. As the sugars elute, they are detected by an electrochemical cell called a **pulsed amperometric detector (PAD)**. A small proportion of the sugars are oxidized as they pass over the gold-plated detector, and when these oxidized sugars bind to the detector plate the concentration is measured as the relative decrease in the standing potential of the detector. A brief pulse of reversed polarity repels the oxidized sugar from the plate. This pulse-cycle is repeated every 300 ms or so. The measuring pulses are summed over time to produce a chromatogram. The PAD is reasonably specific for sugars as many other compounds are not oxidized by comparable electrical pulses. (B) The xyloglucan unit profiles of wild-type *Arabidopsis* and a *mur3* mutant lacking the entire α-L-fucose-(1→2)-β-D-galactose- side-chain from the first xylose. For wild-type XyG, all six possible oligomers are observed; because the galactosyl transferase that normally decorates the Xyl residues

FIGURE 2.13 (Continued) these two oligomers are XXXG and XXFG. The decasaccharide XLFG can be a major unit structure in many species. (B) Arabinoxylglucans. In the Solanales and Lamiales, the major repeating unit is a hexamer, rather than heptamer, with one or two α-L-Ara units added directly to the O-2 position of the Xyl units. The Solanaceae XyG units are separated by two unbranched Glc units rather than one, and the penultimate Glc contains an acetyl group at the O-6 position. The arrows denote the linkages able to be cleaved by the *Trichoderma* endo-β-D-glucanase. Using the single letter designator convention (Table 2.1), these two oligomers are XSGG or SSGG, if one or two Ara units are attached, or XXGG if they are not attached. Some Asterales and related orders have both arabinosyl and galactosyl units attached to XyG oligomers (not shown). Also, some storage XyGs in leguminous species can have XXXXG, and even XXXXXG, units that are decorated with up to four Gal units (not shown) (C) Commelinid glucuronoarabinoxylans. In the GAX from commelinid monocot walls, the α-L-Ara units are added strictly to the O-3 position of the xylosyl units of the backbone polymer. Feruloyl groups (and sometimes other hydroxycinnamic acids) are esterified to the O-5 position of the α-L-Ara units and are spaced about every 50 Xyl units of the backbone. The α-D-GlcAs are added to the O-2 position of the xylosyl units. The feruloyl units of adjacent GAX polymers can couple to crosslink GAXs in the wall. (D) Other glucuronoarabinoxylans. The noncommelinid monocots and all eudicots also contain GAX in addition to the more abundant XyG. However, the α-L-Ara units of these GAXs are attached mostly to the O-2 position instead of the O-3 position. As with the commelinid GAX, the α-D-GlcA units are attached only at the O-2 position.

closest to the reducing end is defective in the *mur3* mutant, only XXXG and XLXG are found in great abundance.

Capillary electrophoresis, where small amounts of charged polymers are separated in liquid phase in columns of very small diameter in an electric field, is also effective in separating an oligomeric series of uronic acid-rich polymers. For neutral oligosaccharides, charged fluorescent dyes have been developed that couple to the reducing end of the oligomer to provide both the electrophoretic mobility and a sensitive means of detection (C). The upper trace shows separation of a mixture of hydrolyzed dextran and β -1,4-xyloligosaccharides of DP1 to DP6; Larger dextran oligosaccharides are resolved by extending the electrophoresis time to 90 minutes. RFU, relative fluorescence units; G, Glucose; X, Xylose.

2.4

Polysaccharide sequence can be inferred by matrix-assisted laser desorption ionization (MALDI)-time of flight (TOF) and electrospray-ionization (ESI) tandem mass spectrometry (MS/MS)

Although EIMS of the partly methylated alditol acetates is the main procedure used by carbohydrate biochemists to establish the linkage structure of unknown polymers (see Box 2.1), new MS techniques greatly extend the mass range that can be analyzed and can provide linkage and sequence information for underivatized oligosaccharides.

One such technique is **matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) MS**. Underivatized polymers are mixed with a material that ionizes them on exposure to brief pulses of a laser. The polymeric ions are differentially accelerated in the mass spectrometer, depending on their size, and molecular masses as great as 200 kDa are detected by a finely tuned calculation of the time interval between laser bombardment and contact with the mass spectrometer anode (A). For the xyloglucan oligomers in (A), the degree

of acetylation is determined by ions of diagnostic mass (the molecular ion M^+ plus m/z 43 per acetyl group).

In **electrospray-ionization (ESI) MS**, water-soluble carbohydrate oligomers are 'nebulized' into a fine mist toward the entrance to the MS against a counter-current of warmed dry air. Oligomers trapped in microdroplets adsorb Na^+ atoms and are collected after evaporation in an **ion trap**. Samples of different mass/charge ratios can then be analyzed by MS for relative abundance of diagnostic ions of interest. In (B), masses diagnostic of additions of one and two galactose units and one fucose unit are detected in the oligomers from xyloglucan from wild-type *Arabidopsis*, whereas *mur2* is missing the fragments diagnostic of fucosylation, and *mur3* has only a single galactose addition. An advantage of ESI MS over MALDI-TOF is that the collection of trapped ions can be fragmented further to gain information on the positions of individual sugars in the

oligomer. In the example in (C), the addition of galactose on either the first or second xylose of a xyloglucan fragment yields m/z 1247. However, in MS/MS of m/z 1247, Gal at the first xylose yields a fragment m/z 659, whereas Gal at the second xylose yields m/z 773. In the wild-type, galactose is

found at both positions (1), whereas in the *murus3* mutant, the galactose is only at the second xylose (2), revealing the effect of the mutation as a defective galactosyl transferase that is unable to decorate the xylose residue closest to the reducing end of the oligomer.

along the glucan is designated by a single letter on the basis of its terminal sugar (Table 2.1).

The XyGs are constructed in block-like unit structures containing 6–11 sugars, the proportions of which vary among tissues and species (Fig. 2.13). While cellotetraose with two or three contiguous xylosyl units is the base unit backbone structure for most XyGs, some variants have been found with cellopentaose and even cellohexaose units with four and five subtending xylosyl units, respectively. The XyGs comprise at least four major variants of structure. The XyGs of noncommelinid monocots and most of the eudicots are fucogalacto-XyGs. The fundamental structure is composed of nearly equal amounts of XXXG and XXFG, but variations can occur and α -L-Ara is added at some places along the glucan chain. Solanaceous species and peppermint (*Mentha x piperita*) have arabino-XyGs in which only two of

every four glucosyl units contains a xylose unit, and the xylosyl units are substituted with either one or two α -L-Ara units to produce a mixture of SXGG, XSGG, and SSGG subunits, where S signifies the terminal arabinosylation in Solanaceous species. Curiously, an acetyl group replaces the third xylosyl unit in the arabino-XyGs.

Commelinid monocots also contain small amounts of XyG, but these contain random additions of one or two xylosyl units isolated along the glucan chain and the rare addition of a Gal as the only subtending sugar. Other members of the class Asteridae have units that have α -L-Ara and β -D-Gal in the same oligomer, and still others have additions of α -D-Xyl or β -L-Gal (Fig. 2.14). Still other types of side-chains, including branched chains, are seen in nonvascular and nonseed vascular plants (Table 2.1). In the laboratory, mutant plants affected in their ability to decorate the xylosyl units of their

TABLE 2.1 Single-letter designators of simple and complex xyloglucan side groups.

Single-letter designator	Terminal sugar	Side group on the glucan chain

Most angiosperm eudicots possess the side groups of D-Gal (L) and L-Fuc (F) attached to the xylose units along the glucan backbone. Both furanose and pyranose forms of L-Arabinose are found, whereas all other sugars are understood to be in the pyranose form. Side groups S, T and U are found in the Asteridae and Solanaceae. The complex branched side groups, including those containing galacturonic acid residues are found in mosses and nonseed vascular plants.

FIGURE 2.14 Orders of the flowering plants, with symbolic descriptions of the major crosslinking glycans and major distinctions illustrated between grasses and other commelinid monocots, noncommelinid monocots, and eudicots. The fundamental XXXG backbone unit structure is found in most species (see Fig. 2.12), backbone variants in both monocots and eudicots are shown. The single letter code (Table 2.1) gives the extended side-groups that have been documented; L [β -D-Gal-(1 \rightarrow 2)- α -D-Xyl-(1 \rightarrow 6)-] and F [α -L-Fuc-(1 \rightarrow 2)- β -D-Gal-(1 \rightarrow 2)- α -D-Xyl-(1 \rightarrow 6)-] are the most common sidegroups, with S [α -L-Araf-(1 \rightarrow 2)- α -D-Xyl-(1 \rightarrow 6)-], T [β -L-Arap-(1 \rightarrow 3)- α -L-Arap-(1 \rightarrow 2)- α -D-Xyl-(1 \rightarrow 6)-], and U [β -D-Xyl-(1 \rightarrow 2)- α -D-Xyl-(1 \rightarrow 6)-] side groups found in the Solanales, Lamiales, and Ericales of the Asteridae line. GAX = glucuronoarabino-xylan (see Fig. 2.13); β -Glucan = mixed-linkage (1 \rightarrow 3),(1 \rightarrow 4)- β -D-glucan (Fig. 2.15).

FIGURE 2.15 Among the angiosperms, the mixed-linkage (1 \rightarrow 3),(1 \rightarrow 4)- β -D-glucan is unique to the Poales. Red arrows indicate cleavage sites by the *Bacillus subtilis* endoglucanase. The unbranched polymers are composed of mostly cellotriose and cellotetraose units connected by single (1 \rightarrow 3)- β -linkages. Smaller amounts of larger cellodextrins up to about nine (1 \rightarrow 4)- β -D-glucose residues are found (not shown).

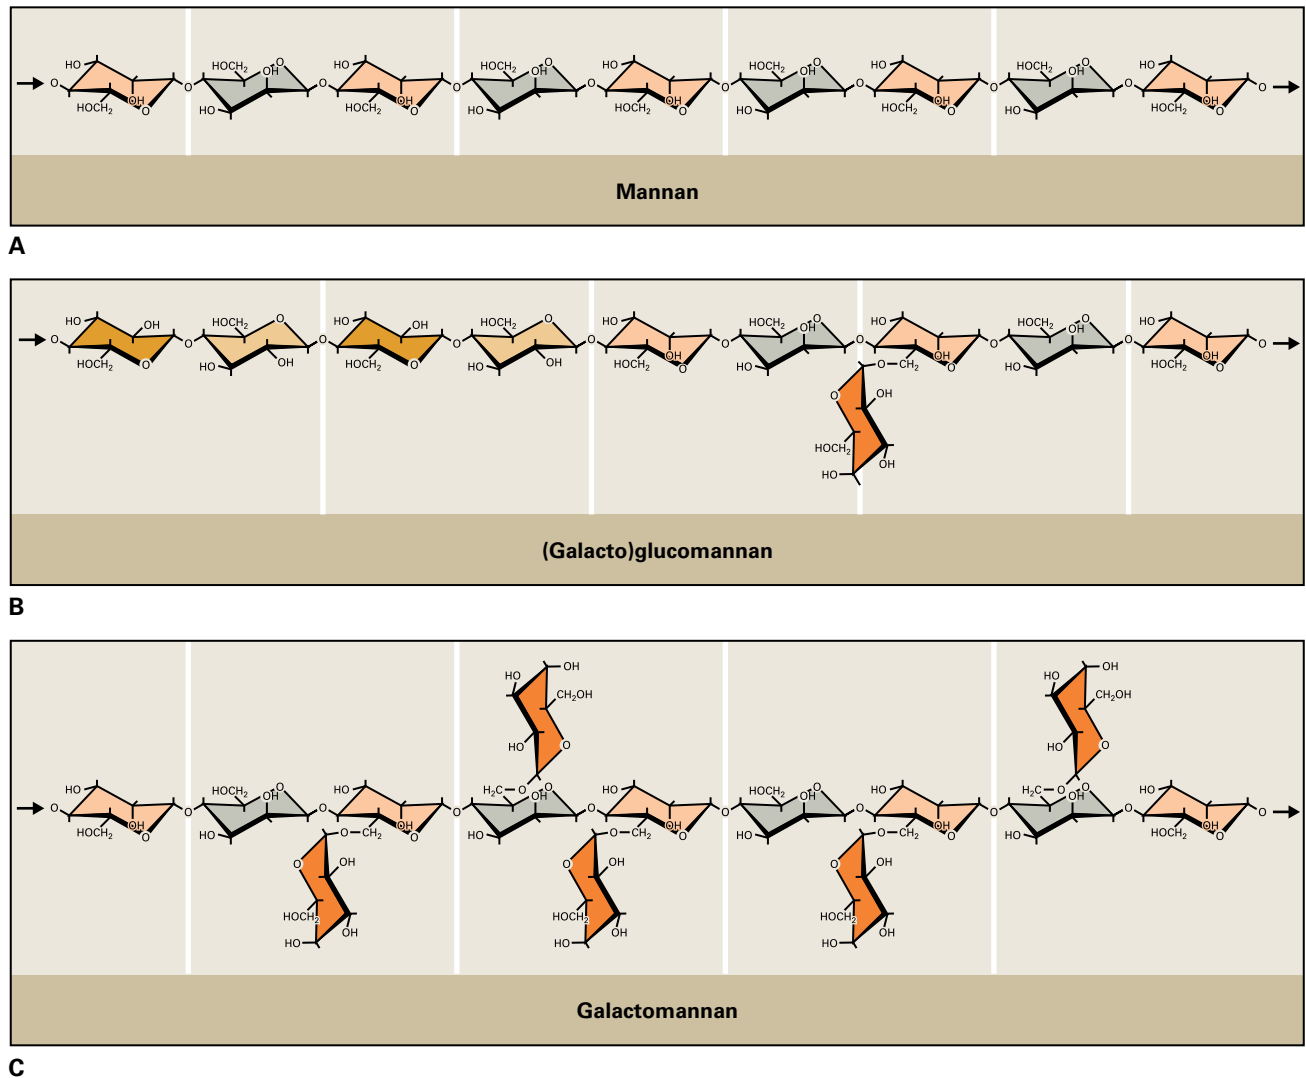

FIGURE 2.16 Crosslinking glycans that contain mannose. The dotted lines mark the (1→4)-β-disaccharide unit structures (see Fig. 2.12). (A) Pure mannans can hydrogen bond into para-crystalline arrays, which are similar in structure to cellulose. (B) (Galacto)glucomannans are roughly equimolar mixtures of (1→4)-β-D-Man and (1→4)-β-D-Glc units, with occasional addition of terminal α-D-Gal units added to the O-6 position of the Man units. Glucomannans are tightly bound to the surface of cellulose microfibrils. (C) Galactomannans have backbones composed exclusively of (1→4)-β-D-mannan with the α-D-Gal units added at the O-6 positions. Gal units interrupt hydrogen bonding and greatly enhance water solubility.

XyGs appear to grow as well as wild-type plants, although tensile strength of the primary walls is compromised if the galactosylated side-chains are missing.

All angiosperms contain at least small amounts of GAX, but their structure may vary considerably with respect to the degree of substitution and position of attachment of α-L-Ara residues (Fig. 2.13). In commelinid monocots, in which they are the major crosslinking polymers, the Ara units are always on the O-3 position. However, in species in which XyG is the major crosslinking glycan, the α-L-Ara units are more commonly found at the O-2 position. In all GAXs, the α-D-GlcA units are attached to the O-2 position.

In the order Poales, which contains cereals and grasses, a third major crosslinking glycan, “**mixed-linkage**” (1→3),(1→4)-β-D-glucans (β-glucans), distinguishes these species from other commelinid species (Fig. 2.15). These unbranched polymers consist of mostly random mixtures of cellotriose and cellotetraose units in a ratio of about 2.5:1 and

connected by single (1→3)-β-D-linkages. Additional cellodextrins of five to nine consecutive (1→4)-β-D-Glc units are all spaced by single (1→3)-β-D-linkages. In aqueous solutions, cellotriose and cellotetraose units result in corkscrew-shaped polymers of about 50 residues that are spaced by the longer cellodextrins. Although absent from all other angiosperms, mixed-linkage (1→3),(1→4)-β-D-glucans of altered cellodextrin unit structure are found in the lichen *Cetraria islandica* and the nonseed vascular plant *Equisetum*.

Other, much less abundant noncellulosic polysaccharides, **mannans**, are found in virtually all angiosperms. In certain algae mannan microfibrils substitute for cellulose as the fundamental scaffold (Fig. 2.16). **Glucomannans** and **galactoglucomannans** potentially interlock the microfibrils in some primary walls. In certain fern species, (gluco)mannans are the major crosslinking glycan, constituting a **type III** cell wall. Extensively substituted **galactomannans** are unable to bind to cellulose and form thick gels upon hydration.

C

FIGURE 2.17 Pectic polysaccharides of plants. (A) Highly methyl esterified chains of (1→4)-α-D-GalA (HG) are secreted by the Golgi apparatus and are de-esterified to varying degrees in certain wall domains by pectin methyl esterases in the wall (see Section 2.3.2). (B) Xylogalacturonans are a separate class of substituted HG, with appendant α-D-Xyl units at the O-3 position of about half of the GalA units. (C) Contorted, rod-like RG I is composed of a repeating disaccharide, →2)-α-L-Rha-(1→4)-α-D-GalA-(1→. About one-third of the GalA units are acetylated at secondary alcohol groups. To the O-4 position of the rhamnosyl units are attached neutral sugar side-chains of branched and linear (1→5)-α-L-arabinans, (1→4)-α-D-galactans, and type I arabinogalactans. Some seed mucilages have nonreducing terminal residues of L-Fuc and L-Gal attached to the O-3 instead of the O-4 positions of Rha.

2.2.3 Pectin matrix polymers are a diverse class of uronic acid-rich polysaccharides

Pectins comprise a mixture of heterogeneous, branched, and highly hydrated polysaccharides rich in D-galacturonic acid. Pectins are easily extracted from the cell wall by Ca²⁺-chelators such as ammonium oxalate, EDTA, EGTA, or cyclohexane diamine tetraacetate (CDTA), or by de-esterifying agents such as Na₂CO₃ or alkali less than 0.1 M.

Pectins perform many functions: determining wall porosity and providing charged surfaces that modulate wall pH and ion balance, regulating cell-cell adhesion at the middle lamella, and serving as recognition molecules that alert plant cells to the presence of symbiotic organisms, pathogens, and insects. Particular cell wall enzymes may bind to the charged pectin network, constraining their activities to local regions of the wall. By limiting wall porosity, pectins may affect cell growth, thereby regulating access of wall-loosening enzymes to their glycan substrates (see Section 2.5.8).

Two fundamental constituents of pectins are **homogalacturonan** (HG) (Fig. 2.17A) and **rhamnogalacturonan I** (RG I) (Fig. 2.17C). HGs are homopolymers of (1→4)-α-D-GalA that contain up to ≈200 GalA units and are about 100 nm long. There are two kinds of structurally modified HGs, **xylogalacturonan** (Fig. 2.17B) and **rhamnogalacturonan II** (RG II) (Fig. 2.18). RG II is misnamed as it is not structurally related to RG I, but was first identified as a rhamnose-containing pectin. RG II has the richest diversity of sugars and linkage structures known, including apiose, aceric acid (3-C'-carboxy-5-deoxy-L-xylose), 2-O-methyl fucose, 2-O-methyl xylose, Kdo (3-deoxy-D-manno-2-octulosonic acid), and Dha (3-deoxy-D-lyxo-2-heptulosaric acid). The highly conserved structure of RG II among flowering plants suggests an important function despite its low abundance in cell walls. Dimers of RG II are crosslinked by borate, two diester bonds per boron atom, between apiose units in the complex sidegroups (Fig. 2.18B). In the *Arabidopsis murus1* mutant, dimers do not form because of a defect in the de novo synthesis of fucose, which alters side-chain structure and reduces its ability to bind to boron. Both the stature of *murus1* plants and the tensile strength of their cell walls are reduced, but normal stature and strength can be rescued by spraying plants with excess boron.

RG I is a rod-like heteropolymer of repeating (1→2)-α-L-Rha-(1→4)-α-D-GalA disaccharide units. RG Is can be isolated from the cell walls by enzymatic digestion with **polygalacturonase** (PGase), but the length of RG I is unknown because there may be runs of HG on the ends of the molecule. While HG and RG II appear to be covalently linked in a single polymer, it is not yet known whether RG I and HG form a continuous backbone, or if one of these molecules attaches as a side-chain to the backbone of the other.

Other polysaccharides composed mostly of neutral sugars, such as **arabinans**, **galactans**, and highly branched **type I arabinogalactans** (AGs) of various configurations and sizes, are attached to the O-4 of many of the Rha residues of RG I (see Fig. 2.17C). In general, about half of the Rha units of RG

I have side-chains, but this ratio can vary with cell type and physiological state. Type I AGs are found only associated with pectins and are composed of (1→4)-β-D-galactan chains with mostly *t*-Ara units at the O-3 of the Gal units.

2.2.4 Structural proteins are encoded by large multigene families

Although the structural framework of the cell wall is largely carbohydrate, structural proteins may also form networks in the wall. There are three major classes of structural proteins named for their respectively enriched amino acid: **hydroxyproline-rich glycoproteins** (HRGPs), **proline-rich proteins** (PRPs), and **glycine-rich proteins** (GRPs) (see Fig. 2.19). All of them are developmentally regulated, with relative amounts varying among tissues and species (Fig. 2.20). All mRNAs for these structural proteins encode signal peptides that target the proteins to the secretory pathway, and like other secretory proteins destined for the cell wall, structural proteins are cotranslationally inserted into the ER.

Extensin is one of the best studied plant HRGPs and consists of repeating Ser-(Hyp)₄ and Tyr-Lys-Tyr sequences that are important for secondary and tertiary structure (Fig. 2.19). The repeating Hyp units predict a “**polyproline II**” rod-like molecule. A single *t*-α-D-Gal residue is added to the Ser residues, whereas one to four arabinosyl units are added to one or all of the four Hyp residues. The conformational structure of PRPs is unknown, but their similarity to extensin suggests they may also be rod-shaped proteins. GRPs, some of which contain more than 70% glycine, are predicted to be β-pleated sheets rather than rod-shaped molecules. Like HRGPs, cell wall GRPs are difficult to extract and may become crosslinked into the wall.

2.2.5 Arabinogalactan proteins are developmentally regulated proteoglycans

Type II AGs are a diverse group of short (1→3)- and (1→6)-β-D-galactan chains connected to each other by (1→3,1→6)-linked branch-point residues, and they are associated with specific proteins and peptides to form **arabinogalactan proteins** (AGPs). AGPs are more aptly described as proteoglycans, as they can consist of more than 95% carbohydrate. AGPs constitute a broad class of molecules located in Golgi-derived vesicles, the plasma membrane, and the cell wall. The site of AGP glycosylation remains undetermined, but it is likely the Golgi apparatus because it involves attachment of large, highly branched galactan chains and subsequent decoration with Ara units (Fig. 2.21). AGPs are often decorated with additional sugars, including *t*-β-D-GlcA-(1→3)- and *t*-α-L-Rha-(1→4)-β-D-GlcA-(1→3)- side groups on the (1→6)-β-D-galactan chains, where *t* is defined as the nonreducing terminal sugar. Characterization of the polysaccharide contents of the Golgi apparatus and secretory vesicles, including glycosylated proteins – shows that a majority of the material present is AGP. Another characteristic of

FIGURE 2.18 Rhamnogalacturonans. (A) RG II is a complex HG with four distinct side groups containing several different kinds of sugar linkages. (B) RG II monomers of about 4,200 kDa can dimerize as boron di-diesters of the apiose residues. Red dots indicate methyl groups, blue dots acetyl groups.

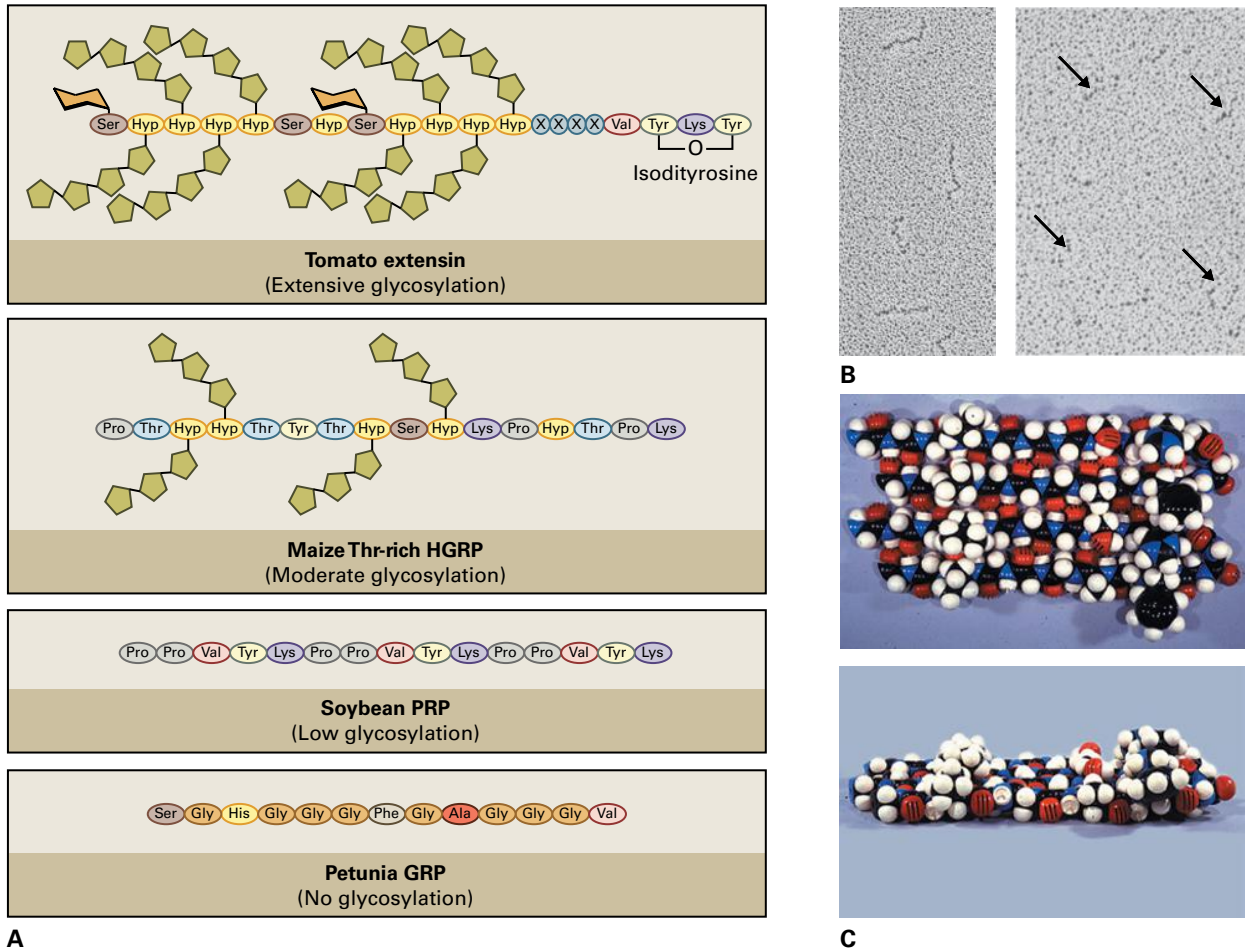

FIGURE 2.19 Comparisons of repeated motifs of extensins, maize Thr-rich proteins, PRPs, and GRPs. (A) A Ser-(Hyp)₄ or related motif found in many flowering plants is heavily glycosylated with mono-, di-, tri-, and tetra-arabinosides that associate with the polyproline helix to reinforce a rod-shaped structure of tomato (*Solanum lycopersicum*) extensin molecules. A Gal unit is attached to the Ser residue. The Tyr-Lys-Tyr motif is the likely position of the intramolecular isodityrosine linkage. An extensin-like Thr-rich protein from maize is moderately glycosylated. The repeated motifs of PRP lack many contiguously hydroxylated Ser, Thr, and Hyp residues—a signal for glycosylation with arabinosides, so PRPs are not as heavily glycosylated. (B) Rotary-shadowed replicas of isolated extensin precursors reveal their rod-shaped structure (left). Removal of the arabinosides results in loss of the rod-shaped structure (right). (C) In contrast to the rod-shaped extensins, the GRPs may form β -sheet structures and are not glycosylated. A *Petunia hybrida* GRP has 14 repeats of the motif shown in (A), and the aromatic residues align on one face of the proposed β -sheet. Source: (B) Stafstrom & Staehelin. (1986). *Plant Physiol* 81:242. (C) Condit & Meagher. (1986). *Nature* 323:178–181.

AGPs is their ability to bind Yariv reagent, a β -D-Glc derivative of phloroglucinol (Fig. 2.21).

Like structural proteins, AGPs are encoded by a large multigene family. Of the few proteins that have been isolated, they can be characterized as enriched in Pro(Hyp), Ala, and Ser/Thr. They possess distinguishing common motifs, but contain domains with similarity to some PRPs, extensins, and the Solanaceous lectins (Fig. 2.21). An interesting clade in the AGP gene family has similarity to fasciclin domain-containing proteins in animal cells, known to function in cell adhesion. While no clear-cut function has been described for AGPs, they are made only in specific cell types, at particular developmental stages, and in response to specific environmental stimuli. Many AGPs are glycosylphosphatidylinositol (GPI)-anchored; a GPI anchor is a glycolipid, with a carbohydrate link to a proteolytically trimmed C-terminus of a protein, attached post-translationally to diacylglycerol,

anchoring the protein to the plasma membrane (Fig. 2.21). Phospholipase C is known to cleave glycosylated proteins from their membrane anchors, where they subsequently can migrate into the cell wall or be recovered into the cytoplasm by endocytosis. In addition to AGPs, many different classes of wall-associated proteins are GPI-anchored, including some proteases, glycosyl hydrolases, and several surface proteins involved in anisotropic cell growth.

2.2.6 Aromatic substances are present in the nonlignified walls of commelinid species

The primary walls of commelinid orders of monocots and Chenopodiaceae (such as sugar beet and spinach) contain significant amounts of aromatic substances incorporated into

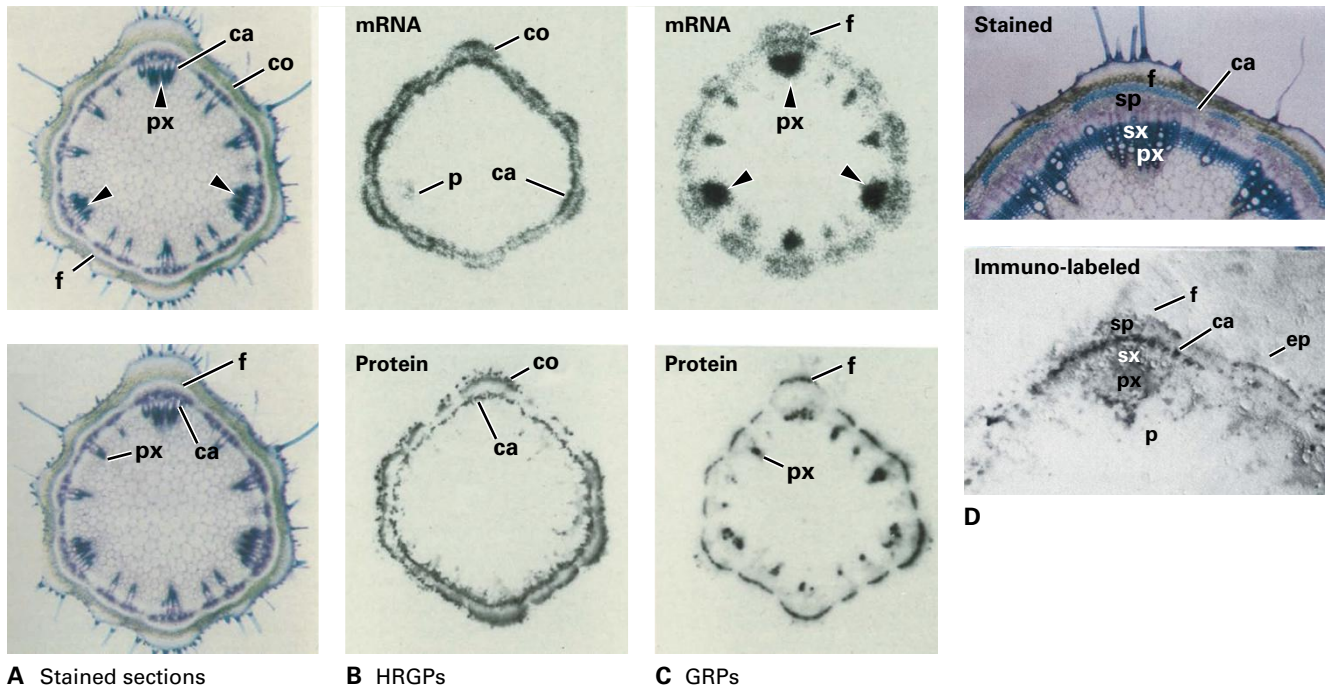

FIGURE 2.20 When cleanly sliced sections of a plant are pressed firmly for a few seconds to a nitrocellulose sheet, soluble carbohydrate, protein, and nucleic acids are left behind, imprinted in a nearly cell-specific pattern. Coined tissue printing, this technique has been instrumental in providing biologists with an extremely simple experimental tool with many uses. (A) Stained sections of the elongating second internode of a soybean (*Glycine max*) stem are provided for comparison with other pairs of sections. (B) *In situ* hybridization with an HRGP cDNA probe and immunolocalization with an HRGP-specific antibody reveal that HRGPs and the mRNA transcripts that encode them are colocalized in cortical (co) and cambial (ca) cells. (C) The same techniques show that GRP mRNA transcripts and their protein products are enriched in phloem (f) and protoxylem (px). Thus, the GRP proteins and transcripts are found primarily in vascular or lignified cells, whereas the HRGPs are located in meristematic cells and cells around the cambium. (D) Magnification of the stained section and tissue print shows that HRGP can be immunolocalized to the cellular level. ep, epidermis; p, pith; sp, secondary phloem; sx, secondary xylem.

their unligified cell wall polymers, a feature that makes them fluoresce under UV light. A large proportion of plant aromatics are the **hydroxycinnamates**, esters of primarily ferulic and *p*-coumaric acids (Fig. 2.22). In grasses, about one of every 20 Ara units of GAX are acylated at their O-5 positions by hydroxycinnamates. Up to half the ferulate units of neighboring GAXs may crosslink via radical dehydrodimerization to form a large variety of dehydrodiferulates, interconnecting GAX into a network (Fig. 2.23). In *Chenopodiaceae*, Gal or Ara side-chain units on some RG I molecules are acylated with feruloyl groups. The hydroxycinnamate *p*-coumarate, and possibly also ferulate, is also reduced to various hydroxycinnamyl alcohols, which form common precursors for lignin and lignan structures; in fact, much of the ferulate may derive from coniferaldehyde (Fig. 2.23).

2.2.7 Evolution of cell wall polymers can be correlated to gain of function

The structural complexity of plant cell walls can involve up to five classes of polymers: cellulose microfibrils, crosslinking glycans, pectins, structural proteins, and lignins and other

phenylpropanoid substances. When did these classes of cell wall molecules appear in the tree of life (Fig. 2.24), and how is each primitive component later modified in structure during evolution to optimize its role in the functional composite? The nine most common monosaccharides found in angiosperm cell walls can all be traced to prokaryotic ancestors as well as the earliest plant species. When did specific glycosyl transferase activities appear, and in which ancestors?

Cellulose is an ancient polymer. It first appears in bacteria, not as a cell wall constituent but as an extruded ribbon of extracellular material that functions as attachment appendages for bacterial adhesion to host cells or a flotation device, called a “pellicle,” on the surface of water to improve aeration. Cellulose microfibrils characteristic of plants are thought to have originated in charophytic algae and extend in distinct stages to nonvascular land plants (mosses, liverworts, and hornworts), primitive vascular plants (club mosses, ferns, and fern allies), and seed plants (gymnosperms, angiosperms) (Fig. 2.24). Cellulose is also found in most algae outside the plant lineage as well as in slime molds and tunicates.

The basic diagnostic structure of xyloglucan, the α -D-Xyl-(1→6)-D-Glu linkage (isoprimerverose), is not found in algae, but appears in mosses and all more recently evolved plants. Naked xyloglucans are poorly soluble in

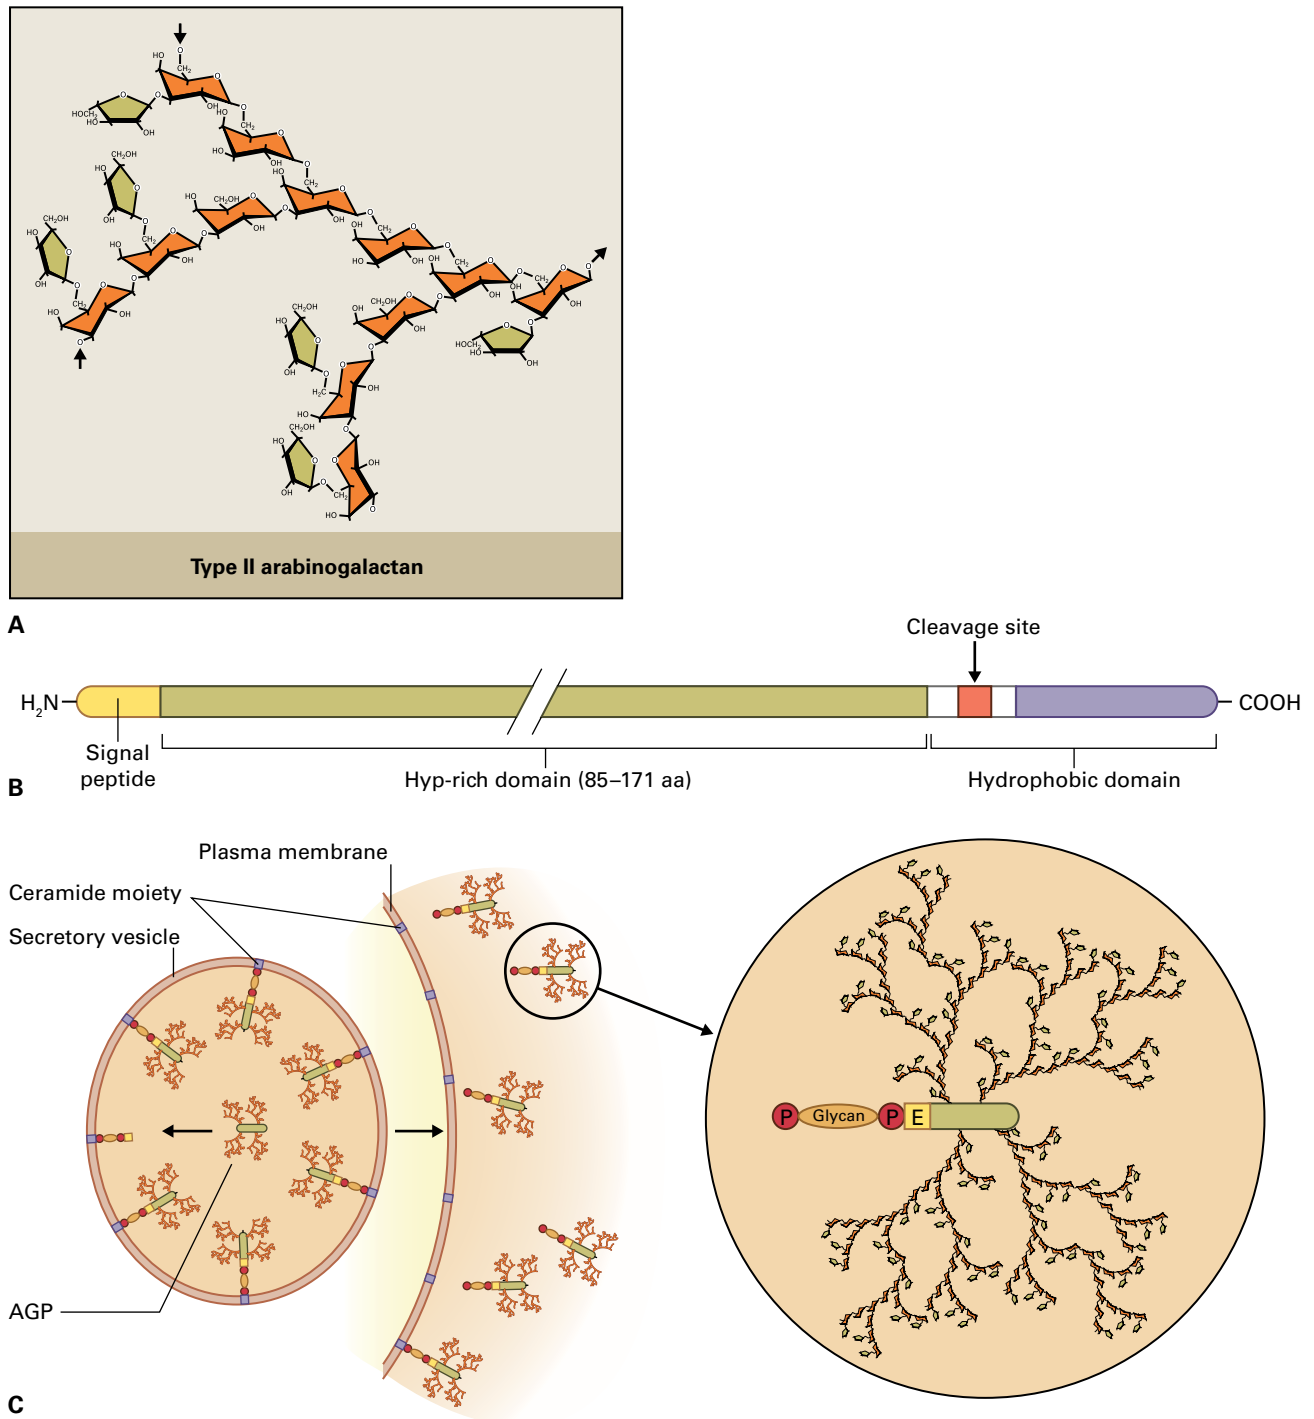

FIGURE 2.21 (A) Arabinogalactan proteins (AGPs) are proteoglycans, many of which are glycosylated with type II AG structures. (B) The AGP genes are characterized by their enrichment in Hyp, Ala, and Ser/Thr residues in domains that are thought to contain the AG chains, but, as with the GRPs, there are no clear-cut unifying motifs. Some of the AGPs contain domains that are homologous to extensins or PRPs, and also contain Cys-rich domains. Each of these domains is glycosylated in different ways. (C) Some AGPs, after cleavage of the C terminus, covalently attach to glycosylphosphatidylinositides (called GPI anchors) during synthesis and secretion in the ER and Golgi apparatus. Once at the exterior of the cell, the AGP portions can be cleaved from the GPI anchor and serve as signal molecules. E, ethanolamine.

water, so appendant sugars are added to xylose residues to increase solubility. These appendant sugars are quite diverse among angiosperms (see Fig. 2.14 and Table 2.1), and this diversity extends to its earliest appearance in mosses, suggesting a function specific to the plant beyond water solubility.

Glucuronoxylans are major noncellulosic glycans of tra-cheary elements in all vascular plants, with arabinoxylans becoming the principal crosslinking glycan of commelinid monocots. The association with vascular tissues is consistent with its absence from the Charophyta as well as liverworts

FIGURE 2.22 Current view of the metabolic pathways from phenylalanine or tyrosine to hydroxycinnamic acids and monolignols. Modifications to the ring are shown left to right across the page, and modifications to the side-chain are shown down the page. Phenylalanine ammonia lyase (PAL) and cinnamate 4-hydroxylase (C4H) or tyrosine ammonia lyase (TAL) initiate the pathway by producing p-coumaric acid. Ring modifications are catalyzed by p-coumaroyl-shikimate/quinate 3-hydroxylase (C3H) and ferulate (coniferyl aldehyde/alcohol) 5-hydroxylase (F5H), caffeoyl-CoA 3-O-methyl transferase (CCoAOMT), and caffeic acid O-methyltransferase (COMT). Reduction of the side-chain is initiated by generation of p-coumaroyl-CoA from p-coumaric acid is catalyzed by HCT, and subsequent products of hydroxylation and methylation are catalyzed by 4-coumarate acid CoA ligase (4CL), cinnamoyl-CoA reductase (CCR), and cinnamyl alcohol dehydrogenase (CAD). Peroxidases couple the monolignols, p-coumaryl alcohol, coniferyl alcohol and sinapyl alcohol, into H- (p-hydroxyphenyl), G- (guaiacyl), and S- (syringyl) lignin units.

and basal mosses and its appearance in the pre-vascular advanced mosses and hornworts. In contrast, mannans (glucmannans and gluco(galacto)mannans), like cellulose, are abundant in many algae including the characean algae and nonvascular land plants. Mannans replace cellulose in *Acetabularia*, a “mannan weed” in the Chrysophyta, as the major structural scaffold. Mannans are the major crosslinking glycan of certain ferns, but their abundance is greatly reduced in vascular plants. Curiously, a form of mixed-linkage (1→3),(1→4)-β-D-glucan found only in Poales and no other angiosperm is also detected in the primitive vascular plant, *Equisetum*. The widely variant distribution of celotriose and celotetraose unit composition between the β-glucans of *Equisetum* and Poales indicates a convergent evolution of synthases.

Though they contain no xyloglucans, charophytes, non-vascular liverworts, basal and advanced mosses, and hornworts all contain uronic acid-rich HGs as major matrix

polymers. The appearance of the characteristic RG I disaccharide (1→2)-α-L-Rha-(1→4)-α-D-GalA remains to be established. However, monoclonal antibodies against the HG backbone detect the polymer in certain liverworts and mosses, and the typical neutral side-chains of (1→5)-α-L-arabinans and (1→4)-β-D-galactans are detected in a wide range of species. The complex pectic polysaccharide RG II, with side-group composition similar to angiosperms, is observed first in the Charophyta. Antibodies against the arabinogalactan portion of AGPs and 3-O-methyl Rha and 3-O-methyl Gal, monosaccharides that commonly decorate them, detect these proteoglycans widely among nonvascular plants.

The appearance of lignins coincides with the evolution of vascular plants. In general, primitive nonseed vascular plants contain only guaiacyl units, whereas the additional methoxy group in the syringyl groups appear in the angiosperms. Syringyl groups appear to be made by a different pathway in the earlier diverging nonseed vascular plant, *Selaginella*.

FIGURE 2.24 Evolution of plant cell wall polysaccharides. Key transitions in polysaccharide composition are shown from the charophytes to nonvascular and vascular land plants.

BOX 2.5

Cell walls and their component polymers can be imaged directly by novel microscopy techniques

Cell walls were first imaged by Robert Hooke in the 17th century using light microscopy (A). When conventional techniques are used to stain plant tissues for electron microscopy, the cell wall appears as a fuzzy zone with little structural information (B). However, taking a series of electron micrographs of a sample tilted through a range of angles in the electron beam has been used to reconstruct the interior structure of a sample from its projections. **Dual-axis electron tomography** has been used to measure individual microfibrils of wood at about 3.2 nm with an unstained core of about 2.2 nm.

A technique called **fast-freeze, deep-etch, rotary-shadowed replica** allows one to visualize cell walls at high resolution and with good preservation of the three-dimensional spatial relationships of the polymers (C). This technique requires three steps:

wall material is frozen rapidly with liquid nitrogen or helium surface ice is removed under vacuum

the exposed surface is coated with a thin film of platinum and carbon to produce a replica, essentially a three-dimensional contour map of the cell wall polymers in their proper orientation

the underlying tissue is dissolved away, and the replica is viewed in the electron microscope.

Because the walls are frozen quickly, little ice damage occurs, and because no chemical fixatives or dehydrants are used, the normal spacing of components remains. Gentle extraction of pectic polysaccharides from cell walls before freezing can reveal fine thread-like crosslinking glycans spanning between the larger microfibrils (C). A glancing fracture through an onion epidermal wall prepared by this technique reveals the lamellar structure of the wall (D).

Isolated cell-wall molecules can also be imaged with the replica technique. The molecules are mixed in glycerol and sprayed on to a freshly cleaved sheet of mica. After

A

E

F

B

D

G

the glycerol has been dried under vacuum, a rotary-shadowed replica is made, and the mica is dissolved by strong acid. Length measurements made directly from electron micrographs allow a minimum molecular mass to be estimated, assuming each sugar residue corresponds to 0.5 nm (E).

However, making replicas is technically difficult and other imaging technologies provide an easier route to imaging at least microfibrils within walls. Field-emission scanning electron microscopy (FESEM) now provides the necessary resolution in scanning rather than transmission EM (F). High-resolution atomic force microscopy (AFM) has the versatility to make measurements in air or under fluid. Sample topography (height data) and elasticity (phase image) can be acquired simultaneously. In dried maize stalks, internal faces revealed microfibrils of minimum cross-section 5 by 10 nm² (G). In atomic force

spectroscopy, the binding forces between a cellulose substrate and an AFM tip coated in xyloglucan or other polysaccharide can be measured. The xyloglucan is covalently linked to the AFM tip and forces to remove the hydrogen-bonded xyloglucan from the cellulose are measured as tens of picoNewtons, approximating to one hydrogen bond per backbone glucose residue.

Types I and II, which differ in chemical composition and are associated with distinct plant taxa (see Fig. 2.14).

2.3.2 Walls of angiosperms are assembled in two distinct types of architecture

The walls of most eudicots and noncommelinid monocots contain equivalent amounts of XyGs and cellulose. These kinds of wall are denoted as Type I walls. XyGs occur in two distinct locations; they bind tightly to the exposed faces of glucan chains in cellulose microfibrils, and they span the distance between adjacent microfibrils, perhaps linking to other XyGs. With an average length of ≈ 200 nm, XyGs are long enough to span the distance between two microfibrils and bind to both of them. Such spanning XyGs have been observed by electron microscopy. Studies using NMR spectroscopy

support this interpretation by finding different mobilities for XyG in the wall, an enzyme-accessible fraction with greater mobility and an enzyme-inaccessible fraction of lesser mobility. Studies of the rheological properties of cellulose–XyG composites made in vitro show that crosslinking of cellulose microfibrils by XyG greatly enhances the elastic properties of the composite.

In Type I walls (Fig. 2.25A), the cellulose–XyG framework is embedded in a pectin matrix that controls wall porosity, among other physiological properties. HG is thought to be secreted as highly methyl esterified polymers, and the enzyme **pectin methylesterase (PME)** located in the cell wall cleaves some of the methyl groups to initiate binding of carboxylate ions to Ca^{2+} . Helical chains of HGs can condense by crosslinking with Ca^{2+} to form “junction zones,” thereby linking two antiparallel chains (Fig. 2.26A). The strongest junctions occur between two chains of at least seven unesterified GalA units each. If sufficient Ca^{2+} is present, some

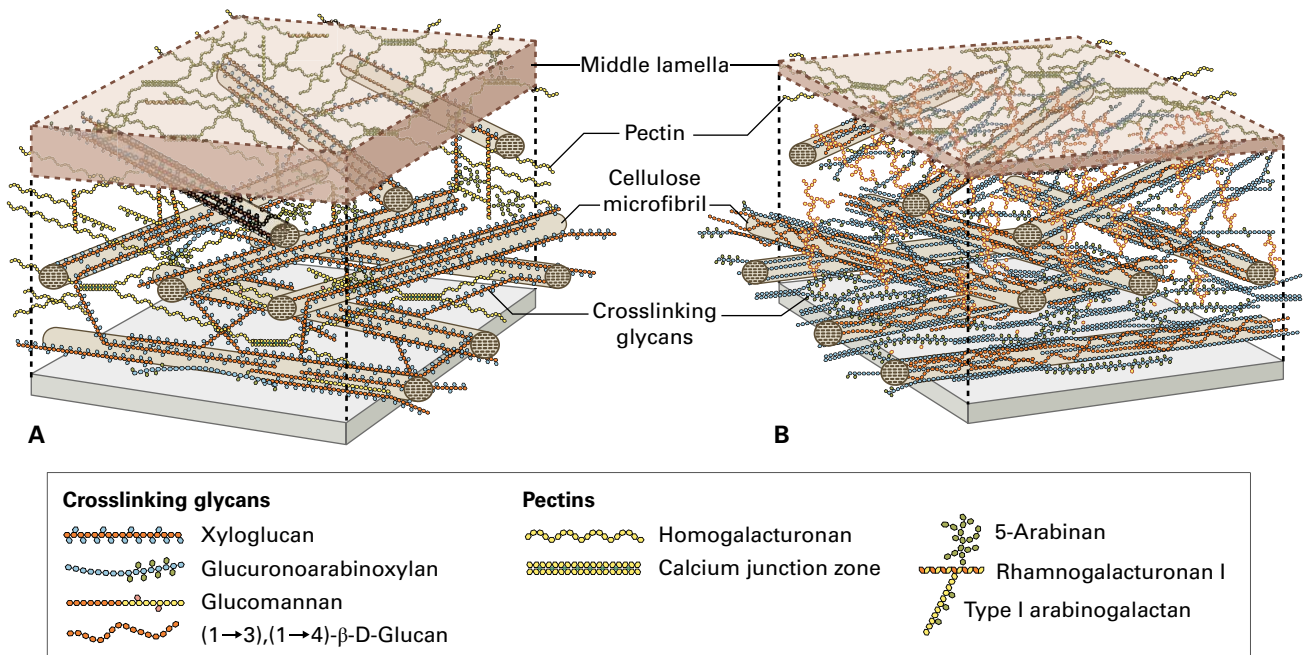

FIGURE 2.25 (A) Three-dimensional molecular model of the Type I wall showing the molecular interactions between cellulose, XyG, pectins, and wall proteins. The framework of cellulose microfibrils and XyG polymers is embedded in a matrix of pectic polysaccharides, HG and RG I, the latter being substituted with arabinan, galactan, and arabinogalactan. Because XyGs have only a single face that can hydrogen bond to another glucan chain and can self-associate, we depict several XyGs as woven to interlace the microfibrils. Many other associations are possible, including bridging of two microfibrils by a single XyG. With hemicellulose-coated microfibril diameters of about 5 nm and a spacing of about 20–30 nm, a primary wall 80 nm thick can have only about five to 10 strata (only three lamellae of microfibrils are shown for clarity). During growth, cleavage or dissociation of XyGs by enzymes loosens the cellulose–XyG network allowing microfibrils to separate. After growth, extensin molecules may interlock the separated microfibrils to reinforce the architecture. Additional proteins may also be inserted to crosslink extensin, forming a heteropeptide network. (B) A three-dimensional molecular model of the Type II wall shows the molecular interactions between cellulose, GAX, pectins, and aromatic substances. The microfibrils are interlocked by GAXs instead of XyGs. Unlike XyGs, the xylans are substituted with Ara units, which block hydrogen bonding. The xylans are probably synthesized in a highly substituted form, and de-arabinosylated in the extracellular space to yield stretches of the xylan that can bind on either face to cellulose or to each other. Porosity of the GAX domain could be determined by the extent of removal of the appendant units. Some highly substituted GAX remains intercalated in the small amount of pectins that are also found in the primary wall. We depicted here the special Type II wall of the grasses (Poales), which synthesize β -glucans during cell enlargement and then hydrolyze most of the polymer after maximal growth rates have been achieved. These cork-screw-shaped molecules contain linear runs of cellobextrins about every 50 glucosyl units or so, and these runs are targets for endo- β -D-glucanases that cleave them. A combination of selective chemical extractions, immunolocalization, and scanning electron microscopy has shown that β -glucans are tightly bound to cellulose microfibrils and rarely extend between them. Unlike the Type I wall, a substantial portion of the noncellulosic polymers are “wired on” to the microfibrils by alkali-resistant phenolic linkages.

A

B

FIGURE 2.26 Possible calcium–pectate interactions in the cell wall. (A) HG may complex with Ca^{2+} to form “junction zones.” Loss of pectin esters generates contiguous runs of HG free acids that can then form “egg box” junctions with Ca^{2+} bridging two antiparallel chains. (B) Antiparallel or parallel chains of partly methylated HG can also be linked in less firmly bound calcium complexes.

methyl esters can be tolerated in the junction, and the HGs can bind in both parallel and antiparallel orientation (Fig. 2.26B). The spacing of the junctions is postulated to create a cell-specific pore size. Rha units of RG I and their side-chains interrupt the Ca^{2+} junctions and contribute to pore definition (Fig. 2.27).

Other properties of the pectin network also regulate porosity. The extent of methyl esterification may remain high

in walls of some cells, and a type of gel may form that contains highly esterified parallel chains of HGs. Some HGs and RGs are crosslinked by ester linkages to other pectins or other polymers held more tightly in the wall matrix and can only be released from the wall by de-esterifying agents. Other pectic polymers may separate sites of borate di-diester crosslinking by RG II dimers along the pectic backbone (see Fig. 2.18). In boron-deficient cell cultures walls swell and porosity

FIGURE 2.27 Pectin matrix establishes the “pore size,” that is, the relative size of the channels formed by the wall matrix that permit molecules to freely diffuse through the wall matrix. This pore size can be established by a combination of the frequency and length of the junction zones, the degree of methylesterification, and the length of the arabinans, galactans, and arabinogalactans attached to RG I that extend into the pores. Additional factors that influence pore size are the frequency of RG II and its dimerization by boron (not shown). The charge density depends on the extent of de-esterification of the HG to yield carboxyl acids unbound to Ca^{2+} . Arrows denote domains of negative charge density in HGs.

increases. Neutral polymers (arabinans or galactans) are pinned at one end to the pectic backbone, but extend into and are highly mobile in wall pores (Fig. 2.27). These neutral polymers also regulate the amount of water that is tightly bound into the wall structure. At some stages of cell development, hydrolases are released that trim these neutral polymers, potentially increasing pore size. In meristems and elongating cells, where Ca^{2+} concentrations are kept quite low, significant de-esterification of HG can occur without Ca^{2+} binding, altering charge density and local pH.

Some Type I walls contain large amounts of protein, including basic proteins that can interact with the pectin network. In these instances, various structural proteins can form intermolecular bridges with other proteins without necessarily binding to polysaccharide components.

Type II walls of commelinid monocots contain cellulose microfibrils similar to those of the Type I wall, but instead of XyG, the principal polymers that interlock microfibrils are GAXs. Unbranched GAXs can hydrogen bond to cellulose or to each other. Attachment of α -L-Ara and α -D-GlcA side groups to the xylan backbone of GAXs prevents formation of hydrogen bonds, thereby blocking the crosslinking

between two branched GAX chains or from GAX to cellulose. In contrast, α -D-Xyl units attached at O-6 of XyG, away from the binding plane, stabilize the linear structure and permit binding to one side of the glucan backbone. Despite the predominance of GAX, Type II walls contain small amounts of XyG that also bind tightly to cellulose.

In general, Type II walls are pectin-poor, but an additional contribution to charge density of the wall is provided by α -D-GlcA units on GAX. These walls have very little structural protein compared with eudicots and other monocots, but can accumulate extensive interconnecting networks of phenylpropanoids, particularly as cells stop expanding (see Fig. 2.25B).

2.3.3 Polymers remain soluble until they can be crosslinked at the cell surface

Many polymers are modified by esterification, acetylation, or glycosylation for solubility during transport. Later, extracellular enzymes de-esterify, deacetylate, or deglycosylate to

generate sites along the polymers available for crosslinking into the cell wall. These sites are determined by long-range binding order of polysaccharides, permitting their assembly into precise cell wall architectures. A range of crosslinking possibilities exists, including hydrogen bonding, ionic bonding with Ca^{2+} ions, covalent ester linkages, ether linkages, and van der Waals' interactions. Because AGPs constitute a majority of the material of secretory vesicles but never accumulate in the wall, they might function as a chaperone-like matrix that prevents premature associations and keeps enzymatic functions in a quiescent state until secretory materials are assembled in the wall.

Assembly processes occur in an aqueous environment, and one of the major components of cell walls is water. This is of structural importance from the viewpoint of maintaining polymers in their proper conformations. Water is the medium that permits passage of ions and signaling molecules through the apoplast; it also provides an environment for enzyme function. The apoplastic space is thought to be at a pH of ≈ 5.5 , although this value averages much heterogeneity in wall structure, and pH can vary widely from the plasma membrane to the middle lamella, and as the wall becomes modified during growth. The pore diameter that limits diffusion of molecules through the primary wall is ≈ 4 nm, but some molecules larger than this limiting diameter can pass through the wall to the plasma membrane, perhaps by way of a small number of larger pores or because they are rod-like rather than globular.

2.4 Cell wall biosynthesis and assembly

2.4.1 New walls are initiated in the cell plate after mitotic division

While a vast majority of the cell wall mass is formed by integration of new polymers into an expanding pre-existing matrix, new cell walls originate *de novo* to form the developing cell plate. As plant chromosomes complete division during telophase of the mitotic cell cycle, the **phragmosome**, a flattened membranous vesicle containing cell wall components, forms across the cell within a cytoskeletal array called the **phragmoplast** (see Chapter 5). The noncellulosic cell wall polysaccharides synthesized in the Golgi and packaged in vesicles fuse with the growing cell plate. The plate grows outward until the edges of membranous vesicle fuse with the plasma membrane, creating two cells. Finally, the new cell wall fuses with the existing primary wall (see Fig. 2.3).

The plant Golgi apparatus is a factory for the synthesis, processing, and targeting of glycoproteins (Fig. 2.28). It has also been shown by autoradiography to be the site of synthesis of noncellulosic polysaccharides. Thus, with the exception of cellulose, the polysaccharides, structural proteins, and a

broad spectrum of enzymes are coordinately secreted in Golgi-derived vesicles and targeted to the cell wall.

2.4.2 Cellulose microfibrils are formed at the plasma membrane surface

The only polymers made at the outer plasma membrane surface of plants are cellulose and callose. Cellulose synthesis is catalyzed by multimeric enzyme complexes located at the termini of growing cellulose microfibrils (Fig. 2.29). These **terminal complexes** are visible in freeze-fracture replicas of plasma membrane. In some algae, terminal complexes are organized in linear arrays, whereas in others—and in all angiosperms—they form six-membered **particle rosettes** (Fig. 2.29). Thus, each of the six components of the particle rosette is expected to synthesize two to six of the glucan chains, and an estimated total of 16, 24, or 36 chains are then assembled into a functional microfibril. In freeze-fracture, the particle rosettes are about 25 nm in diameter, but this size represents only portions of the membrane-spanning and short exterior domains (Fig. 2.29H, I). Hidden in surface views of rosette structures in the plasma membrane, the much larger catalytic domains of cellulose synthases are estimated to be 50 nm wide (Fig. 2.29J).

Terminal complexes appear in the plasma membrane coincident with the activity of cellulose synthesis. Kinetic studies monitoring the pathway of glucose to cellulose have established that UDP-Glc is the primary substrate for cellulose synthase. Isoforms of sucrose synthase, an enzyme that produces UDP-Glc directly from sucrose, are also associated with the plasma membrane and may contribute a localized source of UDP-Glc substrate.

Cellulose synthase produces one of the most abundant biopolymers on earth, yet the plant enzyme has proven curiously difficult to purify in active form. Cellulose synthase activity from plants generally disappears rapidly upon cell breakage, and even under conditions of gentle plasma membrane isolation. Use of certain stabilizing detergents has preserved associated cellulose synthase complexes to produce disorganized microfibrils with UDP-Glc of sufficient crystallinity to diffract X-rays, the first unequivocal demonstration of cellulose synthesis *in vitro* in microsomal membrane preparations from a cell culture. There is still much work to do to define all the accessory proteins of a cellulose synthase complex and to understand the regulation of its activity and turnover and associations with cytoskeletal and cell wall components that stabilize it in the membrane.

The unbranched (1 \rightarrow 3)- β -D-glucan **callose** is a natural component of the initial cell plate, the pollen tube wall, and in transitional stages of wall development of certain cell types. Unlike the wound polymer, pollen tube callose is synthesized by enzymes that do not require Ca^{2+} as cofactors; moreover, these synthases are enzymes distinct from cellulose synthases, encoded by a distinct family of glycosyl transferases.

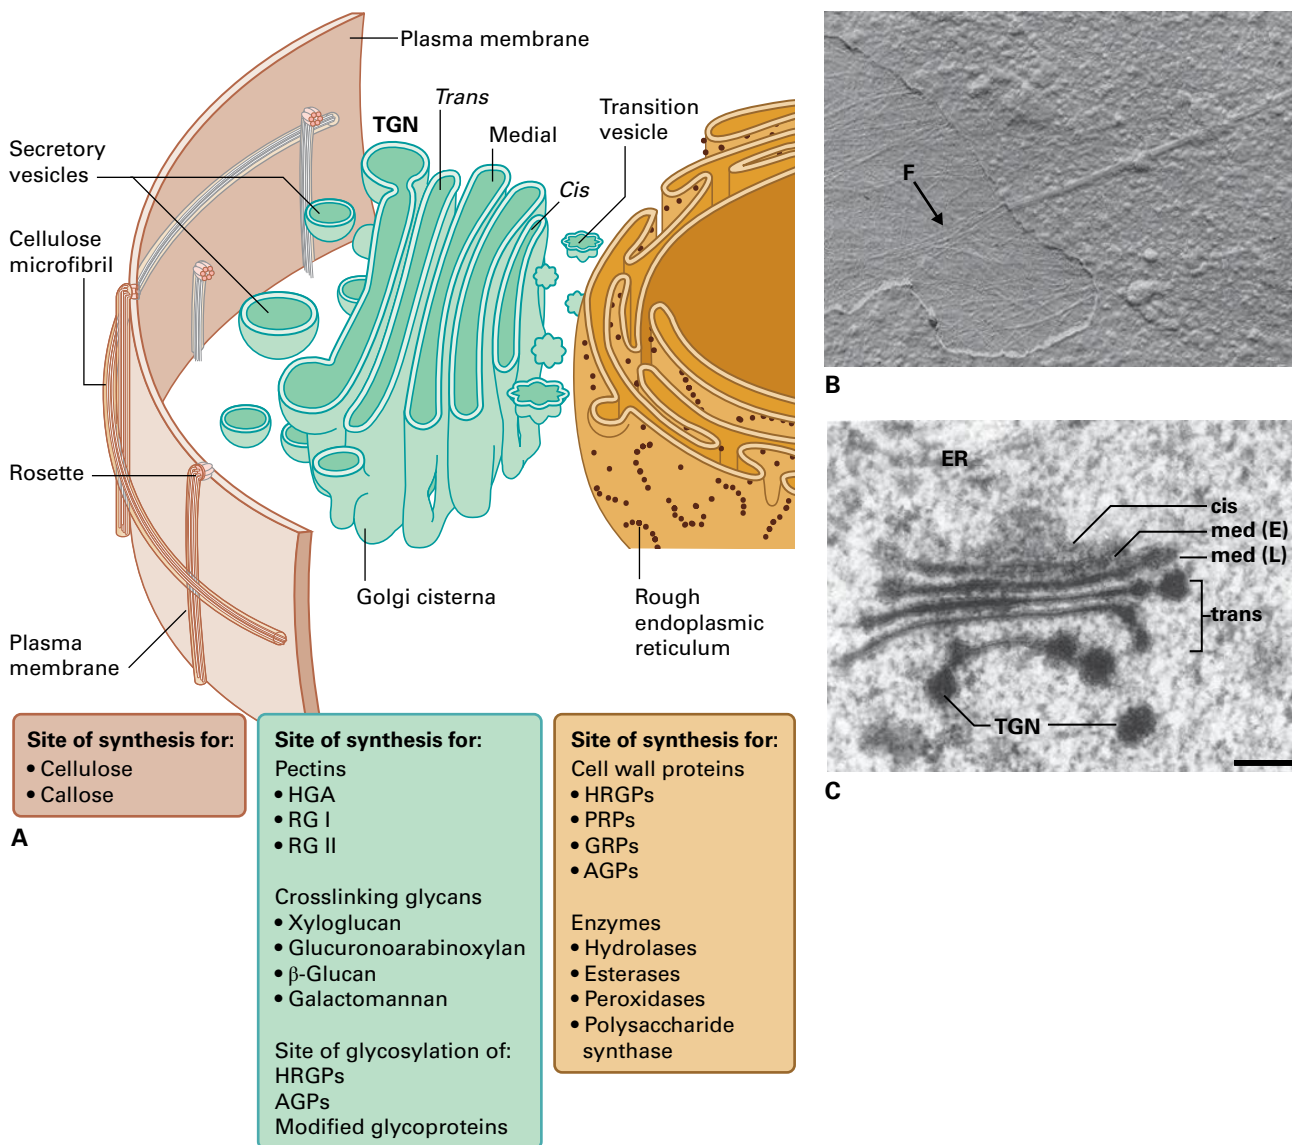

FIGURE 2.28 (A) Cell wall biosynthesis requires coordination of the synthesis of cellulose microfibrils at the plasma membrane surface, the synthesis and glycosylation of proteins and wall-modifying enzymes at the rough ER, and the synthesis of all noncellulosic polysaccharides at the Golgi apparatus. Material destined for the cell wall is packaged into secretory vesicles, transported to the cell surface, and integrated with newly synthesized microfibrils. Assembly of the new wall stratum is estimated to begin when no more than 10 glucose residues of a cellulose chain are made. (B) A replica plate of the E-face (exterior leaf of a fractured membrane bilayer). Numerous vesicles aggregate at the surface. A portion of the membrane has torn away to reveal the underlying microfibrils (F). (C) Cross-section of a single dictyosome body of the Golgi apparatus showing the characteristic development of several membrane sheets, from the cis-face nearest the ER to the trans-face; these develop into the distinctive trans-Golgi-network (TGN), which is the principal vesicle-secreting body. 2.4.3 Golgi-associated enzymes interconvert the nucleotide sugar substrates for polysaccharide synthesis

The reactions that synthesize noncellulosic cell wall polysaccharides in the Golgi apparatus use several nucleotide sugars as substrates. Beginning with formation of UDP-Glc and GDP-Glc, pathways for **nucleotide sugar interconversion** produce various nucleotide sugars de novo in enzyme-catalyzed reactions (Figs. 2.30 and 2.31). Many of these

interconversion enzymes (e.g., epimerases and dehydratases) appear to be membrane-bound and localized to the ER-Golgi apparatus. Guanosine-based nucleotide sugars, such as GDP-Glc and GDP-Man, are used in synthesis of glucomannan, and GDP-Fuc is a substrate in fucosylation of complex glycoproteins, pectins, and some crosslinking glycans (Fig. 2.32).

L-Arabinose is in the furanose ring conformation in most plant polymers containing this sugar, including GAX, 5-linked arabinans, AGP, and extensin, whereas UDP-Ara is exclusively in the pyranose form. Isomerization is catalyzed by UDP-Ara mutase, which interconverts the nucleotide-sugars,

FIGURE 2.29 Terminal complexes associated with cellulose microfibril biosynthesis as imaged by freeze-fracture and rotary shadowing of membranes. The cellular slime mold, *Dictyostelium discoideum*, forms two kinds of terminal complexes. A linear array is associated with the extracellular ribbon of cellulose formed by streaming cells (A), whereas the cell wall of the stalk cells is made by aggregate arrays that appear to be rudimentary rosettes (B). Some algae, such as *Oocystis*, have linear arrays of particles (C). These terminal complexes often pair up at the plasma

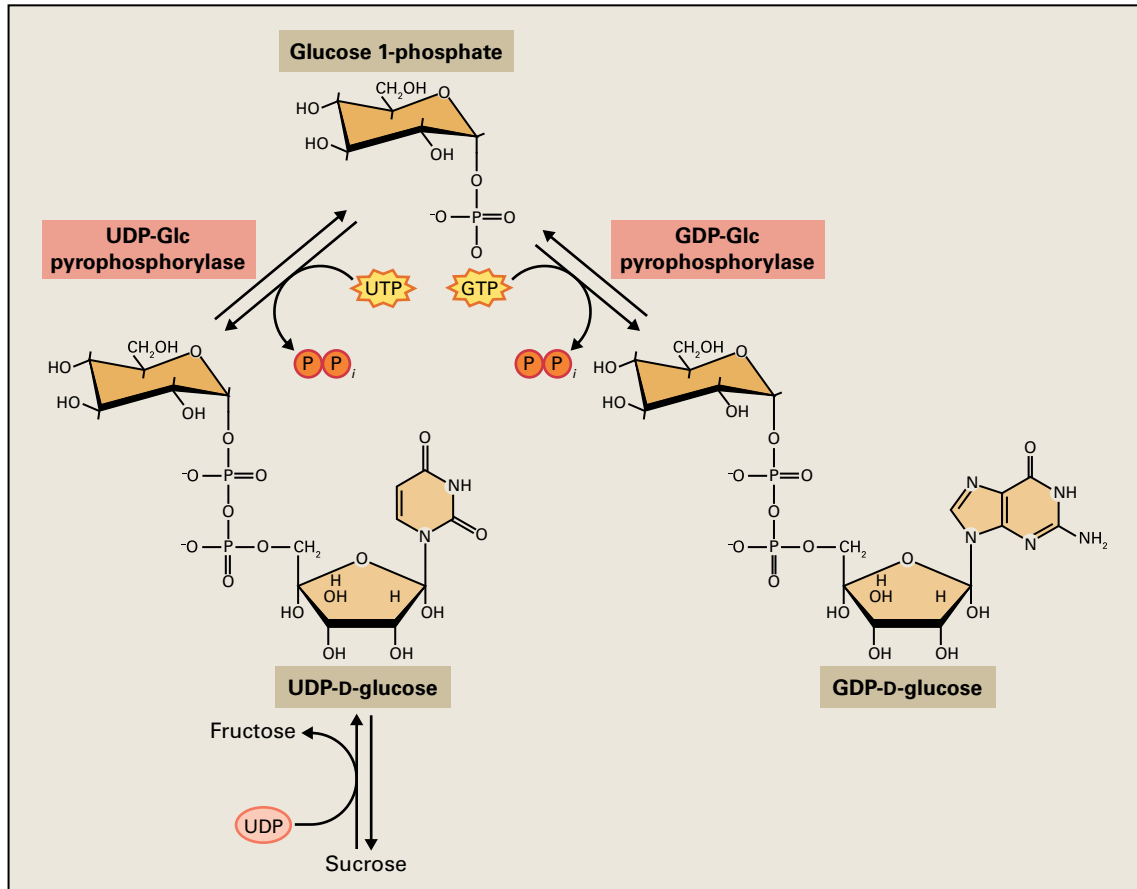

FIGURE 2.30 Central molecule in cell wall biosynthesis, the nucleotide-sugar UDP-Glc. UDP-Glc and GDP-Glc are made from glucose-1-phosphate by action of a pyrophosphorylase, or from sucrose by action of a sucrose synthase.

UDP-Arap and UDP-Araf (Fig. 2.31). UDP-Ara mutase is the enzymatic activity of “reversibly glycosylated protein,” once thought to be an intermediate in xyloglucan synthesis.

Formation of nucleotide sugars occurs via two distinct pathways. De novo synthesis pathways initially produce the full array of nucleotide sugars, which are then used as substrates for synthesis of polysaccharides, glycoproteins, and several other glycosylation reactions. However, several monosaccharides other than Glc may be incorporated into nucleotide sugars via salvage pathways involving C-1 kinases and nucleotide diphosphate-sugar pyrophosphorylases (Fig. 2.31 and 2.32). Salvage pathways are essential to reuse these monosaccharides after they have been hydrolyzed from polymers during assembly and turnover in the cell wall. Some sugars, such as Rha and Xyl,

do not have C-1 kinases, and their carbons must be reused via other pathways. Xyl is returned via the pentose phosphate pathway after isomerization to xylulose.

2.4.4 Crosslinking glycans and pectins are made at the Golgi apparatus

Many reports of the synthesis of noncellulosic wall polysaccharides in vitro include use of membrane preparations enriched in Golgi membranes. In mixed membrane preparations containing plasma membrane and Golgi and UDP-Glc as a substrate, the predominant products are callose, made by

FIGURE 2.29 (Continued) membrane and initiate synthesis of microfibrils in opposite directions (see arrows) (D). The six-membered particle rosettes were first seen in the desmid *Micrasterias*. In this alga, the individual rosettes aggregate in the membrane to form even larger hexagonal arrays that are associated with formation of flat ribbons of cellulose (E). The rosettes are seen on the “P-face,” the inner leaf of the plasma membrane bilayer (F), whereas the impression of the microfibrils and larger particles that apparently fit into the center of each rosette are located in the outer leaf, or “E-face” (G). The rosettes (circled) are found in great abundance only in the membrane underlying the developing thickenings of xylem root vessel elements in cress (H). The inset shows the sixfold symmetry of a single particle rosette from a *Zinnia elegans* tracheary element developing in vitro (I). A substructure can be observed in each of the particles. In these freeze-etch images, only portions of the membrane-spanning domains and extracellular loops of the Cesa proteins can be observed. Cytoplasmic structures (circled) underlying the rosettes in plasma membrane footprints are always at the terminus of a microfibril (arrow) (J). A Markham rotational analysis of one of these shows the reinforcement of hexagonal shape with 60° rotational steps. All other angles of rotation cancel to a circular shape. Bar = 200 nm (K).

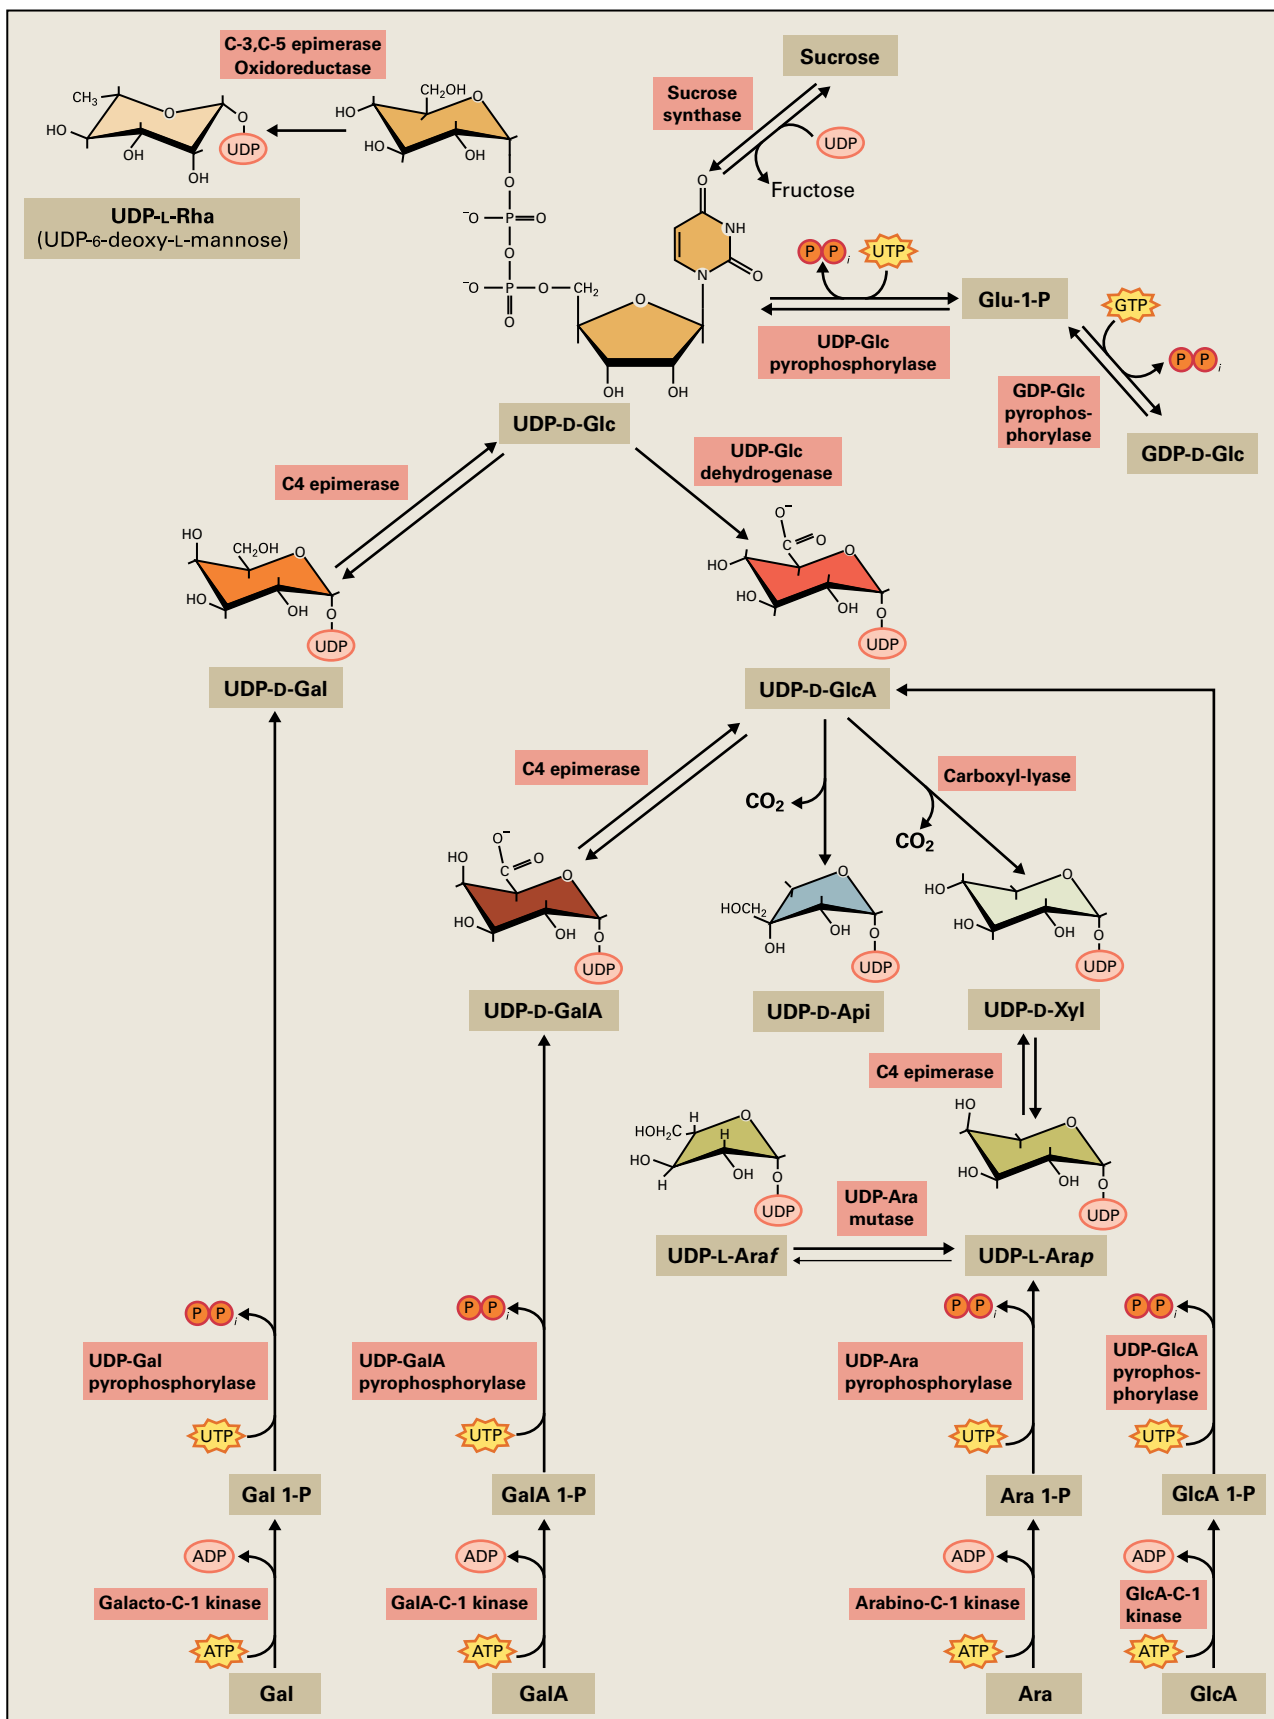

FIGURE 2.31 Major uridine nucleotide-sugar interconversion pathways in plants. UDP-Galp is made from UDP-Glc in an equilibrium reaction catalyzed by a C-4 epimerase. A dehydrogenase oxidizes the O-6 primary alcohol of UDP-Glc to UDP-GlcAp, which is interconverted to UDP-GalAp by a different C-4 epimerase. A carboxyl lyase cleaves the carboxyl group from UDP-GlcAp to produce UDP-Xylp, which is subsequently interconverted by yet another C-4 epimerase to produce UDP-Arap. All of the UDP-sugars made de novo are in the pyranose form; interconversion of the UDP-Arap and UDP-Araf is catalyzed by a mutase originally described as the ‘reversibly glycosylated protein’. The deoxysugar, L-Rha, is made by action of an oxidoreductase and a C-3,5 epimerase using UDP-Glc as substrate. Several sugars, including Ara, Gal, GalA, and Fuc, are ‘salvaged’ back into the nucleotide-sugar pool by C-1 kinases that generate sugar-1-phosphates as direct substrates for pyrophosphorylases.

FIGURE 2.32 The major guanosine nucleotide-sugar is GDP-Man, interconverted by C-2 epimerase action with GDP-Glc. Two key nucleotide-sugars are made from GDP-Man, GDP-Fuc by consecutive action of a C-4,6 dehydratase and C-3,5-epimerase, and GDP-L-Gal from action of a C-3,5 epimerase alone. A salvage pathway incorporates L-Fuc via a C-1 kinase into GDP-Fuc.

wound-inducible contaminating plasma membrane callose synthases or damaged cellulose synthases. This reaction is activated by Ca²⁺, the concentrations of which increase markedly in cells that have been damaged. Thus, the other noncellulosic polysaccharides of interest must be detected and quantified in the presence of a huge background of callose.

FIGURE 2.33 The *B. subtilis* endoglucanase has the unusual ability to hydrolyze a (1→4)-β-D-glucosyl linkage only if the penultimate linkage is a (1→3)-β-D-glucosyl linkage. Because 90% of cereal β-glucans are composed of cellobiosyl and cellotetraosyl units in a ratio of about 2.5:1, the enzyme generates cellobiosyl-(1→3)-glucose (G₄G₃G) and cellotriosyl-(1→3)-glucose (G₄G₄G₃G) oligosaccharides in such a ratio. When the radioactive products of such a digest are separated by HPAEC, the ratio of these oligomeric units is the same from β-glucan synthesized *in vivo* by living plants fed ¹⁴C-glucose or synthesized *in vitro* from isolated Golgi membranes and UDP-¹⁴C-Glc. Characterization of polysaccharide synthase reaction products in such a way confirms that synthesis *in vitro* mimics that *in vivo*. G₄G₄G₄G₃G, cellotetraosyl-(1→3)-glucose.

By treating polysaccharides with sequence-dependent glycanases, researchers can detect characteristic unit structures despite the presence of wound-induced callose. This technique, which verifies that isolated membranes are capable of synthesizing unit structures identical to those made *in vivo*, has been particularly useful for studying *in vitro* synthesis of XyG (Boxes 2.3 and 2.4).

The precise topographic location of polysaccharide synthase enzymes on or within Golgi membranes has been established only for unbranched mixed-linkage β-glucan. The catalytic domain of this synthase is located on the cytosolic side of the Golgi membrane, and the product is extruded into the lumen. UDP-Glc is substrate for the mixed-linkage β-glucan synthase of grass species, and either Mg²⁺ or Mn²⁺ is required as a cofactor. The preservation of β-glucan synthase activity is demonstrated by digestion of the β-glucan product with *Bacillus subtilis* endoglucanase into characteristic tri- and tetrasaccharides in the correct ratio (Fig. 2.33).

For branched polysaccharides, the nucleotide-sugar substrate used for backbone synthesis may be donated from either the cytosolic or luminal side of the Golgi, but branch units are probably added only from the luminal side. Hence, synthesis of complex polysaccharides must be coordinated with transport of some of the nucleotide sugars into the Golgi apparatus. The isolated Golgi apparatus of plants with Type I walls can synthesize very short (1→4)-β-D-glucan chains from either UDP-Glc or GDP-Glc, but the synthesis of XyG is greatly enhanced by addition of near millimolar levels of both UDP-Glc and UDP-Xyl, and also with Mn²⁺ or Mg²⁺ as co-factor. Cleavage of the XyG reaction products yields substantial amounts of the diagnostic XXXG heptasaccharide unit, verifying that the cellular machinery needed to make a complete unit structure can be preserved in a cell-free system. Because only very short chains of (1→4)-β-D-glucan backbone can be made from UDP-Glc in the absence of UDP-Xyl, the glucosyl- and xylosyltransferases appear to be tightly coupled, catalyzing formation of repeating heptasaccharide units cooperatively. Attachment of additional sugars to Xyl units may occur coordinately as well, but additional elaboration involving galactosyl and fucosyl transferases continues during later stages of transit through the Golgi apparatus (see Fig. 2.28). These types of coordinated glycosyl transfers are observed in synthesis of glucomannans with GDP-Glc and GDP-Man, galactomannans with GDP-Man and UDP-Gal, and arabinoxylans with UDP-Xyl and UDP-Ara. In addition, synthesis *in vitro* of HG appears to be coordinated with its methyl esterification.

2.4.5 Syntheses of cellulose and other β-linked polysaccharides are encoded by the *Cellulose* and *Cellulose synthase-like* gene superfamily

Genes encoding vascular plant cellulose synthases have been identified, but the molecular groundwork for identifying *cellulose synthase* (*CesA*) genes was laid first in bacteria the *Acetobacter xylinum* and *Agrobacterium tumefaciens*, which extrude extracellular ribbons of cellulose. These synthase genes and those of other enzymes that bind nucleotide sugars encode four highly conserved domains thought to be critical for UDP-Glc (and certain other UDP-sugars) binding and catalysis (Fig. 2.34A). So far, all other kinds of synthases able to make contiguous (1→4)-β-glycosyl linkages, such as chitin synthases and hyaluronate synthases, contain these four sequences of high amino acid identity. All of these polysaccharide synthases are considered **processive** synthases, which means that the enzyme complex continually adds sugars to the terminus without releasing the polysaccharide.

Analysis of sequences in a cDNA library made from cotton fibers at the onset of secondary wall cellulose formation allowed identification of two highly expressed plant sequences homologous to the *Acetobacter* cellulose synthase gene and containing all four UDP-Glc binding sequences.

The polypeptides that they encode (≈110 kDa) are predicted to have eight transmembrane domains, bind the substrate UDP-Glc, and contain two large domains unique to plants: the plant-conserved region (P-CR) and class-specific region (CSR). In addition, the N-terminal region of the protein contains a Zn-finger motif capable of protein–protein binding and thought to function in coupling individual CesAs into the particles of the rosette complex.

The biochemical mechanisms of synthesis for all (1→4)-β-linked polymers of xylose, mannose, and glucose solve a unique steric problem in that each sugar unit must be inverted nearly 180° with respect to its neighbors. To make such a linkage by addition of one glucose residue at a time, either the synthase or the growing chain must rotate 180°, or the sugar must be added in a constrained position and snap alternately into the proper orientation by some other factor associated with the synthase. Because a cellulose microfibril is composed of several dozen chains, each arising from a different synthase complex, a drastic reorientation of enzyme or substrate would not be expected. A variation of this scheme would be a biochemical “toggle” switch, whereby after each glycosyl transfer the catalytic function alternates between two amino acids within a single active site. The crystal structure of a bacterial cellulose synthase from *Rhodobacter sphaeroides* provides a single site of UDP-Glc substrate binding and catalysis, suggesting a toggling mechanism for this primitive synthase (Fig. 2.34B). The additional P-CR and CSR domains in plant CesAs and *in vitro* dimerization and interactions among CesA isoforms indicate a more complex structure and mechanism. Analysis, however, of the size of the catalytic domains by small-angle X-ray scattering studies indicates the size of the rosette complex demands that each monomer contribute a single (1→4)-β-D-glucan chain (Fig. 2.34C).

All angiosperm species examined have at least 10 distinct *CesA* genes. While some are expressed in a cell- or tissue-specific manner, at least three isoforms can be expressed in a single cell. Also, the three different *CesAs* expressed in cells making primary walls are distinct from the three expressed in cells making secondary walls (Fig. 2.34D). The CSR domain located within the catalytic sequence defines the subclass structure of the gene family by its cysteine-, basic-, and acidic-rich motifs, which are conserved across many species. Further, mutations that cause a deficiency in any of the three isoforms result in drastic loss of cellulose synthesis. When cellulose synthase complexes are extracted from plasma membrane with detergents, the three *CesAs* polypeptides remain associated, indicating that each may fill a specific position in the rosette complex. In a classic biochemical “pulldown” strategy, the use of an antibody specific against one *CesA* polypeptide immunoprecipitates a complex containing the two other *CesA* polypeptides.

How many microfibrils are made by a single rosette? Mounting evidence suggests that it may be only one. Rosettes are assembled in the Golgi membrane and delivered to the plasma membrane intact. From rates of cellulose synthesis, the length of the microfibrils, and the number of rosettes per

FIGURE 2.34 (A) Cellulose synthase genes from *Acetobacter xylinum*, *Agrobacterium tumefaciens*, and *Gossypium hirsutum* (cotton) are characterized by four catalytic motifs; three of the four domains demonstrate absolute conservation of four aspartyl residues (D, DxD, D, in red) predicted to be necessary for substrate binding and catalysis of the glycosidic bond formation. In addition to the four aspartyl residues, the Q/RxxRW motif in the fourth catalytic motif is also conserved in every synthase of a polysaccharide with contiguous (1→4)- β -linked units in which one sugar is inverted with respect to its neighbors. Two sequences, P-CR and CSR, are plant-specific. (B) Crystal structure of a bacterial cellulose synthase, with the catalytic domain compared with a model of a homologous plant CesA catalytic domain minus the P-CR and CSR. N-ter and C-ter connect to the second and third membrane-spanning domains, respectively. The plant sequences containing the catalytic motifs homologous to the bacterial synthase are in yellow, orange, and red; nonhomologous gaps in sequence are in purple and teal. The four conserved aspartyl residues are in red, and the QxxRW in green; N' and C' P-CR and CSR indicate points of insertion of these plant-specific domains. (C) The surface envelope of a plant CesA catalytic domain (CatD) was determined by small-angle X-ray scattering of the recombinant protein in solution. The CatD is predicted to be a two-domain structure, with the smaller domain participating in the formation of a dimer. In the upper right is seen a molecular docking experiment that places the best fit of the domains homologous to the bacterial in the central portion of the CatD. This orientation places the plant-specific CSR sequences in the smaller domain that functions in dimerization. (D) Genes of the CesA/Csl superfamily of Arabidopsis (in red), rice (*Oryza sativa*; in yellow), and maize (*Zea mays*; in green). In all angiosperms studied thus far, at least three CesA genes are co-expressed during both primary wall formation – Arabidopsis AtCesA1, AtCesA3, and AtCesA6 – and secondary wall formation – Arabidopsis AtCesA8,

FIGURE 2.34 (Continued) AtCesA7, and AtCesA4. Orthologous genes of *Oryza sativa* and maize are also expressed similarly. For Arabidopsis, mutations in any one gene (mutant name in parentheses) results in cellulose deficiencies in their respective primary or secondary wall, indicating that all three are essential for cellulose synthesis. The root-hairless mutant *kojak* was traced to a mutation in the *CslD3* gene possibly encoding a cellulose synthase in these tip-growing cells, but the expression patterns and inferred sub-cellular locations suggest that isoforms function in all cells and produce a yet unknown product. Heterologous expression studies have established that at least some members of the Arabidopsis *CslA* group function in mannan synthesis and *CslC* group function in xyloglucan synthesis. The grass-specific *CslF* and *CslH* group members are likely to function in synthesis of the mixed-linkage (1→3),(1→4)-β-D-glucan.

mm², it was estimated that synthesis of one microfibril takes 10 min. A continual supply of rosettes is delivered throughout cell growth; treatment of cells with cycloheximide, a potent protein synthesis inhibitor, results in loss of cellulose synthases from the membrane with a half-life of less than 30 minutes.

Plant cells possess arrays of cortical microtubules that underlie and connect to the plasma membrane. Orientation of the cortical microtubule array often pre-stages the orientation of cellulose microfibril deposition. The cortical array can align cellulose synthase complexes either by direct protein-mediated connection or by defining channels in the membrane in which the synthase can move. Cortical microtubules may guide cellulose synthase complexes in the plasma membrane as the complexes are propelled forward by crystallization of chains within a microfibril. *CesA* proteins fused to fluorescent marker proteins made it possible to image how rosettes move in the plasma membrane, and this has allowed researchers to establish that they follow the orientation of cortical microtubules. However, once microfibril orientation has been established, microtubules can be disrupted using chemical treatments and the orientation will persist, presumably using the previously deposited microfibrils for

guidance. Thus, cellulose microfibrils appear to have the ability to self-align in the absence of cortical microtubules and/or pre-existing cellulose microfibrils, and cortical microtubules may, therefore, only be required for directing cellulose into a new orientation during cell differentiation.

This discovery opened the door for identification of the *CesA* superfamily of genes that includes the **Cellulose synthase-like** (*Csl*) genes (Fig. 2.34D). Several related *Csl* genes may function in the synthesis of many other crosslinking glycans that comprise the plant wall. All of these genes contain the four domains for nucleotide-sugar binding and catalysis, membrane-spanning domains, and plant-conserved regions, but with the exception that some *CslD* genes lack Zn-finger domains, and the CSRs are truncated to a variable extent. Eight subclasses of *Csl* genes are recognized. While most subclasses are represented in all angiosperms, *CslF*, and possibly *CslH*, contain only grass genes, and *CslB* and *CslG* are represented only in eudicots. Some of the *CslD* genes are suspected to be cellulose synthases of tip-growing cells. Heterologous expression of some of these *Csls* has shown them to encode the probable components of the backbone synthases of mannans and glucomannans (*CslAs*), xyloglucan (*CslCs*), and (1→3),(1→4)-β-D-glucans (*CslFs*).

2.4.6 Diversity of polysaccharide structures is accomplished by numerous classes of glycosyl transferases

According to the Carbohydrate-Active enzymes (CAZy) database, which describes families of structurally-related catalytic and carbohydrate-binding modules (or functional domains) of enzymes that degrade, modify, or create glycosidic bonds, there are over 90 distinct families of **glycosyl transferases (GTs)**, with 44 families represented in plants (Box 2.6 for more information on CAZy and other useful on-line databases devoted to cell wall biology). GTs catalyze transfer of activated monosaccharides to another biological compound, usually another sugar, oligomer, or polysaccharide. Family membership is based on structurally related protein catalytic or functional motifs and domains, but implicit in this are the evolutionary relationships of the genes that encode them. Some families are found across many Kingdoms, but several are found only in plants. Family GT2 contains the processive transferases of cellulose and related glycan synthases that form the *CesA/Csl* gene superfamily described above. Families *GT8* and *GT47* are

exceptionally well populated with members that function in nonprocessive substitution of cell wall pectic and crosslinking glycan backbones with several kinds of sugars (Fig. 2.35). Just as group structure of the *CesA/Csl* superfamily reflects divergence in cell wall composition, so do the families of GTs. For example, family *GT8*, which contains members mainly involved in pectin synthesis, comprises four major groups and one minor group, with *Arabidopsis* sequences more abundant in Groups A and B, and grass sequences more abundant in Groups C and D (Fig. 2.35A). The HG backbones are synthesized by at least two *GT8* galacturonosyl transferases (*GAUT*), *GAUT1* and *GAUT7*, that for a Golgi-resident dimer. While a single GT family can use different sugars in catalysis, the linkage configuration and the basic mechanism of glycosyl transfer is generally consistent. Two types of glycosyl transfer are the **retaining** and **inverting** mechanisms, which refer to whether the anomeric configuration is preserved or switched from that of the nucleotide sugar. Most nucleotide-sugars are in the α -D-conformation, and a retaining mechanism would preserve the α -D- (or β -L-) linkage typical for the HG backbone, whereas the inverting mechanism produces a β -D- (or α -L-) linkage.

BOX 2.6

Genomic resources for cell walls

A useful resource for cell wall-associated genes is contained in the Carbohydrate-Active enZYme (CAZy) database (<http://www.cazy.org>), which compiles evolutionarily related genes based on structural motifs and functionalities. Four groups of enzymes, glycosyl transferases, glycosyl hydrolases, lyases, esterases, and a broad collection of cellulose-binding modules function in substrate binding associated with catalysis. A large proportion of the genes in CAZy function in the synthesis and remodeling of the cell wall.

Several web sites are devoted specifically to plant cell-wall gene families. Cell Wall Genomics (<http://cellwall.genomics.purdue.edu>) has assembled over 1,200 genes per species, particularly those of *Arabidopsis*, rice, and maize, involved in sugar and monolignol substrate generation, polysaccharide synthesis and glycosyl transferase activities, ER-Golgi-plasma membrane targeting, wall assembly and remodeling, secondary wall formation, and signaling and response elements in the extracellular matrix. The site also reports on over 900 *Arabidopsis* and 200 maize insertional mutants and their biochemical and spectroscopic phenotypes. Growing collections of these and other mutants are available from the Arabidopsis Resource Center (<http://abrc.org>) and the Maize Stock Center (<http://maize.org>).

A similar site called Cell Wall Navigator (<http://bioweb.ucr.edu/Cellwall/>) is an integrated database and

mining tool for protein families that are involved in plant cell wall biogenesis by comparison within angiosperm species and across Kingdoms. Other sites provide information about glycosyl transferases of rice (<http://ricephylogenomics.ucdavis.edu/cellwalls/gt/>), and a range of genomic resources for *Brachypodium* (<http://brachypodium.pw.usda.gov/>). The functions of specific gene and protein families, such as expansins (<http://homes.bio.psu.edu/expansins/>) and XTHs (<http://labs.plantbio.cornell.edu/XTH/>) contributed by individual labs.

Useful information about cell wall chemistry, as well as biochemical resources used in defining cell wall structure and architecture, are available at WallBioNet: Plant Cell Wall Biosynthesis Research Network (<http://xyloglucan.prl.msu.edu/>) and CarboSource Services, Complex Carbohydrate Research Center, University of Georgia, USA (http://www.ccrcc.uga.edu/~carbosource/CSS_home.html).

Two sites are devoted to development and cataloguing of cell wall monoclonal antibodies and other reagents to probe polysaccharide fine structure at the single cell wall level or for development of tailored carbohydrate microarrays at the Complex Carbohydrate Research Center (http://www.ccrcc.uga.edu/~carbosource/CSS_home.html) and PlantProbes, University of Leeds, UK (<http://www.plantprobes.net>).

FIGURE 2.35 Genes of major nonprocessive glycosyl transferase families of Arabidopsis (in red), rice (*Oryza sativa*; in yellow), and maize (*Zea mays*; in green). (A) In Glycosyl Transferase Family8 (GT8), the largest clade, Group D, encodes galacturonosyl transferases *GAUT1* and *GAUT7*, which interact to iteratively extend GalA units typical of homogalacturonan. This large family of retaining-type transferase genes probably encodes several putative *GAUTs*, and three distinct subgroups of *GAUT*-like (*GATL*) proteins. *GAUT8*, or *QUASIMODO1 (QUA1)*, is involved in the synthesis of rhamnogalacturonan II. The *PARVUS* gene is involved in the synthesis of the tetrasaccharide primer for xylan synthesis. (B) *GT47* encodes inverting-type transferases that add several distinct types of side-group sugars to pectins and crosslinking glycans. Group A contains *MUR3*, which encodes a galactosyl transferase that adds the (1→2)-β-D-Gal residue of the first xylosyl residue from the reducing end of the repeating heptasaccharide unit of xyloglucan. In Group B, *ARABINOSE DEFICIENT1 (ARAD1)* functions in (1→5)-α-L-arabinan synthesis, and in Group C, *XYLOGALACTURONAN DEFICIENT1 (XGD1)*

Family *GT47* consists of five groups of genes that encode at least four different types of activities, including galactosyl-, arabinosyl-, xylosyl-, and glucuronosyl-transferases, all using an inverting mechanism of glycosyl transfer (Fig. 2.35B). Group A, the largest group, contains *MUR3*, encoding a galactosyl transferase that adds the (1→2)-β-D-Gal residue of the first xylosyl residue from the reducing end of the repeating heptasaccharide unit of xyloglucan.

Members of several other gene families have also been functionally characterized (Table 2.2), but there is a long way to go to establish the function of every member. Although members of the *CesA/Csl* gene superfamily share the ability to synthesize (1→4)-β-D-glycans, the (1→4)-β-D-xylans are synthesized coordinately by members of the *GT47* Group B xylan xylosyl transferases (*IRX10B*) and *GT43* gene family (Table 2.2). Like cellulose and the (1→3),(1→4)-β-D-glucan synthases, at least two distinct isoforms of these xylosyl transferases combine to form a synthase complex.

2.5 Growth and cell walls

2.5.1 The cell wall is a dynamic structure

Cell expansion involves extensive changes in the mass and composition of the cell wall. Cell growth, an irreversible increase in cell volume, can occur by expansion (increase in cell size in two or three dimensions) or by elongation (expansion constrained to one dimension). Variety in cell shape may result if either of these two processes occurs at specific regions of the cell surface.

During elongation or expansion, existing cell wall architecture must change to incorporate new material, which increase the surface area of the cell and induces water uptake by the protoplast. The turgor pressure exerted by the protoplast is necessary to drive cell expansion, and this pressure usually remains a constant driving force for expansion. Regulation of wall loosening is considered the primary determinant of rates of cell expansion. Cell wall architecture must be extensible; that is, mechanisms must exist that allow discrete biochemical loosening of the cell wall matrix, permitting microfibril separation and insertion of newly synthesized polymers. Cells may extend tens, hundreds, or even thousands of times their original length while maintaining constant wall thickness. Thus, loosening and continued deposition of new material into the wall must be tightly integrated events (Fig. 2.36).

FIGURE 2.35 (Continued) encodes a xylosyl transferase that adds the (1→3)-β-xylose units to homogalacturonan. Group E contains *FRAGILE FIBER8 (FRA8)*, which functions in the synthesis of the tetrasaccharide primer for xylan synthesis, and *GUT2/XYS1*, which encodes a xylosyltransferase involved in xylan elongation.

TABLE 2.2 Cell-wall-related glycosyl transferases.

Gene family	Known substrates	Predicted activity
GT8	UDP-D-GalA; UDP-D-GlcA; UDP-D-Gal	Retaining transferases involved in pectin and xylan synthesis; galactinol synthesis
GT31	UDP-D-Gal, UDP-D-Glc-NAc, UDP-D-Gal-NAc	Inverting transferases involved in glycosylation of proteins and arabinogalactan synthesis
GT34	UDP-D-Xyl, UDP-D-Gal	Retaining transferases involved in side-group additions to xyloglucan and galactomannan synthesis
GT37	GDP-L-Fuc	Inverting type transferases involved in fucosylation of xyloglucans and glycoproteins.
GT43	UDP-D-Xyl	Inverting transferases involved in xylan polymerization
GT47	UDP-D-Gal, UDP-L-Ara, UDP-D-Xyl, UDP-D-GlcA	Inverting transferases involved in side-group additions to xyloglucan, xylans, and homogalacturonans; synthesis of α -arabinans; synthesis of xylans
GT48	UDP-D-Glc	Callose synthase
GT61	UDP-D-Xyl, UDP-L-Ara	Inverting transferases involved in side-group additions to xylan
GT64	UDP-D-N-acetyl-Glc	Glycoprotein synthesis
GT77	UDP-D-Xyl, UDP-L-Ara	Synthesis of complex pectins and O-linked glycoproteins

The Carbohydrate-Active enZyme (CAZy) database classifies glycosyl transferases based on sequences and common biochemical and protein motifs. Several of these function in the synthesis of cell wall polysaccharides or glycoproteins.

2.5.2 Most plant cells grow by uniform deposition of polymers on all of their cell wall surfaces, but some cells target polymers to a growing tip

In the vast majority of plant cells, growth and deposition of new wall material occur uniformly along the entire expanding wall. However, **tip growth**, growth and deposition of new wall material mostly at the tip of a cell, occurs in some plant cells, notably root hairs and pollen tubes (Fig. 2.37). Root hairs and pollen tubes have different wall compositions, even though they share a common mechanism of growth: pollen tubes contain callose and have distinct homogalacturonan epitopes, whereas root hairs do not. Tip-growing cells expand at prodigious rates for plant cells ($>200 \text{ nm s}^{-1}$ for pollen tubes). The site of expansion in tip-growing cells is focused to the dome-shaped apex, which is filled with secretory vesicles by myosin-mediated delivery on the tracks of actin microfilaments (see Chapter 5).

Cellulose microfibril orientation determines the axis of elongation. In cells that grow by uniform expansion, layers of microfibrils lie unaligned in the wall matrix, but in cells that elongate, microfibrils align in transverse or helical orientations to the axis of elongation.

FIGURE 2.36 Wall loosening and incorporation of new wall polymers are integrated events so that wall thickness is maintained during cell expansion. Because walls are only a few strata thick, loosening with no insertion of new wall material would very quickly thin the wall during growth and cause rupture. In contrast, deposition without loosening would increase wall thickness, because walls would not expand. Vertical arrows denote direction of expansion and separation of exterior microfibrils, and horizontal arrows show location of the addition of new microfibrils on the inner surface of the wall and integration into overlaying strata.

2.5.3 The multinet growth hypothesis explains axial displacement of cellulose microfibrils during expansion of the cell wall

From studies of developing cotton fibers, the **multinet growth hypothesis** was developed to explain how cellulose microfibrils that have been deposited in a transverse or slightly helical orientation are displaced axially as elongation proceeds (Fig. 2.38A). New microfibrils deposited in strata on the inner surface of the wall in a generally transverse orien-

FIGURE 2.37 Rates of vesicle delivery and deposition determine rate of tip growth. To withstand increase in tension in the axial wall of the cylinder of a tip-growing cell, microfibrils must be spooled transversely.

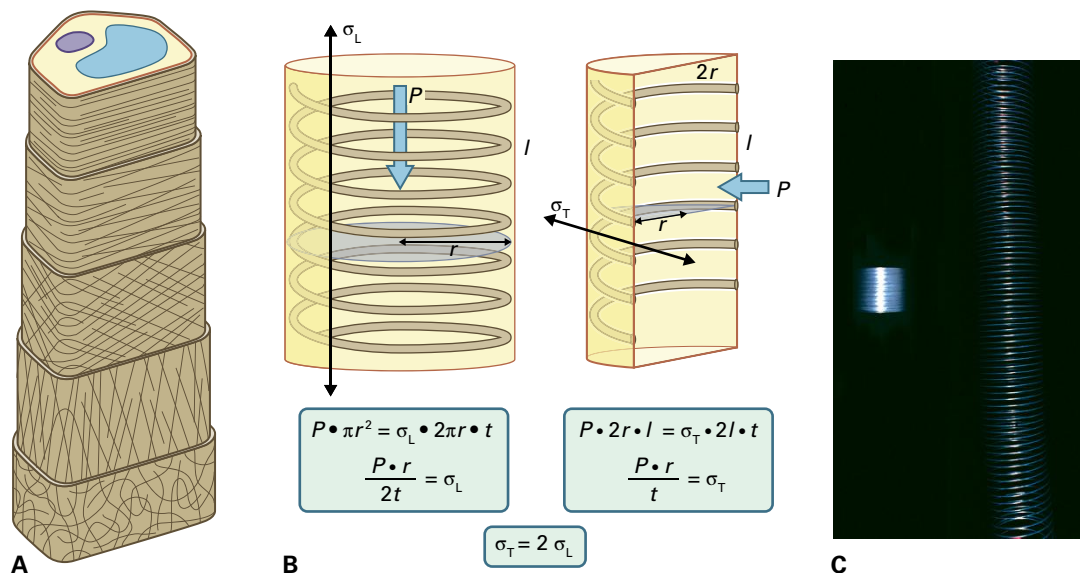

FIGURE 2.38 (A) The original multinet growth hypothesis explains that as walls stretch during growth, microfibrils reorient passively from a transverse direction on the inner wall to a longitudinal direction at the outer wall. (B) Hydrostatic pressure developed by the protoplasm is resisted by a relatively thin cell wall, and tensile force pulling microfibrils apart is several orders of magnitude higher than cell turgor pressure. For example, a spherical cell with a radius (r) of $50 \mu\text{m}$ and 1MPa of turgor (P), enveloped by a cell wall only $0.1 \mu\text{m}$ thick (t), develops 250MPa of tension in the wall. This enormous tension changes as the cell geometry changes. When this cell begins to elongate and become cylindrical, the tension increases to 500MPa tangentially because of change in cell dimension. l , length; σ_L , longitudinal stress; σ_T , tangential stress. (C) Although a Slinky is difficult to extend radially because of the orientation of the coils, it is easily extended lengthwise. Similarly, altering the interaction between tethering crosslinking glycans and transversely oriented cellulose may be the principal determinant of the rate of cell elongation.

tation functionally replace older microfibrils. Older microfibrils are displaced into the outer layers of the wall as new microfibrils are added and become reoriented in a longitudinal direction as the cell elongates. Consistent with this hypothesis, changes in diffraction patterns of polarized light by algal cells, induced by reorientation of the parallel microfibrils, occur primarily in the inner layers of the wall close to the plasma membrane. The driving force for wall extension is turgor pressure generated by the protoplast, but it is the tension created on the microfibrils perpendicular to the outward push of the protoplast that leads to separation of the microfibrils (Fig. 2.38B). A turgor pressure of 1MPa can generate several hundreds of MPa of tension because the volume of a relatively large protoplast is resisted by a very thin cell wall.

The essence of the multinet growth hypothesis is descriptive for many kinds of cells, but microfibrils do not necessarily reorient axially, and significant extension is possible with little reorientation if many wall strata contribute to the expansion. Cellulose microfibrils woven in a shallow helix around the cell prevent the growing cell from becoming spherical. By analogy, the springlike toy, such as Slinky or Flexi, stretches easily along its longest axis, but resists attempts to increase its diameter (Fig. 2.38C); when stretched, the spring extends substantially with only a small change in helical angle, but with a wide separation of the coils. Extension of a cell wall might be viewed as a series of tightly interacting concentric Slinkys in both right-handed and left-handed orientations that reorient at crossed angles during separation (Fig. 2.38A). Given the estimated thickness of the primary wall ($80\text{--}100 \text{nm}$ in meristematic and parenchymatous cells) and the dimensions of matrix

components, only five to ten strata make up the wall. Microfibrils from several strata may even merge somewhat to fill in gaps as new strata are deposited onto the inner surface (see Fig. 2.36).

2.5.4 The biophysics of growth underpins cell wall dynamics

Several different classes of cell wall polymers constitute nearly independent determinants of strength in elongating cells. These include (a) the microfibrils arranged in the transverse axis, which are interconnected with crosslinking glycans; (b) putative networks involving structural proteins or phenylpropanoid compounds; and (c) elements of the pectin network. When plant growth regulators, such as auxin and gibberellin, change *direction* of growth, they do so through changes in orientation of cortical microtubules and cellulose microfibrils. When they change *rate* of growth, their mechanisms include dissociation or breakage of tethering molecules from microfibrils. A mathematical formulation that describes the growth rate of plant cells allows us to define the cell wall properties that must be modified to permit growth.

The driving force for water uptake in elongating cells can be quantified by

$$\delta l/\delta t = Lp(\Delta\Psi_w), \quad (\text{Eq. 2.1})$$

where $\delta l/\delta t$ is the change in length per unit time, Lp is hydraulic conductivity, i.e., the rate at which water can flow across the membrane, and $\Delta\Psi_w$ is the water potential difference between the cell and the external medium. The difference in water potential is the driving force for water movement and comprises two components, $\Psi_\pi + \Psi_p$, the osmotic potential and pressure potential (turgor), respectively. Revising Equation 2.1 to include changes in cellular volume (V) yields Equation 2.2, where growth is defined as a change in volume (V) per unit time, and depends on the surface area (A) of the plasma membrane available for water uptake.

$$\delta V/\delta t = A \cdot Lp(\Delta\Psi_w). \quad (\text{Eq. 2.2})$$

Thus, rate of growth is proportional to membrane surface area, the conductivity of the membrane, and the water potential difference driving water uptake. In nongrowing cells, $\Delta\Psi_w$ and thus $\delta V/\delta t$, equals zero, because the rigid cell wall prevents water uptake and the turgor pressure rises to a value equal to that of the osmotic potential of the cell. By contrast, in growing cells, the $\Delta\Psi_w$ does not reach zero because the wall tethers have been loosened. As a result, cell volume increases irreversibly. This wall-localized event, called **stress relaxation**, serves as the fundamental difference between growing and nongrowing cells (Fig. 2.39).

When turgor is reduced in growing cells by an increase in the external osmotic potential, growth ceases at some pressure before turgor reaches zero. This value, called the **yield threshold**, defines the pressure potential that must be

FIGURE 2.39 Stress-relaxation is considered the underlying basis of cell expansion. When an elongating cell is stretched by turgor, longitudinal stress (indicated by arrows) is borne more or less equally by glycans tethering the cellulose microfibrils. If some tethers are dislodged from microfibrils, or hydrolyzed, they temporarily “relax” and the yield threshold is breached because other tethers are strained. Water uptake results in expansion of microfibrils to take up slack of the relaxed glycans, which once again experience tensile stress.

exceeded before expansion can occur. The increment of growth rate change above the yield threshold is dependent not only on turgor but also on a factor called wall **extensibility**, which is the slope (m) of a general equation, shown as Equation 2.3, where Y is the yield threshold.

$$\text{Rate} = m(\Psi_p - Y) \quad (\text{Eq. 2.3})$$

The biochemical determinants of yield threshold and extensibility have yet to be identified.

2.5.5 The acid-growth hypothesis states that auxin-dependent acidification of the cell wall promotes wall extensibility and cell growth

Despite marked differences in the composition of Type I and Type II walls, the biophysics of growth of grasses and other flowering plants are similar. Although the chemical complexity of the wall is daunting, the similarity of the physiological responses of all flowering plants to acid, auxin, and light of

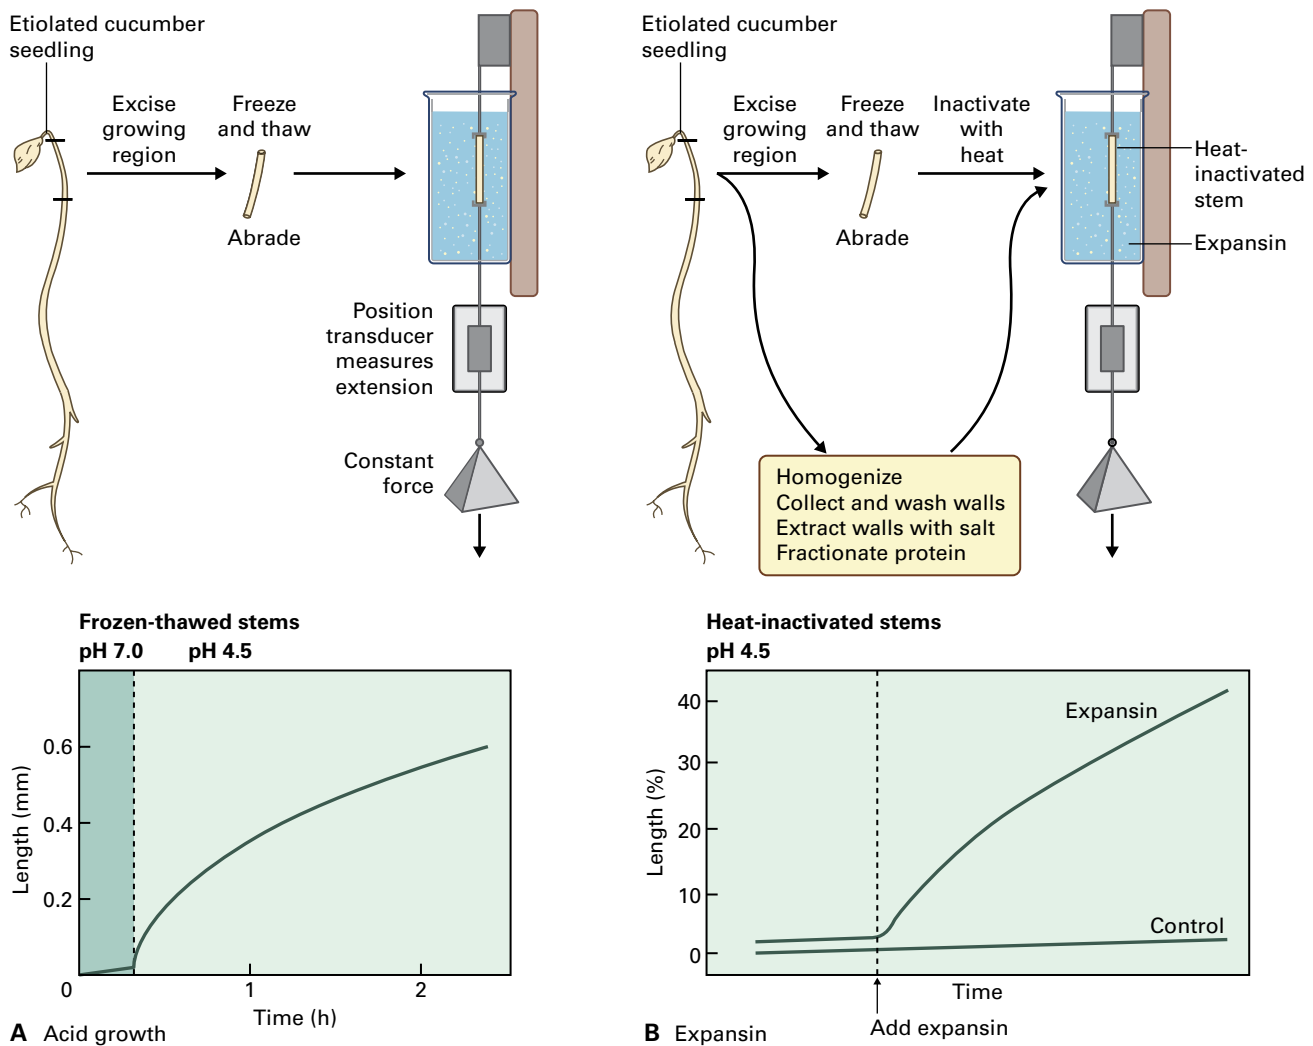

FIGURE 2.40 Sections of growing epicotyl, hypocotyl or coleoptile are frozen, thawed and placed under a constant stress. A position transducer measures elongation continuously. (A) When the bathing solution of the frozen-thawed sections is changed from pH 7 to 4.5, extension occurs almost immediately. (B) If the sections are heat-inactivated, no extension occurs at any pH. However, when expansins are added, extension is restored at acidic pH. Neither plant hydrolases nor xyloglucan endo- β -transglucosylase is able to cause this effect in vitro.

different qualities indicates that a few common mechanisms of wall expansion exist, regardless of the kinds of molecules that tether microfibrils.

Extraction of several kinds of polysaccharide hydrolases from cell walls of tissues rich in growing cells raised the possibility that regulation of these enzymes was a mechanism by which auxin could cause wall expansion. A major breakthrough came with the discoveries that auxin caused acidification of the medium in which elongating tissue sections were bathed, and that H^+ could substitute effectively for auxin (Fig. 2.40). This **acid-growth hypothesis** posits that auxin activates a plasma membrane proton pump that acidifies the cell wall. The low pH, in turn, activates apoplast-localized growth-specific hydrolases that cleave the load-bearing bonds that tether cellulose microfibrils to other polysaccharides. Cleavage of these bonds loosens the cell wall, which decreases turgor, and the resulting water potential difference causes uptake of water. Relaxation of the wall (i.e., separation of microfibrils) passively leads to an increase in cell size.

The basic tenets of the acid-growth hypothesis have stood the test of time, but three problems persist. First, no enzymes have been found that hydrolyze wall crosslinking glycans exclusively at pH lower than 5.0. Second, no reasonable explanation exists for how growth is kept in check once the hydrolases are activated. Third, no hydrolases extracted from the wall and added back to the isolated tissue sections, regardless of external pH, cause extension in vitro.

2.5.6 Regulation of the cellulose/crosslinking glycan network by expansins and xyloglucan-endotransglucosylases/hydrolases

Two large multigene families encode proteins implicated in restructuring the cellulose/crosslinking glycan network: **expansins**, which can catalyze wall extension in vitro without

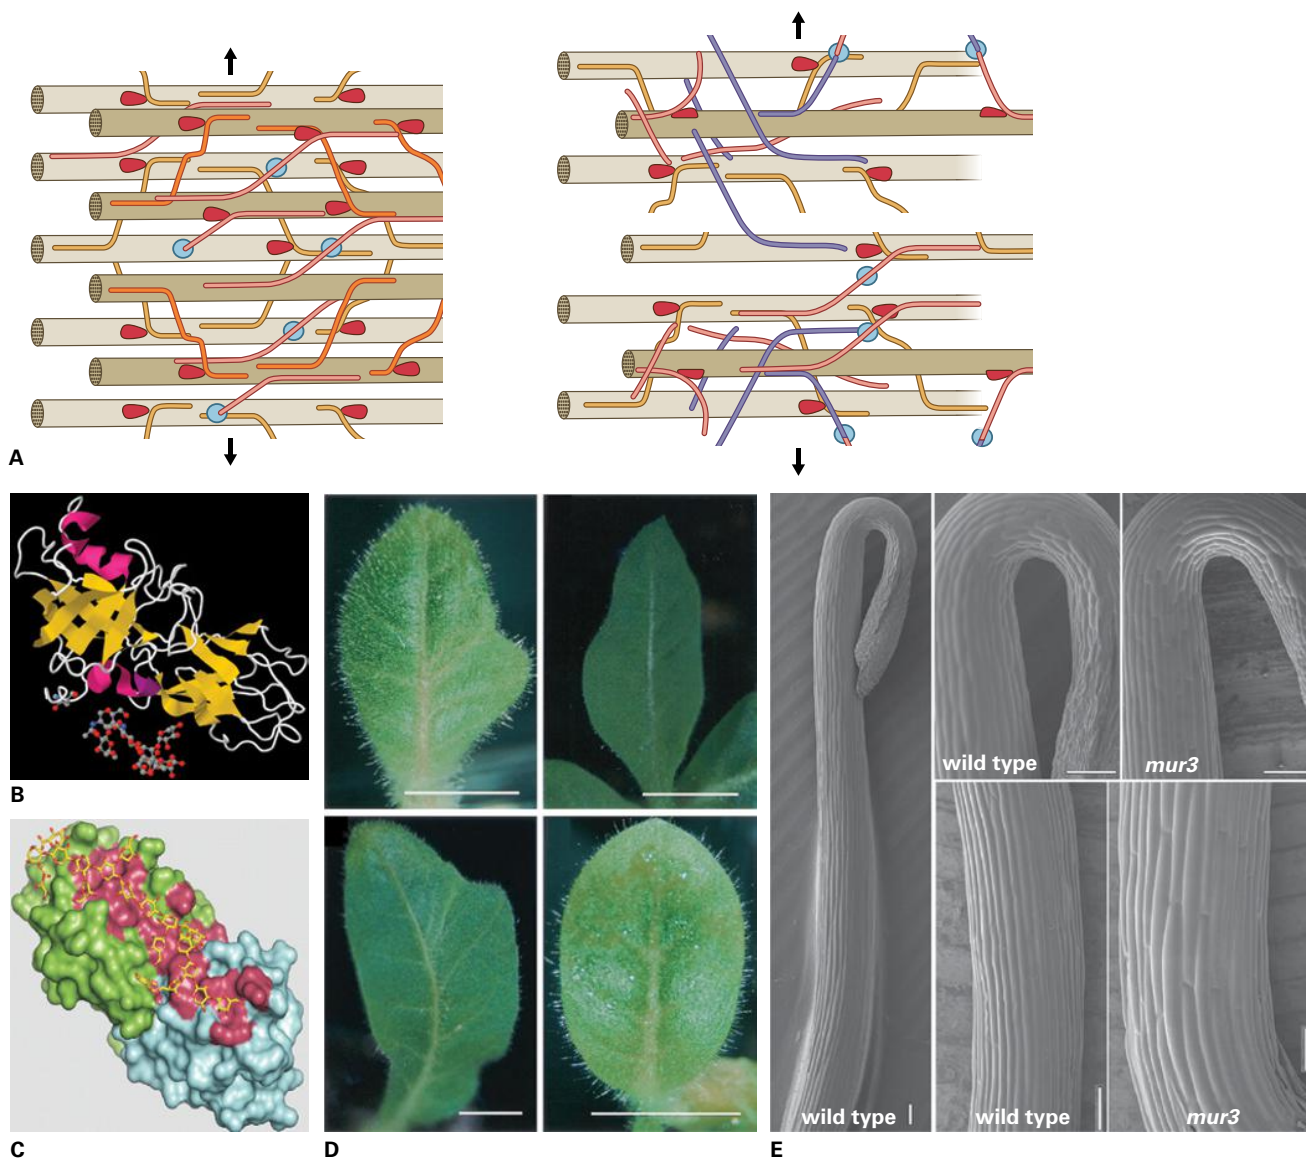

FIGURE 2.41 (A) Microfibril separation driven by cellular osmotic pressure is facilitated by loosening of tethering crosslinking glycans. This is accomplished by expansins, which break steric interactions between crosslinking glycans and cellulose. Members of the endo- β -D-transglucosylase/hydrolase family (XTH) with only endo- β -D-transglucosylase (XET) activity hydrolyze a glycan and reattach one part of the chain to the nonreducing terminus of another. This action by XET functions in forming new tethers as microfibrils from inner lamellae merge with microfibrils of the outermost lamellae as they are pulled apart during wall extension. (B) The crystal structure of the *Zea mays* β -expansin shows the groove or cleft structure characteristic of endohydrolases (Fig. 2.42) but is missing a domain that would contain a catalytic amino acid for hydrolysis. This β -expansin is N-glycosylated, but α -expansins are typically unglycosylated. (C) Alignment of a glucuronoarabinoxylan is modeled in the groove of the *Z. mays* β -expansin. (D) Leaf shape can be manipulated by local induction of expansin expression (arrows), indicating that physical changes in cell wall structure can feed back to control developmental patterns. (E) The *mur3* mutant produces a galactose-deficient xyloglucan in elongating hypocotyls that is poorly recognized by XETs. Cell elongation in *mur3* just below the hook is indistinguishable from that of wild type (upper panels), but epidermal cell swelling at the base of the hypocotyl is observed in *mur3* after elongation has ceased. Source: (E) Peña et al. (2004). *Plant Physiol.* 134:443–451.

any detectable hydrolytic or transglycolytic events, and **xyloglucan endo- β -transglucosylases (XET)**, which cannot induce wall expansion in vitro.

Expansins are ubiquitous in growing tissues of all flowering plants, and they likely catalyze breakage of hydrogen bonds between cellulose and load-bearing crosslinking glycans. Such an activity could disrupt tethering of cellulose by XyGs in Type I walls and by GAXs in Type II walls and by

GAXs and β -glucans in grass walls. Expansins are the only proteins shown to produce wall expansion in vitro (Fig. 2.41A).

Two major evolutionary groups of expansins, termed α and β , are found in all angiosperms, although the α -expansins are more numerous in plants with Type I walls and β -expansins are more numerous in grasses. Because grass α -expansins induce extension of tissues with Type I

walls, it is attractive to think expansins are ubiquitous enzymes involved in the rapid growth responses of both Type I and Type II walls. However, further studies show certain β -expansins have no appreciable activity on Type I cell walls. A notable difference between the two groups is extensive glycosylation of β -expansins, which appears to be absent in α -expansins. A maize (*Zea mays*) pollen allergen belonging to the expansin B family (EXP B1) binds strongly to xylans in Type II cell wall. The crystal structure of EXP B1 shows an unstructured glycosylated N-terminal extension and a two-domain folded structure with a highly conserved open surface spanning the two domains (Fig. 2.41B,C). The surface has many aromatic and polar residues suitable for binding a branched polysaccharide of about 10 residues in length. It has been proposed that expansin uses the strain energy stored in a taut cellulose-binding glycan to dissociate the glycan from the cellulose surface, using a 10-degree shift in angle between domains to cause a one-residue dislocation of the polysaccharide along the binding surface.

Exogenous expansins applied to a meristem induce bulging of the meristem at sites of application, an effect that later is followed by development of leaf primordia. Local transient induction of expansin expression on the flank of developing leaves leads to induction of ectopic lamina tissue and modulation of leaf shape (Fig. 2.41D). Thus, morphogenesis may be manipulated by alteration of the biophysical properties of the cell wall that then impacts gene expression and developmental pathways by yet-to-be-discovered signal pathways.

Several members of the **xyloglucan endotransglucosylase/hydrolase** (XTH) gene family carry out transglycosylation of XyGs, where one chain of XyG is cleaved and reattached to the nonreducing terminus of another XyG chain, an enzyme activity described as xyloglucan endo- β -transglucosylase (XET). Unlike expansins, XETs cannot induce wall expansion *in vitro*. However, transglucosylase activity could function in realignment of XyG chains in different strata during growth, where XET cleaves and ligates xyloglucans with new xyloglucan partners such that wall architecture may be modified without detectable changes in composition (Fig. 2.41A). Support for this proposed function comes from experiments with mutant plants with altered XyG structures for which XETs have reduced substrate affinities. These mutants are unaltered in growth rate and architecture but exhibit cell bulging when growth stops and suffer severe loss in tensile strength (Fig. 2.41E). A mannan transglycosylase/hydrolase has been described that can carry out a transglycosylation reaction in the presence of mannan-derived oligosaccharides. A mixed-linkage endo- β -transglucanase has also been found in *Equisetum*, but no such activity was detected in the grasses.

Since the wall composition of grass Type II wall differs from all other flowering plant species, researchers are also investigating the exo- and endo- β -D-glucanases that hydrolyze grass β -D-glucans to glucose. Addition of purified

exo- and endo-glucanases to heat-killed coleoptiles cannot induce extension growth. However, when antibodies directed against these enzymes are added to enzyme-active walls, they inhibit growth, suggesting that hydrolases also play a role in extension growth.

2.5.7 In Type I walls, cell growth is associated with biochemical changes in the pectin network

The cellulose/crosslinking glycan network lies embedded in a pectin network that may control access of wall-modifying enzymes to their substrates. The self-hydrolysis of isolated walls by nascent enzymes, termed **autolysis**, yields substantial amounts of Ara and Gal from Type I walls, suggesting that changes in the arabinan and galactan side-branches of RG I (see Fig. 2.17C) or AGPs (see Fig. 2.21) occur during growth.

The most marked change revealed by biochemical analysis is the increase in the degree of methyl esterification of wall HGs when newly synthesized pectins are deposited during elongation. The deposition of highly esterified HGs is followed by a de-esterification event that can remove a large proportion of methyl ester groups from the wall when growth stops. Ionized carboxyl groups can form Ca^{2+} -HG junction zones, causing the matrix to become more rigid (see Fig. 2.26). The cell walls of meristematic and elongation zones are characteristically low in Ca^{2+} , and Ca^{2+} -HG junction zones are observed more frequently after cell elongation has stopped. Changes in the esterification of HG have been correlated with growth in many different systems. For example, the degree of methyl esterification is highest in etiolated *Zea mays* coleoptiles and tissue-cultured *Nicotiana tabacum* cells that are actively elongating. Pectic HG is implicated in cell adhesion maintenance simply because middle lamellae of many fruits and vegetables are rich in HG. A pectin glucuronyltransferase that transfers glucuronic acid to RG II is also required for intercellular attachment.

2.5.8 Glycosyl hydrolases and glycosyl lyases modify cell wall polysaccharide structures *in situ*

Over 130 different glycosyl hydrolase families are represented in the CAZy database (Box 2.6), with plant sequences represented in 35 of them. Glycosyl hydrolases cleave single sugars from polysaccharides in the cell wall. Arabinosidase, galactosidase, xylosidase, and fucosidase activities modify side-chains of pectins and crosslinking glycans during different stages of development. The same glycosyl hydrolase gene family can have multiple activities represented within it,

FIGURE 2.42 Fundamental structures of hydrolases. Crystal structures and stereo pairs of three types of *exo-* and *endo*hydrolytic enzymes. The top pair (“pocket”) and bottom pair (“tunnel”) are typical of *exohydrolases*, whereas the middle pair (“groove” or “cleft”) is characteristic of *endo*hydrolases. One can ‘freeview’ the image pair without a viewing device by relaxing one’s eyes and looking through each image in parallel at a comfortable distance, where the apparent distance between the images matches that of your eyes. The 3D image should appear in good focus between the two.

demonstrating that sequence similarity is not a sufficient basis for inferring biochemical function of homologs.

Polysaccharide degrading enzymes are classified as either **exo-** or **endo**hydrolases. Typically *exo*-hydrolases cleave mono- or disaccharides from the nonreducing terminus of the polysaccharide chain, whereas *endo*-hydrolases break glycosidic bonds randomly along a chain that is uninterrupted by side groups. Crystal structures show that *exohydrolases* form cavities or tunnels for insertion of the end of a polysaccharide, but *endo*-enzymes form grooves that can attach to the polysaccharide anywhere along the chain (Fig. 2.42). Like glycosyl transferases, hydrolases have **retaining** and **inverting** mechanisms of catalysis, depending on whether an acyl intermediate is formed before water cleaves the glycosidic bond (Fig. 2.43A and B). Certain classes of carbohydrate-active enzymes possess tethered **carbohydrate-binding modules** (CBM) that provide substrate specificity. Over 60 families of CBMs have been discovered, including those of plant hydrolases. **Pectin**, **pectate**, and **RG**

lyases are *endo*-enzymes that cleave uronic acid-rich polysaccharides without water, creating an anhydro-uronic acid (Fig. 2.43C).

2.5.9 Type I and Type II cell walls exhibit different biochemical changes during growth

Dramatic chemical changes occur in crosslinking glycans of Type II walls of commelinid monocots. A highly substituted GAX (HS-GAX), in which six out of every seven Xyl units bears an appendant group, is associated with the maximum growth rate of coleoptiles. The number of Ara and GlcA side groups along the GAX chains varies markedly, from GAXs for which Xyl units are nearly all branched to those with only 10% or less of Xyl units bearing side groups. Side groups not only prevent hydrogen bonding but also render GAX water

A

B

C

FIGURE 2.43 Mechanisms of catalysis of hydrolases and lyases. (A) “Inverting” glycoside hydrolases break glycosidic bonds in a single step reaction that inverts the anomeric configuration in a reaction mechanism involving oxocarbenium ion-like transition states. In the example here, the β -linkage of the glycoside cellobiose is converted to the α -configuration upon hydrolysis. The reaction occurs with acid/base catalysis typically by two glutamic or aspartic acids. These reactions are carried out when the carboxylic acid/carboxylate groups of the two amino acids are about 6–10 Å apart, allowing enough room for both water and the glycoside in the active site. (B) In “retaining” glycoside hydrolases, the configuration is retained in a two-step reaction involving two oxocarbenium ion-like transition states and a glycosyl–enzyme intermediate. Like the inverting hydrolases, the acid/base and nucleophilic amino acids are typically aspartic and glutamic acids, but spacing of the reactive groups in the active site is about 5.5 Å. In this example, the β -linkage of cellobiose is retained in the β -configuration. In these types of reactions, water can be replaced by other glycosides, and the enzyme can perform transglycosylation reactions to make longer oligomers. (C) In contrast to hydrolases catalyzed by acidic amino acids, lyases use basic amino acids to catalyze the breakage of glycosidic linkages in the absence of water. In this example of a pectate lyase, deprotonation of the C5 carbon is made possible by the electrophilic nature of the carboxyl group of the uronic acid, catalytic divalent Ca^{2+} ions, and the two basic amino acid residues in the active site. Lyase activity results in desaturation of the uronosyl residue between the C4 and C5 carbons, resulting in a puckering of the normally relaxed chair of the pyranose.

soluble. In dividing and elongating cells, highly branched GAXs are abundant, whereas after elongation and differentiation, more and more unbranched GAX polymers accumulate. Cleavage of the Ara and other side groups from contiguously branched Xyl units can yield runs of unbranched xylan capable of binding to other unbranched xylans or to cellulose microfibrils.

Type II walls are also low in pectin content. Chemically, pectins of the Type II wall include both HG and RG I, and HS-GAX is closely associated with these pectins. Interactions between HS-GAX, HG, and RG I could control wall-loosening activities, as suggested for Type I walls. Spacing of the appendant Ara and GlcA units of GAXs could determine porosity and surface charge, functionally replacing the predominant pectic substances in Type I cell wall, as illustrated in Fig. 2.25B. HGs of *Z. mays* pectins, which are methyl esterified, also contain nonmethyl esters, the formation and disappearance of which coincide with the most rapid rate of cell elongation. The chemical nature of the nonmethyl esters is not known. Some arabinans, particularly 5-linked arabinans, are found in walls of dividing cells but are not made during cell expansion.

When grass cells begin to elongate, they accumulate mixed-linkage β -glucans in addition to GAX (see Fig. 2.15). Among the angiosperms, β -glucans are unique to the Poales (see Fig. 2.14) and are one of the few known developmental stage-specific polysaccharides among the angiosperms. Absent from meristems and dividing cells, β -glucans accumulate to almost 30% of the noncellulosic cell wall material during the peak of cell elongation, and then are largely hydrolyzed by cells during differentiation. Because synthesis and hydrolysis of β -glucans occurs simultaneously throughout elongation, the amount that accumulates is a small fraction of the total synthesized. Appearance of β -glucans during cell expansion and acceleration of their hydrolysis by auxin treatment implicate direct involvement of the polymer in growth.

2.5.10 Once growth has ceased, cell wall shape must be locked in place by wall components

Once elongation is complete, the primary wall locks the cell into shape by becoming much less extensible. One component of the locking mechanism for Type I walls may be HRGPs, such as extensin. The flexible regions of these proteins could wrap around cellulose microfibrils, and the rod-like regions serve as spacers. However, we do not know how extensins are crosslinked in the wall. Loss of solubility of extensins in Type I walls is associated with an increase in tensile strength. Other proteins may be necessary to actually lock extensins together. Greater quantities of PRP are synthesized later in cell development and particularly in the same vascular cells as extensin. One hypothesis holds that extensin precursors accumulate in the cell wall during cell division and

elongation, but cannot crosslink wall components in the absence of PRPs.

Instead of Hyp-rich extensin, Type II walls contain a threonine-rich protein, with sequences reminiscent of extensin; crosslinking phenolic compounds are also present. As with extensin, soluble precursors of Thr-rich protein accumulate early in the cell cycle and become insoluble during cell elongation and differentiation. This polymer is prevalent in vascular tissue and in special, reinforced wall structures, such as pericarp. However, much of the crosslinking function in Type II walls probably rests with esterified and etherified phenolic acids, and formation of these crosslinkages accelerates at the end of the growth phase. Once phenolic cross-bridges are in place, they may account for a substantial part of the load-bearing role in fully expanded cells (see Fig. 2.25B).

2.6 Cell differentiation

2.6.1 The plant extracellular matrix is a mosaic of cell wall architectures

At the light microscope level, histochemical stains reveal a diverse distribution of polysaccharides in different cells, and the complexity of polysaccharide structure is resolved even more effectively with highly specific probes. This has been achieved using the natural specificity of enzymes for their substrates and antibodies for particular antigens (Box 2.7). More recently, the advent of microspectroscopy, in which a microscope with modified optics is attached to a spectrometer, has made **chemical imaging** possible. The distribution of a functional group of a molecule can be mapped at the single-cell level (Box 2.7).

Even in a single cell, modifications occur that distinguish between transverse and longitudinal walls. For example, preferential digestion of end walls occurs in sieve tube elements. Some substances, such as waxes, are secreted only to a cell's outer epidermal face. Within a single wall there are zones of different architectures, the middle lamella, plasmodesmata, thickenings, channels, pit-fields and cell corners, and there are domains within the thickness of a wall in which degree of pectin esterification and abundance of RG I side-chains differ (Fig. 2.44).

Comparisons of the sizes of microdomains in the wall with those of the polymers that must fit within them implies that mechanisms exist for packaging and positioning of large molecules. For example, unesterified pectins can be as long as 700 nm, and yet in some cell types, are accommodated in a middle lamella that is only 10–20 nm wide, indicating they must be constrained to lie parallel to the plasma membrane. This microdiversity within walls reveals that the wall is not a homogeneous and uniform building material, but a mosaic of different wall architectures in which various components contribute to the multifunctional properties of the apoplast.

2.6.2 Fruit ripening involves developmentally regulated changes in wall architecture

Most fruits in which the pericarp or endocarp softens during ripening develop thickened primary walls that are markedly enriched in pectic substances, primarily HG and RG I (Fig. 2.45). Texture of ripe fruit pulp is governed by the extent of wall degradation and loss of cell–cell adhesion. For example, the walls of the apple (*Malus domestica*) cortex undergo little change in rigidity and exhibit little separation, whereas walls of the peach (*Prunus persica*) mesocarp and tomato (*Solanum lycopersicum*) pericarp soften considerably through wall swelling and loss of cell adhesion. In tomato, locules containing the seeds dissolve completely in a process called **liquefaction**.

Pectins can constitute more than 50% of the fruit wall. Softening in tomato parenchyma tissue is associated with loss of methyl esters of HG, the consequence of activity of PME, which removes methylester groups from the GalA residues of pectic polysaccharide backbones. The deesterified HG backbone is then susceptible to activity of PGase. PGase I, with a molecular mass of approximately 100 kDa, comprises a 46-kDa PGase II tightly complexed with a β -subunit. The β -subunit is a unique **aromatic amino acid-rich protein** that is synthesized early in fruit development and thought to function as an anchoring component for the PGase II subunit. The β -subunit may solubilize pectins from the cell wall, facilitating progressive hydrolysis by PGase II of the glycosidic bonds within the unbranched HG backbone. Pectin modification within the wall during ripening is tightly regulated, the result of such mechanisms as substrate modification, which restricts

BOX 2.7

Techniques to probe heterogeneity of wall composition at the single cell level

A wide range of antibodies has been raised against cell wall epitopes, most commonly using monoclonal antibody technology or from recombinant phage libraries. Two sites are devoted to development and cataloguing of cell wall monoclonal antibodies and other reagents to probe polysaccharide fine structure at the single cell wall level or for development of tailored carbohydrate microarrays at the Complex Carbohydrate Research Center (http://www.ccrcc.uga.edu/~carbosource/CSS_home.html) and PlantProbes, University of Leeds, UK (<http://www.plantprobes.net>).

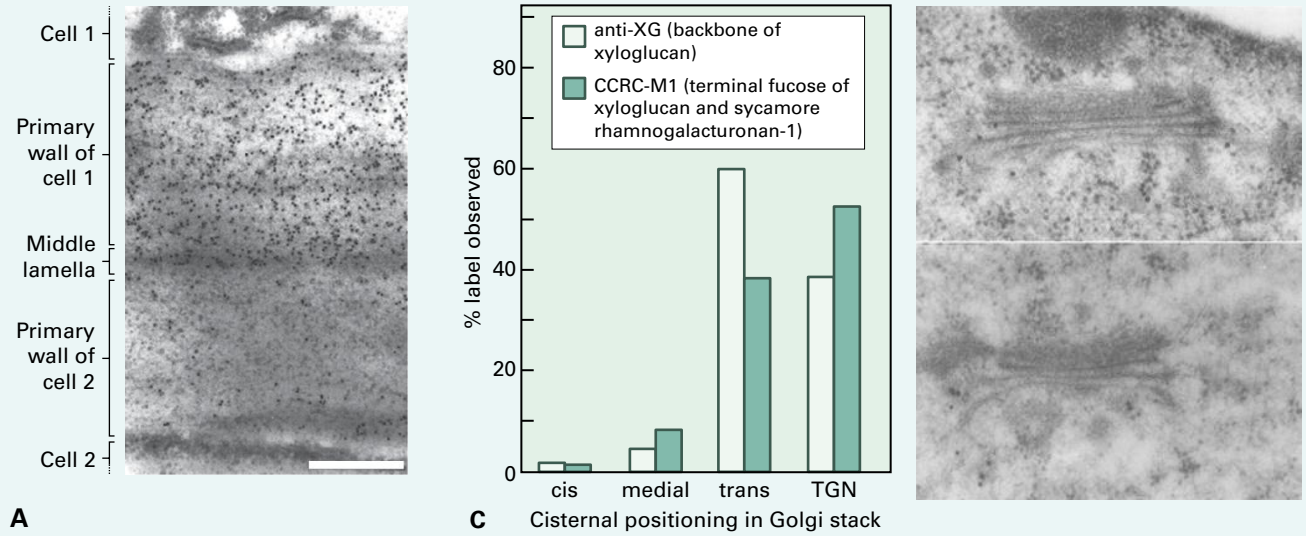

The complexity of polysaccharide structure has made precise characterization of epitopes difficult. These antibodies are used as “designer stains” to label cell walls (A), isolated polymers (B), or their sites of synthesis (C).

Some hydrolytic cell wall enzymes contain a polysaccharide-binding domain, such as the carbohydrate-binding module (CBM) of bacterial and fungal cellulases, and these enzymes can be conjugated directly with colloidal gold to produce probes for use in the electron microscope. Enzymes are denatured before coupling so that catalytic activity is eliminated, yet binding specificity remains. High-resolution images of their binding have been achieved by using semiconductor quantum dots incorporated into a recombinant CBM fused to a molecular tag of repeated histidine (or His) units for direct imaging. Water-soluble and highly luminescent quantum dots of (CdSe)ZnSe bind five histidines at the zinc surface while retaining desirable electronic properties for imaging by transmission electron microscopy (top) or scanning transmission electron microscopy (bottom) to decorate an individual cellulose microfibril (D).

Another means of probing the chemical composition of single cell walls is Fourier transform infrared (FTIR) microspectroscopy. FTIR spectroscopy is an extremely rapid, noninvasive vibrational spectroscopic method that can quantitatively detect a range of functional groups

including carboxylic esters, phenolic esters, protein amides and carboxylic acids, and can provide a complex “fingerprint” of carbohydrate constituents and their organization (E). Several functional groups absorb infrared radiation at characteristic frequencies, making assignments of some specific wall components possible, for example, the methyl esters and carboxylate ions of pectins. The IR beam can be diverted via mirror optics to pass through a sample mounted on a microscope stage. Individual spectra from areas of these dimensions can be collected over a large tissue area by a computer-driven stage to produce chemical images of the sample, as in this map of methyl ester distribution in an *Arabidopsis* hypocotyl (F). Each frequency in the IR spectrum can be represented as a separate map. Another vibrational spectroscopy, FT-Raman spectroscopy, provides a complementary technique for chemical imaging. Raman scattering depends on changes in polarizability of functional groups due to molecular vibration, while infrared absorption depends on changes in intrinsic dipole moments. Spatial resolution of infrared chemical imaging is limited to 10 μm by diffraction effects. Improved resolution, to 1 μm , is obtained with Raman imaging. Sample fluorescence and the inherent weakness of Raman scattering can be problems. For the latter, recent developments in stimulated Raman spectroscopy provides the opportunity for local signal amplification and much improved Raman signal detection. (G) A Raman spectrum of maize cell walls with a red arrow indicating the absorbance at 1600 cm^{-1} corresponding to lignin, and a chemical image of a stem section showing where this signal is most abundant (red).

enzyme access to the substrate, or the presence of enzyme inhibitors, as in the inhibition of PGase II activity by the diffusible products of pectin depolymerization. Inhibitor proteins that inactivate PME and PGases have also been identified that endogenously regulate pectin depolymerization or protect against pathogenic organisms.

Despite extensive deesterification and depolymerization of pectin polymers during ripening, fruit softening does not appear to result directly from these modifications to HG. Using antisense inhibition of PGase, researchers were able to almost completely inhibit such activity, essentially preventing pectic depolymerization in transgenic fruit; however, little or no reduction in softening occurred. Although crosslinking glycans do not appear to undergo extensive ripening-related depolymerization, several glycan-degrading enzymes increase in activity including XET, expansin, and glycan hydrolases. These enzymes may be involved in restructuring the tethering by crosslinking glycans, thereby changing the properties of the network throughout the primary cell wall and contributing to softening of the pericarp tissue and whole tomato fruit.

FIGURE 2.45 Cell walls are the principal textural elements of fresh fruits and vegetables. The walls of fruit change their architecture in different ways during ripening. (A) Apple cortex walls may stiffen and maintain cell adhesions. The 'mealy' texture of an overripe apple is a result of loss of cell–cell adhesion by dissolution of the middle lamella. The middle lamella is enriched in many pectic substances. (B) The walls of the mesocarp cells of peach swell and soften during ripening, whereas those of the endocarp become an exceptionally tough protective shield for the seed. (C) Like the peach, the tomato pericarp walls swell and soften during ripening, but some of the walls completely disintegrate, by a process called liquefaction, to create locules for the developing seeds.

2.6.3 Secondary walls are elaborated after growth of the primary wall has stopped

For many cell types, the differentiation process is associated with the formation of a distinct **secondary wall** on the plasma-membrane side of the primary wall. Regardless of chemical composition, the primary wall is always defined as the structure that participates in irreversible cell expansion. When cells stop growing, the wall is crosslinked into its ultimate shape. At that point, deposition of the secondary wall begins.

Secondary walls often exhibit elaborate specializations. The cotton (*Gossypium hirsutum*) fiber, for example, consists of nearly 98% cellulose at maturity. In some cells, such as

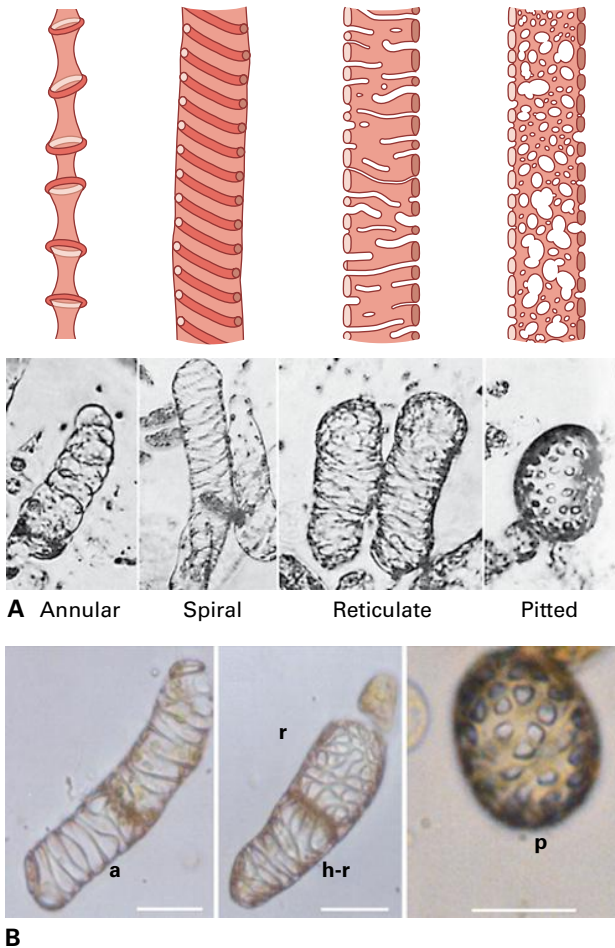

FIGURE 2.46 Secondary wall thickening patterns of vessel elements in a single plant may be annular, spiral, reticulate, and pitted. Many of these patterns are emulated during formation of the tracheary elements *in vitro* by *Zinnia elegans* mesophyll cells in liquid culture (a = annular; r = reticulate; h-r = helical-reticulate; p = pitted). Source: Falconer & Seagull. (1985). *Protoplasma* 125:190–198.

scelereids, vascular fibers, and the stone cells of pear, the secondary wall becomes uniformly thick, composed largely of cellulose microfibrils that can sometimes fill the entire cell lumen. The secondary wall can contain, however, additional noncellulosic polysaccharides, proteins, and aromatic substances such as lignin. In tracheids, secondary walls can form special patterns, such as annular or helical coils or reticulate and pitted patterns (Fig. 2.46). These walls typically contain glucuronoxylans or 4-*O*-methylglucuronoxylans in addition to cellulose. Unlike GAXs of grass walls, these xylans are devoid of Ara but contain a (1→2)- α -D-GlcA residue about every 6–12 xylosyl residues. Collenchyma cells elaborate a primary wall at thickened corners of these cells (Fig. 2.47).

The walls of many cells function long after the cells that produced them are dead and desiccated. For example, orientation of the polymers assembled in walls of living cells results in mechanical strains upon desiccation, strains that result in abscission of plant parts and the dehiscence of fruit coats along defined planes. The paper-thin wings of a maple (*Acer* spp.) samara and feathery tufts of hair cells of dandelion (*Taraxacum*

FIGURE 2.47 (A) Collenchyma cell has reinforced thickenings only in the cell corners. (B) Cellulosic thickenings of the primary wall can be seen when pectins of the middle lamella are stained with Neutral Red. Source: John Tiftickjian, Delta State University.

officinale) and willow (*Salix* spp.) fruits form only upon drying; each structure aids in scattering of seeds (Fig. 2.48).

Many structural proteins are cell-specific, occurring only in the secondary wall. For example, some PRPs concentrate in secondary walls of protoxylem elements of bean (*Phaseolus vulgaris*), whereas some GRP family members are synthesized in xylem parenchyma cells and exported to primary walls of neighboring protoxylem elements. Other GRPs are found in sclereids, associated with both the primary and secondary walls. HRGPs generally are found in primary walls of all tissues, although in widely varying proportion, but a Thr-rich, extensin-like protein of *Z. mays* is more abundant in secondary walls of the firm pericarp of popcorn.

Not all cell wall secondary thickenings represent distinct secondary walls. Some thickened walls have a composition typical of a primary wall but simply contain more strata. Guard cells and epidermal cells thicken the wall facing the environment to a much greater degree than side walls or the inward-facing wall. Pairs of guard cells contain thickenings of radially arranged cellulose microfibrils, especially in walls adjacent to the stoma, which are needed to withstand the enormous turgor pressure generated by the cell during stomatal opening (see Fig. 2.2C). Pectic arabinans in guard cell walls are required for their ability to open and close reversibly. Epidermal cells form specialized exterior layers of cutin and suberin to prevent loss of water vapor, and endodermal cells suberize their contiguous side walls to form the Casparian band that forces water and dissolved solutes to move symplasmically into the stele.

2.6.4 Secondary deposition of suberin and cutin renders cell walls impermeable to water

Suberin is found in specific tissues and cell types, notably the root and stem epidermis, cork cells of the periderm, surfaces of wounded cells, and parts of the endodermis and bundle

FIGURE 2.48 Cells that produce special walls can function long after death. The sycamore-maple uses paper-thin walls of a samara as wings for seed dispersal (A). The hard fruit coat of a willow cracks open along a dehiscence zone upon desiccation (B). The pattern of microfibril deposition creates a physical tension that causes fruit to snap open. Like the dandelion (C), the feather tufts of willow trichomes are used for long-distance seed dispersal.

sheath cells (Fig. 2.49). It is recognized by lipid-specific stains such as Sudan IV, which detects long-chain fatty acids and alcohols, dicarboxylic acids, and hydroxylated fatty acids. The core of suberin is lignin-like and incorporates ferulate esters of fatty alcohols via radical coupling reactions. The attachment of the long-chain hydrocarbons imparts a strongly hydrophobic character to material that prevents water movement.

The polyester cutin and its associated waxes also are found on leaf and stem surfaces, providing a strong barrier to diffusion of water. Waxes generally are esters of long-chain fatty acids and alcohols, but are better described as complex mixtures of these hydrocarbon esters with ketones, phenolic esters, terpenes, and sterols.

2.6.5 Lignin is a major component of some secondary walls

The most obvious distinguishing feature of secondary walls is the incorporation of lignins, complex networks of aromatic compounds called **phenylpropanoids**. With a few exceptions, no lignin exists in Type I primary walls, whereas networks of lignin and other phenylpropanoid compounds are present in Type II primary walls. For Type I walls, lignin synthesis is initiated when secondary wall deposition commences. Three primary phenylpropanoids, the hydroxycinnamyl alcohols or “monolignols”—*p*-coumaryl, coniferyl, and sinapyl alcohols—account for most of the lignin networks. The monolignols are linked by way of ether, or carbon–carbon bonds via radical coupling reactions (see Fig. 2.23), the predominant coupling reaction of a monolignol (invariably at its side-chain β -position) with the phenolic end of the growing polymer (at

FIGURE 2.49 Certain cell walls are waterproofed with suberin. (A) Cell walls of epidermis and exodermis of an onion (*Allium cepa*) root are detected with the blue fluorescent stain for suberin, berberine. (B) Exodermis and endodermis of an ash (*Fraxinus* spp.) are detected with the green fluorescent stain for lipids, fluoroal. Lignin autofluorescence of xylem tracheary elements is shown in blue. FIGURE 2.50 Several different procedures can be used to visualize lignin, including (A) acid fuchsin, which produces an orange fluorescence. In this *Arabidopsis* leaf, lignin can be seen located in spiral thickenings of vessels. Phloroglucinol is a general stain for lignin as seen in cross-section of a *Robinia pseudoacacia* stem (B), or xylem (x) and extraxylary fibers of an *Arabidopsis* floral stem (C). Mäule reagent produces a red color with syringyl lignin, which is derived from sinapyl alcohols, but forms a brown-orange color on reacting with guaiacyl lignin, which is derived from coniferyl alcohol (D). This reagent differentiates a mutant of *Arabidopsis* unable to make syringyl lignin from wild-type plants (E). ph, phloem; pi, pith; e, epidermis. Source: (A) Dharmawardhana et al. (1992). *Can J Bot* 70:2238–2244. (B) Bowes. (1996). *A Colour Atlas of Plant Structure*. Manson Publishers, London. (C) Zhong et al. (1997). *Plant Cell* 9:2159–2170. (E) Chapple et al. (1992). *Plant Cell* 4:1413–1424.

its 4-*O*- or 5-positions). The diversity of monolignols, their radical coupling at several possible sites on each phenolic moiety, and the racemic nature of polymerization all impart remarkable complexity to lignin structure.

Lignins can be detected in tissue sections by specific stains, such as acid fuchsin, the Wiesner reagent (phloroglucinol-HCl), and the Mäule reagent (Fig. 2.50). The Mäule reaction, in which a KMnO_4 oxidation is followed with ammonia, is particularly useful because it distinguishes syringyl lignin and guaiacyl lignin, indicating the former by a bright red color and the latter by yellow (Fig. 2.50). Total lignin is quantified by various methods, either chemically or by NMR and other spectroscopic methods. Degradative acidolysis and thioacidolysis, reductive cleavage, permanganate, nitrobenzene, and alkali/copper oxide oxidation are all used to detect lignin. The former procedures are considered the most diagnostic, specifically cleaving the characteristic β -aryl ether bonds to release monomers and higher oligomers. The **degradation followed by reductive cleavage (DFRC)** method partially cleaves lignins to peracetates of their constituent monomers (as peracetates after the full procedure). The products of oxidations include *p*-hydroxybenzaldehyde, vanillin, and syringaldehyde (and their corresponding acids) from *p*-hydroxyphenyl, guaiacyl, and syringyl lignin units, respectively. Because most plants contain only very low levels (<2%) of *p*-hydroxyphenyl units, lignins are classified by their guaiacyl and syringyl content. Gymnosperms contain predominantly guaiacyl units, whereas woody angiosperms, herbaceous eudicots and grasses exhibit a broad range of ratios of guaiacyl and syringyl residues.

Synthesis of monolignols in plants is well documented and appears to occur in the cytosol. Monolignols can be

glycosylated in reactions associated with the ER and Golgi apparatus, but this glycosylation may simply be for protection and storage; it does not seem to be necessary for membrane transport and targeting. Once in the wall, monolignols polymerize via radical coupling reactions. The radicals are generated by **peroxidases**, which use H_2O_2 as a substrate, or by **laccases**, members of the “blue copper oxidase” family of enzymes that use O_2 . Although monolignol–monolignol dehydrodimerization reactions are implicated in chain initiation, the main lignification event is the addition of a monolignol (radical) to the phenolic end of the growing polymer (see Fig. 2.23) in a so-called endwise process.

During lignification, there are opportunities for cell wall crosslinking by at least two mechanisms. First, each radical coupling reaction of a monolignol at its β -position produces an intermediate quinone methide structure that must be rearomatized by nucleophilic addition at its benzylic or α -position. This is chiefly accomplished by internal trapping to make phenylcoumaran and resinol structures, or simply by proton-catalyzed water addition to produce the α -hydroxy- β -ether compounds (see Fig. 2.23). Carbohydrate hydroxyls may also be coupled, however, to produce lignin-carbohydrate benzylic ethers and yield lignin–polysaccharide crosslinking, although evidence for such lignin-carbohydrate linkages has been difficult to find. In Type II cell walls ferulate esters on GAX undergo radical coupling reactions analogous to those of monolignols. Thus, combinatorial ferulate dehydrodimerization results in a range of dehydrodiferulates and effects powerful polysaccharide–polysaccharide crosslinking (see Fig. 2.23). Moreover, ferulate radicals and radicals from diferulates are compatible with radical coupling reactions going on within lignification. As a result, ferulates cross-couple with

FIGURE 2.51 Endosperm walls of date (*Phoenix dactylifera*) have extremely hard and thick walls of mannan. (A) A low-magnification light micrograph of date endosperm shows that these mannans exclude Toluidine Blue dye. (B) Cotyledon walls of Brazilian legume jatobá (*Hymenaea courbaril*) accumulate “amyloid” xyloglucans that stain lightly with iodine. (C) The aleurone layer, the outermost layer of endosperm cells of grass caryopsis, has cell walls enriched in mixed-linkage β -glucan. The β -glucan is detected with a monoclonal antibody against the (1 \rightarrow 3),(1 \rightarrow 4)- β -D-linkage. Immunofluorescence labeling is viewed by confocal microscopy. Bars = 25 μ m.

monolignols and higher oligomers to integrate into the lignin matrix. Although it is rarely noted as such, these ferulates, in addition to the monolignols themselves, are authentic therefore “monomers” in lignification.

2.6.6 Some secondary walls can serve as storage materials

Another site of diversity among plant species is the secondary walls of the cotyledon and endosperm of developing seeds. These walls contain little or no cellulose but rather consist of a single noncellulosic polysaccharide typically found in the primary wall. These secondary walls serve two functions. First, they provide a strong wall to protect the embryo or impose mechanical dormancy. Second, they contain specialized storage carbohydrates that are digested during germination and converted to sucrose for transport to the growing seedling.

Gal-rich XyG abounds on the cotyledon walls of *Tamarindus*, *Hymenaea courbaril* (jatobá), and similar legumes, as well as species of Primulaceae (primrose family), Linaceae (flax family) and Ranunculaceae (buttercup family) (Fig. 2.51). Glucmannans predominate in cotyledon walls

of some lilies and irises. Seeds of date (*Phoenix dactylifera*), coconut (*Cocos nucifera*) and other palms, coffee bean (*Coffea arabica*), ivory nut (*Phytalephas aequatorialis*), and some Apiaceae all contain a thick cotyledon or endosperm wall of almost pure mannan (Fig 2.51). The endosperm of lettuce (*Lactuca sativa*) seeds, which constitutes the mechanical determinant of dormancy, is more than 70% mannan. All endospermic legumes store galactomannans, but the Man:Gal ratio can vary markedly, yielding a variety of galactomannans with very different physical properties. For example, fenugreek (*Trigonella*) makes an almost fully branched galactomannan, whereas guar (*Cyamopsis*) galactomannans and those of carob (*Ceratonia siliqua*) or locust bean (*Ectomyelois ceratoniae*) are much less branched, which changes their viscosities. Seeds of yet other species accumulate neutral polysaccharides typically found associated with pectins. For example, lupines contain large amounts of (1 \rightarrow 4)- β -D-galactan, and some arabinan.

All grasses accumulate (1 \rightarrow 3),(1 \rightarrow 4)- β -D-glucan in walls of endosperm at some stage in embryo development. Oat (*Avena sativa*) and barley (*Hordeum vulgare*) brans are notably enriched in β -glucans, which make up as much as 70% of the aleurone layer cell walls at maturity (Fig. 2.51).

2.6.7 Global regulation of cell wall synthesis

It is clear that different gene family members must be coordinately regulated to build walls of specific composition. The expression patterns of individual gene family members are being measured using whole or custom microarrays or newer deep-sequencing technologies to define sets of genes that are coregulated. Secondary walls are typically deposited during specific phases of cell differentiation and provide an excellent system for global transcriptional analyses aimed at identifying secondary wall-related gene networks. The secondary wall-specific *CesA* genes and genes involved in lignin biosynthesis are used as markers for finding genes of unknown function that are coregulated with them.

Secondary walls also provide the opportunity to identify key regulatory proteins of gene involved in cell wall synthesis in specific cell types. Gain-of-function experiments with a family of transcriptional activators with conserved N-terminal amino acid domains (NAC domains) and oncogenes of an avian myoblastosis (MYB) viral transcriptional activator show increased and ectopic secondary wall formation (Fig. 2.52). The NAC domain proteins trigger expression of several MYB genes that directly activate genes encoding several enzymes of the monolignol synthesis pathway. These expression networks activated in xylem and fibers cells are balanced by certain WRKY genes that encode a class of repressors that silence vascularization of pith cells.

MicroRNA sequences have also been implicated in regulatory control of transcription factors in *Populus*, and they are upregulated during formation of tension wood. Some cellulose synthases occur as *cis*-oriented pairs, providing antisense transcripts to downregulate synchronously both these and

FIGURE 2.52 Overexpression of two vascular-related “NAC” domain-containing (VND) proteins, VND6 and VND7, induce trans-differentiation of various cell types in *Arabidopsis* into metaxylem- and protoxylem-like vessel elements respectively. Wild-type hypocotyls contain a central vascular bundle (A, D), but cortical and epidermal cells are induced to form metaxylem by ectopic expression of VND6 (B, E) and protoxylem by ectopic expression of VND7 (C, F). *Arabidopsis stomata* (G) and *poplar trichomes* (J) form vascular-like thickenings by ectopic expression of the *Arabidopsis* VND7. Ectopic expression of VND6 also induces vascular thickenings in *poplar trichomes* (I), whereas no such thickenings are observed in wild-type *poplar epidermis* (H). Images were taken using differential interference contrast (A–C) and confocal laser scanning microscopy (D–J). Bars are 100 μm (A–F), 50 μm (H–J), and 10 μm (G); insets in b and c, 20 μm ; inset in d is 10 μm .

other wall-related genes in changing a cell’s developmental program to secondary wall deposition.

2.6.8 Cell walls as sensory panels for signal transduction

Not all specialized functions of cell walls are structural. Cell walls contain molecular elements called receptor-like kinases (RLKs), which facilitate response mechanisms to biotic and abiotic stimuli as well as developmental and positional signals (Fig. 2.53). They can be viewed as sets of intricate sensory panels for signal transduction, although all molecular

elements are not yet fully understood or placed clearly in physiological networks. Feedback mechanisms sensing and restructuring the biomechanical properties of walls and organs in response to stimuli are a major gap in this area. Two sets of molecules that are implicated in some aspects of the mediation of response are leucine-rich repeat (LRR) kinases and wall-associated kinases (WAKs).

LRR kinases populate the plasma membrane and allow signal transduction across this topological barrier. These LRR domains are specialized for interactions with ligands of the plasma membrane–cell wall interface. Examples include R gene disease resistance factors, chimeric LRR–extensin (LRX) proteins that function in root hair development, and proteins that function in meristem identity and transition to organ.

FIGURE 2.53 Domain organization of representative receptor-like kinases (RLKs) and RLK-subfamily affiliations. Many plasma membrane-localized RLKs with different extracellular protein domains have been identified. Each of the structures shown here is representative of a subfamily of closely related sequences. Some of these RLKs, such as *CLAVATA* (*CVL1*), interact with small peptide ligands that are secreted to the apoplast, but others, such as *WAK1*, bind pectins or other cell wall components to form a cell wall–plasma membrane–cytoplasm signal pathway. Leucine-rich repeat (LRR) sequences include the extensin-containing domain protein, *LRX1*, which functions in cell development. The gray line indicates the position of the membrane-spanning domain.

WAKs have a highly conserved serine/threonine kinase cytoplasmic domain, a plasma membrane-spanning region, and a more variable extracellular domain containing EGF (epidermal growth factor) repeats, which are likely to function in ligand recognition. Upon phosphorylation, WAKs bind to pectins and a glycine-rich protein to form a complex in conjunction with kinase-associated protein phosphatase, KAPP. Loss of WAK function results in disruption of normal cell expansion.

2.7 Cell walls as sources of food, feed, fiber, and fuel, and their genetic improvement

Cell walls directly impact the raw material quality of human and animal food, textiles, wood and paper, and they can play a role in human medicine. Modification of various cell wall

FIGURE 2.54 Brown-midrib (bm) mutants of *Sorghum* spp. or *Z. mays* have defects in lignin synthesis that results in a reddish-brown color of leaf vascular tissue (A). Depicted here is a bm2-bm4 double mutant. Certain bm mutants and their combinations in sorghum result in improved nutrition in ruminant animals because of enhanced digestibility; sheep will preferentially graze such mutants (B). Source: (A) Vermerris et al. (2010). *J Exp Bot* 61(9):2479–2490. (B) Wilfred Vermerris, Univ. Florida; in reference to data in Li et al. (2008). *Plant J* 54:569–581.

constituents is a goal in the food processing, paper, agriculture and biotechnology industries. Achievement of this goal depends on understanding the molecular basis for the mechanical and textural properties of plant-derived materials.

The food industry uses isolated AGPs and pectins as gums and gelling agents. Fungal and bacterial wall hydrolases are used to adjust food textures. The cell walls of fruits and vegetables are now recognized as important dietary components, and they may protect against cancer of the colon, coronary heart disease, diabetes, and other ailments. β -Glucans are causal agents in the ability of oat and barley brans to lower serum cholesterol and reduce insulin demand of people with diabetes. Some pectins may have antitumor activities, possibly by stimulating the immune system after uptake through particular cells of the gastrointestinal tract.

Particular foods are being genetically engineered to improve their storage characteristics and maximize consumer appeal. Target enzymes include PGase, PME, and several polysaccharide hydrolases. The results of attempts to change only one parameter of wall metabolism are rarely those predicted, because of the inherent complexity of the wall and ability of plant cells to adapt to change. Such biotechnological applications will become more common as we understand more of the regulation of cell wall metabolism, particularly regulatory mechanisms for polymer synthesis and wall loosening.

With the advent of biotechnology, agricultural researchers are investigating particular enzymes involved in cell wall metabolism in hopes of producing crops with desired characteristics by enhancing commercially valuable traits (e.g., fiber production in flax, cotton, ramie, and sisal) or abolishing costly ones (e.g., modification of lignification of some plant tissues). For example, the pulp and paper industry, which processes trees to cellulose, and the livestock industry, which depends on the transformation of cell walls into muscle tissue, are striving to reduce the lignin content, or to alter the composition/structure to be less recalcitrant, in their respective

sources of fiber and fodder. Reducing lignin content would reduce organochlorine wastes and cut costs tremendously for the paper industry, which currently uses chemical extractions to purify cellulose from wood. Alternatively, altering structure such that lignins can be more readily depolymerized and removed from polysaccharide fiber using simpler chemical treatments would be enormously beneficial. Lignin-carbohydrate interactions exert a great influence on digestibility of forage crops by ruminant animals, and the kind of lignin present rather than the total amount is often the crucial factor. Hence, mutants with altered lignin type may yield new forage crops that exhibit greater digestibility without sacrificing the strengthening function of lignin to the water-conducting cells of the plant; for example, certain natural **brown-midrib** mutants of sorghum (*Sorghum bicolor*) are already known to be more digestible (Fig. 2.54).

Bioenergy derived directly from plants, or the use of plants as feedstocks for fermentation by microbes, has an ever-increasing contribution to the diversifying energy portfolio, with positive impacts for energy security, mitigation of environmental consequences of elevated greenhouse gases, and in stimulation of rural economies. Sucrose and glucose from sugarcane (*Saccharum officinarum*) fermented to ethanol already provide Brazil with energy independence from petroleum fuels. In the USA, production of ethanol from corn (*Z. mays*) grain is a mature industry, but animal feed supplies and food products compete for this substrate. Lignocellulosic biomass consists principally of cell walls, harvested from dedicated bioenergy crops or from dried crop residues, such as sugarcane bagasse or maize and sorghum stover. Lignocellulosic biomass provides a rich source of solar energy trapped as lignin and carbohydrates in a broad range of plants unrestricted by climate or geographic location. Perennial grasses such as switchgrass (*Panicum virgatum*) and *Miscanthus* are considered superior potential feedstocks because they have C4 photosynthesis and a long growing season, can sequester nutrients in rhizomes at the end of the growing season, and exhibit high water use efficiency. However, integration of bioenergy crops

into the agricultural landscape must be sustainable, cost-effective, and present a small agronomic footprint in balance with food and feed production. For this reason, highly productive annual grasses such as sorghum and tropical maize are gaining notice as a bioenergy crop that integrates sustainably in a crop rotation system.

Cell wall polysaccharides are hydrolyzed to glucose and other sugars, which are then metabolized by microbes to produce biofuels. A general consensus is emerging that recalcitrance of lignified cell walls to hydrolysis by enzymes is a key obstacle that could be mitigated by identifying more efficient cell wall-degrading enzymes, expressing them recombinantly in transgenic plants, or modifying biomass composition or biomass quality to facilitate degradation. However, an equally important goal is to maximize the amount of carbohydrate

biomass per hectare to reduce the energy and economic costs of production and transport to refineries.

In a broader view, fermentation is an inherently wasteful process—about one-half of the sugar used is lost as CO₂ during formation of ethanol by yeast. In this instance, enhancing fuel value of biomass as a combustible material, e.g., by elevating lignin content, becomes a worthwhile goal – lignin's fuel value is about 50% higher than that of polysaccharide. Researchers are already exploring ways to chemically convert lignocellulosic biomass to liquid biofuels and to a host of useful substrates that could replace petroleum. A better understanding of the control of cell-wall carbohydrate and aromatic domains and their architecture is likely to lead to major improvements in the energy potential of designed bioenergy crop plants.

Summary

Cell walls are composed of polysaccharides, proteins, and aromatic substances. The primary wall of the cell is extensible but constrains the final size and shape of every cell. Facing walls of adjacent cells adhere to each other at the middle lamella. In some cells, secondary walls are deposited on the inner surface of the primary wall after growth has stopped.

Cellulose microfibrils form the scaffold of all cell walls and are tethered together by crosslinking glycans; this framework is embedded in a gel of pectic substances. There are at least two types of primary walls. The Type I walls of eudicots and noncommelinid monocots have xyloglucan–cellulose networks embedded in a pectin-rich matrix and can be further crosslinked with a network of structural proteins. Type II walls of commelinid monocots have glucuronoarabinoxylan–cellulose networks in a relatively pectin-poor matrix. Ferulate esters and other hydroxycinnamic acids and aromatic substances crosslink the Type II walls.

Plants devote about 10% of their genome to cell wall biogenesis, which encompasses the synthesis of substrates, polymer assembly, and rearrangement during growth. A new cell wall is initiated at the cell plate. Cellulose microfibrils of all vascular plants and some algae are synthesized at the surface of the plasma membrane at terminal complexes called particle rosettes, whereas all noncellulosic crosslinking glycans and

pectic substances are made at the Golgi apparatus and secreted. All cell wall sugars are synthesized *de novo* from interconversion of nucleotide sugars, which are the substrates for polysaccharide synthases and glycosyl transferases.

Cell shape is largely governed by the pattern of cellulose deposition, but cell enlargement is dependent on polymer remodeling enzymes, such as expansin and endo- β -transglucosylase. Cell enlargement is also accompanied by numerous changes in the structure of the wall's crosslinking glycans and pectin matrix. Termination of cell growth is accompanied by crosslinking reactions involving proteins and aromatic substances. Cell walls become specialized for the function of the approximately 40 cell types that plants comprise. The plasma membrane–cell wall interface is the cell's sensory panel for interaction with the environment, and many proteins and protein kinases have been implicated in signaling related to cell specification and growth as well as response to injury from abiotic and biotic factors.

In addition to their use in wood, paper, and textile products, cell walls are the major textural component in fresh fruits and vegetables, and constitute important dietary fibers in human nutrition. They provide a major source of calories for ruminant animals. Cell walls are the lignocellulosic biomass that will likely become a major substrate for biofuel production.

Membrane Transport

*Julian I. Schroeder, Paul C. Bethke,
Walter Gassmann, and John M. Ward*

Introduction

Redistribution of ions and small organic molecules is essential for plant growth, cell signaling, nutrition, movements and cellular homeostasis. To fulfill these essential functions, plants have evolved numerous proteins that mediate the transport of ions, metabolites, and other compounds across the plasma membrane (PM) and organelle membranes of cells. Many of these transporters are selective for the substrate being transported and their activities are regulated. Most plant transporter genes are members of multigene families that show developmental and tissue-specific expression. Research is elucidating central functions of membrane transporters in response to physiological stimuli including abiotic and biotic stresses and how the activities of individual transporters are coordinated within a network at the cell and tissue levels.

3.1 Overview of plant membrane transport systems

3.1.1 Membranes facilitate compartmentalization

One of the earliest events in the evolution of life was the development of a barrier between the sensitive biochemical machinery of replication and the dispersive forces of the outside world.

This barrier is the cell membrane. Delimited by its membrane, the cell can support metabolic, reproductive, and developmental activities that require a stable physicochemical environment. The hydrophobic nature of the membrane lipid bilayer ensures that hydrophilic compounds, including most nutrients and metabolites, can be sequestered on one side of the membrane or the other. During the 1930s, groundbreaking work established that the ability of most molecules to permeate plant cell membranes correlates with their oil : water partition coefficient (Fig. 3.1). The same principle applies to all biological membranes. The finding that the permeability of membranes for water is two orders of magnitude higher than predicted by the lipophilicity of water ultimately led to the identification of transporter-mediated water transport (see Section 3.5).

Plant cells contain many specialized organelles responsible for diverse biosynthetic, catabolic, and storage functions (see Chapter 1). The evolution of eukaryotes and the development of an endomembrane system allowed the homeostatic function of membranes to be carried one step further. Compartmentalization of solutes within membrane-bound organelles not only concentrates reactants and catalysts, but also segregates incompatible processes. This division of labor facilitates metabolic flexibility and efficiency.

3.1.2 Membrane transport underlies many essential cell biological processes

The complete sequence of the *Saccharomyces cerevisiae* nuclear genome reveals that about 2,000 of the 6,000 genes encode membrane-associated proteins, of which a large

FIGURE 3.1 Water displays anomalously high permeability in biological membranes. For most small, uncharged solutes, the ability to permeate biological membranes is correlated with their ability to dissolve in a hydrophobic phase, in this case olive oil. Water is an exception and is 2 orders of magnitude more permeant than predicted. The adjusted permeability coefficient, $P_s \cdot \sqrt{M_r}$, in units of $\text{cm} \cdot \text{h}^{-1}$, is the experimentally determined permeability coefficient for each solute (P_s) multiplied by the square root of the molecular mass of that solute, which adjusts for differences in rates of diffusion.

proportion are transport system components. A similar percentage of the proteins encoded in the 26,000-gene *Arabidopsis* nuclear genome are associated with membranes. Of these, approximately 1,300 protein sequences have been assigned a transport function. In plant cells, membrane transport is central to a wide range of essential processes:

- **Nutrient acquisition.** Plants synthesize vital organic biomolecules from inorganic nutrients, many of which must be absorbed from the soil by roots for assimilation into amino acids and other metabolites. Thus, nitrogen can be absorbed as NH_4^+ or NO_3^- , sulfur as SO_4^{2-} , and phosphorus as PO_4^{3-} (see Chapters 16 and 23). Macronutrients such as potassium (K^+) and calcium (Ca^+) and trace elements such as boron, zinc, copper, and iron are absorbed in inorganic form. Uptake of these essential nutrients is mediated and regulated by specialized nutrient transport proteins (see Chapter 23).
- **Metabolite distribution.** In terrestrial plants, autotrophic tissues such as the photosynthetically active mesophyll cells in leaves supply reduced carbon and other metabolites to heterotrophic tissues. Long-distance transport from source tissues to sinks is accomplished by the phloem. Sucrose and amino acids cross the membranes of phloem companion cells and are loaded into the phloem by way of specific membrane-spanning transport proteins (see Chapter 15).

- **Compartmentalization of metabolites.** Given the many metabolic pathways present within a plant cell, compartmentalization of enzymes and metabolites prevents futile cycling. One classic example relates to starch, which can be synthesized and stored in amyloplasts even while glycolysis proceeds in the cytosol. Starch synthesis depends on importing glucose 6-phosphate across the double membrane of the amyloplast (see Chapter 13). Compartmentalization also enhances metabolic efficiency. In the mitochondrial matrix, for example, the ADP/ATP and NADH/NAD⁺ ratios are greater than in the cytosol, which provides a substrate/product ratio that favors respiratory activity. The corresponding transport mechanisms are required for mitochondrial export of ATP and import of reducing equivalents (see Chapter 14).
- **Energy transduction.** Membrane transport lies at the heart of biological energy conversion. Light energy drives electron transfer in chloroplasts and accumulation of protons (H^+) in the thylakoid lumen. Similarly, oxidation of NADH provides energy for pumping H^+ from the mitochondrial matrix into the intermembrane space. In each case, spontaneous, exergonic flow of H^+ back across the membrane is used to generate ATP. Understanding the mechanisms by which light and high-energy electrons are harnessed to phosphorylate ADP therefore demands knowledge of membrane transport.
- **Turgor generation.** The presence of a rigid cell wall enables plant cells to generate turgor (positive hydrostatic pressure). Turgor generation is accomplished by accumulating salts via specific membrane transporters; this drives water uptake into the cell. In mature cells of most plants, K^+ accumulates in the cytosol and in the large central vacuole, whereas in halophytes the principal cations are K^+ and Na^+ , with Na^+ accumulation in vacuoles. Cations must be balanced by a corresponding concentration of anions to achieve electroneutrality; in vacuoles, the principal anion is usually Cl^- (depending on its extracellular availability), malate, or a mixture of organic and inorganic anions.
- **Waste product excretion.** Metabolism inevitably generates waste products that must be removed from the cytosol.
- **Signal transduction.** Many environmental and hormonal signals that influence plant growth and development are transduced via transiently increasing the concentration of cytosolic free Ca^{2+} . First, Ca^{2+} -permeable channels open in response to particular stimuli and allow passive entry of Ca^{2+} into the cytosol, thus causing an increase in the cytosolic free Ca^{2+} concentration. Second, Ca^{2+} -translocating ATPases or $\text{H}^+/\text{Ca}^{2+}$ exchange transporters subsequently remove Ca^{2+} from the cytosol by pumping it across the plasma membrane and intracellular membranes. Changes in intracellular Ca^{2+} concentrations are sensed by Ca^{2+} -binding proteins that can propagate numerous physiological stimuli (see Chapter 18).

3.1.3 Selective permeability of biological membranes depends on transport systems with integral membrane proteins

Controlled transport of ions, nutrients, and metabolites across the plasma membrane and intracellular membranes is required to integrate whole-plant and cellular metabolism. Transport is made possible by membrane-spanning proteins within the lipid bilayer. These so-called transport proteins can be regarded as conventional enzymes in many respects, with the important exception that transport events are vectorial (i.e., defined by a magnitude and a direction), whereas enzyme-catalyzed reactions are scalar (i.e., defined entirely by magnitude). Like enzymes, all transport systems exhibit some degree of substrate specificity and work by lowering activation energy required for transport.

All membrane transport systems have membrane-spanning, integral membrane proteins. These contain stretches of amino acids that are predominantly lipophilic (hydrophobic) and interact favorably with the fatty acyl chains of membrane phospholipids. Hydropathy analysis (Box 3.1) identifies putative integral membrane proteins using a previously determined amino acid sequence. An α -helix must contain about 20 amino acid residues to span the hydrophobic lipid bilayer. Hydropathy analysis identifies hydrophobic stretches of amino acids that may form a transmembrane helix. Although all transmembrane transport proteins have membrane-spanning components, some transport systems also require soluble regulatory protein subunits for full catalytic activity.

3.1.4 Pumps, channels, and cotransporters are components of membrane transport systems

Membrane transport systems have been categorized as pumps, channels, or cotransporters. Although contemporary biochemical analyses of membrane transporters have blurred the boundaries between these classes (see below), they remain useful. Pumps catalyze active transport, coupling the energy liberated from hydrolysis of ATP (or in a few cases pyrophosphate, PP_i) to transport of a specific molecule against an electrochemical gradient. The H⁺-translocating ATPases in the plasma membrane and the H⁺-translocating PPase in the tonoplast are classic examples of pumps.

In contrast to pumps, channels and cotransporters facilitate passive transport, utilizing energy stored in electrochemical gradients to power transport. Channels help a compound diffuse down its electrochemical gradient by forming aqueous pores in the membrane. The K⁺ and anion channels in the guard cell plasma membrane are

well-studied examples of plant ion channels (see Section 3.3). Unlike channels, cotransporters (often called carriers) transport specific molecules against an electrochemical gradient by linking transport of one molecular species in the energetically unfavorable “uphill” direction to transport of another molecular species, typically H⁺, in an energetically favorable “downhill” direction. The net change in free energy for all molecules transported is negative, allowing the transport reaction to occur without need for direct chemical energy inputs from ATP or PP_i hydrolysis. Cotransporters that catalyze solute flux in the same direction as H⁺ (or Na⁺) flux are known as symporters. Because protons flow passively across most membranes in the direction of the cytosol, symporters typically energize uptake of solute into the cytosol, either from the external medium or from intracellular compartments. Conversely, excretion from the cytosol can be accomplished by antiporters, which exchange solutes for protons. Antiporters are present at the plasma membrane and at endomembranes. Sucrose transporters that link sugar accumulation to H⁺ movement are examples of cotransporters. An overview of the above processes is shown in Figure 3.2.

These distinctions between transporter types do not serve to describe mechanisms of all transporters. As noted below, some ion channels also have cotransporter-like activity, and some cotransporters form an aqueous pore and act similarly to channels. Furthermore, even ATP-hydrolyzing pumps use channel-like domains to transport substrates across the membrane.

3.1.5 Transport rates vary across different transporter types

Transport activity is a function of the transporter rate (number of molecules transported per unit time per transporter) and the number of transporters in the membrane. Pumps are relatively slow with rates of 10² molecules s⁻¹ transported. This is because pumps go through large conformational transitions to couple metabolic reactions to transport. Cotransporters may also undergo conformational changes during transport, but transport rates are greater than those of pumps, in the range 10³–10⁶ s⁻¹. Channels do not undergo conformational changes during transport and can catalyze ion fluxes of 10⁶–10⁷ s⁻¹.

These differences in transport rates explain why the abundance of different transport proteins varies markedly. Pumps have slow rates of transport, and, as described below, generate the proton gradients that drive an array of symporters and antiporters. A square micrometer of membrane may include several hundred to several thousand pump proteins, but typically contains only 1–10 channel proteins. The rapid transport rates of channels facilitate electrophysiological analysis of individual channel molecules (see Section 3.3.2).

BOX
3.1

Hydropathy analysis uses amino acid sequence data to identify membrane-spanning polypeptides

Because all transport systems contain intrinsic membrane proteins, an obvious pair of questions is, “Which domains of the protein traverse the membrane, and which are exposed to the aqueous phases?” For known protein sequences, a simple test has been devised. This test incorporates the recognition that a polypeptide in a predominantly hydrophobic environment (e.g., a membrane) will adopt an α -helical conformation. Given the well-established dimensions of an α -helix (one amino acid residue for every 0.15-nm rise along the helix), and the hydrophobic portion of the membrane lipid (about 3 nm total for the fatty acyl side chains from both leaflets of the phospholipid bilayer), about 20 amino acid residues are required to span the hydrocarbon core of a membrane, assuming that the α -helix is perpendicular to the membrane plane.

The propensity of a stretch of polypeptide to reside in a bilayer can be predicted on the basis of the mean hydrophilicity of component amino acid residues. Common amino acids are assigned a hydropathy index reflecting the aqueous solubility of the amino acid; values range from +4.5 for the most hydrophobic amino acid (isoleucine) to -4.5 for the most hydrophilic amino acid (arginine). The mean hydropathy index of stretches of a protein sequence can be determined by computer; 19 residues with a mean hydropathy index of greater than 1.6 distinguish transmembrane helices from hydrophobic domains buried in the center of globular proteins. Thus, a mean hydropathy index is calculated for residues 1 through 19 of a protein, then residues 2 through 20, and so on. The analysis predicts that highly hydrophilic, even charged, residues can reside in the membrane lipid, provided the number of hydrophobic residues in the vicinity is sufficient to favor stable partitioning in a hydrophobic phase. This prediction is supported by experimental evidence: mutations that introduce charged residues into transmembrane domains do not necessarily alter transport function.

A sample hydropathy plot for the plant K^+ channel protein KAT1 is shown in panel A of the accompanying figure, and the interpretation of the results in terms of transmembrane topology is shown in panel B. Experimental confirmation of predictions arising from hydropathy analysis is highly desirable. Ideally, transmembrane domains can be identified from crystal structures. An alternative experimental approach is to construct chimeric proteins, inserting a reporter enzyme, such as alkaline phosphatase, at various positions within the transmembrane protein. For example, a gene construct that encodes an alkaline phosphatase inserted at one of two locations within KAT1—glutamate-95 (D95) or lysine-128 (K128) (panel B)—is expressed in *Escherichia*

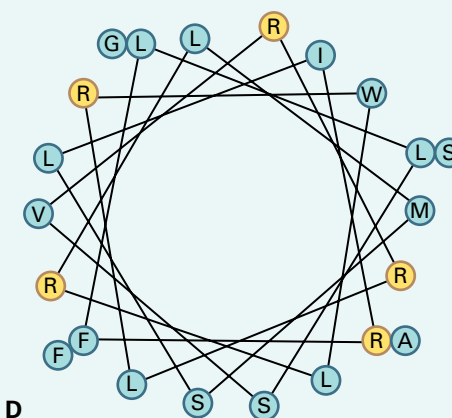

A

B

C

D

coli. If the alkaline phosphatase domain of the chimeric protein is located in the cytosol of *E. coli*, enzyme activity is unstable; if located in an extracellular domain, however, the activity of the enzyme is stable. Alkaline phosphatase activity is detected for chimera D95 but not for chimera K128 (panel C). This finding is consistent with the hydrophathy analysis because D95 and K128 are on opposite sides of the membrane and therefore must be separated by a transmembrane domain. In practice, many such constructs must be used to determine the topology of the complete protein. This method confirmed the transmembrane topology of KAT1 shown in panel B.

More refined theoretical approaches have been devised since the advent of hydrophathy analysis, including techniques to maximize charge–charge pairings within the membrane. Viewed from above the plane of the membrane, the α -helices of a membrane protein can be visualized as helical wheels (panel D). In this representation of the first 22 amino acids of the S4 transmembrane domain of KAT1, each letter represents an amino acid residue (standard amino acid code). Positively charged arginine residues are shown in yellow. Charged residues of opposite polarity on different helices tend to associate with each other, contributing to the tertiary structure of the protein.

FIGURE 3.2 Overview of chemiosmotic processes in an idealized plant cell. In mitochondria and chloroplasts, energy in H^+ gradients is harvested to synthesize ATP. Proton gradients are also established across the plasma membrane and tonoplast by pumps that hydrolyze ATP and PP_i . The electrochemical potential established by these pumps is used to move many ions and small metabolites through integral membrane channels and cotransporters.

3.1.6 Chemical and electrical potential gradients drive transport across membranes

The net direction of transport across a membrane is dictated by the driving force on the transport system. Driving forces can be quantified in terms of the free energy relationships

inherent in transmembrane solute potentials (Box 3.2), whether these involve H^+ , other inorganic ions, or organic solutes such as sugars and amino acids. The magnitude of a transmembrane potential for an uncharged solute ($\Delta\mu$) or for an ion ($\Delta\bar{\mu}$) can be described in units of free energy (kJ mol^{-1}) normally associated with scalar reactions. The polarity (sign) of transmembrane electrochemical potential for a solute determines the direction of flow. At the plasma membrane, a

BOX
3.2

The electrochemical potential of a solute is defined by differences in concentration and charge

The **chemical potential** of an uncharged solute, S , in a given medium is defined by Equation 3.B1, where μ_s° is the **standard chemical potential** of S at 1 molar concentration (1 M), R is the gas constant ($8.314 \text{ J mol}^{-1} \cdot \text{K}^{-1}$), T is absolute temperature (in Kelvin), and $\ln(a)$ is the natural logarithm of the activity, a , of the solute. For uncharged solutes, a can be expressed as molar concentration, but for charged solutes, a is used to account for incomplete dissociation (solubilization) of the solute. The units of chemical potential are Joules per mole ($\text{J} \cdot \text{mol}^{-1}$).

$$\mu_s = \mu_s^\circ + RT \cdot \ln(a) \quad (\text{Eq. 3.B1})$$

Suppose we have a membrane separating two aqueous media, one inside the cell (denoted by the subscript c for cytosol) and the other outside the cell (denoted by the subscript o), as shown in the figure. We can calculate the chemical potential of an uncharged solute S in each of the two media by using Equation 3.B1. For S in medium c and medium o , we can make the calculations shown in Equations 3.B2a and 3.B2b, respectively.

$$(\mu_s)_c = \mu_s^\circ + RT \cdot \ln[S]_c \quad (\text{Eq. 3.B2a})$$

and

$$(\mu_s)_o = \mu_s^\circ + RT \cdot \ln[S]_o \quad (\text{Eq. 3.B2b})$$

Now we can calculate the **chemical potential difference** for S , $\Delta\mu_s$, across the membrane simply by subtracting Equation 3.B2b from Equation 3.B2a. The standard chemical potential terms cancel each other out, and we are left with Equation 3.B3, the relationship that defines the energy stored in a transmembrane solute concentration difference.

$$\Delta\mu_s = RT \cdot \ln[S]_c - RT \cdot \ln[S]_o = RT \cdot \ln\left\{\frac{[S]_c}{[S]_o}\right\} \quad (\text{Eq. 3.B3})$$

The term $RT \cdot \ln\left\{\frac{[S]_c}{[S]_o}\right\}$ is similar to the Mass Action Ratio term in the equation defining Gibbs free energy, $RT \cdot \ln\left\{\frac{\text{[products]}}{\text{[reactants]}}\right\}$, except that here the reactants and products are defined by their position in space (inside or outside of the cell), not by their chemical modification. The vectorial reaction for S is shown in the figure. Convention dictates that we relate the cytoplasmic compartment to the extracytoplasmic compartment when defining chemical potential differences (thus, Eq. 3.B2b was subtracted from Eq. 3.B2a, and not vice versa).

The polarity of $\Delta\mu_s$ is critical in expressing the energetic relationship of the solute across the membrane. A positive value indicates that free energy must be applied to translocate solute into the cytosol, whereas a

negative value indicates that solute will move passively, given an appropriate transport system. A value of zero indicates equilibrium; i.e., solute concentration is the same on each side of the membrane. Just as the Gibbs free energy change describes the equilibrium position of a reaction but not the rate at which equilibrium is reached, so too the magnitude of the chemical potential difference describes the energetics of transport but cannot be used to predict rates of transport.

Let us now consider an ion, I , carrying a net charge of z , which is positive for cations and negative for anions. Because the ion bears a charge, the overall energetic potential of the ion will be influenced by the electrical potential (V_m) across the membrane. This involves adding an extra term to Equation 3.B1, so that we can now express the **electrochemical potential** of the ion as in Equation 3.B4, where $\bar{\mu}_I^\circ$ is the **standard electrochemical potential** of I at 1 molar concentration (1 M), F is the Faraday constant ($96,500 \text{ C} \cdot \text{mol}^{-1}$ [coulombs per mole of electrons]), and v is the electrical potential of the medium in volts. Inclusion of F in the final term has the effect of converting electrical units into $\text{J} \cdot \text{mol}^{-1}$, and since z is dimensionless, all terms in the equation have the same units.

$$\bar{\mu}_I = \bar{\mu}_I^\circ + RT \cdot \ln[I] + zFv \quad (\text{Eq. 3.B4})$$

If we now return to the model cell shown in the figure, we can calculate an **electrochemical potential difference** for the ion I across the membrane in a way analogous to that used to calculate the chemical potential difference for S . Thus, for ion I in media c and o , respectively, we can derive Equations 3.B5a and 3.B5b from Equation 3.B4.

$$(\bar{\mu}_I)_c = \bar{\mu}_I^\circ + RT \cdot \ln[I]_c + zF \cdot v_c \quad (\text{Eq. 3.B5a})$$

and

$$(\bar{\mu}_I)_o = \bar{\mu}_I^\circ + RT \cdot \ln[I]_o + zF \cdot v_o \quad (\text{Eq. 3.B5b})$$

Subtracting Equation 3.B5b from 3.B5a, we obtain Equation 3.B6, where $\Delta\bar{\mu}_I$ is the electrochemical potential difference for I , and $V_m (= v_c - v_o)$ is the electrical potential difference or, more commonly, the membrane potential.

$$\Delta\bar{\mu}_I = RT \cdot \ln\left\{\frac{[I]_c}{[I]_o}\right\} + zF \cdot V_m \quad (\text{Eq. 3.B6})$$

The electrochemical potential difference for an ion is simply the sum of the chemical and electrical potentials. When chemical potential is equal and opposite to

electrical potential, the sum is zero and there is no overall driving force on the ion (i.e., the ion is at equilibrium). For a single ion in media *c* and *o*, setting $\Delta\bar{\mu}_i$ in Equation 3.B6 equal to zero and solving for V_m gives the membrane potential at which the flow for a given ion reverses between inward and outward (Equation 3.B7).

$$V_m = E_{ion} = RT/zF \cdot \ln\{[ion]_o/[ion]_c\} \quad (\text{Eq. 3.B7})$$

This equation can be brought into a more familiar form by replacing the constants *R* and *F*, assuming a temperature around 25°C (*T* = 298 K), and converting the natural logarithm into a base-₁₀ logarithm by multiplying by 2.303:

$$V_m = E_{ion} = 59\text{mV} / z \cdot \log\{[ion]_o/[ion]_c\} \quad (\text{Eq. 3.B8})$$

This potential is referred to as the **equilibrium potential**, E_{ion} , or the **Nernst potential** for that ion.

negative value of $\Delta\mu$ or $\Delta\bar{\mu}$ indicates passive flow from the external medium into the cytosol. Conversely, a positive value indicates that energy input is required for uptake of solute or ion because passive direction of flow is out of the cell.

For an uncharged solute, the free energy expended or released by its transport across a membrane is a function of its transmembrane concentration gradient. For a charged solute, three factors determine driving force: the charge of the solute, the transmembrane concentration gradient, and the difference in electrical potential across the membrane (Box 3.2). This last term is referred to as the membrane potential or membrane voltage and is given the symbol V_m or $\Delta\psi$. Each ionic species has its own concentration-dependent chemical potential, whereas the electrical potential has the same value for every ionic species across a given membrane at a given time. Normally, the membrane voltage across the plasma membrane of plant cells is about -150 mV on the cytoplasmic side relative to the extracellular side. Most organelle membranes are less polarized. A value of -20 mV is commonly cited for the tonoplast, that is, -20 mV in the cytosol relative to the vacuole lumen.

3.1.7 Transmembrane proton gradients are the foundation of the energy economy in plants

Proton electrochemical gradients, often expressed as proton motive force (pmf) in volts (Box 3.3), constitute one of the major energy currencies of the cell, on a par with ATP and NAD(P)H. Transmembrane H^+ potentials established by the electron transfer chains of the inner mitochondrial and chloroplast thylakoid membranes drive the synthesis of ATP (see Chapters 12 and 14). At other membranes in the cell, pumps

hydrolyze ATP to power the transport of H^+ out of the cytosol and into the endomembrane system or extracellular matrix. The resulting transmembrane H^+ potentials are then used to power transport of other ions and solutes across membranes through channels and cotransporters (see Fig. 3.2). First elucidated in the context of ATP synthesis, this chemiosmotic coupling hypothesis is now widely accepted as a universal mechanism of biological energy conservation.

The H^+ pumps at the plasma membrane and organelle membranes are **electrogenic**: they create electrical current because the ions they remove from the cytosol carry charge. Therefore, these pumps not only contribute directly to ΔpH , the chemical component of the proton motive force, but also make V_m , the electrical component, more negative. The quantitative definition of pmf (Box 3.3, Eq. 3.B12) can be used to estimate the free energy contained in the electrochemical potential that is generated by pumping H^+ across the plasma membrane. Typically, cytosolic pH is 7.5 and extracellular cell wall space pH is near 5.5. This 100-fold proton gradient equates to a voltage of approximately -120 mV at 25°C. Assuming a V_m of -150 mV across the cell membrane, pmf is calculated as -150 mV + -120 mV = -270 mV. pmf values ranging from -200 to -300 mV are common in plant cells.

3.1.8 H^+ pumps and K^+ channels are key players in determining the membrane potential of a cell

A membrane potential or voltage results from gradients of cations and anions across the membrane. However, only those ions to which the membrane is permeable at a given time contribute to the membrane potential. For example, when anion channels are activated by signal transduction

BOX
3.3

Proton motive force relates transmembrane pH difference to membrane potential

As shown in Equation 3.B9, the pmf is a measure of the free energy stored in a transmembrane electrochemical potential difference for H^+ , expressed in volts.

$$\text{pmf} = \Delta \bar{\mu}_{H^+} / F \quad (\text{Eq. 3.B9})$$

To calculate $\Delta \bar{\mu}_{H^+}$ (Eq. 3.B10), we write Equation 3.B6 from Box 3.2 explicitly for H^+ .

$$\Delta \bar{\mu}_{H^+} = RT \cdot \ln \left\{ [H^+]_c / [H^+]_o \right\} + zF \cdot V_m \quad (\text{Eq. 3.B10})$$

For H^+ , the charge $z = +1$. Dividing both sides of Equation 3.B10 by F and converting the natural logarithm into a base₁₀ logarithm by multiplying by 2.303, we obtain Equation 3.B11.

$$\text{pmf} = (RT/F) \cdot (2.303) \log \left\{ [H^+]_c / [H^+]_o \right\} + V_m \quad (\text{Eq. 3.B11})$$

Equation 3.B11 can be simplified considerably, because R and F are constants, and the value for the absolute temperature in Kelvin T usually falls within a fairly narrow range. Furthermore, because $\log[H^+]_c = -\text{pH}_c$ and $\log(1/[H^+]_o) = \text{pH}_o$, we can write, for conditions at 25°C, Equation 3.B12, in which the first term on the right-hand side simplifies to 0.0591 V. However, it is more convenient in biological systems to express the pmf (and V_m) in mV, so after multiplying through by 10^3 , Equation 3.B12 becomes $\text{pmf} = 59.1 \text{ mV} [\text{pH}_o - \text{pH}_c] + V_m$, which states that each pH unit change is energetically equivalent to 59 mV of membrane potential.

$$\begin{aligned} \text{pmf} &= [(8.314)(298)(2.303)/(96,500)][\text{pH}_o - \text{pH}_c] + V_m \\ &= 0.0591 \text{ V} [\text{pH}_o - \text{pH}_c] + V_m \\ &= 59.1 \text{ mV} [\text{pH}_o - \text{pH}_c] + V_m \quad (\text{Eq. 3.B12}) \end{aligned}$$

cascades, only then does the typical anion gradient across the plasma membrane actually affect the membrane potential. The amount of ions that need to flow across a biological membrane to change the membrane voltage is actually very small because the cell's capacitance—the amount of charge it can hold for a given V_m —is related to its surface area, and very few electrical charges are needed to charge the small capacitance of most cells (Box 3.4). Membrane potential is a macroscopic parameter. That is, if V_m is measured by comparing the potentials reported by two electrodes placed on each side of the membrane, then no matter how far from the membrane the electrodes are placed, the potential should be the same. Membrane potentials arise across biological membranes in several ways. As noted in Section 3.1.7, metabolically coupled pumps (usually ATPases) that transport H^+ out of the cytosol exert a major influence on the resting value of V_m in cells and tend to drive V_m to negative values (Fig. 3.3). At steady state, continuing operation of electrogenic pumps is compensated by movement of countercharges through other transport systems. Charge movement may consist of a flow of positive charges into the cytosol such as mediated by proton-coupled symporters (see Section 3.4) or a flow of negative charges out of the cell.

The second major factor exerting an effect on the resting value of V_m is the large gradient for K^+ across the plasma membrane and the ensuing transport of K^+ from the cytosol through K^+ channels (see Fig. 3.3). Plants maintain cytosolic K^+ concentrations at around 150 mM. The K^+ concentration in the extracellular wall space is low (e.g. 0.1–5 mM) and at least some K^+ channels are usually open. The tendency of K^+ to exit from the cell through K^+ channels generates an excess

FIGURE 3.3 Mechanisms that control the membrane potential of the plasma membrane. Transfer of positive charge across the membrane from inside to outside makes the membrane potential more negative. Proton pumps and outward K^+ channels are illustrated.

of negative charge inside the cell, yielding a negative value of V_m . However, when membrane voltage becomes too negative, leaking of K^+ from the cell stops. Assuming a 100-fold K^+ gradient across the cell membrane, the negative voltage at which channel-mediated K^+ efflux stops (i.e., the equilibrium potential for K^+ , see Box 3.2) is approximately -120 mV .

BOX
3.4

Biological membrane potentials can change quickly when small amounts of cations or anions flow across the membrane

A membrane potential is the result of a charge difference across the membrane. The charge (Q , in coulombs [C]) stored on a membrane at a particular voltage is a function of the membrane capacitance (C , in coulombs per volt per square meter [$\text{C}\cdot\text{V}^{-1}\cdot\text{m}^{-2}$], i.e., farad per square meter [$\text{F}\cdot\text{m}^{-2}$]) according to the relationship $Q=CV$, where V is voltage. For most biological membranes, C is of the order $0.01 \text{ F}\cdot\text{m}^{-2}$, and for the plasma membrane of a plant cell, V_m averages -150 mV . This yields a net charge of $0.0015 \text{ C}\cdot\text{m}^{-2}$, with anions accumulating in excess of cations on the intracellular side of the membrane compared to the extracellular side.

For a $40\text{-}\mu\text{m}$ -long plant cell, the area of the plasma membrane is 10^{-8} m^2 , assuming the shape of the cell approximates a cube. Hence, converting coulombs to

molar equivalents by using the Faraday constant, the excess negative charge in the cytosol is $(1.5 \times 10^{-3} \text{ C}\cdot\text{m}^{-2}) (10^{-8} \text{ m}^2 \text{ membrane}) / (96,500 \text{ C}\cdot\text{mol}^{-1})$, or roughly $1.5 \times 10^{-16} \text{ eq}$. (Because F refers to the number of ionized species, the results are expressed here in terms of molar equivalents rather than moles.) If the cytosol of this cell occupies 10% of the intracellular volume (with the vacuole occupying most of the rest), the volume of cytosol is 10^{-11} L , so the excess negative charge is $(2 \times 10^{-16} \text{ eq}) / (10^{-11} \text{ L}) = 20 \mu\text{eq}\cdot\text{L}^{-1}$. Given that the total ionic strength of the cytosol is more than $200 \text{ meq}\cdot\text{L}^{-1}$, the ionic imbalance does not exceed 1 part in 10,000. In simple terms this means that very few ions are needed to change the charge of the membrane, because the capacitance of the membrane is very small.

Although the balance between inherently high K^+ permeability and electrogenic H^+ pump activity in plant membranes is usually the main feature that determines their resting V_m , any transport system capable of conducting ions (and therefore current) across the membrane will affect V_m . Under some conditions, membranes exhibit transiently high permeabilities to anions or to Ca^{2+} . This will ordinarily lead to a transient, positive swing in V_m , or membrane depolarization, as anions flow out of the cell or Ca^{2+} ions flow into the cell (see Section 3.3).

3.1.9 Pump, channel, and cotransporter activities interact through their respective impacts on chemical gradients and membrane potential

While it is useful to study individual transporters in isolation, it is important to consider that the action of any transporter in a cell has effects on other transporters by altering the membrane potential or chemical gradients, or both. Thus, the integrated action of pumps, channels and cotransporters determines the ability of a cell to take up nutrients and carry out other physiological functions (Fig. 3.4). Whereas proton pumps actively expend energy to establish a pmf, passive transporters (cotransporters and channels) utilize the energy stored in the pmf. Depending on the transport mechanism of these passive transporters, the electrical potential, the chemical potential, or both are utilized to transport a given solute.

The pmf is especially useful to drive the uptake of negatively charged and neutral solutes. For example, uptake of NO_3^- is energetically unfavorable because V_m is negative,

which would inhibit uptake of a negatively charged nutrient such as NO_3^- . By coupling the uptake of one NO_3^- to the uptake of two H^+ , a H^+ - NO_3^- symporter overcomes this obstacle by mediating the uptake of a net positive charge (see Fig. 3.4). In this way both the H^+ chemical potential and the favorable electrical potential are utilized to enable the uptake of NO_3^- .

The uptake of an uncharged solute like glycine (Gly), on which the negative V_m has no effect, can be mediated by a H^+ -Gly symporter against a glycine gradient (see Fig. 3.4). The function of a 1 H^+ : 1 Gly transporter impacts both the chemical and electrical H^+ potential equally and is balanced out by the extrusion of one proton.

The negative V_m favors the accumulation of positively charged solutes such as K^+ . K^+ is the most abundant cation in the cytosol, and its uptake usually occurs against a fairly steep chemical gradient. Depending on the electrochemical potential for K^+ , uptake of K^+ can occur via channels at intermediate to high external K^+ concentrations (see Fig. 3.4) by utilizing the electrical potential. At lower external K^+ concentrations, K^+ uptake is coupled to the pmf or other favorable potential proposed to occur through a combination of K^+ channels and parallel high-affinity K^+ transporters for which the transport mechanism remains unknown. In the case of a K^+ channel, only the electrical component of the pmf is impacted. By extruding one H^+ per K^+ taken up, the H^+ -pumping ATPase increases the H^+ chemical potential of the extracellular space while maintaining V_m . Therefore channel-mediated K^+ uptake is energetically efficient because it does not dissipate the chemical H^+ gradient.

The energetics of solute uptake has additional implications for regulation of transport function. The steep pmf directed into a plant cell under physiological conditions typically prevents situations where transport is reversed (e.g., release of

FIGURE 3.4 Illustration depicting a plasma membrane H^+ pump (yellow), a channel that functions in K^+ uptake (blue), a H^+ -coupled nitrate transporter (red), and a H^+ -coupled amino acid transporter (green) that mediates the uptake of uncharged amino acids such as glycine (gly). Each solute has its own electrochemical potential (large colored arrows), which is determined by the solute's chemical concentration gradient across the membrane, its electrical charge (if any), and the charge difference across the membrane. If a solute has a higher concentration in the cytosol than in the apoplast, the chemical potential favors solute release. Because living cells generally have a negative membrane potential, the electrical potential favors release of negatively charged solutes and the uptake of positively charged solutes. The electrical potential does not act on uncharged solutes.

NO_3^- and H^+ via a symporter), but when artificial proton and solute gradients are applied, many cotransporters are fully reversible. In either case, there is tight coupling between H^+ and solute transport. Recently obtained crystal structures of cotransporters are revealing how this coupling is achieved. In contrast, ion channels such as a K^+ channel might frequently encounter physiological states where the K^+ electrochemical potential favors K^+ release, for example, when external K^+ concentrations drop after a rain storm. With this class of transporters, gating is important. Gating—the regulation of channel opening and closing—determines under which conditions a channel will allow the movement of substrate (see Section 3.3.5).

3.2 Pumps

3.2.1 F-type ATPases at the inner mitochondrial and thylakoid membranes are H^+ -pumps that synthesize ATP

F-type ATPases (also called ATP synthases) are found in plants at the inner mitochondrial and thylakoid membranes and function in ATP synthesis. These two kinds of membranes contain electron transfer chains driven by redox potential and light energy, respectively, and power the accumulation of protons in the inner membrane space of mitochondria and the lumen of thylakoids (see Chapters 12 and

14). The proton gradient established by these electron transport chains drives “reverse” H^+ flow through the F-type ATPases, thereby resulting in ATP synthesis. One sector of an F-type ATPase, called F_0 in plant mitochondria and CF_0 in chloroplasts, traverses the membrane and forms an H^+ -permeable conduit. The other sector of the enzyme, called F_1 in mitochondria and CF_1 in chloroplasts, readily dissociates from the transmembrane sector, contains adenine nucleotide-binding sites and can hydrolyze ATP *in vitro*. The flow of H^+ through F_0 causes long-range conformational transitions in F_1 that result in the synthesis of ATP.

The subunit composition of F-type ATPases varies according to the ATP-synthesizing membrane in which they are found. Nevertheless, members of this class of H^+ -ATPase contain a “core” of common subunits that are essential for catalysis (Fig. 3.5). Additional subunits probably perform regulatory functions. Regulation is particularly important in chloroplasts at night, when ATP hydrolysis by CF_1 must be prevented in the absence of a light-imposed proton gradient (see Chapter 12).

Crystallographic studies of the F_1 sector $\alpha_3\beta_3\gamma$ complex from bovine mitochondria demonstrated that the three adenine nucleotide-binding sites of the complex (located primarily on the three β subunits), show three distinct conformations. At any given time, one binding site is in an open conformation, another is binding a nucleotide loosely, and the third is binding a nucleotide tightly. These studies lend structural support to the conformational model for proton-driven ATP synthesis, which postulates that ATP is synthesized by F-type ATPases through a process of rotational catalysis.

BOX
3.5

The energetics of solute uptake: some illustrative examples

To illustrate the energetics of solute uptake, let's consider a cell at room temperature that has a 10-fold K^+ gradient across its membrane (higher $[K^+]$ in the cytosol than outside). Using Equation 3.B8 in Box 3.2, we can calculate an E_{K^+} of -59mV . If the membrane potential is more negative than -59mV , the cell can accumulate K^+ using a passive transporter like a channel. If the membrane potential is more positive than -59mV , channel-mediated K^+ fluxes would be directed out of the cell. Hence, in this case, E_{K^+} defines the cell membrane potential range that allows for passive influx of K^+ given the known K^+ concentration gradient. One could also ask the question: assuming a cytosolic $[K^+]$ of 100mM , and an extremely negative membrane potential of -300mV , what is the lowest external $[K^+]$ at which channel-mediated (passive) uptake is theoretically possible? Solving Equation 3.B8 for $[\text{ion}]_o$ one arrives at a concentration of approximately $0.7\ \mu\text{M}\ K^+$!

Although membrane potentials of -300mV have been measured in plant cells and fungi, it may be very hard for plants to maintain such a negative membrane potential and only use channels when solute gradients are steep. For many nutrients, energetically unfavorable solute gradients are overcome by cotransporters, which in plants usually couple solute transport to the pmf. This mechanism has been confirmed for many nutrients, with the exception of K^+ . The proton concentration is higher in the extracellular space (e.g. pH 5.5) than in the cytosol (e.g. pH 7.5). This difference of 2 pH units corresponds to a 100-fold higher proton concentration outside the cell than inside. In a coupled system, the equilibrium potential of each ion is combined to derive an overall equilibrium potential. Equation 3.B13 represents the equilibrium potential equation for uptake of an ion with a single positive charge coupled to the uptake of protons, where m and n designate the transport stoichiometry $m\cdot\text{ion}^+ : n\cdot\text{H}^+$:

$$V_m = 59/(m+n) \cdot (m \cdot \log\{[\text{ion}^+]_o/[\text{ion}^+]_c\} + n \cdot \log\{[\text{H}^+]_o/[\text{H}^+]_c\}) \quad (\text{Eq. 3.B13})$$

Because pH is a logarithmic value, Equation 3.B13 can be simplified to:

$$V_m = 59/(m+n) \cdot (m \cdot \log\{[\text{ion}^+]_o/[\text{ion}^+]_c\} + n \cdot \Delta\text{pH}) \quad (\text{Eq. 3.B14})$$

with $\Delta\text{pH} = \text{pH}_c - \text{pH}_o$.

Assuming $\text{pH}_c = 7.5$ and $\text{pH}_o = 5.5$, and $[\text{K}^+]_c = 100\text{mM}$ and $[\text{K}^+]_o = 1\ \mu\text{M}$, Equation 3.B13 or 3.B14 tells us that a cell needs to hyperpolarize the cell membrane to more negative than -88.5mV for a $1\text{K}^+ : 1\text{H}^+$ transport stoichiometry, or only -19.7mV for a $1\text{K}^+ : 2\text{H}^+$ transport stoichiometry. Channel-mediated uptake would require a membrane potential more negative than -290mV . Even though the logic of this equation is compelling, plant scientists have not yet unequivocally confirmed a $\text{K}^+ : \text{H}^+$ cotransporter for K^+ uptake. Thus, biology does not always conform to elegant theories. In addition, since K^+ channels can adjust the membrane potential to very negative voltages, they were proposed in early research to provide a mechanism for proton pump-driven K^+ uptake at low external K^+ concentrations. But other charged substrates, such as NO_3^- , have clearly been shown to be transported via proton cotransport.

As mentioned in Section 3.1.9, proton coupling is especially useful for the uptake of negatively charged (anionic) substrates. Equation 3.B8 illustrates why: for channel-mediated uptake of an anion with a single negative charge (e.g. NO_3^-) against a 10-fold concentration gradient, the membrane potential would need to be more positive than $+59\text{mV}$ inside the cell, a positive value that occurs only transiently, if at all, in most plant cells. Equation 3.B15 describes the equilibrium potential for a cotransporter that couples the uptake of one anion with one negative charge to the uptake of two protons, and thereby converts the uptake of one negative charge to the uptake of one net positive charge:

$$V_m = 59 \cdot (\log\{[\text{ion}^-]_o/[\text{ion}^-]_c\} + 2 \cdot \Delta\text{pH}) \quad (\text{Eq. 3.B15})$$

Using the same proton gradient as above and uptake against a 10-fold anion gradient, Equation 3.B15 tells us that the membrane potential needs to be more negative than $+177\text{mV}$, a condition that is likely always met.

According to the conformational model, ADP and inorganic phosphate (P_i) first bind to the open nucleotide binding site. Proton flow through the F_o sector of the enzyme causes a rotor composed of the $\gamma\epsilon_{10}$ subunits to rotate relative to a stator formed from the $\alpha_3\beta_3\delta\text{ab}_2$ subunits. Thus proton

flow through F_o is coupled to catalysis in F_1 by rotation of the γ subunit. Rotation of γ alters the conformation of all three nucleotide-binding sites. The tight-binding site opens and releases newly formed ATP into the aqueous medium, the open site is converted to a loose-binding site, and the

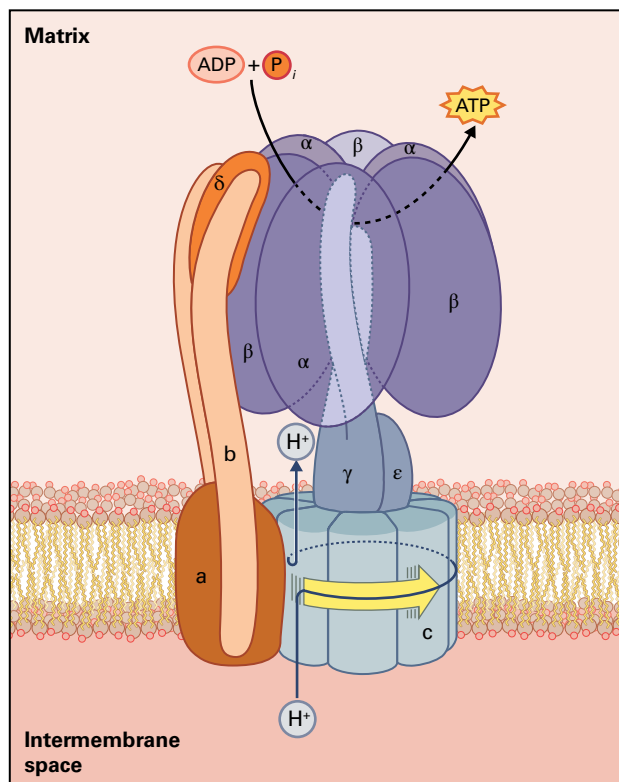

FIGURE 3.5 Structure of the core subunits of the mitochondrial ATP synthase, an F-type H^+ -ATPase. The common subunits of the F_0 sector are known as a, b, and c. In the complex from *E. coli*, these subunits are present in a stoichiometry of ab_2c_{9-12} . Subunit c is a small (8 kDa) and extremely hydrophobic subunit with two transmembrane spans. Subunit b possesses one transmembrane span and is thought to project from the membrane surface to interact with the F_1 sector. A core of five distinct subunit types are present in the F_1 sector in the stoichiometry $\alpha_3\beta_3\gamma\delta\epsilon$. Three nucleotide-binding sites are located primarily on the three β subunits. The yellow arrow indicates the direction in which the c subunits are proposed to rotate during proton translocation. Rotation of the c subunits is thought to drive rotation of the γ subunit and thereby alter the conformation of the nucleotide-binding sites (see Fig. 3.6).

loose-binding site forms a tight pocket in which ATP is produced spontaneously (Fig. 3.6). In net terms, a total of three or perhaps four protons are admitted through the F_0 sector for each ATP synthesized. Video microscopy has been used to visualize rotational catalysis in experiments where either F_1 or F_0 was immobilized, and the other subunit complex was labeled with actin filaments or gold beads that could be observed directly. Rotation rates as high as 500 revolutions per second were observed for the enzyme from *E. coli* labeled with 40-nm gold beads.

3.2.2 P-type ATPases covalently bind the γ -phosphate of ATP during catalysis

The class of ion-motive ATPases known as P-type ATPases is named for the presence of a covalent enzyme–phosphate (E–P) transition state during the reaction cycle. During hydrolysis of MgATP, the γ -phosphate of ATP becomes transiently but covalently bound to an aspartyl residue on the enzyme, forming an acyl–phosphate bond. Structural studies of P-type ATPases suggest that both formation and hydrolysis of this acyl–phosphate bond, in addition to binding of ATP and release of ADP, orchestrate conformational changes within the pump to drive ion transport.

P-type ATPases include the plasma membrane (PM) H^+ -ATPases of plants and fungi, the Na^+/K^+ -exchanging ATPase ubiquitous in the plasma membrane of animal cells, Ca^{2+} -ATPases of the plasma membrane and endomembranes of animals and plants (see Section 3.2.6), and the H^+/K^+ -exchanging ATPase of mammalian gastric mucosa. All P-type ATPases are inhibited by orthovanadate ($H_2VO_4^-$), which forms an analog of the E–P transition state and blocks the reaction cycle. Furthermore, all P-type ATPases share a common domain structure that reflects their functional attributes (Fig. 3.7).

FIGURE 3.6 Model for the synthesis of ATP by an F-type H^+ -pumping ATPase. At any one time, each of the three nucleotide-binding sites has a distinct conformation: One site is open (O), another binds loosely (L), and the third binds tightly (T). Proton flow through the ATP synthase causes the γ subunit to rotate. This rotation changes the conformation of the three nucleotide-binding sites in panel 1 to those in panel 2 such that the O site becomes an L site, the L site becomes a T site, and the T site becomes an O site. ADP + P_i initially bind to a site in the O conformation and are condensed to form ATP on conversion of the binding site to the T conformation. Release of ATP is from the O site (panel 2) and binding of ADP + P_i to the O site (panel 3) occurs prior to the next rotational event.

FIGURE 3.7 Diagrams illustrating the membrane topology and location of the C-terminal auto-inhibitory domain (AID) in P-type H^+ -ATPases (A) and the N-terminal AID in plant PM-type Ca^{2+} -ATPases (B). The two regions of the H^+ -ATPase AID are designated RI and RII. The calmodulin-binding domain (CaMBD) of the Ca^{2+} -ATPase and essential phosphorylation sites in the 14-3-3 binding domain (BD) of the H^+ -ATPase are also indicated.

3.2.3 Unlike the F-type ATPase, which harnesses pmf to drive ATP synthesis, the P-type PM H^+ -ATPase generates pmf by hydrolyzing ATP

The PM H^+ -ATPase is a single polypeptide of about 100 kDa that pumps one H^+ out of the cell for each MgATP hydrolyzed. Different conformations of the enzyme, known as the E_1 and E_2 states, expose the H^+ -binding site to alternate sides of the membrane (Fig. 3.8). The conformational change that exposes the bound H^+ to the apoplast is linked to additional conformational transitions that lower binding-site affinity, permitting H^+ dissociation.

The proton gradient generated by PM H^+ -pumping ATPase is utilized by a variety of cotransporters to energize transport and influences ion channel activity through its impact on V_m . PM H^+ -ATPase is also critical in removing excess H^+ from the cytosol. Many metabolic pathways result in net production of protons, some of which must be removed to prevent acidification of the cytosol. In fact, cytosolic pH is remarkably stable, remaining at 7.1–7.5.

Unlike F-type H^+ -ATPases, which synthesize ATP at the expense of the proton gradient, PM H^+ -ATPases catalyze the same reaction in reverse. How is the direction of the reaction determined? The relative sizes of the driving forces do not answer this question; the ΔG for ATP hydrolysis in the mito-

FIGURE 3.8 Reaction cycle for P-type ATPases. Protons bind to the ATPase in the E_1 conformation. Hydrolysis of ATP and phosphorylation of the enzyme cause a change to the E_2 conformation. The lower affinity of E_2 for H^+ results in the release of protons on the other side of the membrane from where they were acquired. Hydrolysis of the enzyme–phosphate bond releases P_i and returns the ATPase to the E_1 state.

chondrial matrix is probably similar to that in the cytosol, being about $-50 \text{ kJ}\cdot\text{mol}^{-1}$. Likewise, the electrochemical potential for protons ($\text{pmf}\cdot F$) is similar across both the inner mitochondrial and plasma membranes, with a value near $+25 \text{ kJ}\cdot\text{mol}^{-1}$. To resolve this apparent paradox, we must also take into account the reaction stoichiometry, the number (n) of H^+ moved per ATP hydrolyzed or synthesized. In Reaction 3.1, H^+_i and H^+_o refer, respectively, to H^+ on the inside or outside

of the membrane. The free energy relationship is defined in Equation 3.1. If ΔG_{pump} is negative, the pump reaction proceeds from left to right, as written, whereas a positive value indicates the reverse reaction. Thus, for PM H^+ -ATPase, which hydrolyzes one ATP for each proton pumped, $n = 1$ and $\Delta G_{\text{pump}} = -25 \text{ kJ mol}^{-1}$. In contrast, for mitochondrial F-type ATPase, which translocates several protons per molecule of ADP phosphorylated, $n = 3$ and $\Delta G_{\text{pump}} = +25 \text{ kJ mol}^{-1}$. This difference in net direction can be likened to pushing cars uphill. A person might make headway with one car, but additional cars will overcome the force applied by the person and will roll back down the hill.

Reaction 3.1

3.2.4 PM H^+ -ATPases are encoded by a multigene family that exhibits tissue-specific expression

PM H^+ -ATPases in *Arabidopsis* are encoded by genes of the *AHA* family. At least 10 *AHA* genes have been identified, each encoding a distinct PM H^+ -ATPase isoform. The PM H^+ -ATPases of *Solanum lycopersicum*, *Nicotiana tabacum* and other plant species are also members of multigene families. Studies using the *GUS* reporter gene fused to the promoter regions of specific *AHA* genes have revealed that isoform expression is to a degree tissue specific. For example, *AHA3* is expressed selectively in phloem companion cells, the micropyle, and the developing seed funiculus (Fig. 3.9A). Analysis of plants with mutations in the *AHA3* gene demonstrated that *AHA3* is essential for normal pollen formation. In contrast, *AHA10* is expressed principally in developing seeds, especially in the integument surrounding the embryo (Fig. 3.9B). Isoforms also have different biochemical activities. *AHA1* and *AHA2* have K_m values for ATP of 0.15 mM, while the K_m of *AHA3* is 10-fold higher.

3.2.5 PM H^+ -ATPase is regulated by an array of mechanisms.

Most enzymes that play pivotal roles in metabolism are subject to intense regulation, and PM H^+ -ATPase is no exception. The pump is activated in response to lowered cytosolic pH. The C-terminal cytosolic region of the enzyme (see Fig. 3.7A) forms an auto-inhibitory domain consisting of two conserved regions, RI and RII. Removal of the auto-inhibitory domain by proteolytic cleavage or genetic modification activates the H^+ -ATPase considerably.

FIGURE 3.9 Tissue-specific expression of genes for PM H^+ -ATPase isoforms in *Arabidopsis*. (A) Stem cross-section from *Arabidopsis* expressing an *AHA3-c-Myc* fusion protein and labeled for immunofluorescence detection of the H^+ -ATPase. Cell-specific labeling is seen in a subset of phloem (p) cells but not in cortical (c) or autofluorescent xylem (x) cells. (B) The *AHA10* gene promoter is expressed in developing seeds, as shown by *b*-glucuronidase (*GUS*) staining. Two developing seeds (arrows) are shown in an *Arabidopsis* silique. The blue color in the seed to the right indicates expression of an *AHA10-GUS* fusion protein.

Point mutations in either of the two conserved regions have a similar effect.

A striking twist to C-terminal H^+ -ATPase inhibition has been observed during studies with fusicoccin (FC) (Fig. 3.10), a toxin produced by the fungus *Fusicoccum amygdali*, a pathogen affecting peach and almond trees. FC elicits an increase in guard cell turgor, thereby opening stomata and causing leaves to wilt. The toxin's primary mode of action is stimulation of PM H^+ -ATPase, not only in stomatal guard cells but also in a range of plant cell types. FC activates the enzyme by relieving C-terminal auto-inhibition. The FC receptor is a 14-3-3 protein. These soluble proteins function as dimers and bind to target proteins at a defined consensus sequence that includes a phosphorylated Serine (Ser) or Threonine (Thr) residue. Regulation of the H^+ -ATPase by 14-3-3 proteins occurs in the absence of FC in uninfected plants through an interaction of 14-3-3 dimers at its C terminus. Phosphorylation of the penultimate Thr residue stabilizes 14-3-3 binding and increases pump activity. This phosphorylation is sensitive to environmental factors. For example, phosphorylation occurs in guard cells in response to blue light and in root cells in response to aluminum stress.

FIGURE 3.10 Structure of fusicoccin, a toxin produced by a fungal pathogen of plants, *Fusicoccum amygdali*, that stimulates the P-type H^+ -ATPase.

Mutational analysis and X-ray crystallography have been used to establish a model for H^+ -ATPase activation through 14-3-3 binding (Fig. 3.11). In this scheme, H^+ -ATPase exists in an inactive state as a dimer and interactions between the auto-inhibitory domains maintain the pump in an inactive state. Phosphorylation of the penultimate Thr residue promotes binding of a 14-3-3 dimer that prevents inhibition of pump activity by the auto-inhibitory domain. Further association with two additional 14-3-3 dimers and two pairs of H^+ -ATPase monomers results in the formation of an active, hexameric complex. *F. amygdali* has apparently co-opted this native scheme for the regulation of H^+ -ATPase activity, as FC binds to a preformed H^+ -ATPase-14-3-3 complex and stabilizes the enzyme in the active state.

An additional and separate mechanism of activation of H^+ -ATPase contributes to auxin-induced stimulation of proton pumping (see Chapter 2). In this case, auxin upregulates expression of the pump. For example, in *Zea mays* (maize) coleoptiles, auxin stimulates pump expression and cell wall acidification in nonvascular tissue but not in vascular tissue.

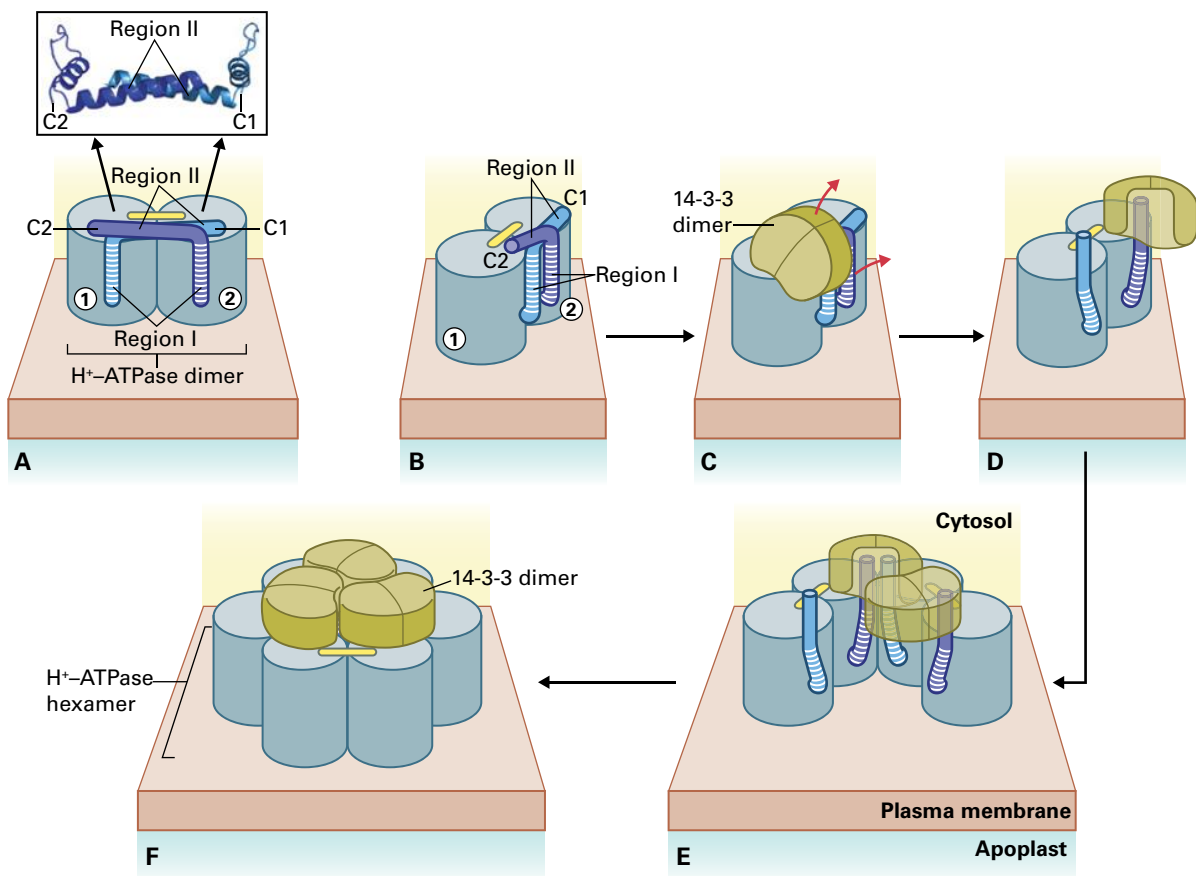

FIGURE 3.11 A model for activation of the PM H^+ -ATPase by phosphorylation and binding of 14-3-3 proteins. In (A) and (B) a H^+ -ATPase dimer (monomers are blue and links between monomers are indicated as yellow links) is shown in an inactive state with interacting C-terminal auto-inhibitory domains (illustrated as blue tubes). In (C) through (E), phosphorylation of the penultimate Thr within the H^+ -ATPase allows 14-3-3 binding. Binding of the H^+ -ATPase with the 14-3-3 induces a conformational change (red arrows), which (D) abolishes the intermolecular contacts of the auto-inhibitory regions II, finally resulting in (E), a complex of two H^+ -ATPase dimers. (F) Association of a third 14-3-3/ATPase dimer generates the active hexameric complex.

3.2.6 Ca^{2+} -ATPases, another group of P-type ATPases, are distributed among various plant membranes

Calcium-pumping ATPases are distributed in the plasma membrane, ER, chloroplast envelope, and tonoplast. These enzymes pump Ca^{2+} out of the cytosol, thereby maintaining the cytosolic concentration of free Ca^{2+} at about $0.2 \mu\text{M}$. This low concentration of free Ca^{2+} is essential in all cells to prevent precipitation of phosphates, but in eukaryotes it has become the basis for stimulus–response coupling pathways. Cytosolic Ca^{2+} can be increased many-fold in response to physiological stimuli without exceeding the low micromolar range.

Names for the two distinct classes of Ca^{2+} -ATPases found in plants reflect the cellular location of homologous pumps in animals. Unlike their animal counterparts which are only found in the plasma membrane, plant Ca^{2+} -ATPases of the plasma membrane type are found in plasma membrane, endomembranes (including ER), and the chloroplast inner envelope. These Ca^{2+} -ATPases are calmodulin (CaM) activated and possess an N-terminal CaM-binding domain (see Fig. 3.7B), in contrast to the C-terminal CaM-binding domain of animal PM-type Ca^{2+} -ATPases. In fact, plant PM-type Ca^{2+} -ATPases are the only examples yet reported of P-type ATPases regulated by their N termini. The second class of Ca^{2+} -ATPases is formed by ER type Ca^{2+} -ATPases, which in animals and plants have no CaM-binding domain. An *Arabidopsis* ER-type Ca^{2+} -ATPase identified by molecular cloning has been localized immunochemically to the ER.

The electrochemical potential against which Ca^{2+} must be pumped by these enzymes is vast, not only because the concentration of cytosolic free Ca^{2+} is several orders of magnitude less than that on the other side of the membrane, but also because the negative membrane potential opposes the export of divalent cations with double the effective force imposed on monovalent cations.

3.2.7 The tonoplast and other endomembranes are energized by vacuolar (V-type) H^+ -ATPases

The lumen of plant vacuoles is acidic, with a pH near 5.5, about 2 pH units lower than that of the cytosol. In most unripe fruits and some citrus fruits, the vacuolar pH can drop below 3, imparting a sour taste to the tissue as a whole. Proton pumping into the vacuolar lumen is catalyzed by V-type H^+ -ATPases that energize the membrane for cotransporter-mediated transport and generate the low pH of the vacuole, where hydrolases with acidic pH optima are located. Evidence is strong that V-type ATPases are also present in membranes of the ER, Golgi, and clathrin-coated vesicles of plant cells (as is the case in yeast and animal cells). The acidic pH of these compartments may contribute to vesicle sorting, membrane trafficking, and protein targeting (see Chapter 4).

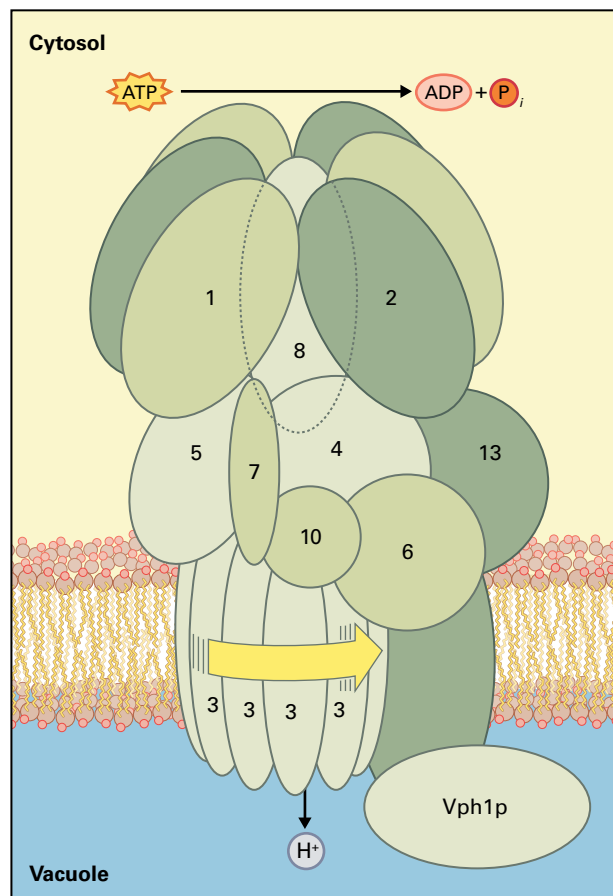

FIGURE 3.12 Structural model of a V-type H^+ -ATPase from *Saccharomyces cerevisiae*. The numbered subunits correspond to the protein products of VMA1–VMA8, VMA10, and VMA13; an additional subunit, Vph1p, is also shown. A hexameric subunit array in V_1 is generated by three copies each of subunit 1 and subunit 2 (homologous to the β and α subunits of the F-type ATPase, respectively). Another eight or so subunits also contribute to V_1 . The V_0 sector contains multiple copies of subunit 3 (a dominant, highly hydrophobic subunit of 16 kDa that arose from a duplication and fusion of the gene for the 8-kDa subunit c of F_0) and four additional subunits.

Sequence analysis has demonstrated that V-type ATPases are distant relatives of F-type H^+ -ATPases that operate solely in the direction of ATP hydrolysis. The ratio of H^+ translocated per ATP hydrolyzed has been measured as 2, although some evidence suggests that pump stoichiometry depends on luminal pH, with a low pH resulting in average ratios less than 2.

At the protein level, the structure–function partitioning in sectors of F-type and V-type H^+ -ATPases has been retained (Fig. 3.12). Thus the V-type enzyme can be separated into a soluble V_1 sector, analogous to F_1 and including the adenine nucleotide binding sites, and a membrane-bound V_0 sector, analogous to F_0 and composing the H^+ pathway through the membrane. As might be anticipated, there is some sequence homology between subunits in the V_1 and F_1 sectors and also between subunits in the V_0 and F_0 sectors. However, V-type H^+ -ATPases have a more complex subunit composition than F-type H^+ -ATPases, and some evidence indicates that subunit composition for the V-type enzyme is variable. V-type

H⁺-ATPases are potently and specifically inhibited by the macrolide antibiotic bafilomycin A₁, an extremely hydrophobic compound produced by *Streptomyces* that interacts with the V_o sector of the enzyme.

3.2.8 The tonoplast has a unique H⁺-pumping inorganic pyrophosphatase (H⁺-PPase)

A supplementary H⁺ pump in the tonoplast of plants uses the free energy of hydrolysis of PP_i, rather than ATP, to pump H⁺. Whether H⁺-PPases may actually also transport K⁺ remains controversial. In contrast to V-type ATPases, the PPase is a relatively simple enzyme composed of a single class of 80-kDa polypeptide that possesses as many as 17 membrane-spanning domains. The functional unit of the pump is probably a homodimer. The H⁺-PPase is ubiquitous in plants, and is found in a few species of Protozoa, Eubacteria, and Archaea. In plants, H⁺-PPases have been mainly localized to the tonoplast and Golgi.

3.2.9 ABC-type pumps are major players in sequestration of amphipathic metabolites and xenobiotics into the vacuole

A wide range of secondary metabolites, including flavonoids, anthocyanins, and breakdown products of chlorophyll, are sequestered in vacuoles where they are isolated from metabolic

pathways or play a defense role. In addition, several xenobiotics—synthetic compounds such as herbicides—can be effectively detoxified by vacuolar sequestration. Transport of these compounds into vacuolar vesicles is dependent on ATP but is not sensitive to protonophores that dissipate the proton gradient. This indicates that transport is directly ATP dependent rather than indirectly dependent through secondary coupling to the pmf. Furthermore, transport is not sensitive to the V-type ATPase inhibitor bafilomycin but is sensitive to vanadate.

Amphipathic compounds are moved across the vacuolar membrane by pumps known as ATP-binding cassette (ABC) transporters. The ATP-binding cassette is widely distributed among enzymes that bind ATP (including F-type ATPases) and includes the so-called Walker A and B motifs (Fig. 3.13). The family of ABC transporters is ancient and is found in all domains of life. Mammalian ABC transporters, which have been extensively characterized, transport a wide range of compounds, including chemotherapeutic drugs and proteins. In bacteria, some ABC transporters are involved in uptake of simple nutrients such as phosphate and amino acids, and in *S. cerevisiae* an ABC transporter exports mating factor. The defining feature of ABC transporters is their domain structure: a stretch of transmembrane spans, followed by a nucleotide-binding fold that incorporates the Walker motifs. This domain structure is duplicated in both the N- and C-terminal halves of the transporter (Fig. 3.13). Crystal structures of ABC transporters show that a single transporter is composed of two transmembrane domains and two nucleotide-binding domains. However, not all ABC transporters are encoded by a single gene: some ABC transporter genes encode half a transporter, which presumably can form homo- or heterodimers,

FIGURE 3.13 Model of MRP2, a vacuolar ATP-binding cassette (ABC) transporter from Arabidopsis. Two nucleotide-binding folds, NBF1 and NBF2, each contain Walker motifs A and B. The NBFs are separated by transmembrane domains containing multiple integral membrane helices.

FIGURE 3.14 Transport of a glutathione-conjugated xenobiotic and a chlorophyll catabolite by AtMRP2, an ABC transporter from *Arabidopsis*. (A) Structures of the glutathione-conjugated xenobiotic dinitrophenol (DNP-GS) and a linear tetrapyrrole from *Brassica napus* (Bn-NCC-1). In the Bn-NCC-1 structure, R represents a malonyl group. (B) Concentration-dependent uptake of DNP-GS and Bn-NCC-1 by AtMRP2.

and some transporters are encoded by four genes (two transmembrane domain and two nucleotide binding domain genes), or a combination of these.

Whole genome sequences indicate that plants possess well over a hundred ABC transporter genes, constituting the largest transporter gene family, suggesting roles as diverse as those described for other organisms. For example, many xenobiotics are sequestered in plant vacuoles after glucosylation, and ABC transporters are possibly involved in sequestration. Other compounds, including flavonoids and some xenobiotics, are known to be transported by ABC transporters as glutathione conjugates (GS-conjugates). In these cases, the compound must first be linked to glutathione by a glutathione S-transferase reaction. Yet other compounds (e.g. the linear tetrapyrrole catabolites of chlorophyll) are transported without prior conjugation. One *Arabidopsis* ABC transporter, MRP1, appears to translocate GS-conjugates exclusively. Another, MRP2 (Fig. 3.13), translocates not only GS-conjugates but also unmodified chlorophyll catabolites (Fig. 3.14). Several mammalian ABC transporters also demonstrate broad substrate specificities that are atypical of transport systems in general; most non-ABC transporters exhibit strong selectivity for the preferred substrate.

A great deal remains to be discovered concerning plant ABC transporters. The complete crystal structures of two *E. coli* ABC transporters, the vitamin B12 importer BtuCD and the lipid exporter MsbA, suggest that transport mechanism might depend on each specific transporter. A comparison between the structures of BtuCD and MsbA showed that number and position of transmembrane helices varies. For example, the complete BtuCD transporter has 10 + 10 transmembrane alpha helices rather than the canonical 6 + 6, and they are arranged in such a way to accommodate entry of the large vitamin B12 substrate from the aqueous periplasm. The lipid substrate for MsbA is thought to enter from the inner leaflet of the plasma membrane between the transmembrane

domains of the transporter. The MsbA structure was obtained in the absence of lipids, so it is not clear whether the transporter has a lipid-filled pore that can accommodate a hydrophobic substrate, or whether the substrate is “flipped” to the other side of the membrane in a reaction occurring at the interface of the ABC transporter and the membrane lipid.

3.3 Ion channels

3.3.1 Ion channels are ubiquitous in plant membranes

In the early 1950s, voltage-activated selective fluxes of ions that cause action potentials were described during classic studies on squid axons. Action potentials are generated when the membrane is depolarized to a voltage more positive than a threshold. A substantial further depolarization then follows, but this is transient and the membrane potential (V_m) returns rapidly to its negative resting potential, typically after 0.001 to 0.002 s in axons. Such cells are said to be “excitable.” In the nervous systems of animals, action potentials have well-known signal propagation roles. Some types of plant cells are excitable, such as algal cells, although the action potentials are about three orders of magnitude slower than those of their animal counterparts. The best-studied action potentials in plants occur in the giant internodal cells of charophyte algae, where their function remains unknown (Fig. 3.15). A few terrestrial plant cells are also excitable, especially those exhibiting rapid changes in size. In *Mimosa pudica*, leaf stroking evokes an action potential that causes the pulvinus, a hinge region at the base of the leaf, to lose turgor and collapse the leaf. Some insectivorous plants (e.g., *Dionaea muscipula* and *Drosera* spp.) also use action potentials to couple the sensing of prey to subsequent leaf movements.

FIGURE 3.15 An action potential as seen in the large internode cells of some algae. In response to a depolarizing, stimulating pulse, the membrane potential rapidly depolarizes further. This depolarization phase is followed by a much slower repolarizing phase, during which ion fluxes return the V_m to nearly its initial value.

These rather specialized examples appear to be exceptions, and the major roles of plant ion channels are substantially different from animal paradigms. Little was known about plant ion channels before the mid 1980s, when technologies developed for neurophysiological investigations were applied to plant cells and demonstrated the presence of ion channels in a “non-excitabile” plant cell, the guard cell. Ion channels are now known to be present in all plant cell types and at all membranes that have been analyzed. Research on guard cell ion channels has led to present models of the functions of a network of plant ion channels acting in concert to mediate physiological processes. Studies in specific cell types (e.g., guard cells, root epidermal cells, and xylem parenchyma) have employed the tools of electrophysiology, genetics, molecular biology, and genomics to assign and model specific properties and biological functions of various classes of plant ion channels.

3.3.2 Ion channels are studied with electrophysiological techniques

The **patch clamp** technique (Box 3.6) made possible dramatic advances in our understanding of plant ion channels. Developed by the early 80s for detecting and characterizing ion channels in excitable animal cells, the technique is also applicable to plant plasma membranes and intact plant vacuoles. In essence, the patch clamp technique allows detection of small electrical currents that ions carry as they flow through channels. The experimenter can control all the components of the electrochemical driving force, meaning the media on both sides of the membrane and, by using a feedback amplifier, the transmembrane voltage.

The patch clamp technique can be used to resolve the activity of single protein molecules (channels) as they conduct ions. Channel activity in single cells can also be measured. Using the whole-cell patch clamp technique, the activity of hundreds or thousands of ion channels in a single cell can be quantified, and changes in activity in response to diverse cellular messengers and stimuli can be studied. By comparing changes in ion fluxes to physiological responses, such as the swelling or shrinking of guard cells, the function of specific channel types has been determined. A major advantage of the patch clamp technique is that transport activity can be analyzed in relatively small cells, meaning that most if not all types of plant cells are amenable to this approach.

Alternatives to the patch clamp technique include the construction of planar lipid bilayers (Fig. 3.16) for the measurement of single channels, and classical microelectrode impalement techniques (Fig. 3.17) for the study of large, whole cells that are not cytoplasmically connected to one another by plasmodesmata. Lipid bilayers can be used to study the activities of channels at intracellular membranes that, by virtue of their dimensions, are not amenable to conventional patch clamp analysis (e.g., ER). Microelectrode impalement recordings can be made using cells with relatively intact cell walls, whereas the patch clamp technique requires the isolation of plant protoplasts.

3.3.3 Ionic fluxes through channels are driven solely by electrochemical potential differences

Ion flow through channels is passive. In contrast to pumps or ion-coupled cotransporters, the direction of ion flow through a channel is dictated simply by the electrochemical potential gradient for that ion, $\Delta\bar{\mu}_{\text{ion}}$ (see Box 3.2). The current passing through a single channel (Fig. 3.18) can be plotted as a function of the membrane potential to yield a current–voltage (I – V) relationship for the channel (Fig. 3.19). If the single channel I – V relationship is linear, it is said to be Ohmic and according to Ohm’s law $I = V/R$, where R is the resistance. The slope of this relationship, $1/R$, is the single-channel conductance (g), measured in picosiemens (pS). The value of g is a measure of the transport rate of the channel and is characteristic for a given channel type under particular conditions. Typically, g increases with the concentration of the permeant ion, so it is important to specify the recording conditions under which g is measured.

Channel-mediated currents that flow into the cytosol are defined as negative, are shown as downward deflections on current traces, and may be carried either by an influx of cations into the cell or an efflux of anions leaving the cell. Conversely, outward currents carried by cation efflux or anion influx are defined as positive and are shown as upward (positive) deflections on current traces. When $\Delta\bar{\mu}_{\text{ion}} = 0$, there is no overall driving force acting on the ion, so the net flux of that ion through the channel is zero, and the current it carries

BOX
3.6

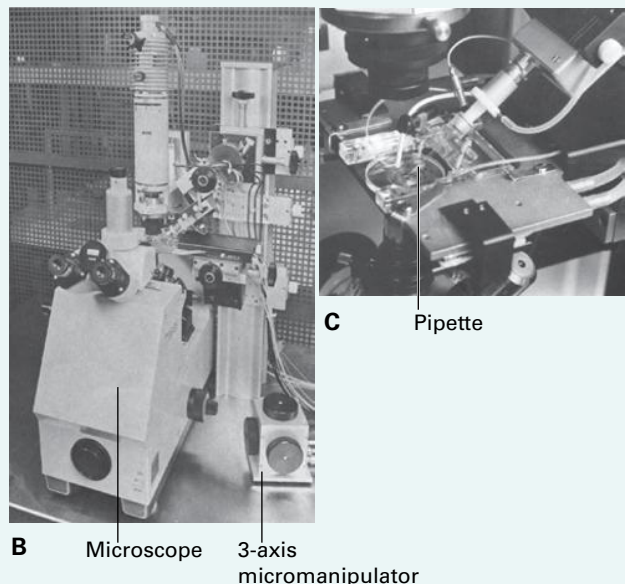

The patch clamp technique is used to measure ionic currents

The patch clamp technique arose from elegant technical advances, theoretical considerations and early “noise” analyses of neurotransmitter activated ion currents. Pushing a blunt-tipped, heat-polished glass micropipette against a biological membrane, and simultaneously applying suction to the inside of the micropipette can form an electrically tight seal. The high resistance of this seal ($>1 \text{ G}\Omega$, or 10^9 ohms) limits current leak between the membrane and pipette (panel A), and the small size of the membrane patch that covers the pipette tip (a few square micrometers) greatly reduces the background noise, allowing the resolution of single proteins, channels.

A typical patch clamp recording apparatus is shown in panels B and C. The patch clamp technique utilizes several recording modes (panel A). Initial seal formation attains cell-attached mode, which can record the activities of individual ion channels but does not allow control of medium composition on the cytosolic side of the membrane. Despite its limited use in plant cells, this recording mode can be applied to channels that lose activity when the cytoplasm is perturbed. Pulling the pipette away from the rest of the membrane generates an inside-out patch, in which the cytosolic face is exposed to the bathing medium. The solution composition on both sides of the membrane is now defined. Alternatively, the membrane patch that covers the pipette tip can be disrupted with a high-voltage pulse or suction, thereby giving electrical access to the inside of the cell. The activities of the ensemble of ion channels in the entire cell membrane can then be monitored in this frequently used whole-cell mode. The relatively large volume of medium in the pipette exchanges rapidly with the cell contents, and becomes the defined intracellular solution. Finally, if the pipette is pulled away from the cell after attainment of the whole-cell mode, a membrane bleb is also pulled away and reseals itself across the pipette tip as an outside-out patch.

To convert the electrical current through an open channel to a rate of transport (ions s^{-1}), the single channel current is divided by the absolute unitary electrical charge of an electron ($1.6 \times 10^{-19} \text{ A}\cdot\text{s}$) and by the charge (valence) of the ion being investigated. For example, Ca^{2+} ions have a charge of +2. A channel-mediated current of 1 pA (10^{-12} A) for the divalent cation Ca^{2+} represents a turnover rate of more than 3 million Ca^{2+} ions per second:

$$[(10^{-12} \text{ A})]/[(1.6 \times 10^{-19} \text{ A}\cdot\text{s})(+2)] = 3.125 \times 10^6 \text{ ions}\cdot\text{s}^{-1}$$

FIGURE 3.16 Measurement of channel activity in planar lipid bilayers. A bilayer of purified lipids can be formed across a small (0.1-mm-diameter) hole in a Teflon partition that separates two chambers. Electrodes are dipped into solutions on either side of the partition and connected to an amplifier. Fractionated plant membrane vesicles introduced into one of the chambers fuse spontaneously with the artificial membrane, thereby incorporating channels into the bilayer and allowing the currents they carry to be measured.

FIGURE 3.17 Recording whole-cell membrane currents with a two-electrode voltage clamp. The cell is impaled with a voltage microelectrode, which is used to establish the electrical potential across the membrane, and a current electrode, which measures the current flowing in or out of the cell.

is also zero. The membrane potential at which the driving force on a specific ion is zero is called the equilibrium or Nernst potential, E_{ion} , for that ion. The equations to calculate E_{ion} were introduced in Box 3.2 (Equations 3.B7 and 3.B8).

3.3.4 Ion channels exhibit ionic selectivity

Channels are not thought to require large conformational changes to catalyze transport. Nevertheless, it would be wrong to think of channels merely as sieve-like pores in a membrane, because they exhibit two additional properties that are essential for their function: **ionic selectivity** and **gating**.

Ion channels display selectivity for their ionic substrates. Most classes of ion channels in plant cells usually discriminate in favor of either cations or anions. Cation channels can

FIGURE 3.18 The recorded activity of a single channel taken from a tonoplast membrane patch. The prevalence of the conductive (O state) increases with imposed membrane voltage in the negative range. O_1 , one channel open; O_2 , two channels open; O_3 , three channels open.

FIGURE 3.19 Current-voltage (I - V) curve for a single channel.

be further subdivided into those that select K^+ or Na^+ over other monovalent cations, those that are relatively nonselective among monovalent cations, and those that are permeable to divalent cations, particularly Ca^{2+} . Most plant plasma membrane anion channels appear to allow permeation of a wide range of anions, including Cl^- , NO_3^- , or organic acids. Distinct types of anion channels in the tonoplast have been described that select either for Cl^- or for organic acids such as malate.

Up to this point, we have emphasized that ion fluxes through channels are monitored as electrical currents. However, currents themselves provide no information on which ions are flowing. In general, this information on ionic selectivity of a channel can be gained through a measurement of the reversal potential (E_{rev} ; see Box 3.7) of the channel under various ionic conditions. E_{rev} is defined as the

voltage at which the current through the channel reverses from inward to outward. In other words, E_{rev} is the zero-current voltage, an experimentally derived parameter for a given transporter. If E_{rev} for the channel is in accord with E_{ion} , the equilibrium potential of a given ion based on biophysical theory (see Box 3.2), this is good evidence that the ion in question is carrying the current. However, channels are often not perfectly selective for a given ion; in these cases, E_{rev} can be evaluated to determine ionic selectivity of one type of ion relative to another type of ion (see Box 3.7). For example, the permeability of a channel for K^+ ions can be determined relative to that of Na^+ ions. The fact that channels are selective implies that sites capable of interacting with and distinguishing between specific ions must be located within channel pores. In some cases, these sites have been identified at a molecular level.

BOX 3.7

Ionic selectivity of ion channels can be determined by measurements of the reversal potential of the channel under various ionic conditions

From a biological point of view, one of the principal interesting features of ion channels in plant cells concerns the identities of the ions that flow through them. Frequently, this issue of ionic selectivity is addressed through measurement of E_{rev} for the channel-mediated currents in various ionic conditions.

Take the example of a channel for which patch clamp recordings of single-channel currents are obtained in symmetrical conditions (100mM KCl on both sides of an outside-out membrane patch). These records of current can be plotted as a function of voltage in the form of a current–voltage (I – V) relationship (see figure). As seen for the curve with square data points, the zero-current potential (E_{rev}) is 0mV under these symmetrical conditions. However, for either K^+ or Cl^- , the logarithm term in Equations 3.B7 or 3.B8 that define the E_{ion} reduces to 0 because the concentration ratio of either ion is 1 (and $\ln 1$ or $\log 1 = 0$). Now, let us suppose that the external KCl concentration is decreased to 10mM in the continued presence of 100mM KCl in the pipette. Now there is a 10-fold concentration difference across the pipette, which is reflected in the I – V curve with circular data points (see figure). The value for E_{rev} is now -59 mV. Comparing this value with E_K (-59 mV) and E_{Cl} ($+59$ mV) shows, by the coinciding values of E_{rev} and E_K , that the channel has perfect selectivity for K^+ over Cl^- . If the channel is permeable to more than one ionic species, its reversal potential is the mean of the individual ionic equilibrium potentials, weighted according to their respective permeabilities.

Selectivity ratios for different permeant ions are often determined in so-called bi-ionic conditions, in which each permeant ion is selectively present on just one side of the membrane. In graphs A and B, for example, the same

outside-out patch was bathed with either 100mM K^+ (A) or 100mM Na^+ (B). In both cases, the pipette contained 100mM K^+ . As expected, E_{rev} was close to 0mV with equal concentrations of K^+ across the membrane. With K^+ inside and Na^+ outside, however, E_{rev} shifted to -58 mV. This value can be used to compute a permeability ratio for Na^+ and K^+ . For the example of a cation channel with permeability both to K^+ and Na^+ , then $E_{rev} = (RT/zF) \ln\{P_{Na}[Na^+]_o/P_K[K^+]_i\}$, where P_{Na}/P_K is the permeability ratio for Na^+ with respect to K^+ .

In this example, the channel has a 10-fold higher selectivity for K^+ over Na^+ . A word of caution: calculated permeability ratios do not reflect precise transport selectivity, but do help distinguish more and less permeant ions.

3.3.5 Ion channels are gated by voltage or ligands, through changes in open state probability

Ion channels are tightly controlled by conformational shifts between open (O) or closed (C) states. To catalyze ion movement, the channel must first switch into its open state. This switching between O and C states is what gives rise to the discrete transitions in current shown in single-channel recordings (see Fig. 3.18). Alternation between the O and C states is represented by Reaction 3.2. In nearly all channels, activation is controlled by membrane voltage, a ligand/second messenger, covalent modification, or a combination of these. When a factor activates a channel, the equilibrium of Reaction 3.2 shifts from left to right.

Reaction 3.2

The contribution of an individual type of channel to whole-cell or whole-vacuole currents can be defined as in Equation 3.2, where I is the ionic current across the whole cell or vacuole, N is the number of channels, i is the current that flows through the channel when open, and P_o is the probability that the channel is in its open state. Activation of a channel-mediated current usually involves an increase in P_o (Fig. 3.20). For example, voltage-dependent gating can transform a linear current to voltage relationship measured at the single-channel level (see Fig. 3.19) to a distinctly nonlinear current-voltage relationship across the whole plasma membrane (Fig. 3.21). Changes in N can also be achieved through covalent modification (e.g., phosphorylation) or ligand binding.

$$I = N \cdot i \cdot P_o \quad (\text{Eq. 3.2})$$

3.3.6 Voltage-dependent K^+ channels at the plasma membrane

Whole-cell recordings made over a range of holding voltages indicate that currents flow across the plasma membrane in both directions, into and out of the cytosol. These inward and outward currents have two components: an instantaneous current, and a time-dependent current that increases over a period of several hundred milliseconds. Plotting the time-dependent currents as a function of membrane potential makes it apparent that the currents are voltage activated. Activation occurs only beyond a **threshold voltage**, which is more negative than E_K for the inward current and more positive than E_K for the outward current. These time-dependent currents were identified and characterized as inward-rectifying and outward-rectifying K^+ -channel currents in guard cells and are now known to be widely distributed in different types of plant cells (see Fig. 3.21). Molecular (see Section 3.3.8) and biophysical evidence demonstrates definitively that time-dependent inward and outward currents are carried by separate

FIGURE 3.20 The open state probability (P_o), defined as the proportion of total recording time that the channel resides in its open state, is plotted as a function of the holding voltage. Here, P_o shows a progressive increase as V_m becomes more negative.

classes of ion channels. The channels carrying these currents are said to rectify. Like valves, rectifying channels carry current mainly in one direction. For this reason, the channels are referred to as inward-rectifying K^+ channels and outward-rectifying K^+ channels.

Outward K^+ channels contribute to net release of K^+ from guard cells during stomatal closure and from pulvinar cells during leaf movements. Research on guard cells led to the model that inward K^+ channels take up K^+ from the cell wall; the resulting K^+ accumulation contributes to cell turgor or K^+ nutrition as in root epidermal cells. Inward K^+ channels can take up K^+ only at potentials more negative than E_K . In cases where the membrane is depolarized or the extracellular K^+ is in the low micromolar range, K^+ is accumulated by both “low- or medium-affinity” K^+ channels and “high-affinity” K^+ transporters.

3.3.7 Plant cell inward-rectifying K^+ channels function in net K^+ uptake into plant cells and are encoded by a family of voltage-gated channels

Inward-rectifying K^+ channels, also called K^+ influx channels or K^+_{in} , preferentially conduct K^+ ions into the cytosol and are activated by more negative membrane potentials (hyperpolarization). They were first characterized in stomatal guard cells and proposed to mediate K^+ uptake into guard cells, which is required for stomatal opening. Inward-rectifying K^+ channels mainly activated by membrane voltages more negative than the cell resting membrane potential also exist in animal cells. These K^+ channels function to inhibit the electrical excitability of cells such as neurons and cardiac muscle cells. Although plant K^+ channels play a role in regulating the membrane potential of cells, the function of plant inward-rectifying K^+ channels in mediating long-term K^+ uptake differs from the typical function of inward-rectifying K^+ channels in animal cells. As we

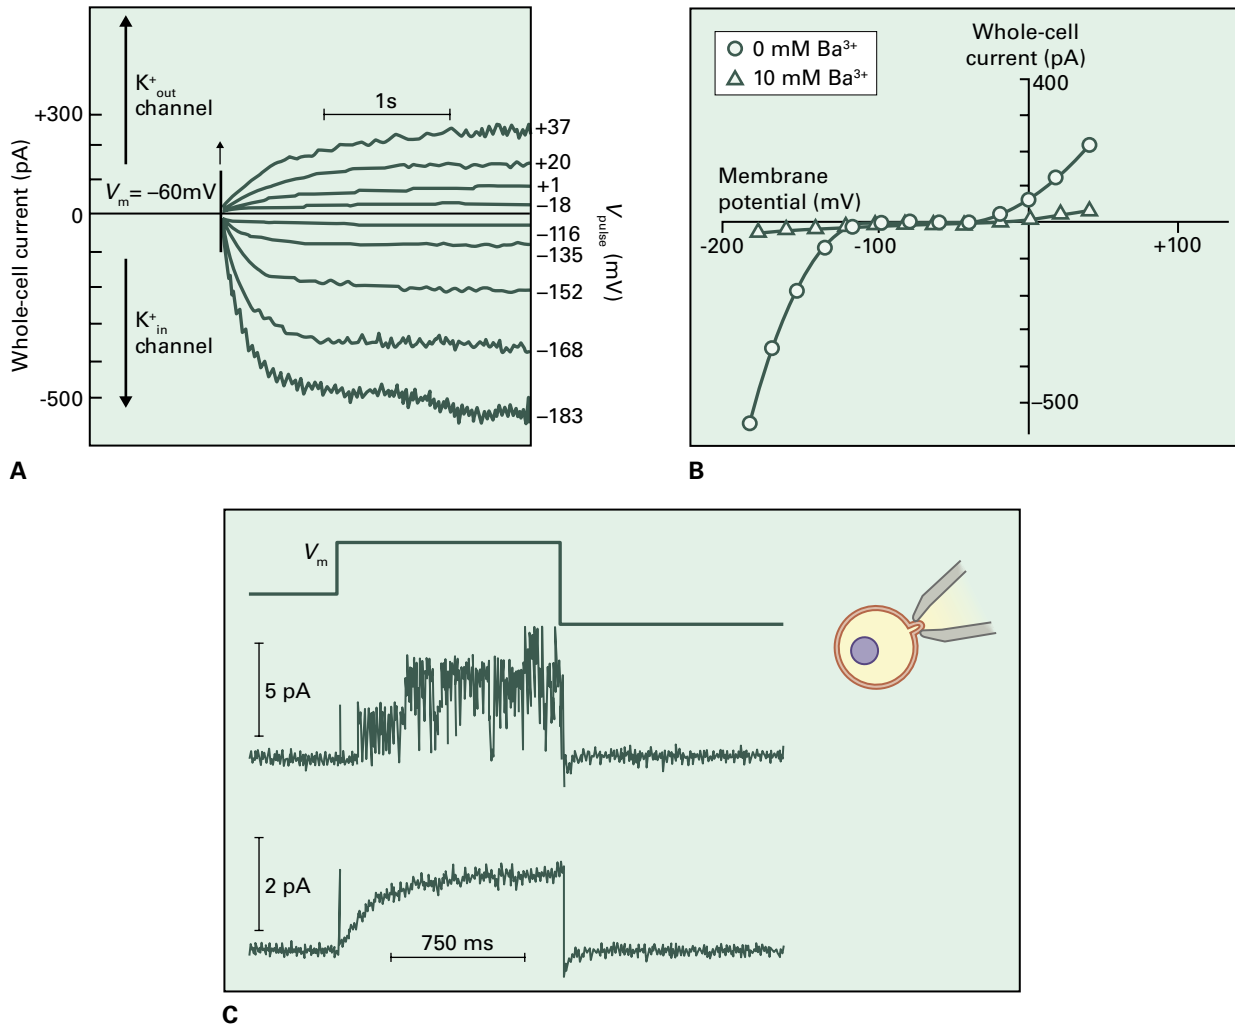

FIGURE 3.21 Whole-cell K^+ channel currents in a guard cell as measured by the patch clamp technique (see Box 3.6A). (A) Electrophysiology data traces: In response to a series of successive voltage pulses, K^+ ions flow through channels in the plasma membrane. The sequentially recorded current traces, corresponding to the applied voltages between -183 and $+37$ mV, are superimposed in this plot. The applied voltages during each voltage step are indicated to the right of the steps. (B) Current–voltage relationship for the time-dependent currents measured toward the end of voltage pulses where currents reached a plateau (steady state) in (A). Downward-deflecting currents in (A) and the corresponding negative currents in (B) correspond to the plant inward-rectifying K^+ (K^+_{in}) channels identified in guard cells. Upward-deflecting currents in (A) and the corresponding positive currents in (B) correspond to the plant outward-rectifying K^+ (K^+_{out}) channels. (C) Measurement of single K^+_{out} channels in a small guard cell membrane patch. Top inset: applied positive voltage pulse to the plasma membrane. Middle: Example trace of single K^+_{out} channels recorded in response to the above voltage pulse. will see in Section 3.3.8, the molecular structure of plant K^+ influx channels differs substantially from that of animal inward-rectifying K^+ channels, and this further differentiates these two classes of channel.

The first eukaryotic K^+ influx channels were cloned from plants and functionally characterized by expression in *Xenopus* oocytes. *Xenopus* oocytes were found to provide a powerful system for characterizing the functions of plant transporters ranging from K^+ channels, to cotransporters and aquaporins, as described later. This class of K^+ channels has now been characterized in numerous cell types. Electrophysiological analyses of plant K^+ influx channels expressed in *Xenopus* oocytes have confirmed their unique properties.

Plant K^+ influx channel subunits are products of a multigene family, members of which exhibit tissue-specific expression. One member, KAT1 (see Box 3.1), is expressed selectively in guard cells (Fig. 3.22A); another, AKT1 (Fig. 3.23), is found in roots and hydathodes (see Fig. 3.22B). The AKT1 gene of *Arabidopsis* has been disrupted using T-DNA insertional mutagenesis (see Chapter 6). The resulting mutant, referred to as *akt1-1*, exhibits reduced K^+ uptake (Table 3.1) and substantially less growth in media with low K^+ concentrations and added ammonium ions, which block high-affinity K^+ uptake transporters belonging to the KUP/HAK/KT family (Fig. 3.24). The analysis of K^+ uptake in *akt1-1* mutants indicates that AKT1 encodes a medium-affinity K^+ uptake channel under physiological conditions.

FIGURE 3.22 Tissue-specific expression of plant inward-rectifying K^+ channels. (A) *KAT1*-mediated *GUS* expression in the guard cells of an *Arabidopsis* seedling. (B) *AKT1*-mediated *GUS* expression in (from left to right) mature roots, lateral roots, and hydathodes of *Arabidopsis*.

FIGURE 3.23 Structure of the inward rectifying K^+ channel *AKT1*. There are six transmembrane spans, S1 through S6, with a membrane-intrusive loop between S5 and S6. This loop makes up the pore domain (P-domain) of the channel. Two helix-breaking proline residues at each end of a 20-residue span force the loop back into the membrane. The functional channel works as a tetramer, with the P-domains of each subunit interacting to form a narrow constriction that contains the K^+ selectivity site.

(B) Lagarde et al. (1996). *Plant J* 9:195–203.

3.3.8 Plant cell K^+ influx channels are members of the Shaker family of voltage activated ion channels

Several structural features define plant K^+ influx channels as members of the *Shaker* family, a superfamily of voltage-gated K^+ , Ca^{2+} , and Na^+ channels found in animal cells and named for the *Drosophila* mutant from which the first outward-rectifying K^+ channel was cloned. A characteristic feature of *Shaker* channels is evident in plant inward rectifying K^+ channels. The fourth transmembrane α helix, known as the S4 domain, exhibits a regular pattern of positively charged resi-

dues, lysine (Lys) or Arg, every third residue, so that the charged residues tend to project from one side of the helix. This region of the protein forms the **voltage sensor**, which is involved in opening the channel in response to a permissive voltage (Fig. 3.25). As a change in voltage is imposed across the membrane, the S4 helix is thought to screw into the membrane (for K^+ channels), with the conformational transition opening the “gate” that controls ion flow through a separate part of the protein. Interestingly, all *Shaker*-type animal voltage-gated K^+ , Na^+ , and Ca^{2+} channels are activated by depolarization of the plasma membrane, whereas the *Arabidopsis* *KAT1* channel was the first voltage-gated channel identified that is activated by hyperpolarization of the membrane, despite sharing a very similar predicted overall structure. This adaptability of the *Shaker* “bodyplan” to opposite gating requirements was discovered by analyzing *KAT1* and is underscored by the fact that the major depolarization-activated K^+ channels in guard cells (*GORK*) and root stelar cells (*SKOR*) also belong to the *Shaker* family of ion channels.

Inward-rectifying K^+ channels are tetramers, in which each of the *Shaker* subunits contributes to the pore through which ions flow (Fig. 3.26). The pore domain (P-domain) of each subunit is located between the fifth and sixth transmembrane spans, looping into the membrane and out of it again. It is the P-domain that endows the channel with its ionic selectivity, with the conserved sequence TxGYGD providing a hallmark characteristic of many plant (and animal) K^+ channels. In addition to the four *Shaker* subunits, the functionally intact inward rectifying K^+ channels may include additional subunits, which might play a role in regulating channel properties.

3.3.9 The activity of voltage-dependent K^+ channels at the plasma membrane is regulated by voltage and phosphorylation

As befits their central role in cell biology, outward and inward transporting K^+ channels are also subject to regulation by factors other than membrane voltage. In guard cells (Fig. 3.27), where they have been studied most intensively, outward rectifying K^+ channels are activated by the small increase in cytosolic pH that can be elicited by abscisic acid (ABA). Inward K^+

* Each value is the mean rate of uptake (nanomoles per gram fresh weight per hour) \pm SEM (n = 4).

FIGURE 3.24 *Arabidopsis akt1* mutants deficient in the *AKT1* inward rectifying channel demonstrate diminished growth in comparison with wild type (WT). The difference in growth rates is particularly pronounced at limiting concentrations of K^+ .

FIGURE 3.25 The voltage-sensing S4 domain screws out of the membrane in response to application of a depolarizing voltage. By analogy with animal Shaker channels, this region is thought to twist slightly in the membrane when voltage is applied, so that it projects slightly from the membrane surface, just as a corkscrew does if twisted through a cork.

FIGURE 3.26 Structure of the Shaker K^+ channel, viewed from the side (left) and top (right). In the side view, the foremost of the four subunits that contribute to the pore is omitted to show the center of the channel. Positively charged regions are shown in blue, negatively charged regions in red.

channels are downregulated by increased cytosolic $[\text{Ca}^{2+}]$. Evidence for control by phosphorylation has come from a study of ABA-insensitive *abi1* mutants of *Arabidopsis*. The *ABI1* locus encodes a protein phosphatase 2C. Mutants display much less outward rectifying K^+ channel activity. In wild-type plants, ABA upregulates outward K^+ channel activity and downregulates inward K^+ channel activity (Fig. 3.27).

3.3.10 Monovalent cation channels at the vacuolar membrane are $[\text{Ca}^{2+}]$ -sensitive and mediate vacuolar K^+ mobilization

Vacuoles are usually thought of as organelles for accumulation and storage of solutes, but in some circumstances massive solute loss from vacuoles is required. One important example is during osmotic adjustment, which can involve massive net salt loss from the cell and hence from the vacuole. Thus, hypo-osmotic stress involves mobilization of ions from vacuoles to restore normal cell turgor, and during stomatal closure ions must be lost from guard cell vacuoles. Ion channels facilitate this mobilization of ions. In the case of guard cells, two different classes of K^+ -permeable channel are competent in releasing K^+ from the vacuole. The interesting features of these channels relate to their complementary modes of regulation.

Both types of channels activate instantaneously in response to an imposed voltage. The fast vacuolar (FV) channel, which exhibits little selectivity among monovalent cations, is inhibited when cytosolic $[\text{Ca}^{2+}]$ exceed $1 \mu\text{M}$ and is activated when cytosolic pH increases (Fig. 3.28). Conversely, the vacuolar K^+ (VK) channel, which is highly selective for K^+ over other

FIGURE 3.27 Model describing how a network of ion channels functions in mediating stomatal closure by ABA or other stimuli. The right stomatal guard cell shows mechanisms that lead to solute efflux that mediates stomatal closing: Ca^{2+} -permeable channels, the S-type and R-type anion channels that are activated by Ca^{2+} -dependent and Ca^{2+} -independent pathways and the K^+ out channels. The left guard cell depicts parallel mechanisms that function in stomatal opening. Elevated Ca^{2+} down-regulates plasma membrane proton pumps and K^+ in channels thus inhibiting stomatal opening and contributing to the plant ion channel network.

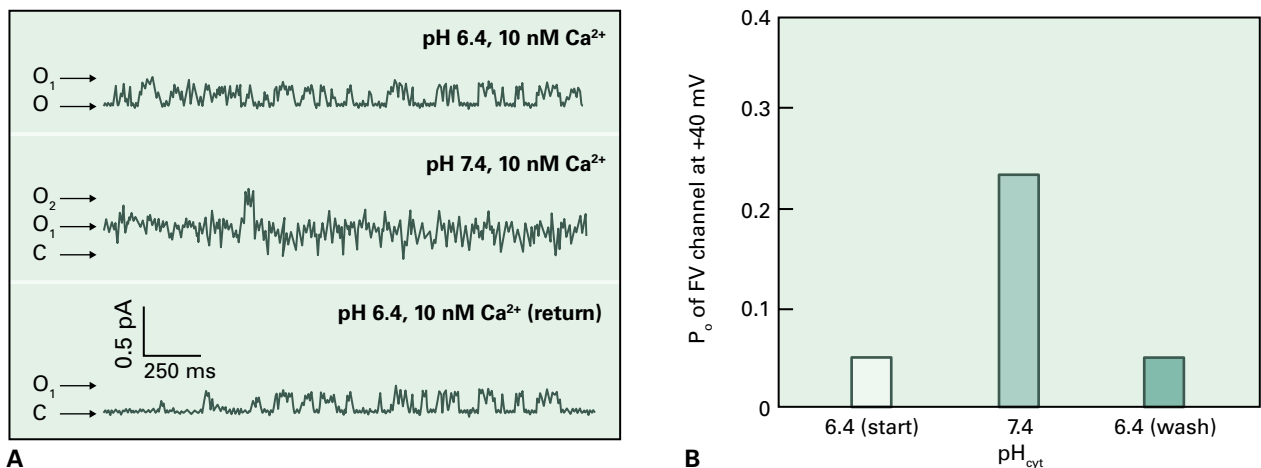

FIGURE 3.28 Activities of vacuolar FV K^+ channels depend on cytosolic pH and Ca^{2+} . (A) The activity of a single FV channel from a *Vicia faba* guard cell tonoplast is strongly influenced by pH. O_1 , one channel open; O_2 , two channels open; C, closed. (B) Increasing cytosolic pH from pH 6.4 to 7.4 increases the open state probability (P_o) of the channel.

monovalent cations, is activated by cytosolic $[\text{Ca}^{2+}]$ in the nanomolar to low micromolar concentration range (Fig. 3.29) and is inhibited by increasing cytosolic pH.

Stomatal closure is often, but not always, preceded by an increase of $[\text{Ca}^{2+}]$ in the guard cell cytosol, so VK channels are well poised to respond by opening and releasing K^+ from vacuoles (Fig. 3.27). However, stomata can also close in the absence of a change in $[\text{Ca}^{2+}]$, in which case an increase in the sensitivity of signaling proteins to cytosolic $[\text{Ca}^{2+}]$ and an

increase in guard cell cytosolic pH are likely to play a role in responding to the primary closing stimulus. In these cases, FV channels will open. The presence of complementary channel types, each fulfilling the same function of vacuolar K^+ release, may provide an example of how parallel mechanisms often mediate biological processes.

While the molecular identity of FV channels is still unknown, a VK channel, TPK1, has been identified in *Arabidopsis*. TPK1 (Fig. 3.30) was originally isolated based on

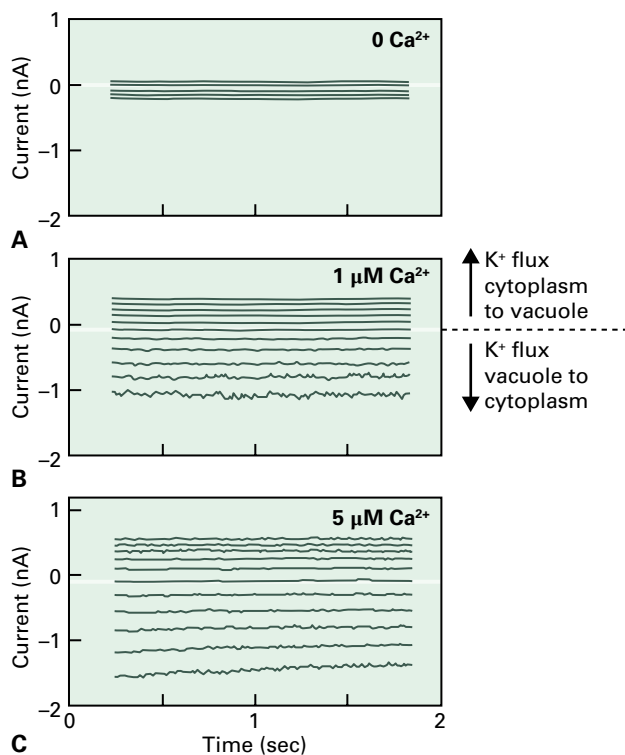

FIGURE 3.29 (A) Vacuolar K^+ -selective and Ca^{2+} -activated (VK) channel currents across the vacuolar membrane of guard cell protoplasts from *Vicia faba*. At a low cytosolic Ca^{2+} concentration ($<0.1 \mu M$) VK channels are not activated in guard cell vacuoles. (B and C) Elevation of the cytosolic Ca^{2+} concentration to $1 \mu M$ (B) or to $5 \mu M$ (C) causes a strong activation of the K^+ -selective VK channels as identified and characterized in guard cells. In contrast to the strongly voltage dependent K^+_{in} and K^+_{out} channels in the plasma membrane (see Fig. 3.28), VK channels are active at both positive and negative voltages and are almost instantaneous, showing no lag after application of the voltage pulse. Source: Ward & Schroeder. (1994). *Plant Cell* 6:669–683.

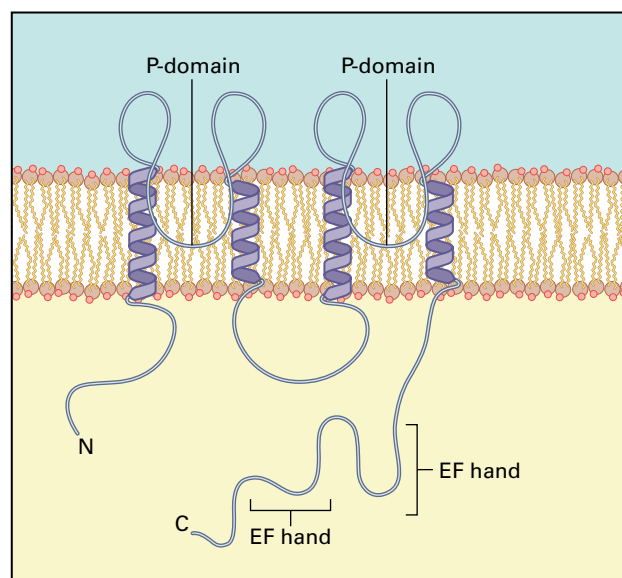

FIGURE 3.30 An outward rectifying K^+ channel. TPK1 has just four predicted transmembrane spans but two P-domains. Toward the C terminus are two high-affinity Ca^{2+} binding motifs known as EF hands.

an EST encoding a protein with the highly conserved pore-forming “P-domain” motif TxGYGD. This channel is a member of the “two-pore” K^+ channel family, so-called because there are two P-domains in each subunit. In contrast to *Shaker*-type channels, TPK1 has only four transmembrane spans in each subunit. Two potential Ca^{2+} -binding motifs, called EF hands, reside towards the C terminus of the protein. Although two-pore K^+ channels have been characterized in *S. cerevisiae* and *H. sapiens*, those channels do not possess EF hand sites. The functional attributes of TPK1 as a K^+ channel were confirmed by heterologous expression, and the channel was subsequently localized to the tonoplast.

3.3.11 High-affinity K^+ transporters are present at the plasma membrane

Besides the biophysically and physiologically well-studied functions of K^+ channels, plants possess a large number of K^+ transporters that do not belong to typical ion channel families. The KUP/HAK/KT family includes high-affinity K^+ uptake transporters and is conserved between plants and fungi. However, the transport mechanism of this important class of K^+ uptake transporters remains unknown and does not follow the dogma of proton coupled cotransport. In one study of *Arabidopsis* roots an apparent proton-coupled K^+ uptake mechanism was reported, but this has not been confirmed and may represent an exception or minor activity.

3.3.12 Calcium channels make use of steep gradients in $[Ca^{2+}]$ to mediate Ca^{2+} flow into the cytosol

Ca^{2+} ions are taken up into the cytosol predominantly by ion channels, rather than proton-coupled transporters. Why is this the case? Most likely because the cytoplasmic $[Ca^{2+}]$ is maintained at very low levels in all eukaryotic cells. Activity of the Ca^{2+} -ATPases discussed in Section 3.2.6 maintain cytoplasmic $[Ca^{2+}]$ at approximately 0.0001 millimolar (or 10^{-7} M), whereas the $[Ca^{2+}]$ in soils, the apoplast and vacuoles can be 0.1 to >1 mM. Thus negative membrane potentials at the plasma membrane and vacuolar membrane can easily pull Ca^{2+} ions into the cytosol through Ca^{2+} channels.

3.3.13 The activity of plasma membrane Ca^{2+} channels is regulated by low molecular weight signaling molecules and voltage

Patch clamp studies, mainly of guard cells, have provided ample evidence for the presence of Ca^{2+} channels in the plasma membrane. Plant Ca^{2+} channels are usually not perfectly selective for Ca^{2+} , but are permeable to other cations.

Still, because of the steep Ca^{2+} concentration gradient into the cell and the very low $[\text{Ca}^{2+}]$ in the cytosol, even a non-selective Ca^{2+} -permeable channel will cause a rapid rise in cytosolic $[\text{Ca}^{2+}]$ when activated. One of the major Ca^{2+} channels in the guard cell plasma membrane is most active at hyperpolarizing potentials, but the threshold of activation is also determined by signals such as ABA and reactive oxygen species. Although several gene families are likely candidates for Ca^{2+} channels, the molecular identity of the guard cell plasma membrane hyperpolarization-activated Ca^{2+} channels remains unknown.

Among likely candidates for plant Ca^{2+} channels are members of the cyclic nucleotide-gated channel (CNGC) and plant glutamate receptor-like homolog families. An *Arabidopsis* Ca^{2+} -permeable CNGC, called DND2, functions in transducing a Ca^{2+} signal in response to pathogen-specific molecules such as lipopolysaccharides. Another member of this family, CNGC18, is required for polarized tip growth of pollen tubes, a process that involves fluxes of ions such as Ca^{2+} into the growing tip. Glutamate (Glu) receptors in animals play important roles in regulating the excitability of neuronal cells. Surprisingly, plants possess homologs of these proteins: the *Arabidopsis* genome includes 20 members of the *GLR* gene family. In *Arabidopsis* roots, the *GLR3.3* gene is required for induction of transient depolarizations and Ca^{2+} influx upon exposure of roots to wounding, Glu and a few other amino acids. Pharmacological studies have implicated Glu-like receptors in microtubule depolymerization and growth cessation of *Arabidopsis* roots in response to aluminum; however, the biological function of Glu receptors in plants is still largely unknown.

3.3.14 Ca^{2+} -permeable channels in endomembranes are activated by both voltage and ligands

It appears that several different classes of Ca^{2+} -permeable channels may be present in intracellular membranes of plants. Although some studies had suggested that typical animal organellar Ca^{2+} channels, the IP_3 receptors and ryanodine receptors, exist in plants, plant genome sequences revealed that no close homologs exist to either of these animal counterparts. Thus it remains controversial whether the animal IP_3 and cADPR signaling paradigms are relevant in land plants. The recent sequencing of the *Chlamydomonas reinhardtii* genome has revealed that this unicellular alga expresses a canonical IP_3 receptor and other animal-like ion channels that have not been found in land plants.

In plant vacuoles, slow vacuolar (SV) channels are Ca^{2+} -permeable cation channels. These SV channels exhibit rather slow, time-dependent activation over several hundred milliseconds in response to membrane depolarization and are strongly activated by Ca^{2+} -calmodulin (Fig. 3.31). The plant vacuolar SV channel may be the best characterized plant ion channel located in a membrane other than the plasma membrane. This channel is ubiquitous and abundant in the vacuolar membrane of terrestrial plants. Channel density based on patch clamp data has been calculated to be 1 SV channel or more per μm^2 . The SV channel is permeable to several cations including Ca^{2+} , K^+ , Na^+ , and Mg^{2+} . A physiological function of SV channels in Ca^{2+} wave propagation in roots has been found that supports the previous model that

FIGURE 3.31 Activity of the SV channel currents increases with increasing cytosolic concentration of Ca^{2+} . The free Ca^{2+} concentration on the cytoplasmic membrane side of guard cell vacuoles was increased from 10 nM (upper left) to 50 μM (lower right). The upward deflection time-dependent currents at elevated Ca^{2+} correspond to the ubiquitous SV channel currents in plant vacuoles. Current traces in each panel are in response to voltage pulses to +100 mV. pA, picoampere; pF, picofarads. Dashed lines show zero current level. Source: Pei et al. (1999). *Pl Physiol* 121:977–986.

these Ca^{2+} -permeable channels can allow conditional release of Ca^{2+} from vacuoles.

SV channel activity is tightly regulated by multiple factors including voltage, with positive membrane potentials promoting opening. Increases in cytosolic $[\text{Ca}^{2+}]$ increase the channel open probability and shift the voltage dependence to less positive values. The sensitivity of the channel to $[\text{Ca}^{2+}]$ is increased by the presence of calmodulin and magnesium. Vacuolar $[\text{Ca}^{2+}]$ has an opposite effect and promotes channel closure. Protein phosphorylation and dephosphorylation regulate channel activity through action on more than one site. Channel activity is also inhibited by acidification on either side of the membrane.

The SV channel from *Arabidopsis*, TPC1, has been cloned, and is a member of the two-pore channel family. The TPC family contains voltage-gated cation channels consisting of two homologous domains, each having six transmembrane helices and one pore domain (Fig. 3.32). Each of the homologous domains is likely to have an evolutionary relationship to the six transmembrane domains and single pore in *Shaker*-type K^+ channels. Two Ca^{2+} -binding EF-hands are located in a cytosolic loop that links the two halves of the SV channel and these are sites for potential regulation by calcium.

Why are there so many candidate types of Ca^{2+} -permeable channels in plant cells? There is as yet no definitive answer to this question, but we can speculate. The activation of different

channel types might result in different dynamic patterns of the Ca^{2+} signal, for example, by mediating localized rises in $[\text{Ca}^{2+}]$ and different rates of change in concentration. The additional information encoded by location and changes in concentration might render downstream responses stimulus specific. This notion is supported by stimulus-specific Ca^{2+} elevation patterns observed in plants, and by Ca^{2+} -based signaling pathways that rely on different Ca^{2+} pools.

3.3.15 Plasma membrane anion channels facilitate solute release during turgor adjustment and elicit membrane depolarization after stimulus perception

Anion channels are ubiquitous in the plant plasma membrane, where they are thought to play several essential roles. This class of ion channels was first characterized in guard cells, where they function in controlling solute release during turgor adjustment in response to physiological signals that cause stomatal closing. Cellular loss of anions is affected by Ca^{2+} -activated anion channels, of which at least two kinetically distinct classes, the rapidly activating R-type and the slowly activating S-type, have been identified in guard cells

FIGURE 3.33 Anion channels in guard cells. (A) Current–voltage relationship for rapidly activating (R-type) anion channels. (B) Steady-state current–voltage relationship for slowly activating (S-type) channels.

(Fig. 3.27). These well-characterized Ca^{2+} -activated anion channels are also gated by voltage (Fig. 3.33). The equilibrium potential for Cl^- ions (E_{Cl^-}) is usually a positive value because cytosolic $[\text{Cl}^-]$ exceeds the extracellular $[\text{Cl}^-]$ (see Box 3.2). The opening of these channels results in massive efflux of Cl^- from cells and membrane depolarization. This depolarization can activate outward rectifying K^+ channels during salt loss. Anion channel activity is therefore the pacemaker of plant cell turgor reduction. Physiological stimuli that trigger stomatal closing via activation of S-type anion channels include ABA, elevated CO_2 , pathogenic elicitors and ozone.

The *Arabidopsis* *SLAC1* gene was shown to encode the major subunit of S-type anion channels in the plasma membrane of guard cells. Studies had suggested that S-type anion channels are a central regulator of stomatal closing by allowing controlled release of anions from guard cells, which also depolarizes guard cells and drives K^+ release. Indeed, mutants in the *SLAC1* gene are impaired in stomatal closing in response to numerous physiological stimuli and second messengers, including ABA, CO_2 , darkness, low humidity, $[\text{Ca}^{2+}]$, and reactive oxygen species, including ozone.

Ca^{2+} -activated anion channels are also subject to additional types of regulation. In a range of cell types, including guard cells, ATP has an activating effect. Anion channel activity is not supported by nonhydrolyzable ATP analogs, and the inhibitory effects of ATP removal are prevented by protein phosphatase inhibitors. Ca^{2+} -dependent and Ca^{2+} -independent protein kinases function in anion channel activation in guard

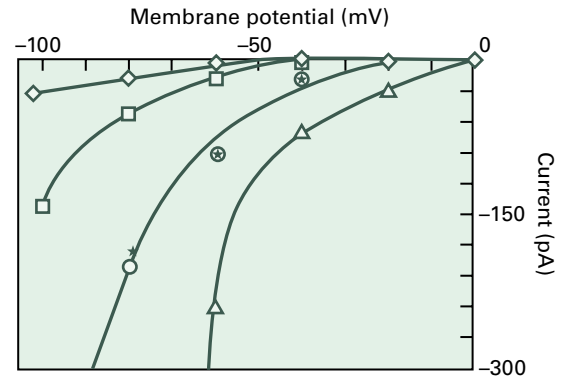

FIGURE 3.34 Current–voltage relationship for vacuolar uptake of malate through time-dependent anion channels in the tonoplast. Malate uptake by anion channels is strongly promoted by negative membrane potentials and increases with cytosolic malate concentration. In this figure, cytosolic malate concentrations were 10 mM (open diamonds), 20 mM (open squares), 50 mM (open circles), and 100 mM (open triangles)—all with a vacuolar malate concentration of 10 mM. Malate uptake with equal concentrations of malate (50 mM) present on both sides of the membrane is indicated by stars.

cells. All this evidence points to control of anion channel activity through phosphorylation by protein kinases, which has been further characterized in the oocyte system.

3.3.16 Vacuolar malate transporters that participate in malate sequestration have been identified

In most glycophytic plants, a major anionic constituent of the vacuole is malate. Plants exhibiting crassulacean acid metabolism (CAM) take up and release malate from vacuoles on a diurnal basis. Malate uptake into the vacuolar lumen is driven by the cytosol-negative V_m (Fig. 3.34). Ca^{2+} -dependent protein kinases can activate vacuolar malate uptake channels. Selectivity studies, in which the ionic forms of malate are titrated between the un-protonated (malate^{2-}) and the singly protonated ($\text{H}\cdot\text{malate}^-$) forms, strongly suggest that the permeant form is malate^{2-} (Fig. 3.35), which would effectively maximize the use of V_m as a driving force. Because the vacuolar pH is notably lower than that of the cytosol (by about 2 pH units in most plants, but by as much as 4 pH units at the end of the night in CAM plants), the malate^{2-} that enters the vacuole will be rapidly protonated and its concentration effectively lowered in favor of the $\text{H}\cdot\text{malate}^-$ and $\text{H}_2\cdot\text{malate}$ forms. The pH difference across the tonoplast helps sustain the concentration difference that drives malate^{2-} into the vacuole. Conversely, reverse flow into the cytosol is very unfavorable. Malate is therefore likely to exit vacuoles of CAM plants through a completely independent pathway, perhaps by way of a cotransporter.

Two kinds of vacuolar malate channels have been identified at the molecular level. One channel whose activity corresponds with previously characterized inward rectifying malate channels (because malate is negatively charged this corresponds to malate fluxes into the vacuole) is a member

FIGURE 3.35 Accumulation of malate in the roots of CAM plants. Malate^{2-} is thought to enter the vacuole through malate-selective channels. These channels are strongly inward rectifying and do not allow substantial malate²⁻ efflux. Once inside the vacuole, malate²⁻ is protonated to $\text{H}\cdot\text{malate}^{1-}$ and $\text{H}_2\cdot\text{malate}^0$. This maintains the effective concentration difference for malate²⁻ across the membrane.

of the *ALMT* (aluminum-activated malate transporter) gene family. Promoter fusions of the *AtALMT9* gene in *Arabidopsis* showed that it was preferentially expressed in mesophyll cells. T-DNA insertion mutants of *AtALMT9* had strongly reduced vacuolar malate channel activity.

The second kind of malate channel, the *Arabidopsis* tonoplast dicarboxylic acid transporter (*AtDT9*) was identified by homology with a sodium/dicarboxylic acid cotransporter in *H. sapiens* kidney. *AtDT* protein localizes to the vacuole in mesophyll cells. Mutant *Arabidopsis* plants lacking a functional *AtDT* gene had 25% less malate in leaves than wild type. Redundancy in function between *AtALMT9* and *AtDT* is likely since knockout mutants in *AtALMT9* that strongly reduce channel activity as measured by patch clamp analysis have only slightly reduced amounts of vacuolar malate.

3.4 Cotransporters

3.4.1 Cotransporters facilitate transport against an electrochemical potential difference

Cotransporters utilize the downhill gradient of H^+ or Na^+ for the uptake or export of solutes against an uphill gradient. They couple a thermodynamically favorable influx of H^+ or

Na^+ to drive an unfavorable transport reaction such as the uptake of Cl^- . Cotransporters that transport the substrate and coupling ion (usually H^+ in plants) in the same direction are called symporters. Symporters are uptake transporters, and most sugar, amino acid, peptide, Cl^- , NO_3^- , SO_4^{2-} , and phosphate uptake occurs via symporters. Antiporters transport the coupling ion and substrate in opposite directions and act as exporters. Antiporters for sucrose, Na^+ , K^+ , NO_3^- , and BO_3^{3-} are known. Symporters and antiporters are present in the plasma membrane and in endomembranes (see Fig. 3.2). Both symporters and antiporters use (and dissipate) the proton motive force, which needs to be continuously maintained by the action of H^+ pumps in the plasma membrane and organelle membranes.

Like the vast majority of enzymes, cotransporters are relatively specific for their substrates. In the case of organic substrates, for example, cotransporters readily distinguish between isomers, transporting L-amino acids and D-sugars in marked preference to the respective D- and L-isomers. Among amino acids, acidic, basic, and neutral amino acids are all transported by distinct plasma membrane cotransporters. A wide range of cotransporter types are found in all membranes. The prominence of H^+ -coupled transport systems in the plant cell plasma membrane illustrates that organisms living in relatively dilute media depend on energized solute transport.

3.4.2 Cotransporters are often characterized in heterologous systems

Cotransporters are very difficult to identify by biochemical approaches because they are not abundant (see Section 3.1.5) and do not execute reactions (such as ATP hydrolysis) that can be assayed without reconstitution in membranes. The most widely applicable and successful approach applied to plant cotransporters has been *S. cerevisiae* complementation. For this approach, yeast mutants that are defective in growth on the solute of interest are transformed with cDNA from a plant library. Transformed yeast colonies able to grow on the particular solute express a functional plant transporter. The encoding DNA sequence can then be obtained. The large number of yeast transport mutants, and the ease and rapidity with which genetic studies can be conducted in yeast, make this an attractive experimental system. As a result, the first plant plasma membrane cotransporters for sugars, amino acids, peptides, inorganic cations (e.g., K^+), and inorganic anions (e.g., SO_4^{2-}) were identified using this approach.

Cotransporter proteins are highly hydrophobic. A structure predicted by hydrophathy analysis often exhibits 12 transmembrane spans, with the most extensive hydrophilic loop appearing between transmembrane spans 6 and 7 (Fig. 3.36).

Single-celled oocytes from the South African clawed frog *Xenopus laevis* are a popular alternative heterologous

FIGURE 3.36 Structural model illustrating the orientation of a generalized cotransporter in a membrane.

expression system for plant channels and transporters. The large size of oocytes, around 1 mm in diameter, allows impalement by micropipettes and microelectrodes (Fig. 3.37), to monitor transporter-mediated membrane currents. Furthermore, the plasma membrane of oocytes is relatively quiescent with respect to transport activity, so the background activity of endogenous transporters rarely contributes substantially to the fluxes or currents measured in experiments with heterologously expressed transporters. Expression of heterologous transporters in oocytes is achieved by microinjection of *in vitro* synthesized cRNA into single cells, where the cRNA provides the template for translation. Typically, transport activity is monitored between 2 and 4 days after cRNA microinjection, when expression is at a maximum.

Experimental evidence for H^+ -coupled transport has been derived from two classes of experiments. The first method, which uses microelectrodes to monitor the V_m across the cell membrane, is restricted to assessment of plasma membrane symporter activity (Fig. 3.38A). When a cell is bathed in substrate—even an uncharged one like a sugar—the plasma membrane often depolarizes very rapidly, indicating that positive electrical charge (usually H^+) is flowing into the cell. These depolarizations show that the H^+ -coupled transport systems are electrogenic (carry electrical charge). An alternative experimental approach that is applicable to a variety of membranes involves the use of fractionated membrane vesicles (Fig. 3.38B). Vesicular

FIGURE 3.37 *Xenopus* oocytes can be readily injected with cRNA encoding putative transporters using an injection pipette. After a few days incubation to allow time for translation of new protein, transport assays, such as electrophysiology or uptake of radiolabeled substrate, can be used to study transport activity.

Source: GeneClamp 500. Axon Instruments Inc., Foster City, CA.

uptake of a radioisotope-labeled substrate is compared in the presence and absence of a proton gradient. In the presence of a proton gradient of the appropriate polarity, substrate accumulation inside the vesicles indicates H^+ -coupled transport (Fig. 3.38B).

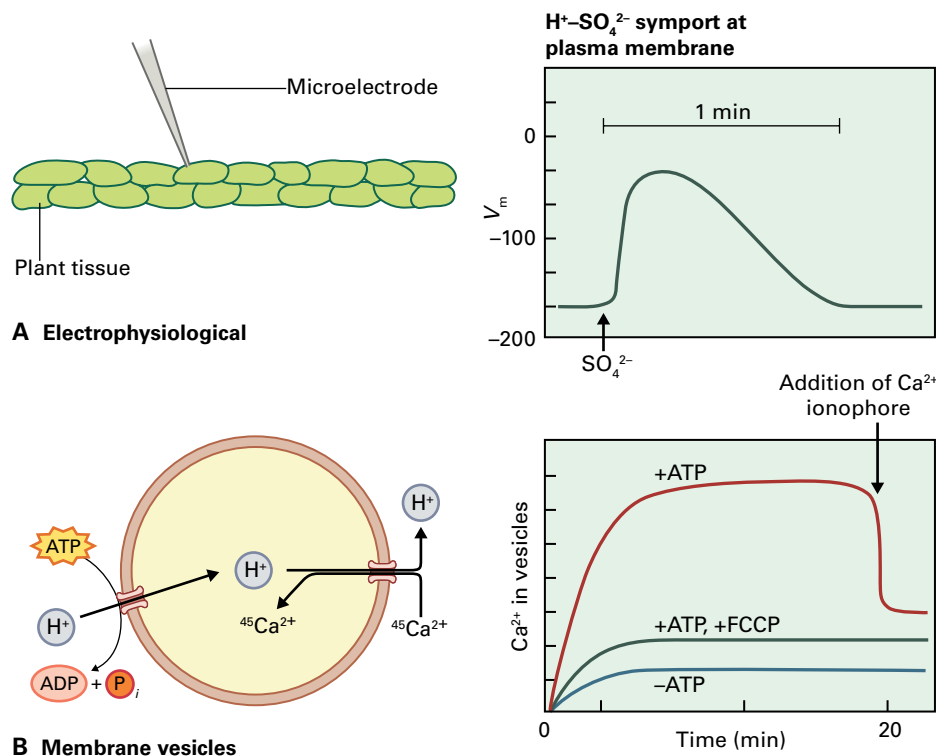

FIGURE 3.38 Methodologies for demonstrating H^+ -coupled solute transport by cotransporters. (A) The cell is impaled with a glass micropipette containing an electrolyte and an electrode. This microelectrode, in conjunction with another electrode in the bathing solution, is used to measure the voltage across the membrane. An uncharged or anionic substrate is introduced into the bathing solution. If a cation is cotransported with the substrate, positive charge flows into the cell, the membrane depolarizes, and V_m increases. Ion substitution experiments and alkalization of the medium often identify the cation as H^+ . If the transported substrate is anionic, membrane depolarization implies that at least two H^+ are transported per monovalent anion, or three H^+ per divalent anion. (B) Vesicles are incubated with a radiolabeled substrate (e.g., $^{45}Ca^{2+}$), and filtered through narrow-pore nitrocellulose. The filter is then washed and the vesicle-associated radioactivity is quantified. This method allows comparison of vesicular uptake in the presence and the absence of a pmf. If the cytosolic face of a vesicle is exposed to the medium, endogenous H^+ -ATPase activity can establish an inside-acid pmf. This gradient is used to drive uptake of the radiolabeled substrate, as shown in the accompanying graph of Ca^{2+} uptake (red line; +ATP). Addition of a Ca^{2+} -selective ionophore (indicated by vertical arrow above graph) results in Ca^{2+} leakage from the vesicle and demonstrates that Ca^{2+} has been accumulated within the vesicle rather than bound to it. In the absence of ATP (-ATP, blue line), or in the presence of compounds that eliminate the proton gradient (FCCP: carbonyl cyanide p-[trifluoromethoxy] phenylhydrazone; green line), Ca^{2+} accumulation is much reduced.

3.4.3 In some cases, ion-coupled solute transport involves Na^+ rather than H^+

Although H^+ -coupling prevails as a mechanism for energizing cotransporter-mediated transport in plants, examples of Na^+ symport have been found. In some marine algae, uptake of NO_3^- and some amino acids is Na^+ dependent. The plentiful concentration of Na^+ in sea water (approximately 480 mM) results in a large inwardly directed electrochemical gradient for Na^+ across the plasma membrane (Fig. 3.39). However, uptake of K^+ at micromolar concentrations is also Na^+ dependent in some freshwater aquatic plants and charophyte algae. Although the Na^+ concentration of freshwater is considerably less than that of sea water, it is nevertheless possible for Na^+ coupling to energize transport because the V_m component of the electrochemical driving force for Na^+ is sufficiently large to overcome the smaller concentration difference for this ion across the plasma membrane. The genes encoding this Na^+/K^+ transport activity have not yet been isolated from freshwater plants and charophyte algae. However, this Na^+/K^+ transport

activity has been found for a subfamily of the HKT transporter gene family in grasses (see Chapter 23). At high Na^+ concentrations these HKT transporters can become Na^+ channel-like transporters, mediating Na^+ influx into cells. A different subfamily of plasma membrane HKT transporters (class 1 HKT transporters) are Na^+ transporters and provide a major mechanism for protecting land plants from over-accumulation of Na^+ in leaves by removing Na^+ ions from the xylem sap before it is unloaded into leaves. HKT marker-assisted breeding of highly active HKT transporters from wild plant varieties is producing domesticated crops that show improved salinity tolerance, an important agricultural trait.

3.4.4 Transcriptional and post-translational controls regulate cotransporter activity

H^+ -coupled transport systems are capable of generating impressive amounts of solute accumulation. As a corollary, H^+ -coupled cotransporters must be subject to tight regulation

FIGURE 3.39 A large electrochemical potential for Na⁺ exists across the plasma membrane of marine algae, such as *Acetabularia*, shown here.

if physiological concentrations of solutes are to be maintained in the cytosol. Two forms of control predominate. Transcriptional control is evident for many cotransporter genes, with expression being de-repressed during periods of substrate starvation. In the presence of substrate, expression of the cotransporter is repressed and transport is evident only at a low rate. An example of probable transcriptional control is shown in Figure 3.40 for uptake of K⁺ into roots of *Arabidopsis*: K⁺ starvation, which enhances K⁺ uptake capacity in roots, correlates with expression of the K⁺ uptake transporter AtHAK5, although no evidence has been obtained that AtHAK5 is a H⁺-coupled cotransporter. Knockout of the *AtHAK5* gene in *Arabidopsis* results in a greatly reduced high-affinity K⁺(Rb⁺) influx, showing that AtHAK5 is a major component of the classical inducible high-affinity K⁺ influx activity identified in roots. Furthermore, double knockout of the *AtHAK5* gene and the inward K⁺ channel gene, *AKT1*, leads to almost complete removal of K⁺(Rb⁺) influx at low concentrations and severe growth defects. An exception to induction of transporters by nutrient starvation is cotransporter-mediated NO₃⁻ transport, which is induced rather than repressed by its substrate.

Post-translational control of cotransporters can also regulate transport activity. This has been documented in the giant internodal cells of the charophyte alga *Chara*, which can be internally perfused with defined media. There, a high rate of H⁺-coupled Cl⁻ transport into the cell is observed in the absence of cytosolic Cl⁻, but the rate declines almost to zero as cytosolic Cl⁻ increases to a modest concentration of 10 mM.

FIGURE 3.40 Expression of K⁺ transporter gene *AtHAK5* is induced by K⁺ starvation. *Arabidopsis* plants grown with sufficient K⁺ have undetectable *AtHAK5* mRNA expression in roots. Plants grown for 7 days in the absence of K⁺ show expression of *AtHAK5* as detected by RT-PCR (left panel). K⁺ starvation-induced *AtHAK5* promoter-*GUS* activity is shown in the right panel. When K⁺ is re-supplied, *AtHAK5* expression returns to the low basal level. The *AtHAK5* transporter was shown to mediate the major component of the “classical” K⁺ starvation-induced high-affinity K⁺(Rb⁺) uptake in *Arabidopsis* roots. Source: Gierth et al. (2005). *Plant Physiol* 137(3): 1105–1114.

This phenomenon, known as trans-inhibition, results from relatively tight binding of cytosolic Cl⁻ to the cotransporter at the active site. Thus, the greater the cytosolic Cl⁻ concentration, the more the cotransporter becomes locked up in its substrate-bound form, and the less the cotransporter is able to take up Cl⁻ from outside the cell.

3.4.5 Many metabolites are transported by specific cotransporters within the major facilitator superfamily

Plant cells contain a rich diversity of proton-coupled transporters for uncharged nutrients and metabolites. Many are encoded by genes in the major facilitator superfamily (MFS). Most is known about plant H⁺-coupled uptake transporters (symporters) and relatively little about H⁺-coupled efflux transporters (antiporters). This is primarily due to the efficiency of using *S. cerevisiae* mutants to identify uptake transporters by heterologous expression (see Section 3.4.2). *S. cerevisiae* is also used to study uptake transport activity in detail when radiolabeled substrates are available. The *Xenopus* oocyte expression system and electrophysiology have been very useful in identifying substrates for coupled transporters. One benefit to this system is that radiolabeled substrates are not necessary, however, transport needs to be

FIGURE 3.41 Electrophysiological analysis of *AtPLT5* (*At3g18830*) transport activity in *Xenopus* oocytes. Oocytes were clamped at -40 mV, and substrates were applied extracellularly as indicated. Downward deflections represent inward H^+ current coupled to substrate transport into the oocyte. Top trace: oocyte injected with *AtPLT5* RNA; while bottom trace, uninjected oocyte. The results show that arabinose, xylose, rhamnose, ribose, and fucose are all transported by *AtPLT5*, but maltose is not. Source: Reinders et al. (2005). *J Biol Chem* 280(2): 1594–1602.

electrogenic—a charge must be transported across the membrane for transport activity to be detected. For example, *AtPLT5*, an *Arabidopsis* homolog of sugar alcohol permeases (within the MFS), was analyzed by expression in oocytes (Fig. 3.41). *AtPLT5* transports a wide range of sugars including hexoses, pentoses and tetroses, as well as sugar alcohols such as sorbitol.

Many transporter genes are present in multiple copies and are members of gene families. The reason for this apparent redundancy is not completely understood. The transcribed proteins could be functionally redundant, but there are other likely possibilities. Multiple genes could provide fine-tuned expression patterns or differences in activity, regulation, localization, or protein turnover. The gene family that encodes sucrose transporters (SUTs) in *Arabidopsis* has provided some insight into the question of why plant transporters often exist as members of multigene families. *Arabidopsis* has nine *SUT* genes whose expression patterns differ. *AtSUC2*, for example, is expressed in companion cells and is essential for phloem loading, whereas *AtSUC1* has similar transport activity but is expressed in pollen, trichomes, and roots and is essential for pollen function. *AtSUC5* is expressed in seeds and is important for seed development. There are differences in transport activity as well. SUTs most closely related to *AtSUC1* have a high affinity for sucrose with K_m values for sucrose of less than 2 mM. *AtSUC9*, one member of this group, has a very high affinity for sucrose ($K_m = 66$ μ M) compared to other SUTs. At the other end of the spectrum, the less homologous gene *AtSUT4* encodes a transporter with a K_m for sucrose of 12 mM. There are differences in membrane localization: *AtSUT4* is localized to the tonoplast while other SUTs reside in the plasma membrane. Two *SUT* genes, *AtSUC7* and *AtSUC8*, are pseudogenes. Therefore, even though nine *SUT* genes are present in *Arabidopsis*, there is little functional

redundancy, and aside from the pseudogenes each SUT can be assigned a unique function.

Most plant sugar transporters, including H^+ -coupled monosaccharide transporters for glucose, are members of the MFS. However, plant genes outside of the MFS also encode important proton-coupled transporters for uncharged solutes. Examples of symporters are purine permeases (PUPs), ureide permease (UPS), and the urea permease *AtDUR3*. Members of the multidrug and toxic efflux transport (MATE) family function as antiporters, and some transport uncharged solutes. For example, *TT12* transports anthocyanins into the vacuole.

3.5 Water transport through aquaporins

3.5.1 The direction of water transport across membranes is determined by hydrostatic and osmotic pressures

Most biologists have, at some time or another, observed the simple effects of hyperosmotic treatment of plant tissue: The tissue becomes flaccid, and at the cellular level, plasmolysis occurs. The rapidity of plasmolysis bears testimony to the high degree of permeability that biological membranes exhibit towards water.

Two components of water potential, determine the directionality of water flow through membranes: the hydrostatic pressure difference ($\Delta\Psi_p$) across the membrane, and the osmotic pressure difference ($\Delta\Psi_s$) across the membrane (see Chapter 15, Box 15.1). Formally, the flux of water across the

membrane (J_v) is proportional to the driving force (Eq. 3.3), where L_p , the constant of proportionality, is the permeability of the membrane to water, expressed in terms of surface area, $\text{m}\cdot\text{s}^{-1}\text{MPa}^{-1}$ (i.e., $\text{m}\cdot\text{s}^{-1}\text{m}^2\text{N}^{-1}$, where N is the force in Newtons, $\text{kg}\cdot\text{m}\cdot\text{s}^{-2}$); σ , known as the reflection coefficient, expresses the ability of the osmotically relevant solutes to permeate the membrane relative to water. For completely impermeant solutes, $\sigma = 1$, whereas for solutes with equal permeability to water, $\sigma = 0$. In practice, most osmotically active solutes encountered in physiological conditions (ions, sugars, and so forth) are much less permeable than water, and σ can be considered to equal 1. In conditions of osmotic equilibrium, $J_v = 0$ by definition, so $\Delta\Psi_p$ and $\sigma\Delta\Psi_s$ are equal and opposite.

$$J_v = L_p(\Delta\Psi_p - \sigma\Delta\Psi_s) \quad (\text{Eq. 3.3})$$

3.5.2 Water movement occurs through the membrane lipid bilayer and through channels called aquaporins

Water passes through the lipid component of biological membranes, despite the fundamentally hydrophobic characteristics of the fatty acyl chains in the phospholipid bilayer. The permeability of bilayer membranes to water can be demonstrated in artificial systems—either liposomes or planar lipid bilayers. A parallel major pathway for water movement across membranes that allows for much more rapid water movement has been identified. This pathway uses water channel proteins called aquaporins.

3.5.3 Aquaporins are members of the major intrinsic protein family

Aquaporins are integral membrane proteins in the major intrinsic protein (MIP) family and are present in bacterial, plant and animal cells. They are small (25–30 kDa), very hydrophobic proteins with six transmembrane spans containing internal sequence homology indicative of origins from a gene duplication and fusion (Fig. 3.42). Aquaporins are also characterized by the highly conserved NPA (Asn-Pro-Ala) residues present in both the N- and C-terminal halves of the protein. Aquaporins are present in all plant membranes associated with the secretory system including the plasma membrane, tonoplast, ER and Golgi. Plants have many aquaporin genes (more than 30 in *Arabidopsis*) that are classified within four subgroups: plasma membrane intrinsic proteins (PIPs), tonoplast intrinsic proteins (TIPs), nodulin 26-like intrinsic membrane proteins (NIPs), and small basic intrinsic proteins (SIPs).

The discovery of aquaporin function was achieved in 1992 by expressing the complementary RNA from an animal MIP homolog in *Xenopus* oocytes. When the oocytes were then

FIGURE 3.42 Structure of an aquaporin showing the six transmembrane helices and two conserved NPA (Asn-Pro-Ala) residues.

subjected to hypo-osmotic shock, the rate of swelling was considerably faster in the aquaporin-expressing oocytes than in controls. This work was followed by research showing similar functional aquaporin properties for a plant homolog expressed in *Xenopus* oocytes.

Intriguingly, some plant aquaporins can transport other small, uncharged solutes that are important for plant nutrition, stress responses, or signal transduction. The list of compounds that permeate some plant aquaporins includes CO_2 , urea, glycerol, NH_4^+ , methyl ammonium, boric acid, H_2O_2 , silicic acid, lactic acid, formamide, arsenic, and acetamide.

Aquaporins exist as tetramers in membranes, but the functional pores are formed by monomers (Fig. 3.43). The X-ray crystallographic structure of plant aquaporins has been solved in both the closed and open gated states. The pore is formed by two loops containing NPA domains (see Fig. 3.42) that dip into the membrane from either side. Selectivity is conferred at the tightest constriction of the pore by the aromatic/arginine region. Gating of the pore depends on the position of loop D, the cytoplasmic domain between the fourth and fifth transmembrane spans. Loop D blocks the pore in the closed state (see Fig. 3.43).

3.5.4 Aquaporin expression and activity are regulated

Aquaporin gene expression is regulated by many environmental factors, including light quality and intensity, water and nutrient availability, salt stress, drought and anoxia. In addition, aquaporin activity is regulated by cytoplasmic pH and protein phosphorylation. Under some conditions, such as anoxia, cytoplasmic acidification causes aquaporin inhibition through protonation of a conserved histidine (His). Protein phosphorylation of conserved Ser residues also leads to channel closing. Phosphorylation is catalyzed by a

Ca²⁺-dependent protein kinase that may form a component of a signaling pathway linking water stress to channel activity. Cytoplasmic Ca²⁺ may also have direct effects on aquaporin activity: a binding site for divalent cations was discovered during analysis of the X-ray structure.

Results from several studies using vesicles derived from the plasma membrane and tonoplast show a much higher (100-fold) water permeability of the tonoplast. It is likely that, in

those studies, the activity of plasma membrane aquaporins was not maintained during vesicle isolation. However, the results may point out differences in regulation between plasma membrane and vacuolar aquaporins. More recent studies have shown that both plasma membrane and tonoplast have high water permeability (up to 500 μm s⁻¹). Water permeability across both plasma membrane and tonoplast is controlled predominantly by aquaporins.

Summary

Membrane transport plays a fundamental role in many biological processes in plant cells, including generation of cell turgor, energy, movements, signal transduction, nutrient acquisition, waste product excretion, and metabolite distribution and compartmentalization. Four fundamental classes of transport systems are present at all membranes. *Pumps* catalyze transport of ions or complex organic molecules against their thermodynamic gradients. At membranes other than the ATP-synthesizing membranes of mitochondria and chloroplasts, pumps are generally driven by ATP hydrolysis. At all membranes, H⁺ pumps remove H⁺ from the cytosol and generate a proton

gradient and an electrical gradient (pmf) across each membrane. *Ion channels* mediate transport at very high rates and play diverse roles in plant biology. Channels can be regulated between open and closed states, and activation is frequently controlled either by membrane voltage or by protein modification through second messengers (e.g. Ca²⁺) or through phosphorylation/dephosphorylation. Channels that are very highly selective for K⁺ reside in the plasma membrane and tonoplast. Anion channels and less selective cation channels are also present in both membranes. These channels have essential roles in signal transduction, cell expansion, nutrient acquisition and

redistribution. *Cotransporters* translocate a wide range of simple solutes, including ions, sugars, and amino acids. Cotransporters are distinguished from pumps by not requiring ATP hydrolysis to drive transport, and from channels by coupling the uphill accumulation of a solute to the energetically favorable movement of a second solute. In plants, cotransporters are generally energized through coupling to proton motive force (pmf)-driven H⁺ transport. Some examples of channels and cotransporters, many of which were discussed in more detail in this chapter, are summarized in Table 3.2 for cationic substrates, and in Table 3.3 for anionic substrates. *Aquaporins* facilitate rapid transport of water across the plasma membrane and tonoplast.

All classes of transport systems have been identified at the molecular level; in many cases, structural aspects of the transport system can be related to solute permeation and to control of transport system activity. These

transport systems play important roles in numerous processes, including central roles in the responses of plants to abiotic and biotic stresses. Identifying specific transporters that fulfill particular roles requires consideration of four aspects of transport: the charge of the nutrient or metabolite, the concentration of the molecule on each side of the membrane under physiological conditions, the precise location of the transport step within the organism and the regulation of the proteins by physiological stimuli. These four aspects determine the type of transporters capable of carrying out specific transport functions. In virtually all cell types, transporters capable of facilitating translocation in either direction under a variety of conditions need to be present in order to maintain cellular homeostasis and promote growth and development. Consequently, plants have a large number of genes encoding transporters for the many solutes and transport steps encountered in the whole plant.

TABLE 3.2 Transporters of cationic substrates and nutrients.

Substrate	Transporter	Transporter Family	Membrane*	Function
K ⁺	K ⁺ _{in} channel AtKAT1	Shaker-type voltage-gated K ⁺ channel	PM	K ⁺ influx channel; stomatal opening
K ⁺	AtAKT1	Shaker	PM	K ⁺ influx channel; K ⁺ uptake in roots
K ⁺	K ⁺ _{out} channels GORK, SKOR	Shaker	PM	K ⁺ release in guard cells (GORK) and stelar cells
K ⁺	TPK1 (AtKCO1)	Two-pore K ⁺ channel (4 TM)	T	Vacuolar K ⁺ (VK) channel; K ⁺ release from vacuole activated by increase in cytosolic Ca ²⁺ concentration, stomatal closing
K ⁺	AtHAK	KUP/HAK/KT	PM	High-affinity K ⁺ uptake into roots and likely other cells
Fe ²⁺	AtIRT1	ZIP	PM	iron uptake in roots
Fe ²⁺	AtNRAMP3/4	NRAMP	T	iron release from vacuole
Ca ²⁺	DND1/2	CNGC	PM	Ca ²⁺ influx; signaling; e.g. in guard cells
Ca ²⁺	GLR3.3	glutamate receptor	PM	transient depolarization, Ca ²⁺ signaling in roots
Ca ²⁺	TPC1	Two-pore channel (2 x 6 TM)	T	Slow vacuolar (SV) channel; Ca ²⁺ , K ⁺ , Na ⁺ and Mg ²⁺ permeable

* PM, plasma membrane; T, tonoplast.

TABLE 3.3 *Transporters of anionic substrates and nutrients.*

Substrate	Transporter	Transporter family	Membrane*	Function
Anions	S-type anion channel, AtSLAC1		PM	anion release during stomatal closing
Malate	AtALMT		PM	Al ³⁺ -activated malate release in roots, Al ³⁺ detoxification
Malate	AtALMT9	ALMT family	T	Cl ⁻ and malate transport into vacuoles in mesophyll cells
Malate	AtDT9	dicarboxylic acid transporter	T	malate transport into vacuoles
Anions	R-type anion channel, ALMT12	ALMT family	PM	Anion efflux from guard cells during stomatal closing
NO ₃ ⁻	AtNPF6.3/ AtNRT1.1	NPF	PM	low-affinity H ⁺ -coupled nitrate transporter
NO ₃ ⁻	AtNRT2		PM	high-affinity H ⁺ -coupled nitrate transporter; requires second integral membrane protein for function; no sequence homology between NRT1 and NRT2 family
NO ₃ ⁻	AtCLCa	CLC chloride channel	T	1 H ⁺ /2 NO ₃ ⁻ antiporter for nitrate transport into vacuole; nitrate storage
Phosphate		PHT family	PM	H ⁺ -coupled phosphate uptake in roots
Sulfate		SULTR family	PM	members are low- or high-affinity H ⁺ -coupled sulfate uptake transporters; some also permeable to molybdate and selenate

* PM, plasma membrane; T, tonoplast.

Protein Sorting and Vesicle Traffic

Alessandro Vitale, Danny Schnell, Natasha V. Raikhel, and Maarten J. Chrispeels

Introduction

To function properly, a plant cell must direct many thousands of different polypeptides to specific metabolic compartments, cytoplasmic structures, and membrane systems. Membrane-bound proteins occur in more than a dozen organelles and compartments, including the vacuolar membrane or tonoplast, the plasma membrane, membranes of the endoplasmic reticulum (ER), Golgi apparatus and peroxisomes, outer and inner envelopes of the chloroplast and mitochondria, and in thylakoid membranes. Soluble proteins are present in all subcellular compartments, including the cell wall and, with the only possible exception, the lumen of Golgi cisternae. Some proteins are unique to a particular structure, compartment, or membrane; other, very similar, proteins with comparable amino acid sequences, structures, and functions occur in more than one compartment. For example, invertases occur in the vacuole and cell wall, whereas water-channel proteins (aquaporins) are found in the tonoplast, plasma membrane and ER. Cells therefore require the necessary machinery to sort each protein and direct it to its proper destination.

4.1 The cellular machinery of protein sorting

4.1.1 Protein sorting requires peptide address labels and sorting machinery, and usually requires crossing at least one membrane

How do these thousands of proteins find their way to the correct subcellular location? All proteins, except those that remain in the compartment where they are made, have one or more **targeting domains** that act as an address label (see Box 4.1 on how they are identified). Targeting domains are short amino acid sequences or peptide motifs but can also be post-translational modifications, such as glycans (oligosaccharides). Targeting domains are often located at the N-terminus of a protein, but may be present in the C-terminus or elsewhere in the polypeptide.

Each compartment or membrane system requires a different targeting domain. Likewise, the compartment contains

BOX
4.1

Targeting signals and machineries have been identified using isolated organelles, permeabilized cells, transient transformation and transgenic plants

Different approaches have been used to study targeting signals. Signals that target proteins to chloroplasts, mitochondria, and peroxisomes, can be studied *in vitro* by incubating purified organelles with precursor proteins and determining the conditions necessary for protein uptake into the organelle. This makes it possible to determine which cytosolic proteins and small molecules (e.g., ATP or GTP) are necessary for import. Instead of using isolated organelles, one can also incubate precursor proteins with permeabilized protoplasts.

The secretory system is too complex and cannot be reconstituted *in vitro* with isolated subcellular fractions. Researchers have relied on transient expression systems or stable transformed plants to study protein sorting in the secretory system. Immunocytochemistry or organelle fractionation is used to determine the subcellular compartment(s) in which the protein accumulates (see Box 4.2). Pulse-chase experiments (Box 4.3) provide information on protein processing, traffic routes, and turnover. Because targeting signals are conserved between plant species, one can delete or mutate a putative targeting signal or add it to another protein, and then examine the effect of these mutations on the subcellular location of the protein. When a signal peptide is fused at the N-terminus of a prokaryotic enzyme its presence is sufficient for the protein to enter the ER, traffic along the secretory pathway, and be secreted (see Section 4.7.2). Similar experiments led to the identification of signals for sorting to vacuoles (see Section 4.8.1).

The discovery of green fluorescent protein (GFP), and the subsequent development of other fluorescent proteins that emit different colors, has revolutionized studies of protein traffic, organelle biogenesis, and dynamics. Fluorescence microscopy allows one to

identify precisely the subcellular localization of a given protein and visualize *in vivo* the dynamics of protein traffic and of organelle movement. By fusing GFP with sorting signals or with resident proteins of different compartments virtually any organelle, membrane, or cellular compartment can be “lit up” in a colored form within a living tissue. This approach has established that the Golgi stacks of plant cells, here seen as green dots in a leaf epidermal cell expressing a fusion between GFP and the transmembrane domain of a Golgi protein, move throughout the cytoplasm along tracks formed by actin microfilaments (red in the figure) and the ER network, unlike those of mammalian cells that are positioned in a perinuclear location in association with microtubules.

highly selective sorting machinery that recognizes a specific targeting domain. The interaction between targeting domain and sorting machinery directs the protein to the proper compartment by mediating translocation across one or more compartment membranes. Targeting domains have different names, depending on the location to which a protein is being targeted (Table 4.1). Although the targeting domain is essential for protein transport, it may not be part of the active protein, and proteases often remove the targeting domain to create a functional, mature polypeptide.

Because most proteins are made in the cytosol, the majority of proteins within organelles and compartments must be translocated across one or more membrane. Plastid and mitochondrial DNA encode a small number of proteins (<100)

that are synthesized by ribosomes within these organelles, but the vast majority of chloroplast and mitochondrial proteins are nucleus encoded.

Most proteins have hydrophilic surfaces and therefore do not readily pass through the hydrophobic lipid bilayer. Proteinaceous channels or pores in membranes allow protein entry (Fig. 4.1). Usually, polypeptides are translocated in an extended or unfolded conformation, but a fully folded protein can sometimes pass through a membrane as in peroxisomes and chloroplast thylakoids. As a polypeptide passes through a channel, it is assisted by molecular **chaperones** (for a detailed discussion of chaperones, see Chapter 10). By inhibiting molecular interactions that may cause polypeptides to fold incorrectly and aggregate, chaperones increase the yield of

TABLE 4.1 Peptide address labels for targeting to different organelles and compartments.

Destination	Address label (targeting domain)
ER	Signal peptide (SP)
Chloroplast	Transit peptide
Mitochondrion	Presequence
Nucleus	Nuclear localization signal (NLS)
Peroxisome	Peroxisome targeting signal (PTS)
Vacuole	Vacuolar sorting signal (VSS)

**FIGURE 4.1** A proteinaceous channel and chaperones facilitate the passage of a protein through the lipid bilayer. Chaperones bind a polypeptide on both sides of the membrane (in the cytosol and the organelle interior). They keep the polypeptide in an unfolded state in the cytosol and help it to fold correctly in the organelle interior.

correct tertiary structures but not the rate of protein folding. Some cytosolic chaperones interact with nascent proteins, keeping them unfolded so they can pass through a protein channel. Other chaperones bind to the amino acid chain as it emerges from the membrane and facilitate folding. Still others function as repair stations to correct minor misfolding. The many members of one family of chaperones—the 70-kDa heat shock proteins (Hsp70)—fill all these roles, interacting with a wide spectrum of proteins.

4.1.2 Protein sorting can be a multistep process requiring more than one targeting domain

The general features of protein sorting appear to apply to all compartments. Proteins destined to locations other than the cytosol carry a targeting domain that is recognized by cytosolic factors needed to deliver the polypeptide to the sorting machinery at the compartment surface. These factors act together to deliver the unfolded protein to a specific receptor on the target membrane, thereby opening a channel consisting of several polypeptides. A translocation motor that hydrolyzes nucleoside triphosphates drives protein transport through the membrane, after which the transported protein folds with the help of additional chaperones and ATP.

Targeting of proteins from the cytosol to the compartment surface can occur after protein synthesis is complete (post-translational) or during translation on cytoplasmic ribosomes (cotranslational). Proteins in the first group are released in the cytosol and targeted to a variety of destinations, including plastids, mitochondria, peroxisomes, and nuclei (pathways 1 and 2 in Fig. 4.2). Most proteins destined for the **secretory pathway** are synthesized on ribosomes bound to the ER. The synthesis and translocation of these proteins are coupled, such that the polypeptide chain is transported across the ER membrane as it emerges from the ribosome (pathway 3 in Fig. 4.2).

After passing through a membrane, proteins may be transported to special compartments within semi-autonomous organelles (e.g., the thylakoid membrane in plastids) or transported to other compartments after membrane translocation (e.g., vacuolar and plasma membrane proteins). Transport to a final destination or retention in a compartment usually requires a second targeting domain such as a vacuolar sorting signal. The domains of proteins with multiple targeting and retention signals interact sequentially with various sorting machineries until the final destination is reached. Integral membrane proteins typically insert into the membrane during the translocation process by laterally diffusing within the lipid bilayers once they enter the translocation channel. In many cases the transmembrane segments of these proteins serve the dual purpose of a targeting signal and a membrane anchor.

4.2 Targeting proteins to the plastids

4.2.1 Transport of proteins into chloroplasts involves a removable transit peptide

Although plastids (see Chapter 1) contain their own DNA and ribosomes, most of their proteins are encoded in nuclear DNA and synthesized in and imported from the cytosol. The biosynthesis of proteins encoded by chloroplast DNA is discussed

FIGURE 4.2 All nuclear encoded mRNAs are translated in the cytosol. Pathways 1 and 2: proteins destined for mitochondria, chloroplasts, peroxisomes, or the nucleus and those that are to remain in the cytosol are released from the polyribosomes and may remain bound to chaperones (Pathway 2) or folded (Pathway 1). An exposed targeting sequence will cause the proteins to bind to a receptor (in the cytosol or on an organelle) and then be targeted to that compartment. Pathway 3: if the nascent polypeptide has a signal peptide then the polyribosome will attach to an ER membrane and the protein will be released in the lumen of the ER or become part of the ER membrane. Subsequently proteins will be sorted in the secretory system and either secreted or end up in the plasma membrane, or be transported to the vacuole or the tonoplast.

in Chapter 10. Chloroplasts have an envelope consisting of an outer and an inner membrane and an internal membrane system of thylakoids. These membranes define three aqueous compartments: the intermembrane space in the envelope, the stroma within the inner membrane, and the thylakoid lumen (Fig. 4.3). Thus, proteins must be directed not only into the plastid, but also to the proper location within the organelle.

Chloroplast proteins encoded by nuclear DNA are translated in the cytosol as precursors with an amino-terminal **transit peptide** of ≈ 30 –100 amino acids that targets polypeptides to the chloroplast and enables their translocation into

the stroma. After translocation, a peptidase removes the transit peptides of stromal precursor proteins. Proteins that lack a transit peptide cannot be imported, and if the transit peptide is added to the amino terminus of a protein that is foreign to the chloroplast this chimeric precursor protein is imported. The import of chloroplast precursors occurs at contact sites (proteinaceous channels) between the outer and inner envelope membranes and precursor proteins that are in transit span both envelope membranes.

Although the vast majority of the roughly 2,500 nucleus-encoded proteins that enter chloroplasts have a transit peptide,

FIGURE 4.3 Biosynthesis of chloroplast proteins and their targeting to five different compartments in the chloroplast. Chloroplast proteins may be encoded by nuclear DNA (nDNA) or chloroplast DNA (ctDNA); the respective mRNAs are translated by ribosomes in the cytosol (80S ribosomes) or in the chloroplast stroma (70S ribosomes). Proteins made as precursor polypeptides in the cytosol may be targeted to the outer or inner envelope membranes or may enter the chloroplast stroma. Once across the envelope membranes, proteins may remain in the stroma compartment or may be targeted to the thylakoid membrane, thylakoid lumen, or inner envelope membrane.

a comparison of chloroplast proteomics data with genome sequence data suggest that several hundred proteins are targeted by mechanisms that do not involve a transit peptide. Among this group, a small number of chloroplast proteins (e.g., nucleotide pyrophosphatase/phosphodiesterase, α -amylase, and α -type family of carbonic anhydrases) appear to be targeted to the ER via a signal peptide and then directed to the chloroplast in a mechanism involving vesicle trafficking from the secretory pathway. These proteins are unique among chloroplast proteins in that they contain N-linked glycans that are added in the ER (see Section 4.6.7).

4.2.2 To enter chloroplasts, proteins pass through a proteinaceous channel with the aid of molecular chaperones

Import into chloroplasts can be studied by incubating purified chloroplasts with radioactively labeled precursor proteins (obtained by *in vitro* translation of mRNA in the presence of radioactive amino acids). The accepted model for chloroplast protein import entails two steps and requires chaperones on both sides of the chloroplast envelope and a

group of proteins, collectively called the protein import translocons. The translocons are integral membrane complexes named Toc (translocon at the outer envelope membrane of the chloroplast) and Tic (translocon of the inner envelope membrane). Toc and Tic complexes come into contact at the point of protein import to allow transport directly from the cytosol into the chloroplast. To translocate proteins, both translocons use energy in the form of nucleoside triphosphates.

Cytosolic chaperones (Hsp70 homologs) hold proteins in an unfolded or partially folded state while their transit peptides interact with receptors within the Toc complex. The receptors are associated with a membrane channel through which the imported polypeptides pass (Fig. 4.4). The Toc receptors, Toc34 and Toc159, are specific GTP-binding proteins tightly anchored in the outer membrane with their GTP-binding domains exposed to the cytosol. A third protein, Toc75, forms the membrane channel through multiple β -barrel transmembrane segments. The GTP-binding and hydrolytic activities of the Toc receptors regulate the protein import process by controlling translocation of the polypeptide through the channel. Toc34 and Toc159 are encoded by gene families in most plants and genetic studies suggest that members of these families form distinct translocons that are important in regulating the import of different classes of proteins. A fourth protein, Hsp70 IAP (import intermediate-associated protein), a homolog of Hsp70, is found within the intermembrane space of the envelope. It is proposed to facilitate passage of the protein from the Toc to the Tic complex. Two Tic components, Tic110 and Tic40, associate with a molecular chaperone in the stroma, Hsp93 (93-kDa heat shock protein family member) and these three form a molecular motor that pulls proteins across the envelope via cycles of ATP hydrolysis.

After entering the chloroplast stroma a protease removes the transit peptide. If the protein is to remain in the stroma, it will be folded with the help of a class III chaperone called chaperonin (see Chapter 10). By contrast, soluble proteins that function in the thylakoid lumen, and membrane proteins that become part of the thylakoid, are held by chaperones in an unfolded state for passage to their next destination. Inner-membrane proteins are inserted into the membrane during translocation across the Tic complex or from the stroma after completion of translocation. Proteins targeted to the outer membrane do not enter the transport channel but instead enter the membrane directly from the cytosol.

4.2.3 Targeting into the thylakoid lumen requires a bipartite transit peptide and targeting to the thylakoid may follow four different paths from the stroma

After import, many chloroplast polypeptides are further sorted to the inner envelope membrane, to the thylakoid membrane, or to the thylakoid lumen. Proteins destined for

FIGURE 4.4 Mechanism of protein import into chloroplasts. At the top of the figure, chaperones in the cytosol hold a protein with its transit peptide exposed in an unfolded conformation. The protein on the left has a stromal targeting domain only (red), whereas the protein on the right has a bipartite transit peptide with both stromal and thylakoid (yellow) domains. The transit peptide is bound by receptors in the outer membrane (Toc159 and Toc34). They deliver the protein to the Toc channel (Toc75) via a GTP hydrolysis cycle. The Toc complex associates with the Tic complex (X and Tic110), and the polypeptide is pulled into the stroma via ATP-dependent binding to the stromal Hsp93 chaperone. Proteins that remain in the stroma (e.g., Rubisco) lose their transit peptides and are folded and assembled with the assistance of the Hsp60 chaperone and ATP hydrolysis. Proteins that function in the thylakoid membrane enter the stroma via the same pathway, but are targeted to the thylakoid via one of four pathways. Thylakoid membrane proteins (e.g., LHCPs) are engaged by the chloroplast signal recognition particle (cpSRP) and are inserted into the membrane via GTP hydrolysis. Other membrane proteins (Cf_oH, PsbX, Y, K) insert spontaneously without the assistance of other proteins or nucleoside triphosphate hydrolysis. Some thylakoid luminal proteins (e.g., OE33 and plastocyanin) are targeted by the chloroplast SEC (cpSEC) pathway by binding to chloroplast Sec A in an ATP-dependent reaction. Other luminal proteins (e.g., OE23 and OE16) fold rapidly in the stroma and are targeted by the twin arginine translocation (TAT) pathway using the pH gradient (Δ pH) across the membrane.

the thylakoid lumen, such as plastocyanin, contain a bipartite transit peptide. The stromal targeting domain of the transit peptide guides the protein to the stroma, where a protease removes it. This exposes a second targeting domain just behind the first one in the amino acid sequence (Fig. 4.4). This luminal targeting domain then directs the protein across the thylakoid membrane to the lumen, where a second protease removes it. The transit peptides of proteins integral to the thylakoid membrane direct proteins into the stroma and hydrophobic transmembrane regions of the mature protein itself, rather than a removable targeting domain, direct the protein to and into the thylakoid membrane.

There are at least four pathways for targeting to the thylakoid: two for soluble luminal proteins and two for membrane proteins (Fig. 4.4). In contrast to the Toc and Tic machinery, the components of the thylakoid targeting pathways are closely related to the protein targeting pathways that operate in bacteria, suggesting that protein targeting to the thylakoid has been conserved during evolution from the original bacterial endosymbiont.

(1) The translocation of luminal proteins, such as OE33 and plastocyanin, by the **cpSEC pathway** requires ATP and a soluble protein and is stimulated by a pH difference (ΔpH) between the chloroplast stroma and the thylakoid lumen. Isolation and characterization of the targeting components show them to be homologous to the bacterial secretory translocation system and is therefore referred to as the cpSEC pathway (chloroplast SEC pathway). (2) Other thylakoid luminal proteins, such as OE23 and OE17, are transported by an ATP-independent process that requires only the pH gradient. A twin-arginine motif (RR) located preceding the hydrophobic region in the second region of the transit peptide, is essential for protein transport on the ΔpH pathway. Consequently, this pathway is referred to as the **twin arginine translocation** or **TAT pathway**. It represents one of the rare cases in which fully folded proteins are transported across a membrane and appears to have evolved to accommodate proteins that rapidly fold into their three-dimensional structures in the stroma prior to transport into the lumen. Although the receptors and potential channel proteins have been identified for the TAT pathway, the mechanism by which transport occurs without disrupting membrane integrity is to date unknown.

(3) The third pathway, for integral thylakoid membrane proteins such as light-harvesting chlorophyll-binding protein (LHCP), requires GTP rather than ATP and is stimulated by the presence of a ΔpH . This pathway also requires a stromal factor, which has been identified as a chloroplast homolog of the signal recognition particle (SRP), a ribonucleoprotein complex involved in targeting proteins to the ER (see Section 4.6.2) and is therefore called the **cpSRP pathway**. (4) The fourth pathway is termed the **spontaneous pathway** because no energy requirements or protein components have been identified. Proteins such as the CFoII subunit of the thylakoid ATP synthase and the PsbX, K, and Y subunits of the photosystems utilize this pathway.

4.3 Targeting proteins to mitochondria

4.3.1 Transport into mitochondria relies on targeting domains, called presequences, and an import apparatus

Mitochondria, like chloroplasts, have both an outer membrane (OM) and an inner membrane (IM) that define two separate aqueous compartments: the intermembrane space and the mitochondrial matrix, each containing unique proteins (Fig. 4.5A). The enzymes of the electron transport chain lie in the inner membrane, whereas glycine decarboxylase and most of the enzymes of the tricarboxylic acid cycle are found in the matrix.

The majority of mitochondrial proteins (hundreds) are encoded by nuclear DNA, translated in the cytosol and synthesized as precursors with an amino-terminal targeting

FIGURE 4.5 (A) The four compartments of the mitochondrion. (B) Schematic representation of an amphipathic polypeptide helix with charged amino acids on one side and hydrophobic amino acids on the other side. (C) Two-dimensional projection of a typical presequence of an ATPase subunit imported into mitochondria, with hydrophobic amino acids to one side and charged amino acids on the other.

domain, called a **presequence**, that facilitates entry into mitochondria. Despite the superficial resemblance between chloroplast transit peptides and mitochondrial presequences, the latter do not target proteins to chloroplasts, and transit peptides do not target proteins to mitochondria. Analysis of mitochondrial presequences indicates that many can form positively charged amphipathic α -helices; these have hydrophobic amino acid residues on one face of the helix and charged residues on the other (Fig. 4.5B,C). After a protein

enters a mitochondrion, the presequence is cleaved by an endopeptidase, just as in the chloroplast.

Proteins are transported to mitochondria in an unfolded state with the help of the chaperone, cytosolic Hsp70, and imported by an import apparatus that spans both inner and outer membranes at a point of contact. Once the protein is in the matrix, folding is catalyzed by another chaperone, Hsp60, and by proteins called TOMs and TIMs (translocases of outer and innner membranes, respectively) (Fig. 4.6).

FIGURE 4.6 Protein import into the mitochondrial matrix. Polypeptides are held in an unfolded configuration in the cytosol by chaperones such as Hsp70. After binding to an import receptor in the outer membrane the polypeptide is transferred to a proteinaceous pore and is threaded through it and through a pore in the inner membrane at a site where the two membranes are in contact. A matrix processing protease cleaves the presequence and chaperones help to fold the protein in the mitochondrial matrix. Numbers indicate sequence of events.

Several features distinguish mitochondrial from chloroplast protein transport. Mitochondrial import machinery proteins do not share sequence identity with those of the chloroplast. Furthermore, transport into the mitochondrial matrix requires an electrochemical potential across the inner membrane, in addition to ATP. Which mechanisms at the surface of these organelles contribute to the fidelity of protein sorting between mitochondria and chloroplasts? As in chloroplasts, transport of some proteins into the mitochondrial inner membrane and the intermembrane space requires two signals. Integral inner membrane proteins initially engage the Tom complex, but can utilize one of two Tim complexes to facilitate membrane insertion. Membrane proteins with a single transmembrane segment utilize the same Tim23 complex utilized by matrix proteins. Complex, multi-spanning membrane proteins, including the nucleotide and metabolite transporters, utilize the Tim22 complex. In both cases the hydrophobic amino acid sequences including one or more transmembrane segments serve to trigger insertion of the protein into the membrane during translocation. Mitochondria also contain numerous proteins in the intermembrane space that are involved in electron transport. These proteins are initially transported through the Tom complex, but do not engage the Tim complexes. Rather, a specific mitochondrial import and assembly (MIA) machinery in the intermembrane space exists to assist in their folding and assembly.

Some proteins can be dual-targeted to both chloroplasts and mitochondria. These proteins typically perform basic maintenance functions within the organelles, including DNA and RNA maintenance, protein translation, and protein processing. Dual targeting of proteins occurs by two mechanisms. In one case, the gene for a protein might encode two alternative targeting domains that are generated by selection of alternative transcription or translation start sites or alternative mRNA splicing. In the second case, proteins can carry a single targeting domain with characteristics of both chloroplast and mitochondrial targeting signals. These ambiguous targeting domains are recognized by the targeting components of both organelles.

4.4 Targeting proteins to peroxisomes

4.4.1 Uptake of proteins by peroxisomes involves removable or intrinsic peroxisome targeting signals

Peroxisomes are specialized organelles that participate in many essential metabolic pathways (see Chapter 1). Plants contain at least three types of peroxisomes: (1) germinating seeds, young seedlings, and senescent leaves contain glyoxysomes that metabolize fatty acyl chains (see Chapters 1, 14,

and 20); (2) peroxisomes in leaves play a major role in photorespiration (see Chapters 1 and 14); (3) some root nodules of tropical legumes that export ureides contain peroxisomes with unique enzymes of nitrogen metabolism (see Chapters 1 and 16). Peroxisomal enzymes also mediate steps in the biosynthesis of important plant hormones and signals, including jasmonic acid, salicylic acid, indole acetic acid, reactive oxygen species (ROS), and nitric oxide (NO). The importance of peroxisomes for the plant life cycle is shown by the observation that mutants that disturb peroxisome biogenesis are often embryo lethal.

Peroxisomes are surrounded by a single membrane and do not contain DNA or ribosomes. It appears that the membrane component of peroxisomes is initially derived from the ER via a budding process. However, all soluble peroxisomal proteins and many membrane proteins must be synthesized by cytosolic ribosomes and imported from the cytoplasm into pre-existing peroxisomes. At least two distinct peroxisome targeting signals, PTS1 and PTS2, are involved in the import of proteins into the peroxisomal matrix.

The tripeptide PTS1 (Ser-Lys-Leu, SKL) or a closely related variant targets most proteins destined for the peroxisomal matrix. This short sequence is located at the carboxyl terminus of many peroxisomal proteins and is not removed after translocation into the peroxisome. Deletion of this carboxyl-terminal signal abolishes import of nearly all peroxisomal proteins that carry it. In a few proteins, import is not abolished, suggesting that additional peroxisome targeting signals may be present within the protein. PTS2 consists of a cleavable amino-terminal targeting domain and is used by a subset of peroxisomal matrix proteins. Passenger proteins fused to PTS-like sequences are directed correctly into peroxisomes.

Protein import to peroxisomes requires not only a peroxisomal targeting signal but also ATP. Although the transport of some PTS1-containing proteins requires cytosolic factors, such as members of the Hsp70 family, it is not known whether chaperones are needed for import of all proteins, and the relationship between chaperones and protein import is an active area of research. Peroxisomal protein import also is distinguished by the observation that fully folded and oligomeric proteins can be imported into the organelle.

Mutants deficient in peroxisome biogenesis, including mutants in the import machinery for peroxisomal matrix proteins, called *pex* mutants, have mutations in *Peroxin* or *PEX* genes. More than 30 *pex* mutants have been identified in yeast (*Saccharomyces cerevisiae*) and mammals and half a dozen in *Arabidopsis*. In addition, many of the remaining *PEX* genes for which there are no clear phenotypes have been identified in the *Arabidopsis* genome. In yeast and other fungi the PEX5 receptor protein in the cytosol binds cytosolic PTS1-containing proteins (Fig. 4.7) and the PEX7 receptor also in the cytosol binds PTS2-containing proteins. These complexes then dock at the peroxisomal membrane to other PEX proteins that constitute the proteinaceous pore for protein import.

FIGURE 4.7 Import of peroxisomal protein carrying the PTS1 targeting signal. A correctly folded protein in the cytosol such as catalase may carry an exposed PTS1 that will bind to a cytosolic receptor (PEX 5) and the complex docks at a receptor in the peroxisomal membrane (PEX 14). The polypeptide is transferred to a proteinaceous pore consisting of several PEX subunits and transported into the peroxisomal matrix. The cytosolic receptor is released and recycled. Numbers indicate sequence of events. Source: Lodish et al. (2013). *Molecular Cell Biology*, 7th edition. W.H. Freeman.

4.5 Transport in and out of the nucleus

4.5.1 Proteins enter and leave the nucleus via nuclear pore complexes

Many macromolecules that function in the nucleus, including regulatory proteins, histones, RNA polymerases, and heterogeneous nuclear RNA-binding proteins, are synthesized in the cytoplasm (Fig. 4.2). In some cases, DNA from plant pathogenic bacteria and viruses is also selectively imported from the cytoplasm into the nucleus. Concurrently, tRNAs and mRNAs are synthesized, modified, and processed in the nucleus and exported to the cytoplasm. The nuclear envelope, which regulates these transport activities, comprises three structural elements: the outer and inner membranes with their intermembrane space (perinuclear space); nuclear pore complexes (NPCs); and

the nuclear lamina. The outer nuclear membrane is continuous with the ER and, like rough ER, is studded with ribosomes (see Chapter 1 for a detailed description).

The nuclear envelope has hundreds of NPCs, located where the two nuclear membranes meet (Fig. 4.8). Proteins, ribonucleoprotein complexes, and RNA move in and out of the nucleus through these pores. Each NPC has multiple copies of at least 30 different proteins called nucleoporins (Nups). Each NPC constitutes a passive diffusion channel ≈ 9 nm in diameter. Small proteins of <40 kDa can diffuse passively through this pore, whereas larger proteins enter the nucleus through active transport. However, even small nuclear proteins such as the 20-kDa histones usually enter the nucleus by active transport rather than by diffusion.

4.5.2 Importins and exportins help transport proteins that contain specific localization signals into and out of the nucleus

Most polypeptides destined for the nucleus have address labels, called **nuclear localization signals** (NLSs), consisting of one or more short internal sequences with basic amino acids. NLSs share certain characteristics, but there is no strict consensus sequence. They generally contain several residues of arginine and lysine and may also have proline residues that disrupt helical domains. The position of the NLS within the amino acid sequence of a protein varies, and they are not cleaved from nuclear proteins after translocation. Therefore the proteins can re-enter the nucleus if they are exported to the cytosol or released when the nuclear envelope is disassembled during mitosis. Many nuclear proteins require more than one NLS for efficient nuclear targeting *in vivo*, which suggests that protein structure may play an important role in NLS presentation and in the ability of independent NLSs in the same polypeptide to function in a cooperative manner.

Many viral proteins have NLSs, and PKKKRKV is the NLS of the large T-antigen of the simian virus SV40, which has been studied in great detail. A mutation that causes a single amino acid change at the third position abolishes NLS function and prevents nuclear import causing the large T-antigen to remain in the cytosol. Another class of NLS, designated bipartite, is typified by nucleoplasmin and the *Zea mays* (maize) transcription factor opaque-2 (Table 4.2). Mutations in either basic motif alone do not affect function, whereas mutations in both basic motifs significantly impair nuclear targeting.

Three cytosolic proteins play a role in the import of a protein carrying an NLS: importin α , importin β , and Ran, a monomeric G-protein that can exist in either the GTP-bound or GDP-bound conformation. Importins can act singly or as a bimolecular $\alpha\beta$ complex. The first step of nuclear import is the binding of an NLS-containing cargo protein to importin to form a bi- or trimolecular complex. This complex diffuses into the pore and binds successively to different Nups. After entering the nucleoplasm, interaction of the complex with

Ran-GTP results in a conformational change that causes the cargo protein to be released with the formation of an importin–Ran-GTP complex. This complex will be exported back to the cytosol. Keeping this cycle going requires a GDP-GTP exchange factor (Ran-GEF) in the nucleoplasm and a GTPase accelerating protein (Ran-GAP) in the cytosol. The cycle is illustrated in Fig. 4.9. The rapid dissociation of the cargo complex in the nucleoplasm creates a concentration gradient of the complex that promotes its diffusion through the NPC, and the asymmetric distribution of Ran-GAP and Ran-GEF makes the cycle possible.

A similar mechanism is responsible for protein export. Three types of nuclear export signals (NESs) have been identified and the best understood are the leucine-rich motifs. Proteins with this motif bind to an exportin–Ran-GTP complex. This complex diffuses through the pore, interacting transiently with Nups and finally an interaction with NPC elements on the cytosolic side stimulates GTP hydrolysis and a change in the conformation of Ran, so that the complex falls apart and the exported protein is released into the cytosol.

Traffic into the nucleus can be regulated by complexing with a cytoplasmic protein that masks the NLSs, by phosphorylation and dephosphorylation, by association with membranes, or by environmental stimuli such as light. Some nuclear proteins show tissue-specific nuclear localization: they are present in the nucleus in some tissues but excluded in others. In the last few years evidence from several genetic screens indicates that Nups affect various processes like auxin response, cold-stress tolerance, flowering time, and plant microbe interactions.

mRNAs that have been processed in the nucleus remain associated with specific hnRNP (heterogeneous ribonucleoprotein) proteins in a messenger ribonucleoprotein (mRNP) complex. These complexes leave the nucleus after binding to the mRNP exporter, a heterodimeric protein.

4.6 ER is the secretory pathway port of entry and a protein nursery

Eukaryotic cells contain an extensive membrane network consisting of flattened sacs (cisternae), small vesicles, and other compartments—all of which are collectively referred to as the endomembrane system (see Chapter 1). Major components of the system are the ER, the Golgi apparatus, vacuoles, the plasma membrane, and different types of endosomes. This membrane network hosts the secretory pathway, a biochemical pathway that allows the secretion of proteins from the cell. Proteins synthesized by this pathway are termed secretory proteins, but not

FIGURE 4.9 Mechanism of import of a transcription factor (TF) into the nucleus. The cycle starts with the NLS of a TF binding to an importin molecule (see + sign); the complex enters the nucleus through the NPC and in the nucleoplasm it reacts with Ran-GTP so that the TF is released; Ran-GTP bound to importin will leave the nucleus; hydrolysis of GTP will cause a conformational change producing a Ran-GDP that can enter the nucleus and react with a GDP-GTP exchange factor to produce Ran-GTP.

Source: Lodish et al. (2013). *Molecular Cell Biology*, 7th edition. W.H. Freeman.

all of them are secreted because many are sorted to and reside and function in the different compartments of the endomembrane system. Thus the secretory pathway also functions in the biogenesis of its own compartments and membranes, including the tonoplast and the plasma membrane. The major routes of traffic along the secretory pathway have been determined by fractionation of subcellular compartments (Box 4.2) coupled with radioactive pulse-chase experiments (Box 4.3). These techniques are still used now, in addition to the more recent use of fusions with fluorescent proteins (Box 4.1).

Thousands of different proteins involved in every major process of plant development, reproduction, and response to the environment, as well as many storage proteins are synthesized by the secretory pathway. Essential functions of the plant endomembrane system, not shared with many other eukaryotes, include the biogenesis of multifunctional vacuoles, the use of the ER as a storage compartment, the formation of the cell plate during cytokinesis, the biosynthesis of

cell wall polysaccharides and proteins, and polarized growth of certain cell types. The endomembrane system also stores calcium, synthesizes lipids for delivery elsewhere, and regulates steps in hormone synthesis, transport, and signaling. Many human and viral proteins of medical interest are also secretory proteins, and scientists are exploiting the plant endomembrane system for a safer and more cost-effective production of recombinant pharmaceuticals (Box 4.4).

4.6.1 Proteins travel in vesicles through the endomembrane system like cargo in containers

The major biosynthetic traffic route of the secretory pathway is from the ER to the Golgi and ultimately to the plasma membrane for secretion or to the tonoplast for delivery to vacuoles (Fig. 4.10). Passage from the Golgi to vacuoles is mediated by the *trans*-Golgi network (TGN) and multivesicular bodies (MVBs). As detailed in Section 1.5.2, two regions of the TGN can be morphologically identified: the early TGN (or Golgi-associated TGN) has a cisternal appearance and is strictly associated to the *trans*-cisternae of the Golgi apparatus, whereas the late TGN (or free TGN) has a grape-like appearance and is detached from the Golgi. The terms “early” and “late” refer to the direction of the biosynthetic secretory pathway. It should be noticed that the late TGN and MVBs are also involved in endocytosis from the cell surface (Fig. 4.10). Because endocytic traffic has an opposite direction compared to biosynthetic traffic, the late TGN is also termed “early endosomes”, whereas MVBs are termed “late endosomes”. A trademark of the secretory pathway is the formation of vesicles that bud off from one cisterna or compartment and then dock and fuse with the next one. The biosynthetic, forward or anterograde traffic must be matched by reverse or retrograde traffic of equal magnitude if the different compartments are to maintain their characteristic proteins. Furthermore, soluble and integral membrane proteins unique to each compartment must either remain behind when vesicles are formed to carry their cargo forward or be rapidly retrieved back to the compartment of residence by retrograde traffic (Fig. 4.11). The formation by budding of a vesicle requires that a coat of proteins be recruited from the cytosol. Before the vesicle can dock and fuse with its target compartment this coat must be stripped off again. Vesicles traveling between different compartments and in different directions have unique protein coats that contribute to the specificity of sorting.

4.6.2 The first sorting decision takes place during translation and requires the presence of signal peptides for entry into the ER

For nearly all secretory proteins, the first sorting decision is made when ribosomes involved in their synthesis become attached to the ER, creating rough ER (see Chapter 1). Rough

Sucrose density gradients are used to separate subcellular organelles for analysis of their contents

How do we find out in which subcellular compartment a protein is located? One way to answer this is to separate the organelles present in a homogenate on a sucrose gradient, on the basis of their density (isopycnic density centrifugation). The tissue must be homogenized gently in a buffered medium that is more or less isotonic with the cytosol to keep the organelles intact. Vacuoles, Golgi apparatus, plasma membrane, and ER usually fragment and form microsomes, most of which are from the ER, the most extensive endomembrane system. Newly synthesized proteins released in the lumen of the ER end up in the lumen of ER-derived microsomes. Removal of cell wall fragments, starch grains, and nuclei by a brief centrifugation at 2,000g results in a cleared homogenate that can be loaded on top of a sucrose gradient and centrifuged to separate the components.

In an isopycnic gradient with a sucrose concentration of 16% at the top and 48% or 60% at the bottom each organelle will travel to the region where the density of the gradient matches its own (figure). Such gradients can be used to separate organelles that have the same size, such as mitochondria and peroxisomes, or the microsomal vesicles that are derived from different membrane systems. The density of these vesicles reflects the protein-to-lipid ratio of the different compartments from which they are derived.

After centrifugation, the gradients are fractionated and assayed to determine which fractions have a particular protein of interest. Identification of each organelle (whether intact or fragmented into vesicles) is by means of a well-characterized marker enzyme or protein, preferably one unique to that organelle. Clathrin-coated vesicles and other organelles that lack characteristic enzyme activities can be identified with

antibodies raised against a characteristic protein (e.g., clathrin). As proteomes of the different compartments are being characterized with growing speed, and genomics is providing thousands of gene sequences, the repertoire of antibodies available against proteins specific for each compartment is rapidly growing as well. An enzyme assay or

immunoblot can be used to determine which gradient fractions contain the protein of interest and, by comparing its distribution with that of marker proteins, investigators can identify the subcellular location of the protein of interest.

4.3**

Pulse-chase allows monitoring of traffic and protein stability

The fate of proteins can be followed by pulse-chase experiments in which cells or organs are exposed during a short time (pulse) to a radioactive precursor (amino acid or sugar). To stop incorporation of radioactivity, an excess of nonradioactive forms of the same amino acids is then added (chase) and a first sample is immediately collected (pulse, or zero time chase). Other samples are collected after different time intervals and represent the different chase time-points. The protein of interest is then selected from each sample with appropriate antibodies and analyzed by electrophoresis. Finally, proteins in the gel are revealed by autoradiography. The *total amount* of the protein of interest will obviously be the same in each sample (it can be visualized by protein blot, gels on the right in each panel), but the *radioactive amount* will vary with time (gels on the left in each panel). If a protein is destined to be secreted (A), its radioactive form will appear in the cell incubation medium during the chase and in parallel will disappear from the cells. To determine traffic routes, individual samples can be

subjected to subcellular fractionation before immunoprecipitation: the radioactive protein will be detected in the compartment of synthesis at the end of the pulse (if the pulse time is not longer than the time taken to move to the next compartment) and then, at different chase times, in the compartments of transit and their final residence. Pulse-chase protein labeling was developed in the laboratory of Nobel Laureate George Palade in the 1960s and allowed him to determine that secreted proteins start their life in the ER and then travel through the Golgi. Pulse-chase also allows one to follow with time the processing of proteins from larger precursor to smaller mature forms (B, notice that a small amount of newly synthesized precursor is always present in the cell and can be revealed by protein blot) and to measure protein half life (C, protein with short half life). The administration, during the experiment, of specific inhibitors of protein processing or of trafficking steps also allows one to determine the role of processing on traffic and the influence of traffic on protein stability.

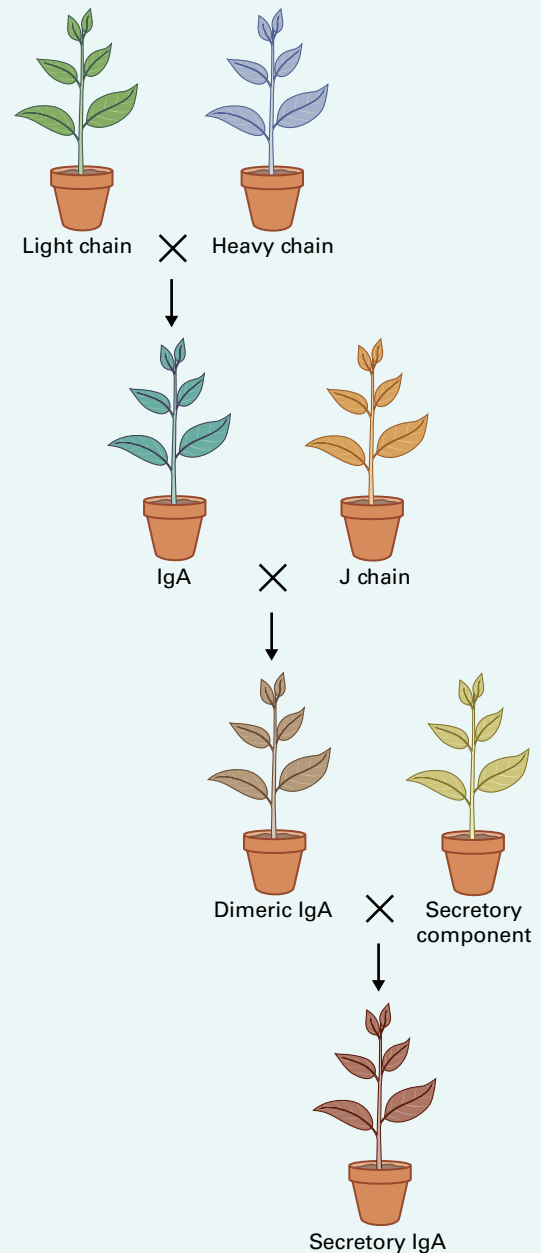

BOX
4.4

Many proteins that have important applications in the pharmaceutical industry are secretory proteins and can be produced in transgenic plants

Many human and viral proteins that are used for medical applications are secretory proteins. Antibodies provide an excellent example, as today they are the single most important group of pharmaceuticals. The secretory protein family also includes all proteins of blood serum and of milk, peptide hormones, digestive enzymes, proteins of the extracellular matrix, such as collagen, and many viral antigens. Plants have been investigated as bioreactors for the production of many of these proteins, and antibodies produced in transgenic plants are already undergoing clinical trials. Growing plants is much less expensive than cell growth in fermentors, and plant-produced compounds are free from potential contamination by pathogenic viruses or prions. Plants could therefore be safer and more cost-effective bioreactors for the pharmaceutical industry, although this needs to be verified in large-scale production, and regulatory and public acceptance issues will need to be taken into consideration. The manufacture of drugs will only be permitted, if ever, in crop plants if the strictest containment conditions are observed by the manufacturers.

Antibodies are particularly stable in the apoplast and they can accumulate in transgenic plants up to 1% or even 10% of total protein, depending on the plant tissue and the specific antibody molecule. The production of secretory immunoglobulin A (SIgA), a very complex molecule, has been a remarkable success of plant biotechnology. SIgAs are the main antibodies found in mucosal secretions, such as saliva, tears, and gut secretions, and have the unusual characteristics of being produced by the cooperation of two cell types. Like most antibodies, the basic unit is a tetramer composed of two light and two heavy chains. This unit is assembled and dimerized by a joining (J) chain in the ER of plasma cells to form dimeric IgA (dIgA, actually a nonamer). dIgA is secreted and then recognized by a receptor present on the basolateral surface of epithelial cells. Transcytosis causes transport of the receptor/ligand complex to the apical surface, where a protease releases the dIgA associated with a portion of the receptor (called secretory component, SC), resulting in the formation of the full, 10-subunit SIgA molecule. SIgA can be faithfully assembled in the ER when the four sequences (heavy and light chains, joining chain, and SC) are individually

expressed in transgenic plants that are then crossed until the final form is synthesized in a single plant, opening the way for cost-effective, large-scale production of this pharmaceutical.

ER is particularly abundant in cells that specialize in protein secretion (e.g., cereal aleurone cells triggered to secrete hydrolases by gibberellic acid) or protein storage (e.g., storage parenchyma cells of developing seeds). The luminal (internal) space of the ER is topologically distinct from the cytosol and equivalent to the vacuolar and extracellular spaces, because of

the mechanism of vesicle budding described above and illustrated in Figure 4.11. In other words, once a protein is in the lumen of the ER, the protein need not pass through another membrane to move from one compartment to another of the endomembrane system and become an extracellular or a vacuolar protein. Similarly, during intracellular traffic, integral

FIGURE 4.10 Overview of the secretory pathway and endocytosis. Proteins synthesized on the rough ER travel to the Golgi and TGN. They can then be transported to the vacuole via MVBs or secreted. Proteins retrieved from the cell surface in endocytic vesicles arrive at the free TGN (early endosomes) and can then be recycled back to the plasma membrane or delivered to the vacuole via MVBs (late endosomes). The different types of vesicles involved are indicated.

membrane proteins maintain their orientation with respect to the membrane, and if they reach the plasma membrane their luminal domains will become extracellular.

As they are being synthesized, soluble secretory proteins cross the membrane completely, whereas integral membrane secretory proteins become part of the ER membrane. Why do the ribosomes synthesizing these classes of proteins bind to the ER, and how do proteins cross the lipid bilayer? The nascent polypeptide chains of these proteins have at their amino terminus a sequence termed signal peptide (see Table 4.1), usually of about 16–30 amino acids, that directs the polypeptide chain to the ER membrane, begins the process of translocating the entire protein into the lumen of the

ER, and is finally removed by a specific protease of the ER (Fig. 4.12). Such **signal peptides** are found on nearly all soluble secretory proteins and on many integral membrane proteins of the secretory system. Signal peptides differ from one another in amino acid sequence but share important structural features: located at the N-terminus of a polypeptide they typically consist of a short sequence containing one or more positively charged amino acids followed by at least six hydrophobic amino acids and then additional amino acids before the cleavage site (Table 4.3). Using recombinant DNA techniques to produce chimeric proteins, it has been found that a signal peptide attached to a cytosolic protein leads to translocation into the ER lumen, indicating that it is a

sufficient signal for this process to occur, and that the signal peptides of different secretory proteins are interchangeable among plant, animal, and yeast proteins.

A signal peptide is first recognized by the **signal recognition particle (SRP)**, a ribonucleoprotein complex that contains a small RNA molecule of ≈ 300 nucleotides and six different proteins. SRPs ordinarily reside in the cytosol, where they await the protrusion of a signal peptide on a nascent protein being made on a polysome. Recognition between the signal peptide and the SRP must occur when the nascent polypeptide is ≈ 70 amino acids long, with ≈ 40 amino acids protruding beyond the surface of the ribosome. SRP binds to the hydrophobic core of the signal peptide causing arrest of translation until the entire assembly makes contact with the SRP receptor and docks on the ER membrane. The receptor is an integral membrane protein composed of two different GTP-binding polypeptides. Once docking has occurred, the SRP and one of the two polypeptides of the receptor dissociate from the signal peptide, utilizing the energy obtained by GTP hydrolysis. After the SRP is released into the cytosol, the ribosome and its nascent polypeptide dock onto the translocation complex, a transmembrane protein channel in the ER membrane consisting of three integral membrane proteins (Fig. 4.12). Release of SRP relieves the block in translation and the growing polypeptide extends across the channel into the ER lumen. As the polypeptide enters the lumen of the ER, the signal peptide is cotranslationally cleaved

by signal peptidase, an enzyme complex at the luminal side of each ER translocation channel. The block and then release of translation makes it unnecessary that cytosolic chaperones maintain the growing polypeptide in an unfolded state (unlike what happens for translocation into mitochondria or chloroplasts). Furthermore, the block ensures that folding only occurs within the ER lumen, where a number of ER-specific modifications, necessary for the productive folding of many secretory proteins, occur (see Section 4.6.5).

4.6.3 Topogenic sequences are needed for the correct orientation of integral membrane proteins

Membranes of the endomembrane system contain integral proteins. Some have only one transmembrane segment whereas others have many transmembrane segments, connected by peptide loops on both sides of the membrane (Fig. 4.13) and with amino- and carboxy termini that can be located on either side of the membrane.

How are these proteins inserted into the ER in their correct orientation? Let us first consider the simplest case: a protein with a single transmembrane domain in which the amino terminus protrudes into the lumen of the ER. Such proteins have signal peptides that function exactly as described in the

FIGURE 4.13 Orientation of membrane proteins. Membrane proteins are classified according to their topological organization in the membrane. Type I and type II proteins have one transmembrane protein domain (an α -helix of 17–24 amino acids) located at the carboxyl (COOH) or amino (NH_2) termini, respectively. Also, type I has a cleaved signal peptide, but type II does not. Multispanning proteins can have their two termini on the same side or on different sides of the membrane depending on number of spans. Tail-anchored proteins are similar to type II proteins but they have very few amino acids following the transmembrane domain. Unlike other transmembrane proteins, they are inserted post-translationally. Glycosylphosphatidylinositol (GPI) anchored proteins are initially synthesized as type I proteins and the luminal portion is later transferred by a transamidase to a phospholipid in the membrane.

previous section. The signal peptide is cleaved as the protein begins to traverse the membrane. Then, part way through the membrane, protein translocation stops. A hydrophobic transmembrane amino acid sequence acts as a “stop transfer,” or **membrane anchor sequence**. The ribosome then detaches from the translocon and polypeptide synthesis is completed in the cytosol. This type of integral membrane protein, with a cytoplasmic carboxyl terminus, is called a type I membrane protein. Proteins that exhibit the reverse orientation, called type II, do not contain a removable signal peptide. Rather, the internal hydrophobic transmembrane domain acts as a non-removable signal peptide: it directs translocation into the ER lumen of the sequence that follows it, leaving in the cytosol the domains that precede it. The glycosyl transferases in the Golgi have this orientation.

Tail-anchored (TA) proteins have the topology as that of type II but with a luminal C-terminal domain composed of only a few amino acids (often less than ten) or none; for this reason their active site is always exposed to the cytosol. During synthesis, the hydrophobic domain of TA proteins is still sequestered within the ribosome when the stop codon is reached and the ribosome starts to disassemble, so that it never becomes available to SRP interactions. TA proteins are therefore inserted post-translationally into the target membrane. A number of TA proteins are active in different compartments of the secretory pathway but are always first inserted into the ER membrane. Others are inserted and active on the outer envelope of mitochondria and plastids.

In proteins with multiple hydrophobic membrane-spanning domains (termed type III), the loops between the transmembrane domains are usually hydrophilic. The first transmembrane domain acts as a signal peptide (the amino terminus remaining in the cytosol), and the second domain functions as a membrane anchor sequence; the third domain acts again as a nonremovable signal peptide, the fourth as a membrane anchor sequence, and so on. Although both SRP

and SRP receptors are necessary for the integration of the first transmembrane domain, they are not needed for the third, fifth, and subsequent domains.

4.6.4 Some proteins are anchored in the membrane by lipid molecules

Some membrane proteins are anchored to the membrane by a glycosylphosphatidylinositol (GPI) moiety. These proteins have a cleavable N-terminal signal peptide and a single C-terminal hydrophobic domain that terminates at the stop codon. Close to this domain there is a consensus recognized by an ER transamidase complex that removes the hydrophobic domain and replaces it with a preassembled GPI anchor. These GPI-anchored proteins are therefore membrane anchored but fully exposed to the ER lumen (Fig. 4.13). They then usually traffic along the secretory pathway to the plasma membrane, thus exposing the functional polypeptide on the cell surface. The consensus recognized by the transaminidase is rather complex, but algorithms have been developed to identify it. Using these algorithms combined with proteomic analysis of purified proteins, more than 200 *Arabidopsis* GPI-anchored proteins have been putatively identified. Arabinogalactan proteins, phycocyanins, lipid transfer proteins, and β -1,3 glucanases are highly represented members. The GPI anchor can be removed *in vivo* by the action of a phospholipase, thus releasing the protein in the cell wall as a soluble polypeptide (Fig. 4.14). Such processing may have a signaling function.

Protein modifications by the covalent linkage of lipids to the polypeptide chain occur in the cytosol (see Section 1.2.4 and Fig. 1.10 for a detailed description of these modifications). These modifications allow attachment to membranes leaving the whole polypeptide exposed to the cytosol and therefore

FIGURE 4.14 Synthesis of GPI-anchored proteins. GPI-anchored proteins are initially synthesized as type I proteins. The luminal portion is later transferred by a transamidase to the preformed GPI anchor. After reaching the cell surface, the protein can remain membrane-anchored or be released by phospholipases into the cell wall environment. The signal peptide is in red; the original hydrophobic domain is in dark blue.

have a function topologically similar to the transmembrane domain of TA proteins. Palmitoylation is the only reversible lipid modification and often occurs on myristoylated polypeptides: because myristic acid does not promote strong attachment, reversible palmitoylation can regulate cycles of membrane attachment and release that are used by signaling proteins. Prenyl transferases involved in this process are heterodimers. A unique geranylgeranyl transferase, with specific α and β subunits, is involved in the modification of Rab GTPases, which are a large family of regulators of vesicular traffic. Geranylgeranyl transferase and farnesyl transferase involved in the modification of many other proteins have instead a common α subunit and a specific β subunit. Loss-of-function mutants of the α subunit or the farnesyl transferase β subunit are lethal in yeast and in animals that have been investigated but not in *Arabidopsis*, where they give rise to enhanced ABA response and homeotic mutations. This is consistent with the finding that the *Arabidopsis* transcription factor APETALA1 (see Chapter 19) and a number of other plant proteins involved in tissue differentiation have prenylation signals, and that APETALA1 mutated in its farnesylation consensus loses its function.

4.6.5 Folding of secretory proteins occurs in the ER lumen in an environment that differs from the cytosol, and is assisted by helper proteins that constitute a large proportion of the ER proteome

The chemical environments of the ER lumen and the cytosol are different. Free calcium in the plant cytosol is normally at submicromolar concentrations whereas in the ER it is about 100 times greater. The most abundant proteins of the ER are Ca^{2+} -binding proteins and are regulated by Ca^{2+} . Examples include calnexin and calreticulin, proteins that act as molecular chaperones as well as Ca^{2+} -binding proteins.

The reducing environment of the cytosol makes disulfide bond formation a very rare event. By contrast, the ER lumen, like the extracellular space, is oxidizing and thus favors the formation of disulfide bonds that play fundamental roles in the folding and assembly of many secretory proteins.

Correct folding of newly synthesized proteins can fail. Adverse environmental conditions (such as oxidative stress and alterations in temperature), changes in protein synthesis rates due to stress, and gene mutations increase the chances of irreversible aggregation, but the results of in vitro denaturation/renaturation experiments show that, without the assistance of helpers, most proteins are anyway on the verge of failing to fold correctly. All subcellular compartments where protein synthesis occurs are equipped with chaperones and enzymes that have the role of avoiding unspecific aggregation of newly synthesized polypeptides, thus favoring folding efficiency.

Many proteins that reside in the ER are directly or indirectly involved as folding helpers (Fig. 4.15):

- Signal peptidase is a multisubunit membrane complex that removes the signal peptide of newly synthesized proteins. Removal is cotranslational and is usually required for correct folding.
- The binding protein (BiP) and endoplasmic reticulum chaperonin, are the ER members of the heat shock chaperone 70 and 90 families. Both are very abundant soluble proteins in the ER lumen. BiP transiently associates in an ATP driven process with many, perhaps most, newly synthesized secretory proteins, inhibiting unspecific aggregation during polypeptide folding and the assembly of multimeric proteins. Endoplasmic reticulum chaperonin plays a similar role but it is much less promiscuous than BiP and seems specific for multicellular eukaryotes, since it has not been found in yeast.
- Protein folding starts cotranslationally, thus often leading to erroneous disulfide (S–S) bond formation in the ER lumen. The S–S bonds that were formed need to be rearranged to allow correct folding. Protein disulfide isomerase (PDI), a soluble oxidoreductase, acts as a disulfide donor to folding intermediates. PDI is then reoxidized by flavoproteins of the ER so it can start a new round of isomerization (see Chapter 10).
- Peptidyl prolyl *cis-trans*-isomerases catalyze the *cis-trans* isomerization of prolyl-peptide bonds, which can be a rate-limiting folding step.
- Many secretory proteins are cotranslationally glycosylated on specific asparagine (Asn) residues by oligosaccharyl-transferase, an enzyme complex active at the luminal side of any translocation channel of the ER membrane. This modification, termed N-glycosylation, increases the solubility of many folding intermediates.
- The enzymes glucosyltransferase I and II and UDP-Glc:glycoprotein glucosyltransferase (UGGT) modify Asn-linked glycans in a reaction cycle that, together with transient association to the ER lectins calreticulin and calnexin, helps correct folding of glycoproteins.

Because of their fundamental role in the synthesis of the thousands of secretory proteins, the ER folding helpers are necessary for virtually any process of plant life. Mutations in their genes, overexpression or underexpression can affect plant development, reproduction, or stress resistance (Table 4.4).

4.6.6 The ER quality control system monitors proper folding and assembly of secretory proteins, and disposes of misfolded polypeptides

Incorrectly folded polypeptides are sequestered and degraded as soon as possible, to minimize harm to the cell. The ER lumen, being the folding compartment not only of its own

FIGURE 4.15 Chaperones and folding helpers aid in the folding of proteins in the ER. BiP binds to hydrophobic motifs to prevent aggregation. If present, N-glycosylation sites are recognized by oligosaccharide transferase and glycans are transferred to the nascent polypeptide chain. Glucosidase I and II remove glucose residues (G) from the glycans and UDP-Glc-glycoprotein glucosyltransferase (UGGT) adds back one glucose. This cycle causes binding and release of the glycopolypeptide by the two lectins calnexin and calreticulin (CNX/CRT). Protein disulfide isomerase (PDI) catalyzes the formation of correct disulfide bonds. Eventually, the newly synthesized protein either completes correct folding and proceeds to traffic to its correct destination or remains permanently misfolded and is targeted for degradation in the cytosol or the vacuole.
 Source: Modified from Liu & Howell S.H. (2010). *Plant Cell* 22:2930–2942.

residents but also of proteins destined for many other locations, retains newly synthesized polypeptides until they have acquired their correct conformation. This function probably evolved to reduce the probability that malfunctioning

proteins would reach their destinations. The three functions of promoting correct folding, retaining proteins until they are correctly structured and degrading defective proteins are collectively termed **ER quality control**.

TABLE 4.4 Some effects of mutations in *Arabidopsis* genes encoding ER folding helpers.

Protein	Mutation	Phenotype
Oligosaccharyltransferase subunits SST3a and SST3b	T-DNA insertions (double mutation)	Gametophytic lethal
Glucosidase I	point mutations at <i>knopf</i> locus (EMS treatment)	Seedling lethal Reduced content of cellulose
UDP-glucose:glycoprotein glucosyltransferase	Point mutation that causes an mRNA splicing defect	ER quality control is less stringent Restores brassinosteroid sensitivity in a <i>bri1</i> mutant, in which the brassinosteroid receptor is structurally defective but functionally active
BiP2	T-DNA insertion	Reduced secretion of pathogenesis-related proteins Reduced resistance to <i>Pseudomonas syringae</i> Hypersensitivity to salicylic acid analogs and to tunicamycin Hyperactivation of endoplasmic, calnexin and protein disulfide isomerase genes upon treatment with salicylic acid analogs
Endoplasmic	T-DNA insertion immediately upstream of the gene (expression is severely affected but not abolished)	<i>clavata</i> -like phenotypes inhibition of pollen tube elongation and pollen fertility

FIGURE 4.16 BiP facilitates the assembly of trimers of the *Phaseolus vulgaris* protein phaseolin. Phaseolin homotrimers are mainly held together by hydrophobic interactions between α -helical domains: the three C-terminal domains indicated in green in the folded monomer interact with those indicated in red of an adjacent monomer, to form a trimer with a triangular shape. The C-terminal α -helical domains were fused to a secretory form of GFP (sGFP, consisting of GFP preceded by a signal peptide) and the chimeric polypeptide (termed sGFP418) was expressed in a transgenic plant. Protoplasts were prepared and pulse-labeled with radioactive amino acids. When proteins were immunoprecipitated with anti-BiP antibodies and analyzed by SDS-PAGE and fluorography, sGFP418 was shown to be the major polypeptide associated to BiP (lane 1). Treatment of the immunoprecipitate with ATP abolished this association (lane 2) and sGFP418 could be immunoprecipitated with anti GFP antiserum from the released material (lane 3). When a similar experiment was performed on sGFP, as a control, no association with BiP was detected (not shown). This indicates that the same domains involved in phaseolin assembly promote interactions with BiP. When phaseolin assembles into trimers these interactions are abolished.

Source: Modified from Foresti et al. (2003). *Plant Cell* 15:2464–2475.

Many clues on ER quality control have been obtained studying the activity of the chaperone BiP. BiP binds preferentially to stretches of seven amino acids rich in hydrophobic amino acids. These sequences are not exposed at the protein surface in the folded and assembled proteins, thus providing an explanation for why, for example, BiP only binds to unassembled monomers of the bean (*Phaseolus vulgaris*) vacuolar

storage protein phaseolin but not to assembled trimers. The domains of phaseolin monomers that directly interact to form trimers contain BiP binding sites that are masked upon assembly (Fig. 4.16). By binding, BiP prevents the nonspecific interaction of such domains during folding, thereby preventing proteins from denaturing or aggregating. BiP is an ATPase, and the hydrolysis of ATP causes it to release the

partially folded protein, affording additional chances to fold correctly. Correct folding of a protein may involve several cycles of BiP binding, ATP hydrolysis, and dissociation. The interactions with ER residents such as BiP provide a mechanism for the second feature of ER quality control that is the retention of not yet folded or assembled proteins in the ER.

When polypeptides are permanently misfolded or the subunits of multimeric proteins cannot assemble, the misfolded chains or the unassembled subunits are degraded. This is the third feature of ER quality control. Mechanisms have evolved that measure the time unproductively spent in the ER in the effort of folding or proper assembly, so that only defective proteins are degraded whereas normal intermediates of folding are not. Degradation in many cases occurs by first retrotranslocating the defective polypeptide back into the cytosol and then targeting it by ubiquitination for proteasome degradation. However, certain defective proteins are sorted to the vacuole for degradation, either through Golgi-mediated vesicular traffic or by autophagy of ER portions, both in yeast and plant cells.

4.6.7 Many secretory proteins are N-glycosylated during translocation in the ER

As mentioned before, N-glycosylation occurs in the ER. Attachment of N-linked glycans (oligosaccharides) occurs as the nascent polypeptide chain emerges into the ER lumen. Such glycans, which exhibit a (glucose)₃(mannose)₉(N-acetylglucosamine)₂ ((Glc)₃(Man)₉(GlcNAc)₂) structure, are then modified, first in the ER and later in the Golgi apparatus (see Section 4.8.5). These glycans are built up, one sugar residue at a time, on dolichol pyrophosphate, a polyisoprenoid lipid of the

ER, and are then transferred as a unit by the ER enzyme oligosaccharide protein transferase to certain Asn residues (Fig. 4.17). The residues that receive these glycans are almost invariably in an Asn-X-Ser or Asn-X-Thr configuration, where X can be any amino acid except proline. However, not all Asn-X-Ser/Thr configurations in a given secretory protein are necessarily N-glycosylated, because cotranslational folding of polypeptides can inhibit access of the oligosaccharyltransferase. Large-scale analysis indicates that two-thirds of potential N-glycosylation sites are actually glycosylated. After a glycan is transferred to a nascent polypeptide chain, the three glucose residues are quickly removed by two α -glucosidases that reside in the ER (glucosidase I and II). The resulting glycan, with the structure (Man)₉(GlcNAc)₂, is referred to as a high-mannose glycan.

N-linked glycans are highly hydrophilic and increase the water solubility of many polypeptides, thus allowing the production of a wider variety of protein conformations. They also protect proteins from proteolytic attack and have a major role in protein folding and quality control in the ER. Calnexin and calreticulin, two ER-resident lectins, help glycoproteins fold by binding to high-mannose chains from which two of the three glucose residues have already been removed. Such binding may result in the release of a correctly folded glycoprotein upon removal of the last glucose. In cases where these lectins release an incorrectly folded glycoprotein, an ER-located UDP-glucose:glycoprotein glucosyltransferase can add one glucose to the high-mannose chain. Cycles of addition and removal of glucose and interactions with the ER lectins take place until the glycoprotein is correctly folded. A folded glycoprotein is not a substrate for re-addition of glucose residues and thus cannot interact with calnexin or calreticulin. This system monitors the process of glycoprotein folding and may participate with other chaperones in retaining unfolded glycopolypeptides in the ER lumen.

FIGURE 4.17 Cotranslational transfer of a glycan (oligosaccharide) from a lipid carrier in the ER to an Asn residue of a nascent polypeptide chain. Glycans consisting of (Glc)₃(Man)₉(GlcNAc)₂ are assembled on dolichol carriers and transferred to an Asn residue as soon as a susceptible residue appears in the lumen of the ER. Removal of glucose residues and readdition of one residue is part of the folding process, which is aided by chaperones like BiP and protein disulfide isomerase (PDI).

4.6.8 The unfolded protein response optimizes the quality control functions of the ER

The workload of the ER as a protein factory is not the same in all tissues and may depend on the stage of development or on environmental or biotic stresses. Plant cells, as well as other eukaryotic cells, have a sensing and signal transduction mechanism that regulates transcription and translation of specific genes to adapt the secretory pathway machinery to the level of ER loading needed. The genes encoding ER folding helpers are major targets of this signaling, and the most dramatic changes occur if the ER is loaded with an unusually high amount of newly synthesized misfolded proteins. For this reason, the

mechanism has been termed unfolded protein response (UPR). Chemicals that inhibit correct protein folding in the ER, such as inhibitors of N-glycosylation, reducing agents or amino acid analogs, are potent UPR inducers and are used to study this mechanism, but the UPR is also involved when development or stress responses lead to rapid increases in secretory protein synthesis. The synthesis of individual secretory proteins with genetic defects that negatively affect their folding—by preventing signal peptide cleavage for example—also induces the UPR.

The UPR sensors/transducers are transmembrane proteins of the ER that monitor the accumulation of misfolded proteins and trigger the appropriate cellular responses. Four such sensors have been identified in plant cells: the membrane-associated transcription factors bZIP17, bZIP28, and bZIP60, and the kinase IRE1 (Fig. 4.18).

FIGURE 4.18 Misfolded protein accumulation in the ER affects the behavior of at least four plant ER membrane proteins that signal the UPR. Upon misfolded protein accumulation the transcription factors bZIP28 and bZIP17 traffic to the Golgi complex, where their cytosolic domains are cleaved off by the Golgi-resident proteases S1P and S2P. They then enter the nucleus and activate transcription of target genes. The transmembrane protein ATF6 of mammalian cells has little sequence similarity with these plant proteins but has a very similar mechanism of action. IRE1 is present in plants, animals, and yeast. Upon ER stress IRE1 dimerizes and autophosphorylates its cytosolic portion, leading to the activation of an endonuclease domain. Plant IRE1 produces alternative splicing of the mRNA encoding the transmembrane transcription factor bZIP60, leading to the synthesis of a form without the transmembrane domain. This form reaches the nucleus where it upregulates the transcription of target genes. In mammalian and yeast cells, IRE1 instead splices the otherwise inactive mRNAs encoding the transcription factors XBP1 and HAC1, respectively. Besides this, active IRE1 also promotes degradation of specific mRNAs.

Transcriptome analysis of *Arabidopsis* plants treated with folding inhibitors (e.g., tunicamycin) shows that virtually all ER folding helpers described in Section 4.6.5, many proteins of the secretory traffic machinery, subunits of the ER translocation channel and of protein degradation machineries, as well as certain transcription factors are all upregulated. Downregulated genes encode almost exclusively secretory proteins, mostly of the cell wall. This is consistent with the model in which UPR increases the synthesis of folding helpers and the machinery for the degradation of misfolded polypeptides, and lowers the workload of the ER by attenuating the synthesis of cargo secretory proteins and at the same time stimulating protein traffic.

A further level of ER sensing mechanism has been discovered by studying changes occurring during plant pathogen attack (the major pathogen-induced proteins are secreted or vacuolar hydrolases). It was found that transcriptional induction of BiP precedes that of the hydrolases, instead of following it, as would be expected by the general UPR model. Thus the ER appears to “prepare” itself for the increased load instead of responding to it. It was then determined that the promoters of many plant genes induced as part of the UPR have an additional *cis*-acting regulatory sequence that allows upregulation by NPR1, a master regulator of systemic acquired resistance, through the action of a novel transcription factor.

It should also be noted that, compared to mammals, plants have a higher copy number of certain ER folding helpers, which may reflect specialized functions. BiP is encoded by a single gene in the vertebrates that have been analyzed, but it is the product of multigene families in many plants. Out of the three BiP genes of *Arabidopsis*, BiP1 and 2 are constitutively expressed at high levels and induced to a limited extent upon UPR, whereas BiP3 is present at extremely low levels in normal conditions and is induced 40–50 times upon UPR. Besides canonical calreticulin (two proteins in *Arabidopsis*, CRT1 and CRT2), an additional isoform (CRT3) has been identified in plants. *Arabidopsis* CRT3 has a specific role in the synthesis of plasma membrane kinase-like receptors such as the brassinosteroid receptor BRI1 and the elf18-responsive EF-Tu receptor (EFR), which is involved in plant innate immunity. CRT3 has an unusual C-terminal domain and cannot be substituted by CRT1 or CRT2 in these functions.

4.7 Protein traffic and sorting in the secretory pathway: the ER

4.7.1 Vesicle budding and fusion is mediated by SNAREs and GTPases

Vesicle traffic occurs between many different compartments and it is therefore necessary for the vesicle and the target membrane to be appropriately identified. Vesicle budding is driven by the recruitment of cytosolic proteins that will form

multimeric protein complexes, thus “coating” the vesicle. The different coats recognize the cytosolic tails of transmembrane proteins that will be incorporated into that specific vesicle. Four types of coats have been identified to date (see Fig. 4.10). (1) COP I (coat protein I) vesicles form at the Golgi apparatus and mediate retrograde traffic from the *cis*-Golgi to the ER (COP Ia-type vesicles) and between Golgi cisternae (COP Ib-type vesicles; see also Fig. 1.25A). (2) COP II (coat protein II) vesicles play the opposite role: they form at the ER and promote anterograde traffic to the Golgi apparatus. (3) Clathrin-coated vesicles (CCVs) mediate traffic from the late TGN (or free TGN) to MVBs and from the plasma membrane to the TGN and to MVBs (see also Fig. 1.36). Because MVBs serve as intermediate compartments between the TGN and vacuoles, some researchers also refer to them as prevacuolar compartments. Here, as in Chapter 1, we will use the term MVB. CCVs therefore mediate anterograde biosynthetic traffic to vacuoles as well as endocytotic traffic from the cell surface to the cell interior. Both types of vesicles share a common clathrin cage, but their coat contains different adaptor proteins that specifically link to clathrin the cytosolic tails of receptors that function in the different pathways (see Section 4.8.2). Although the term “adaptor protein” is used mainly in the case of CCVs, polypeptides with similar functions are part of the other type of coated vesicles. (4) Retromer-coated vesicles mediate the recycling of receptors from MVBs to the TGN. Other types of vesicles certainly exist, but their coats are yet to be identified. Recruitment of COP I, COP II, and clathrin, but not of the retromer, requires specific GTPases, which are part of the complexes. Before fusion to the target compartment, vesicles are uncoated by GTPase or ATPase activities. Assembly of the vesicle coat, budding of the vesicle, uncoating and subsequent fusion are shown in Fig. 4.19A–D. The discovery that the fungal metabolite brefeldin A inhibits specific coat recruitments has provided an important tool to study protein traffic along the secretory pathway (Box 4.5).

Proper identification and fusion to the target compartments is achieved through the interaction of vesicle proteins that include SNARE proteins (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor). SNAREs that occur on transport vesicles are called v-SNAREs, whereas t-SNAREs are present on the targets with which the vesicles will fuse. In plants, t-SNAREs are also called syntaxins or SYPs; SYP stands for “syntaxin of plants”. Plants have a complex secretory system and a large number of SNARE genes: 21–26 SNARE genes have been identified in yeast (the range is because some assignments are uncertain), 20 in *Drosophila*, 35–36 in humans, 60–69 in *Arabidopsis*, and 57–80 in rice (*Oryza sativa*). Some *Arabidopsis* T-DNA insertion mutations in SNARE genes have no obvious phenotype, suggesting genetic redundancy, whereas other insertions are embryo or gametophyte lethal even though they belong to small families with extensive sequence identity. Therefore, new and creative approaches are required to address the specific function of these SNAREs (Box 4.6).

SNAREs, which can vary considerably in size and structure, are sufficient for artificial vesicle fusion *in vitro* and

FIGURE 4.19 Vesicle budding and fusion with a target membrane. (A) Vesicle budding starts with the recruitment of a small GTP-binding protein to a patch of the donor membrane. Complexes of coat proteins that are in the cytosol then bind to the cytosolic domains of receptors that are complexed with cargo proteins on the inside of the vesicle or to transmembrane proteins that may also be cargo. (B) Once the vesicle has pinched off, the GTPase activity of the GTP binding protein causes GTP hydrolysis and P_i release. (C) This results in uncoating of the vesicle. (D) Vesicle fusion occurs when the v-SNAREs encounter the right t-SNAREs on the target membrane so that they can form the four-helix bundles that involve the two SNAREs and another protein called α -SNAP. (E) Four-helix bundle of α -SNAP and SNAREs.

Source: Lodish et al. (2013). *Molecular Cell Biology*, 7th edition. W.H. Freeman.

necessary for this process in vivo, but in cells they act in combination with other proteins to allow accurate and efficient recognition and fusion between vesicles and their target membranes. Among these proteins are Rab proteins, which constitute a large family of Ras-related GTPases. The GTP-bound form of a given Rab is recruited from the cytosol to its specific vesicle and interacts with effectors on the target membrane, probably acting as a tethering factor before SNAREs interact and promote actual fusion.

Most SNAREs are tail-anchored proteins, and they all share a coiled coil domain of 60–70 amino acids in their cytoplasmic

portion that allows SNAREs to assemble in four-helix bundles called *trans*-SNARE complexes (Fig. 4.19E). One helix comes from a v-SNARE, one from its cognate t-SNARE, and two from a protein called α -SNAP that is tethered to the target membrane by a lipid anchor. These complexes are instrumental in facilitating the fusion of the vesicle membrane with its target membrane. The membrane fusion event allows the deposition of the vesicle contents into the target compartment. Once delivery is complete, the complex is dissociated. Dissociation of the four-helical bundle requires soluble NSF (*N*-ethylmaleimide sensitive factor). After the

**BOX
4.5****Vesicle cycling and brefeldin A action**

Brefeldin A (BFA) is a small fungal metabolite that has been a valuable tool to study vesicle trafficking because it blocks vesicle traffic from the ER to the Golgi. The molecular target of BFA is a Sec7-type GTP exchange factor (GEF) for small G proteins of the ARF class; ARF-GEF that catalyzes the activation of the GTPase ARF. Activated ARFs recruit COP I coat proteins and form transport vesicles. BFA traps the ARF*GDP/GEF complex on membranes, preventing GDP/GTP exchange, vesicle coat recruitment and vesicle formation. A major effect of BFA is the re-distribution of Golgi membranes and enzymes to the ER causing the formation of a BFA compartment that contains both ER and Golgi proteins. Thus, if the traffic of a given protein is inhibited by BFA or an unstable protein is stabilized by this drug, this is taken as an indication that the protein of interest normally travels through the Golgi apparatus. However, there are differences in the BFA response between mammalian and plant cells. In mammalian cells, the loss of COP I coats causes the formation of membrane tubules

that eventually fuse with ER. By contrast, in plant cells, BFA treatment does not cause tubulation of the Golgi. The Golgi stacks initially retain their morphology except for the *cis*-cisternae. The remaining cisternae fuse with the ER to form hybrid stacks, or fuse with other Golgi to form oversized Golgi complexes that are continuous with the ER. Incorrect sorting in the TGN caused by BFA also gives rise to altered secretory vesicles that become trapped in aggregates known as Golgi bodies. Within a given cell there are multiple ARF-GEFs implicated in different trafficking steps. Eight genes have been identified in *Arabidopsis*. Not all of them are BFA-sensitive and the function of all of them is not known, but BFA also affects the ARF-GEF protein GNOM, which is localized in early endosomes (late or free TGN), thus preventing auxin efflux carrier proteins, the PIN proteins, from cycling between the plasma membrane and early endosomes.

**BOX
4.6****Functional analysis of two homologous SNAREs**

A clever genetic approach was used to study the cellular machinery that recognizes C-terminal vacuolar sorting signal (ctVSS). Seeds of transgenic plants that expressed a chimeric construct with an added ctVSS were mutagenized and the plants were examined for evidence that the protein had been secreted. The construct, called VAC2, encoded the clavata3 (CLV3) protein fused with a functional ctVSS at its carboxyl terminus. Wild-type CLV3 is a secreted protein that negatively regulates the proliferation of the shoot apical meristem by binding and activating the plasma membrane CLV1/2 LRR kinase receptor. Because VAC2 is sorted to the vacuole it cannot act on the CLV3 receptor on the plasma membrane and transgenic plants that express VAC2 have a normal phenotype. Mutations in the machinery that recognizes ctVSS may cause VAC2 to be secreted and the excess of

CLV3 activity at the cell surface will reduce the size of the meristem. Such a phenotype can be readily identified by visual inspection of the plants.

Using this genetic assay the function of two conditionally redundant v-SNAREs, VTI11, and VTI12 that are 60% identical were identified. They localized at the TGN with a specific group of t-SNAREs, SYPs. However, analysis of both mutants showed that VTI11 and VTI12 can substitute for each other in their respective SNARE complexes. Interestingly, a double mutant cross between *vit11* and *vit12* is embryo lethal. By crossing plants expressing VAC2 with *vit11* and *vit12*, it was shown that trafficking of VAC2 (ctVSS) required the SNARE VTI12 but not VTI11.

Source: Adachi et al. (2003). *Proc Natl Acad Sci USA* 100:7395–7400.

SNARE complex is dissociated by a GTP-requiring process, the v-SNARE is recycled back to its original compartment.

4.7.2 Soluble proteins do not need sorting signals to travel from the ER lumen and be secreted, but most ER residents have signals that promote their recycling from the Golgi complex back into the ER

Soluble proteins that have been released into the lumen of the ER but have no other targeting or retention signals, are packaged at ER export sites, traffic through the Golgi apparatus and are eventually secreted. When plants or plant cells are transformed with transgenes that encode chimeric proteins consisting of a signal peptide from any secretory protein and a cytosolic or bacterial polypeptide that is not ordinarily secreted, the resulting protein enters the ER, and if it is not misfolded, it is secreted (see Box 4.1). For this reason, the pathway leading to secretion from the cell is often called the **default pathway**, and this holds true for any eukaryotic cell.

Some membrane proteins, on the other hand, appear to have motifs that promote their traffic to the Golgi. Investigation on a number of integral membrane proteins has identified di-acidic (such as DXE), dibasic ([RK]X[RK]), or dihydrophobic (YF) motifs that are present on their cytosolic tails, and when these motifs are mutated, the proteins remain in the ER. These sequences interact with components of the COP II complex, and it has been directly shown that

increased synthesis of integral membrane cargo results in increased number of ER export sites, an effect that has not been obtained by overexpression of soluble secretory proteins. This suggests that default traffic of soluble proteins may take advantage of the traffic of certain membrane proteins.

If secretion is a default pathway for soluble proteins that enter the ER, it follows that retention in the ER needs signals. Most ER-resident proteins actually enter COP II-mediated anterograde traffic along the secretory pathway, but when they reach the Golgi apparatus they are retrieved to the ER by COP Ia-mediated retrograde traffic. For many soluble ER residents, retrieval occurs because they have a carboxyl-terminal tetrapeptide, in most cases HDEL or KDEL, recognized by the integral membrane receptor ERD2p, which shuttles between the Golgi apparatus and the ER. Affinity of ERD2p for the tetrapeptide is low at pH close to neutrality and higher at the slightly acidic pH of the Golgi apparatus, thus providing a mechanism for efficient retrieval of ER residents (Fig. 4.20). It should be kept in mind that in heterooligomeric proteins of the ER it is sufficient that the signal be present on just one subunit. Thus, polypeptides that do not have the tetrapeptide can also use this retrieval mechanism. Experimentally adding a KDEL or HDEL tail to proteins that ordinarily are secreted usually causes their efficient retention in the ER. This technique has been exploited to increase protein accumulation in transgenic plants avoiding possible degradation of the recombinant protein by acidic proteases present in the apoplast and vacuole, or by the proteasome if synthesis occurs in the cytosol. Conversely, removing HDEL from an ER resident such as calreticulin allows its secretion at a rate similar to that of naturally secreted proteins.

FIGURE 4.20 *The KDEL retention signal is recognized by the KDEL receptor ERD2p. Many ER residents are present at high concentrations and may passively diffuse into COP II vesicles that travel to the Golgi. They will be retrieved from the Golgi by COP Ia vesicles because at the lower pH of the Golgi, there is greater binding between the KDEL sequence and the ERD2p receptor. ERD2p cycles back to the ER because it has an ER retrieval motif recognized by COP Ia. At the pH of the ER the receptor releases its ligand.*

How are integral membrane proteins of the ER retrieved? Many of them have two positively charged amino acids at positions -3 and -4 from the end of their cytosolic tail. The motif is KK if the tail is constituted by the C-terminus of the polypeptide and RR if it is the N-terminus. These motifs allow direct interactions with the COP Ia complex.

Not all ER residents use retrieval mechanisms. Some of them are retained without ever entering traffic to the Golgi. The mechanisms are not clear but the length of transmembrane domains may play a role. The membrane bilayer changes in lipid composition as it moves from one compartment to the next of the secretory pathway. Bilayers more distant from the ER are thicker. Proteins with short transmembrane domains (17 amino acids or fewer) have difficulty proceeding in forward traffic, simply because of mechanical constraints: the next membrane is too thick for them. By changing the length of the single transmembrane domain of a model chimeric type I protein it was found that a hydrophobic sequence of 20 amino acids allows anterograde traffic but the protein remains in the Golgi, and 23 amino acids allow progression to the plasma membrane.

4.7.3 Plant proteins with the KDEL signal can also be delivered to the cell surface or to vacuoles

Some plant proteins have a KDEL motif but function in a compartment different from the ER, thus having apparently the “wrong” localization signal. The first such protein to be discovered was the 22-kDa auxin-binding protein 1 (ABP1), located mainly in the ER. However, a minor proportion of ABP1 molecules are always present at the cell surface, where they positively regulate clathrin-mediated endocytosis of the PIN auxin efflux facilitators. Binding of auxin to ABP1 blocks this activity and inhibits PIN endocytosis. This led to the idea that, when necessary, the cell may be able to allow or regulate the secretion of ER residents. A conformational change in the protein could alter the way the KDEL tail is displayed and inhibit its interaction with the KDEL receptor, ERD2p.

The vacuolar cysteine proteases (they have a key cysteine residue in their active site) of the sulfhydryl-endopeptidase class, called SH-EP, have a transient KDEL signal. During seed germination, these proteases have a role in the hydrolysis of storage proteins and in cell death. Like many other proteolytic enzymes, SH-EPs are activated by post-translational removal of the C-terminal propeptide that carries KDEL. SH-EP first accumulates in the ER as large accretions easily detectable with the electron microscope in enlarged ER cisternae and is subsequently delivered to the vacuole (Fig. 4.21). Deletion of the KDEL sequence by genetic engineering causes the enzyme to be secreted, indicating that, perhaps surprisingly, the ER retention motif is necessary for its correct sorting to the vacuole. Thus, in this case the KDEL signal functions as a mechanism to allow first high accumulation in the ER and then rapid, massive vacuolar delivery and activation.

4.7.4 In cereal endosperm cells, certain plant storage proteins assemble into large insoluble polymers that form protein bodies

The widespread globulin seed storage proteins of the 7S and 11S classes, as well as the less common 2S albumins (Box 4.7) traffic from the ER along the secretory pathway to vacuoles specialized for the high accumulation of proteins termed protein storage vacuoles, PSV (see also Section 1.7.3). In contrast, storage proteins of the prolamin class typical of cereals, form very large electron-dense, round-shaped, insoluble accretions with diameters of 0.5–2.0 μm within the ER lumen. These structures, which are in essence huge polymers, can be delivered to storage vacuoles by autophagy-like processes that bypass the Golgi apparatus or they are permanently stored in the ER-derived protein bodies (PB), formed when the ER membrane surrounding the aggregate pinches off from a cisterna (Fig. 4.22). Accumulation in PBs is particularly evident in maize, sorghum (*Sorghum bicolor*), millet

BOX
4-7

Seed storage proteins have unusual structures and accumulate in storage vacuoles or ER-derived protein bodies

Most plant seeds contain abundant storage proteins that constitute the major source of protein for human food and animal feed. Seed storage proteins are unique to plants and can be divided into four classes: 7S, 11S, 2S (named after their sedimentation coefficient expressed in Svedberg units), and prolamins. Each class usually includes polypeptides produced by a family of very similar genes. Their synthesis, transport and accumulation involve the different compartments of the secretory system. 7S, 11S, and 2S storage proteins accumulate in protein storage vacuoles (PSVs), whereas prolamins form protein bodies (PB) directly from the ER. Seed storage proteins evolved for the purpose of storing reduced nitrogen to be used in the first stages of seed germination. Seed PSVs also contain other abundant secretory proteins for plant defense such as lectins, enzyme inhibitors and ribosome inactivating proteins. For example, seeds of the common bean (*P. vulgaris*) contain ~5% phytohemagglutinin, a lectin that is toxic to mammals and birds, and 1% α -amylase inhibitor, a protein that inhibits the α -amylases of mammals and insects.

The most common storage proteins are the salt-soluble 7S and 11S globulins, present in seeds of probably all plants although in different relative proportions. Both the **7S and 11S globulins** are synthesized as soluble polypeptides that form trimers in the ER and then proceed to PSVs via the Golgi and MVBs. In MVBs and PSVs, the polypeptides of the 11S class undergo a single event of proteolytic processing that forms subunits of 40 and 20 kDa. The two new subunits remain linked by a disulfide bond, and the proteolytic event exposes new hydrophobic residues that interact leading to the dimerization of the original trimers. Despite the low primary sequence similarity, 7S and 11S proteins have very similar secondary and tertiary structures, and the trimers that they form are nearly identical: compare the structure of the soybean (*Glycine max*) 11S trimer shown here with that of the phaseolin (the 7S storage protein of *P. vulgaris*) trimer shown in Fig. 4.16. The basic unit is repeated twice in a symmetrical fashion in each folded polypeptide and is comprised of a β -barrel and three α -helical segments. The latter are fundamental for trimer assembly. The β -barrel is unusual: it is termed “double-stranded β -helix” or “jelly-roll” barrel-like structure and is a hallmark of the large cupin superfamily of proteins. The cupin domain is considered by evolutionists to be an ancient protein-folding unit, having originated in prokaryotic ancestors and now present in all organisms with many diverse functions. The cupin domain is possibly the most compact existing form of polypeptide folding and is very resistant to heat and proteolysis,

features that are probably important in storage proteins. It is also a major plant allergen.

2S storage proteins, particularly abundant in certain oilseeds such as oilseed rape (*Brassica napus*), are structurally unrelated to the 7S and 11S proteins. They traffic as monomers along the secretory pathway to PSVs. Post-translational proteolysis that starts in MVBs can remove an N-terminal propeptide or an internal propeptide, or both, depending on the species. The major feature of 2S albumins is the presence of four conserved disulfide bonds, two of which link the two subunits originating from internal proteolytic processing. Unlike the 7S and 11S globulins, this protein class has a remarkably high methionine content, a feature that has attracted the interest of biotechnologists for the improvement of the essential amino acid balance in seeds, until it was discovered that 2S albumins elicit allergic responses in mammals.

Prolamins are the least common but most diverse group of storage proteins. They are restricted to grasses and have been intensely investigated because they are the major seed proteins in wheat, maize, barley, sorghum and rye. They have the common feature of being soluble only in solutions containing more than 50% alcohol or upon reduction of their inter-chain disulfide bonds. The major prolamins in cereals of the Triticeae tribe (wheat, barley, and rye) can be divided into sulfur-rich, sulfur-poor, and high molecular weight proteins. The last have inter- and intra-chain disulfide bonds that lead to the formation of large polymers, whereas sulfur-rich prolamins have only intra-chain bonds. The sulfur-rich and high molecular weight prolamins have evolved by the attachment of a repeated sequence to a 2S albumin. The repeats are usually motifs of about six to eight amino acids, with a high content of proline or glutamine (hence the name prolamins), that occur several times in succession or are more dispersed within less conserved sequences. The sulfur-poor prolamins lack the 2S albumin domain. Glutenins, the high molecular weight prolamins of wheat, are responsible for the elastic properties of dough, and therefore for the bread-making performance of wheat flour. Inflammatory responses to gliadins, the sulfur-rich prolamins of wheat, and glutenin are the molecular basis of coeliac disease.

In wheat and sorghum, the prolamin types described above are less abundant and the major prolamins have evolved more recently, although they also contain repeats and polymerize thanks to disulfide bonds.

High molecular weight prolamins form large polymers that most probably constitute the fundamental core of a PB, to which other prolamins then associate. The protein

body is then essentially an extremely large heteropolymer that forms within the ER and is unable to enter vesicle-mediate traffic along the secretory pathway. In certain

plant species, such as maize, PBs remain as isolated structures, whereas in others, such as wheat, they can end up in PSVs, probably through autophagy.

FIGURE 4.22 Illustration of the formation of protein bodies and the transfer of protein bodies into vacuoles by autophagy. In some cereals, such as maize, protein bodies remain in the cytosol, surrounded by ribosomes. In other cereals, such as wheat, they undergo autophagy and end up in PSVs.

and rice. Prolamins do not have transmembrane domains or KDEL-like signals. These proteins are unique to plants, and their polymerization and accumulation pose a number of interesting questions. Prolamins are the product of a number of gene families (see Box 4.6). They are in most cases insoluble in aqueous buffers and need either more than 50% alcohol or reducing agents to be solubilized. Apart from these characteristics, prolamins are far from being a homogeneous class of proteins in terms of sequence. How are PBs formed? The following features have been established:

- An individual PB is formed by the ordered assembly and accumulation of many different prolamin subunits. Some subunits are monomeric when expressed alone whereas others form homopolymers, often because of the formation of interchain disulfide bonds. An example of the former is wheat (*Triticum aestivum*) γ -gliadin, whereas maize γ -zein and wheat high molecular weight glutenin are polymeric (see Box 4.6).
- Unusually extensive interactions with chaperones like BiP occur during prolamin synthesis, suggesting prolonged exposure of hydrophobic sequences. Additional helpers are being discovered by analyzing cereal mutations: the distribution of the abundant 22-kDa α -zeins within maize PBs is altered when the *floury 1* gene, encoding a transmembrane protein of the ER, is mutated.
- Some prolamin subunits are able to form PBs with high efficiency when ectopically expressed in vegetative tissues of transgenic plants. This implies that PB formation does not require any tissue- or cereal seed-specific machinery apart from the prolamins themselves. Assembly into an insoluble polymer is sufficient to avoid entering protein trafficking from the ER to the Golgi apparatus.

Electron-dense, insoluble accretions within the ER are also formed in mammalian cells in pathological conditions, when the ER quality control system is unable to rapidly dispose of defective proteins, but the developmentally regulated use of the ER to accumulate protein permanently as storage

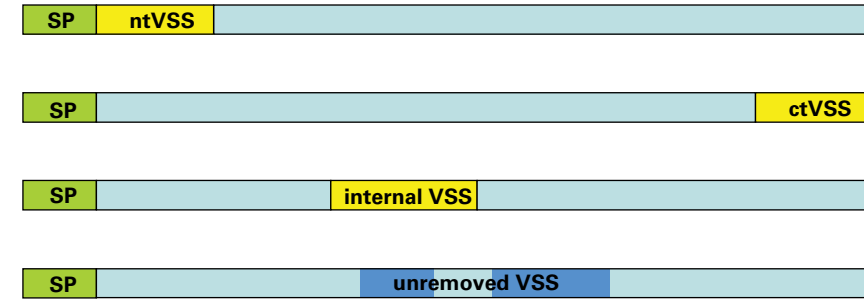

material, or temporarily for rapid mass delivery to vacuoles, is unique to plants.

4.8 Protein traffic and sorting in the secretory pathway: the Golgi apparatus and beyond

4.8.1 Targeting proteins to the vacuole depends on short vacuolar sorting signals

Plant cells have different types of vacuoles: lytic vacuoles that function in breakdown processes have an acidic pH and contain numerous hydrolases, whereas PSVs have a neutral pH and are especially prominent in cell types specialized for protein storage (see Chapter 1). The importance of the vacuole is shown by the observation that mutants in vacuolar biogenesis are embryo lethal. As discussed above, in certain cases, vacuolar delivery does not involve the Golgi apparatus, but most vacuolar proteins traffic through this compartment and are sorted at the TGN to MVBs and then finally they reach the vacuole.

Delivery of soluble proteins to the vacuole requires specific **vacuolar sorting signals** (VSSs) as well as targeting machinery. There are many similarities between plants and yeast with respect to vacuolar targeting, but plant VSSs do not function properly in yeast. In most cases VSSs are short stretches of amino acids that constitute, or are part of propeptides (Fig. 4.23). Propeptides are defined as peptides that are removed by proteolytic enzymes in MVBs or vacuoles as part of the protein maturation process. Propeptides can be either at the carboxyl terminus, at the amino terminus immediately following the signal peptide, or internal. These terminal propeptides carrying vacuolar sorting information are known as N-terminal (ntVSSs) and C-terminal VSSs (ctVSSs). In the

case of internal propeptides, after their removal the two remaining portions of the mature vacuolar protein remain often linked by a disulfide bond that had formed in the ER, as for example in the 2S storage albumins, or in ricin, the two-chain ribosomal inactivating protein of castor bean (*Ricinus communis*). Finally, VSSs exist that are located in surface loops of undetermined size and remain as part of the mature protein. Propeptides that contain VSSs are both necessary and sufficient for vacuolar targeting. If a gene construct is introduced into a plant cell and the VSS is absent from the coding sequence, the resulting protein is secreted. Conversely, a ctVSS, ntVSS, or internal VSS added to a nonvacuolar soluble secretory protein is sufficient to direct that protein to the vacuole, and this often occurs irrespective of the position in which the VSS is placed in the chimeric protein. These properties have not been demonstrated for the surface loops that appear to function as VSSs in proteins that lack propeptide-located VSSs.

Irrespective of their position in the polypeptide, a number of VSSs present in propeptides share a loose motif in which one isoleucine (Ile) or leucine (Leu) is fundamental: point

FIGURE 4.23 Vacuolar sorting signals. (A) Location of signals along the polypeptide. Green and yellow portions are absent from the mature protein. A signal peptide (SP, green) is present on any soluble secretory protein irrespective of the final location and is removed co-translationally; therefore it does not have a role in vacuolar sorting. Yellow boxes indicate propeptides, which are removed post-translationally upon vacuolar delivery and can contain a N-terminal VSS (ntVSS), C-terminal VSS (ctVSS), or internal VSS. The blue box indicates an unremoved VSS, which will be exposed on the surface of the folded protein and can be constituted by different portions of the polypeptide. (B) Examples of propeptides that contain or constitute VSSs. The loosely conserved motif of sequence specific VSS is shown in blue. The isoleucine (I) or leucine (L) residue that has been shown to be fundamental is in red.

mutations in Ile or Leu lead to loss of function of the signal and secretion of the protein. These signals are collectively termed sequence-specific VSS (ssVSS). Several VSSs however do not have this motif. Extensive site-directed mutagenesis of these other sequences, which are usually ctVSS, has shown that enrichment in hydrophobic amino acids is important, but no apparent consensus can be identified. Because these studies indicate that ctVSSs interact with components of the vacuolar sorting machinery, the sorting machinery presumably recognizes some structural feature or features of the ctVSS.

4.8.2 Vacuolar sorting receptors deliver cargo to the vacuole

Proteins that are transported to plant and yeast vacuoles or animal lysosomes are sorted from secreted proteins by transmembrane receptors that direct them to the appropriate forming vesicles (Fig. 4.24). These receptors bind specifically to the peptide domains (or glycans, in mammalian lysosomal

FIGURE 4.24 Vacuolar and lysosomal sorting receptors. The structures of the plant vacuolar signal receptor VSR/BP80, the yeast vacuolar signal receptor Vps10 and the mammalian lysosomal cation-independent mannose-6-phosphate receptor (CI-M-6-R) are shown.

hydrolases) that function as sorting signals. These receptors cycle continuously and move with their cargo in clathrin-coated vesicles from the TGN to MVBs and are returned empty in retromer vesicles. The different VSSs on plant vacuolar proteins are recognized by plant vacuolar sorting receptors (VSRs).

Like many integral membrane proteins of vacuoles or lysosomes, the sorting receptors for plant and yeast vacuoles or animal lysosomes contain in their cytosolic domains di-leucine (LL) or tyrosine-based (in most cases NPXY or YXX Φ , where Φ represents a hydrophobic amino acid) motifs recognized by adaptor proteins of clathrin-coated vesicles. When these motifs are mutated the receptors are mis-sorted to the plasma membrane. Traffic of these proteins is blocked by brefeldin A, consistent with the fact that they pass through the Golgi apparatus.

The first plant VSR to be identified was purified from developing pea (*Pisum sativum*) cotyledons and shown to bind on an affinity column to immobilized ntVSS but not to ctVSS peptides. Most likely this VSR mediates the sorting of a subset of vacuolar proteins. This VSR is a type I transmembrane protein with a long luminal domain followed by a short transmembrane domain and a short cytoplasmic domain (Fig. 4.24). The cytoplasmic domain contains a diacidic motif for export from the ER and has a tyrosine motif that interacts with the clathrin coat adaptor proteins at the TGN. VSRs are encoded by a multi-gene family in pea and *Arabidopsis* (seven genes, not uniformly expressed in all tissues) and have been identified in *P. vulgaris*, *Cucurbita* sp., wheat and rice. Despite sharing high amino acid identity, VSRs have been implicated in different types of vacuolar transport pathways. In vitro binding studies indicate that receptors of the VSR class directly bind ssVSS, but their ability to recognize other VSSs is unclear. VSR homologs recycle between the Golgi apparatus

and MVBs, where they are enriched at steady state, and are also found in highly purified preparations of clathrin-coated vesicles: these locations are expected based on the above described general mechanism of action of vacuolar receptors. Different VSR proteins may be needed for different sets of proteins (e.g., vacuolar hydrolases, lectins or storage proteins) and of course for different VSSs.

4.8.3 Traffic to protein storage vacuoles involves several different mechanisms

In storage parenchyma cells and other cell types in storage roots and in bark parenchyma that store proteins, a particularly large proportion of newly synthesized proteins enters the secretory pathway, to be delivered to PSVs (see Box 4.7). In the cotyledons of developing seeds PSVs appear to arise de novo as the storage parenchyma cells greatly enlarge and accumulate more protein. During this process, the central lytic vacuole eventually disappears.

The post-Golgi transport of storage proteins to PSVs involves electron-dense protein-filled vesicles, which can be readily observed by electron microscopy and have a high density in sucrose gradients (Fig. 4.25). These vesicles, termed dense vesicles (DVs), are then incorporated into MVBs and the storage proteins are finally delivered to the PSVs (Fig. 4.26). DVs do not have a clathrin coat and, surprisingly, they seem to lack any type of coat. This suggests that DVs may not originate by a budding process but rather they may be remnants of Golgi cisternae or TGN after clathrin-coated vesicles and vesicles destined for the cell surface have been released. The VSR cargo receptor is present at low levels in DVs, nevertheless, the abundant storage proteins of the 11S and 2S classes are in part secreted into the cell wall in the *vsr1* mutant of *Arabidopsis*. Furthermore, 2S albumins and ricin, which accumulate in the PSV of castor bean endosperm, have a ssVSS (see Box 4.6). The VSSs of many PSV proteins have been identified suggesting a role for one or more as yet unidentified VSRs.

It appears that the protein in DVs is highly condensed. This aggregation (or polymerization) can be seen by electron microscopy in the *cis-medial* Golgi of developing pea cotyledons (see Fig. 4.25) and *Arabidopsis* embryos and could have an important role in storage protein sorting to vacuoles. It is likely that sorting of a large aggregate or polymer does not require a 1:1 ratio between receptor and cargo molecules. The type I receptor-like protein RMR (abbreviation for receptor homology region transmembrane domain-Ring H2 motif protein) is found within DVs, MVBs and in PSVs, and binds several ctVSS. RMR proteins, encoded by a gene family, may have a role in the condensation of storage proteins and in their sorting, and may act in concert with receptors of the VSR class, which have a region of homology with RMR proteins in their luminal portion (see Fig. 4.24).

mRNA sorting also plays a role in the correct accumulation of storage proteins. Cereal endosperm contains rough ER as well as ER-derived PBs with attached polyribosomes. In rice, these PB contain prolamins, but the same cells also

FIGURE 4.25 Dense vesicles (DVs) in storage parenchyma cells of developing pea (*Pisum sativum* L.) cotyledons. (A) A clear cis (*c*) to trans (*t*) polarity in the cisternal structure of the Golgi apparatus is visible. Newly formed DVs (arrows) are seen attached to the first two cis-cisternae. Condensation of storage proteins proceeds as cisternal progression occurs, as indicated by the denser content of DVs. (B) Upon immunogold staining, the DV content is labeled with antibodies against the 7S and 11S seed storage proteins (large and small gold particles). (C) At right, a clathrin-coated vesicle is budding from a DV. The clathrin cage can be easily recognized (arrowhead). Bars: 200 nm. Courtesy of David G. Robinson.

make glutelins, soluble storage proteins that accumulate in PSVs. Glutelin and prolamins mRNAs are not randomly distributed: prolamins mRNAs are preferentially associated with protein body ER and glutelin mRNAs with cisternal ER. This differential targeting is dictated by the 3' untranslated regions of the respective mRNAs and is mediated by actin filaments.

4.8.4 Bypassing the Golgi apparatus: alternative pathways to vacuoles and secretion

The vast amount of information we have presented in the previous sections points to the Golgi apparatus as the major crossroad for biosynthetic secretory protein trafficking. However, protein delivery to vacuoles and the cell surface can in certain instances bypass this crossroad and even occur without translocation into the ER. So far the number of proteins known to follow these “alternative” routes is quite limited and therefore the extent of their contribution to total secretion or vacuolar delivery remains to be established. The mechanisms involved in these “alternative” routes are poorly characterized but the common landmark is that, unlike Golgi-mediated trafficking to the vacuole and cell surface, they are not sensitive to brefeldin A. This drug blocks the correct sorting of several tonoplast proteins, except for α -TIP, the tonoplast aquaporin of storage vacuoles. This observation has been the first indication that a plant secretory protein can bypass the Golgi apparatus, and indeed, known motifs for interaction with clathrin adaptor proteins or ER-exit motifs for interaction with COP II are not present in α -TIP.

The transport of soluble storage proteins to the vacuole may also bypass the Golgi (Fig. 4.26). For example, in developing *Cucurbita* sp. cotyledons, large vesicles filled with highly condensed storage protein, termed Precursor Accumulating (PAC) vesicles appear to be transporting the abundant 2S storage proteins directly from the ER to the PSVs. This mechanism that transports highly condensed protein and bypasses the Golgi has also been demonstrated for the KDEL-containing SH-EP and for prolamins in the endosperm of certain cereals (see Sections 4.7.3 and 4.7.4). Thus, protein interactions can lead to protein accretion and traffic from the ER to the vacuoles without the involvement of the Golgi. In wheat endosperm cells, prolamins and the chaperone BiP, which ordinarily is an ER resident, are present both in the PB and in the vacuole. Perhaps ER-derived PBs are taken up directly into vacuoles, either by membrane fusion or, more likely, by engulfment akin to autophagy. As we illustrated in Section 4.7.4, in other cereals (e.g., maize and sorghum), the ER-derived PBs persist in the cytoplasm and do not enter the vacuoles. PBs, PACs, and DVs seem to reflect a common tendency of seed storage proteins to form polymers/large condensed structures that are either permanent or transient. Depending on the storage protein type this can occur already within the ER itself (PBs, PACs) or later along the secretory pathway (DVs). The final result can be either total inhibition of traffic (PBs) or vacuolar delivery, mediated (DVs) or not (PACs) by the Golgi apparatus. In any case, these mechanisms have probably evolved to allow high accumulation of very large amounts of protein at the lowest possible energy cost for the cell.

Cutin, a major component of the plant cuticle, is a polymer of fatty acids synthesized by the ER and polymerized in the extracellular space. *Arabidopsis* mutants that are affected in the final step of secretion of cuticular lipids accumulate lipid

A

B

inclusions in the ER but not in the Golgi, suggesting that the latter is not involved in the normal process of monomer secretion and that direct ER to plasma membrane trafficking exists. This is also supported by the fact that brefeldin A-insensitive trafficking from the ER to the cell surface of several proteins and lipids has also been observed in mammalian cells.

Finally, small vesicles containing soluble proteins that do not derive from precursors with a signal peptide are detectable in the cell wall of several plant tissues and plant cell cultures (Fig. 4.27A). They therefore constitute a direct cytosol-to-cell surface membrane trafficking pathway that does not involve the ER and Golgi apparatus. These secreted vesicles have a double membrane when they are still in the cytoplasm: their secretion occurs upon fusion between their outer

membrane and the plasma membrane, a process morphologically similar to the release of internal MVB vesicles into the vacuolar lumen (Fig. 4.27B). However, the plant structures involved in this alternative secretion are immunologically distinct from plant MVB and are not affected by brefeldin A. The function of secreted vesicles in plants is not yet known. In animal cells, secreted vesicles originate from the fusion of MVB with the plasma membrane (generating exosomes) or by direct budding from the latter into the extracellular space (shedding microvesicles). They participate in cell-to-cell signaling either by discharging luminal content into the target cell cytosol by membrane fusion or through interactions between the extracellular domains of their membrane proteins and plasma membrane receptors.

4.8.5 Complex N-linked glycans are derived from high-mannose N-linked glycans during processing in the Golgi complex

When Asn-linked glycans become attached to nascent polypeptides they have three terminal Glc residues that play a role in protein folding and are removed by ER glucosidases (see Section 4.6.7). Furthermore, ER resident mannosidases can remove up to three Man residues. Therefore, at the moment of exit from the ER, N-glycosylated proteins have glycans, called **high-mannose glycans**, with the structure $(\text{Man})_{9-6}(\text{GlcNAc})_2$. These can be further modified by glycosidases and glycosyltransferases as the newly synthesized proteins travel through the Golgi complex. When the end product contains additional residues besides the original GlcNAc and Man, the glycan is termed a **complex glycan**. Golgi-mediated modifications follow defined pathways where in most cases the product of one reaction is the necessary substrate for the next. Distribution of processing enzymes in the *cis*-, medial, and *trans*-Golgi cisternae is polar, with mannosidase I enriched in the *cis*-Golgi and so on (see Chapter 1). The pathway of glycan modification until the formation of $(\text{GlcNAc})_2(\text{Man})_3(\text{GlcNAc})_2$ is identical in animals and plants, whereas further modifications diverge (Fig. 4.28). The most extensively modified structure found in plants and also called the Lewis antigen, is $(\text{Fuc})_2(\text{Gal})_2(\text{GlcNAc})_2 \text{Xyl}(\text{Man})_3\text{Fuc}(\text{GlcNAc})_2$, where the residues in bold are what remains of the original high mannose chain. This is often present in secreted plant glycoproteins. A common structure found in vacuolar glycoproteins is $\text{Xyl}(\text{Man})_3\text{Fuc}(\text{GlcNAc})_2$, which is derived from $(\text{GlcNAc})_2(\text{Man})_3\text{Fuc}(\text{GlcNAc})_2$ by the action of vacuolar *N*-acetylglucosaminidase. It should be noted that a wide variety of intermediate complex structures exist and that a number of

glycoproteins have glycans that are not modified during transit through the Golgi, mainly because in a folded polypeptide glycans are not always fully exposed on the protein surface to the action of Golgi enzymes. Thus, the presence of complex glycans is used as evidence that a glycoprotein has passed through the Golgi, but the absence of modifications cannot be used as evidence that this has not occurred. There are marked differences between plants and mammals in residues added to N-linked glycans by Golgi glycosyltransferases and in the type of chemical linkages used. Unlike plants, mammalian complex glycans never have $\alpha 1,3$ -Fuc or $\beta 1,2$ -Xyl residues attached to the proximal GlcNAc and to the core Man, respectively, and rarely have terminal $\beta 1,3$ -Gal residues. They instead often have $\alpha 1,6$ -Fuc linked to the proximal GlcNAc and terminal sialic acid linked to $\beta 1,4$ -Gal. These differences, in particular the $\alpha 1,3$ -Fuc and $\beta 1,2$ -Xyl, make plant glycoproteins unusually immunogenic in mammals and contribute to plant food and pollen allergy in humans. This characteristic has implications in the use of plants as bioreactors for the production of pharmaceuticals. Scientists have developed different strategies to solve the problem. One is the addition of KDEL or HDEL at the C-terminus of a given pharmaceutical: rapid recycling from the Golgi apparatus does not allow glycan processing by Golgi enzymes and thus the oligosaccharides remain of the high mannose type. On some pharmaceuticals human complex glycans are important for function, and a more sophisticated approach is the “humanization” of the plant Golgi complex: knockout mutations are stacked together with expression of human Golgi enzymes, to eliminate unwanted plant modifications and substitute them with human ones. The strategy is feasible because, surprisingly, mutant *Arabidopsis* plants that lacks GlcNAc transferase I, a necessary enzyme to convert high-mannose glycans to complex glycans does not show defects when raised under normal growth conditions although it is more sensitive to environmental stress.

FIGURE 4.28 Processing of plant and mammalian N-linked glycans in the ER and Golgi. The differences are in late Golgi maturation events, which occur in the medial and *trans*-Golgi cisternae. In the complex glycans of plants fucose (Fuc) is attached by an $\alpha 1,3$ linkage, vs $\alpha 1,6$ in mammals, and galactose (Gal) with a $\beta 1,3$ linkage, vs $\beta 1,4$ in mammals. The xylose (Xyl) residue attached by a $\beta 1,2$ linkage is also found in invertebrates and is unusually antigenic in mammals. NeuAc, sialic acid.

Source: Faye et al. (2005). *Vaccine* 23:1770–1778.

This indicates that processing of N-linked glycans into complex structures is not essential for plant growth, development or reproduction. Conversely, mice lacking GlcNAc transferase I die around the 10th day of gestation resulting from defects in cell–cell recognition and signaling.

4.8.6 Serine, threonine, and hydroxyproline residues can be O-glycosylated

Carbohydrates can be attached to the hydroxyl group of threonine, serine, or hydroxyproline. These structures are termed O-linked glycans and can be constituted by a single monosaccharide or may contain several residues. Proline hydroxylation also occurs in some animal proteins such as collagen, but hydroxyproline O-glycosylation has been found only in plants. Unlike N-linked glycans, polymeric O-linked glycans are formed by the post-translational, sequential addition of sugars. Conclusive evidence that all plant O-glycosylation reactions occur in the Golgi apparatus is still lacking, but immunomicroscopy studies, and analogy to O-glycosylation of serine and threonine residues in mammalian cells, suggest that this is the case. Bioinformatic analysis has identified 20 putative β 1,3 galactosyl transferases in *Arabidopsis* which may be involved in O-glycosylation or in the modification of N-linked glycans: 17 are predicted to be type II membrane proteins with Golgi location.

The superfamily of hydroxyproline-rich glycoproteins (HRGPs) is unique to plants and includes arabinogalactan proteins (which are GPI-anchored proteins (see Section 4.6.4), proline-rich glycoproteins, extensins, and solanaceous lectins. In arabinogalactan proteins, short side chains containing arabinose, rhamnose, and glucuronic acid are attached to a branched Gal backbone core linked to hydroxyproline (see Chapter 2). In extensin, hydroxyproline residues are O-glycosylated with short side chains containing one to four arabinose residues, and many serine residues in the Ser(Hyp)₄ repeats are O-glycosylated with galactose. At least three types of arabinosyl linkages are involved; thus, the synthesis of these side chains requires three different arabinosyltransferases, enzymes that transfer an arabinose residue from UDP-arabinose to the polypeptide.

4.9 Endocytosis and endosomal compartments

4.9.1 Endosomal compartments

Cells have a vesicle-mediated pathway for uptake of extracellular macromolecules and internalization of plasma membrane proteins. This process is called endocytosis (see Chapter 1) and involves the TGN and MVB as sorting

stations. Because of this role, the late (free) TGN and MVB are therefore also termed early and late endosomes, respectively (see Section 4.6.1).

In plant cells, endocytosis was first investigated using electron-dense cationized ferritin particles, because these are readily taken up in an endocytic process and easily visualized with the electron microscope. The pathway starts with an invagination of the plasma membrane and the formation of small, vesicles that bud towards the cytoplasm and traffic to the late (free) TGN (Fig. 4.29, see also Fig. 4.10). The process is analogous to the formation of coated vesicles described earlier (see Section 4.7.1). Two internalization pathways operate in parallel: one relies on CCVs, with coats similar to those of vesicles moving from the late (free) TGN to MVBs, but the protein coats of the vesicles in the other pathway have not been identified. In electron micrographs, CCVs appear to have spikes (see Fig. 1.33) and recruitment of clathrin from the cytosol requires specific adaptor protein complexes that bind clathrin on one side and the cytoplasmic domains of transmembrane receptors on the other. The extracellular domains of these transmembrane receptors interact with the proteins being internalized and determine the specificity of the endocytic process. After a cargo-laden clathrin-coated vesicle has formed, the neck region of the vesicle is severed by the motor protein dynamin, a small GTP-binding protein

FIGURE 4.29 Endocytic pathways. Endocytic vesicles form by invagination of the plasma membrane and can either have clathrin coats or coats of unknown composition. They will deliver their content to early endosomes (free TGN). From there, content can be delivered to late endosomes (MVBs) and finally to the vacuole or be recycled back to the plasma membrane. In the latter case the early endosomes function as recycling endosomes. Some receptors follow the traffic from the plasma membrane to the vacuole and are broken down there, others simply cycle between the plasma membrane and the early/recycling endosomes.

(see Fig. 1.33A). A 70-kDa chaperone-like protein causes the released clathrin-coated vesicle to uncoat in a process that requires ATP. The uncoated vesicle can then fuse with the TGN. In the TGN, the internalized plasma membrane proteins can be either recycled back to the plasma membrane via secretory vesicles, or sorted into clathrin-coated vesicles and sent to MVBs (late endosomes) and vacuoles for degradation (Fig. 4.29). The borate transporter BOR1 provides an interesting example of the breakdown of a plasma membrane protein by endocytosis. When plants are borate starved the transporter is abundantly present on the plasma membrane of root cells. When borate is added to the growth medium, BOR1 is quickly endocytosed and transferred to vacuoles for breakdown.

The initial formation of the endocytic vesicles at the plasma membrane may be driven by the presence of the ligand (ligand induced endocytosis) or it may be constitutive. Both types of endocytosis have been observed in plants, as illustrated by studies on endocytosis and signaling treated in the next paragraph.

4.9.2 Endocytosis and signaling

Endocytosis plays an important role in plant signaling events that involve receptor-like kinases (RLKs), a large class of plasma membrane receptors with 600 members in *Arabidopsis* and more than 1000 in rice. A subclass of these receptors has extracellular leucine-rich repeats (LRRs) and is referred to as

LRR-RLK. The first convincing example of ligand-induced endocytosis in plants was the isolation of the *Arabidopsis* LRR-RLK Flagellin Sensing 2 (FLS2) receptor that recognizes the bacterial elicitor flagellin (flg22). In transgenic lines that express a fusion of FLS2 and GFP, the plasma membrane is fluorescent indicating the location of the receptor. Only after activation of the receptor with flg22, was FLS2-GFP endocytosed and sent to vacuoles for degradation via MVBs (Fig. 4.29). Activation of a receptor may not always be required for its translocation to the late TGN/early endosomes and can also occur within this compartment. For example, the brassinolide receptor BRI1, also an LRR-RLK, is present at the cell surface and at the TGN, even in the absence of brassinolide, indicating constitutive endocytosis. BRI1 binds brassinolide at the cell surface, but the receptor does not initiate its signal transduction cascade there. It is first internalized via a constitutive recycling mechanism, transferred to the TGN and only then becomes active. It is possible that activation requires additional proteins found only at the TGN.

Another important regulatory process that involves endocytosis is the creation of auxin gradients, which requires two plasma membrane proteins: AUX1 involved in auxin uptake and the PIN family of auxin efflux carriers. The different PIN proteins in the plasma membrane have polarized distribution, either in the apical or basal part of cells. In roots the PIN2 carrier is constitutively recycled between the plasma membrane and the late TGN in a process that requires the ARF-GEF GNOM (see Box 4.5). This recycling along with PIN2 breakdown in the vacuole is responsible for creating auxin gradients.

Summary

Cells contain numerous metabolic compartments and membranes that have unique sets of proteins. Nearly all of these proteins are synthesized in the cytosol. How do they reach their correct destinations? Polypeptides have sorting domains that act as address labels for each destination. In some cases specific amino acids are part of the unique label, in other cases certain types of amino acids are required or the secondary structure is important. These sorting domains are usually short segments of polypeptide that may or may not be removed after the proteins reach their destination.

Many sorting domains interact with cytosolic receptors that in turn bind to one of the proteins that make up proteinaceous channels consisting of several polypeptides that are specific for each membrane (e.g., ER, chloroplast envelope, peroxisome, etc.). Passage of a polypeptide through a channel requires the participation of chaperones and energy in the form of ATP, GTP, or both. Chaperones help keep proteins unfolded in the cytosol before passage through the channel and are required to fold the protein correctly once it has crossed

the membrane. In some cases proteins fold in their three-dimensional shape in the cytosol and then still can pass through a proteinaceous channel.

All living cells maintain an active secretory pathway having many functions besides protein secretion. The secretory pathway also transports proteins to vacuoles, maintains the protein complement of its various membrane systems and is involved in endocytosis. Proteins move between the various compartments of this pathway as cargo in vesicles. All proteins that have a signal peptide are translated on rough ER and enter the secretory pathway via translocation into the ER lumen. Correct folding is necessary not only for proper protein function, but also for transport. Proteins that are not correctly folded or cannot be assembled into oligomers are degraded by proteasomes after retrotranslocation back to the cytosol or in vacuoles. This degradation is part of the quality control system that the cell exerts over its complement of proteins. The folding process itself requires the participation of a number of chaperones and folding helpers that reside in the ER. When protein folding is impaired by

stress conditions the cell mounts an unfolded protein response (UPR) that causes enhanced expression of genes encoding ER chaperones and attenuation of the translation of proteins destined to enter the ER.

The secretory pathway targets proteins to the ER, Golgi, TGN (early endosomes), multivesicular bodies (late endosomes), vacuoles, and the plasma membrane. Transport between these various compartments generally requires vesicle budding and fusion. Vesicle formation and sorting are complex processes that involve integral membrane proteins (e.g., receptors and syntaxins) and cytosolic proteins (e.g., vesicle coat proteins). Coat formation is necessary for vesicle budding. Vesicles always uncoat before fusing with their target compartments.

Cells make extensive use of highly regulated GTP-binding proteins/GTPases to regulate and provide energy for secretory pathway activity. Molecular genetics (finding mutants) and chemical genetics (applying chemicals to inhibit specific steps) are proving to be valuable tools in identifying components of this vesicle sorting machinery.

Cells also have a vesicle-mediated mechanism, called endocytosis, for taking up proteins and delivering them to endosomes for subsequent transfer to vacuoles. Endocytosis is also responsible for the back-and-forth transport of plasma membrane receptors that may become activated when they reach the TGN/early endosomes or routed to the vacuole for breakdown.

The Cytoskeleton

Tobias I. Baskin

Introduction

Despite the importance of membrane-bound organelles illustrated in the preceding chapters, the eukaryotic cell requires more than a set of defined compartments to function. Eukaryotic cells organize their components spatially, fixing some at defined locations in the cell, moving others to attain optimal positions. The contents of eukaryotic cells (and in some cases, the cells themselves) are mobile. Poking a cell with a fine needle stimulates its contents to move vigorously. A century ago, these directed movements were considered an unmistakable indicator of life; amusingly, this essential cellular property was described as *irritability*.

Directed movements of the cell and of its contents are mediated by the **cytoskeleton**, a network of filamentous protein polymers that permeates the cytosol. Plants contain two kinds of filaments, one built from the protein, actin, usually called *actin filaments* and the other built from the protein, tubulin, called *microtubules*. In this chapter, first each family is introduced and its properties described; second, principal cytoskeletal functions are illustrated; and, finally, the role of the cytoskeleton is described in mitosis and cytokinesis. The cytoskeleton evolved before plants diverged from animals and main features of the cytoskeleton have been conserved in both. Thus, much of the information presented applies to both animals and plants. However, the plant cytoskeleton has evolved unique functions, many of which will be highlighted.

5.1 Introduction to the cytoskeleton

5.1.1 Cells contain a dynamic, filamentous network called the cytoskeleton

When Robert Hooke viewed thin slices of cork through his microscope, he called the large empty spaces he saw “cells,” because they reminded him of the spartan chambers inhabited by monks. Actually, Hooke was seeing only the walls of dead cells. Living cells, by contrast, are far from bare, empty spaces. Even the image of a cell with nucleus and organelles all floating in a more or less clear cytoplasm ignores the true complexity of the cell. Modern microscopes and staining techniques reveal that cells are packed with a dynamic filamentous network, a network that anchors, guides, and transports macromolecules, supramolecular complexes, and organelles (Fig. 5.1).

5.1.2 The cytoskeleton provides structure and motility and facilitates information flow

At any one time, a typical cell contains millions of protein molecules engaged in thousands of activities, ranging from biosynthesis to degradation. Few of these proteins function as single

FIGURE 5.1 Different views of the same cells in the root of *Arabidopsis thaliana*. (A) Section stained with a reagent specific for cell walls. This image resembles what Hooke saw when he coined the term cell. (B) Adjacent section imaged with Nomarski optics, a technique that makes visible many organelles, such as nuclei, mitochondria, or plastids. These and other organelles were discovered in the 19th and 20th centuries as microscopes improved. (C) The same section seen in B, imaged with fluorescence microscopy. The bright fibrous elements are microtubules, a major component of the cytoskeleton. The section was treated with an antibody that recognizes microtubules and then was stained with a fluorescence-tagged second antibody that binds the first. The cell cytoskeleton was discovered after further refinements in microscopy and the development of specific molecular reagents.

polypeptide chains. Instead, they form complexes comprising anywhere from several to many hundred subunits. Moreover, the complexes themselves do not function in isolation. The products of a reaction sequence must find their way from one complex to another, for example, in biochemical pathways or as information flows from the exterior of the cell to the nucleus. All of this miniaturized machinery must withstand molecular bombardment from **Brownian motion** (see Box 5.1)—thermal noise—that occurs at physiological temperatures. The bombardment is intense: at 25°C, the standard temperature for biochemical measurements, a globular protein 5 nm in diameter will be hit by solutes about 1 billion times per second.

It should thus come as no surprise that cells have evolved means to organize their teeming internal contents, not only to dampen the effects of thermal noise but also to facilitate reactions of increasing duration and complexity. One such adaptation uses compartments to sequester and concentrate components (Chapter 1). A second such invention is the cytoskeleton.

5.1.3 The cytoskeleton consists of a network of fibrous polymers

The cytoskeleton is a network of interconnected fibrous polymers that run throughout the cell within the cytosol (Fig. 5.2). This network provides structural stability to cytoplasm, anchoring proteins and other macromolecules, and supporting organelles during and after their synthesis. Besides structural stability, the cytoskeleton also gives cells the property of motility, both internal and external. Cellular components can move actively within the cell, such as during cytoplasmic streaming, and many cell types change shape and move within their environment. The cytoskeleton also participates in processing cellular information. For example, elements of the cytoskeleton are known to converge on the plasma membrane at sites associated with transmembrane receptors. Finally,

many elements of the cytoskeleton consist of asymmetric subunits so that the polymers themselves are like an arrow, providing directional cues within the cell (Fig. 5.3).

The cytoskeleton comprises three classes of polymer: intermediate filaments, actin filaments, and microtubules. These polymers are similar in being extremely long and formed from protein monomers polymerizing via noncovalent bonds; they differ in their specific behaviors and functions. Actin filaments and microtubules share many properties of assembly and regulation whereas intermediate filaments are somewhat distinct.

5.1.4 Intermediate filaments are probably absent from plants

In animal cell cytoskeletons, **intermediate filaments** are constructed from a group of well-described proteins, such as keratin or vimentin. The filaments are named for their thickness: at 10–15 nm in diameter, they are thinner than microtubules and thicker than actin filaments. Apparently, plant cells do not contain a filamentous system that is independent of microtubules and actin nor do plant genomes contain sequences unmistakably homologous to animal intermediate-filament proteins. In animal cells, intermediate filaments function primarily to add strength and resiliency (e.g., keratin filaments toughen skin cells). In plants, analogous functions can be handled by the cell wall.

One place where intermediate filaments might be needed in plants is inside the nucleus. Among animals and fungi, the intermediate filaments with the most conserved function are the lamins. These form the **nuclear lamina**, a sheet-like structure lying just inside the nuclear envelope, thought to maintain nuclear shape, to reinforce the large nuclear pore complexes, and to ensure that chromatin can be successfully anchored (see Chapters 1 and 4). In plants, a structure partially resembling the nuclear lamina is evident in electron

Robert Brown (1773–1858), pictured here in an 1835 portrait by Pickersgill (A), discovered the motion that bears his name while pursuing his passion, botany. Even though Brown studied medicine at university and was serving in the army, he had amassed so great a knowledge of botany that Sir Joseph Banks hired him to sail as a ship's naturalist aboard *The Investigator* on a voyage of discovery to Australia. The voyage lasted for years, circumnavigating Australia twice. During that time, Brown collected more than 4,000 species, most of them new to science and many in previously unknown genera. The difficulties he faced were physical and intellectual: *The Investigator* was cramped, damp, and unseaworthy, and the botany of his day had only just begun to classify plants “naturally” (that is, evolutionarily). Nonetheless, Brown's treatment of the Australian flora remains essentially intact today.

Brown's zeal for botany spurred him to become an excellent light microscopist. He realized that traits needed to support a natural classification of plants could be found in the early stages of development, which are microscopic. In Brown's day, the best microscopes had only a single lens, because the theory for properly correcting compound lenses had yet to be developed. Despite their simplicity, single-lens microscopes can reveal subcellular detail. The micrograph (B) shows a peel of onion epidermis viewed through a microscope used by Brown. Using dark-field illumination with the substage mirror shows the nuclei clearly against a dark background. From observations such as this, Brown coined the term “nucleus,” and before the advent of cell theory he correctly surmised that it was a feature of every plant cell. He discovered cytoplasmic streaming in the stamen hairs of *Tradescantia* and delighted in showing this vivid cellular action to his friends, including such luminaries as Charles Darwin and William

Hyde Wollaston (British chemist and inventor of the prism used in Nomarski optics, which today provides the best images of streaming in the stamen hairs—see Box Fig. 5.2A). Brown's major microscopical interest was the fertilization of plants. He was the first to correctly outline the anatomy of seeds and their embryos, and he discovered the naked ovule of gymnosperms, which allowed him to rationalize the classification of this group.

Important though these discoveries were, Brown's enduring fame rests on an 1827 discovery, made while examining pollen. He saw particles inside the grain moving randomly—rapidly and without cessation. (It was not the pollen itself he saw move, as often erroneously stated. Skepticism about his observations has been refuted by recent recreations of Brown's 1827 observations of Brownian motion with the very microscope Brown himself used, pictured here ready for use, C.) Brown was not the first person to observe this incessant movement; others had seen it before and surmised they were seeing the essence of life. But Brown observed the motion in pollen grains preserved for months in alcohol as well as in suspensions made by grinding a variety of rocks and minerals. He correctly concluded that the motion has a physical, not an organic, explanation. Later scientists quantified the motion to derive fundamental insight into the stochastic character of the molecular world. For example, French physicist and Nobel Prize winner Jean-Baptiste Perrin used Albert Einstein's formula for Brownian motion to calculate the size of the water molecule. It is apt that the incessant movement of particles bears the name of the indefatigable botanist, Robert Brown.

micrographs, and chromatin in plants no less than in animals requires anchoring for regulated gene expression. Nevertheless, while proteins arguably analogous to lamins are present in plant nuclei, their sequences are so distinct from those of animal lamins that it cannot be said whether they are deeply diverged homologs or independently evolved proteins. Therefore, while plants might possess filament-forming proteins in addition to actin and tubulin, these have yet to be characterized in detail and are almost certainly distinct evolutionarily from intermediate filaments.

5.2 Actin and tubulin gene families

5.2.1 Actin and tubulin are encoded by multigene families

Actin filaments are polymers of the protein actin; **microtubules** are polymers of the globular proteins, α - and β -tubulin. Actin binds ATP and is evolutionarily related to certain other ATP-binding proteins including heat-shock proteins and hexokinase; tubulin binds GTP and is distantly related to several types of G protein. Actin and tubulin occur in all eukaryotes, and homologs are present in prokaryotic genomes: for example, the tubulin-relative FtsZ forms a filamentous ring needed to effect cell division, and the actin-relative MreB

FIGURE 5.3 Diagrams showing functions of the cytoskeleton. (A) Anchorage. The cytoskeleton anchors organelles and other macromolecular assemblies (e.g., polysomes). (B) Motility. The cytoskeleton supports active and directed intracellular movement of cellular components. (C) Polarity. The informational content of cytoskeletal fibers depends on the polarity of the fibers, which are formed from asymmetric subunits that define a direction along the polymer. In this example, cargo is assembled at one site, moved through the cell via the cytoskeleton, and delivered to a second location.

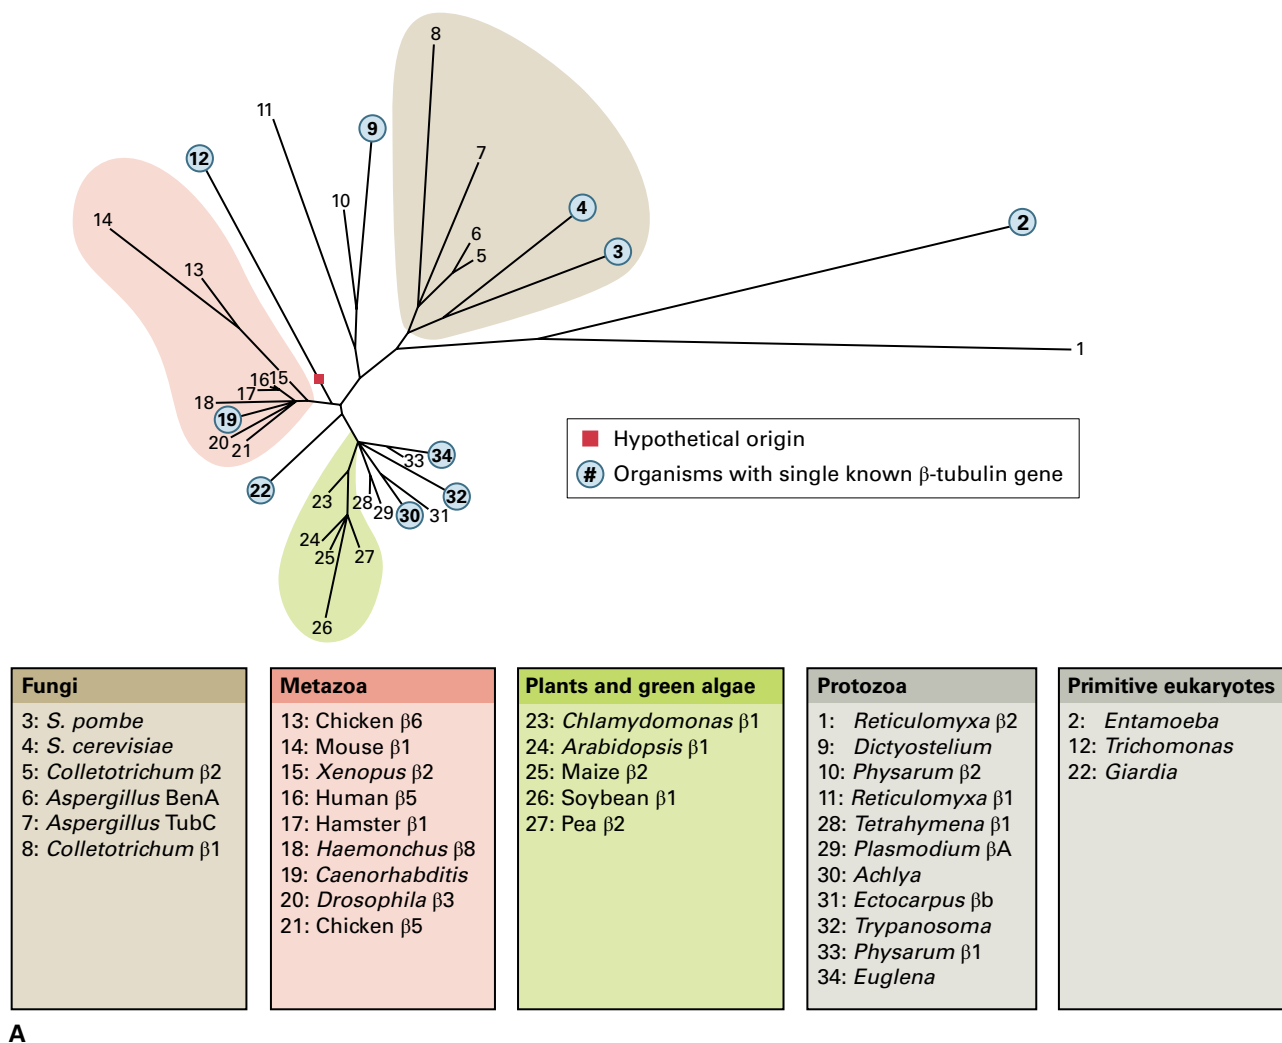

forms filaments required for the asymmetric cell shape of certain prokaryotic species. Evidently, the cytoskeleton was invented before the origin of eukaryotes.

In unicellular species, actin and tubulin are usually encoded by single-copy genes. In multicellular species, however, actin and tubulin are usually encoded by **gene families**. In vertebrates, actin and tubulin gene families typically contain between four and nine members, whereas in certain lineages of vascular plants, families are larger; for example, β -tubulin is represented by 20 genes in poplar (*Populus trichocarpa*), and actin by 100 genes in *Petunia hybrida*. Comparing the sequences within each family across kingdoms demonstrates they encode proteins that are usually at least 90% identical. Thus, actin and tubulin are in general highly conserved proteins that appear to have arisen from single-copy genes present before multicellular eukaryotes diverged (Fig. 5.4).

5.2.2 Several models explain gene family evolution

Why are these cytoskeletal proteins encoded by gene families? The different family members (called **isoforms**) could be distinct functionally, could allow for flexible regulation of transcription, or could reflect historical accident. These explanations are not mutually exclusive, and each probably describes part of the evolutionary process.

These explanations are well illustrated by experiments on the actin gene family in *Arabidopsis thaliana* (thale cress). Among plant genomes, this species has a relatively small collection of actin genes, expressing five isoforms in reproductive tissues and three others in vegetative tissue. Considering the vegetative isoforms, two of them (ACT2 and ACT8)

A

FIGURE 5.4 Evolutionary divergence of β -tubulin sequences. (A) Overview. The length of each branch is proportional to the rate of evolution of the sequence. The tree has been constructed to emphasize rates of divergence, not phylogenetic relationships. Note the clustering of tubulins within the major groups of eukaryotes and the predicted origin of β -tubulin before the radiation of the eukaryotes. As shown by the long branches, only a few β -tubulin sequences are thought to have undergone comparatively rapid evolutionary change. (B) Phylogenetic tree showing putative evolutionary relationships for the coding sequences of β -tubulins in plants. The tree was rooted with a green algal sequence. Clades include sequences from grasses (blue) and dicotyledons (brown), indicating that a gene family was present in the common ancestor and suggesting specialization. Similar conclusions have been reached for α -tubulin, as well as for actin. Arath, arabidopsis; Goshi, cotton; Medtr, medicago; Soltu, potato; Zinel, zinnia; Elein, goosegrass; Orysa, rice; Setvi, setaria; Triae, wheat; Zeama, maize.

FIGURE 5.4 (Continued)

differ from each other by only two amino acids but by dozens of silent nucleotide changes, supporting the hypothesis that these have long diverged and are under strong selection. When these two genes are both knocked out, the double-mutant resembles wild-type plants closely, except for failing to make root hairs, a cell appendage that places large demands on the actin cytoskeleton (see Section 5.6). Furthermore, root hairs remain defective in this background even when the remaining vegetative isoform (ACT7) is expressed from one or both of the ACT2 and ACT8 promoters. Taken together these results show that ACT2 and ACT8 are distinct functionally from ACT7. However, reciprocal experiments show that ACT2 or ACT8 give rise to plants indistinguishable from wild type when either is the sole vegetative actin isoform expressed, provided that the amount of protein expressed is sufficiently great. Thus, ACT7 is functionally redundant with the other vegetative isoforms and its evolutionary trajectory is driven by regulatory demands or historical accident.

For tubulin, delineating the functions of specific isoforms is made even more complex because this protein is modified post-translationally (not only by phosphorylation, but also by acetylation, glutamylation, and detyrosination). Thus, each genetic isoform gives rise to several biochemical isoforms. Although certain tubulin genes have distinct expression patterns, others do not, and functional replacement experiments in plants have yet to be reported.

5.3 Characteristics of actin filaments and microtubules

Although made from distinct proteins, actin filaments and microtubules assemble by a similar process and share several characteristics. Like the synthetic polymer nylon, many biological polymers consist of molecular subunits linked by covalent bonds (e.g., as in RNA or polypeptides). In contrast, cytoskeletal

polymers have macromolecular subunits linked by non-covalent bonds, typical of quaternary protein structure. This allows microtubules and actin filaments to be dynamic, assembling or disassembling in response to factors that govern protein-protein interactions, such as ionic strength or temperature.

5.3.1 Spontaneous assembly of cytoskeletal polymers allows analysis of polymerization

The ability of actin filaments and microtubules to assemble spontaneously has the practical consequence that researchers can isolate and handle the protein in the form of subunits and can initiate polymerization *in vitro* by one of several simple manipulations. The time course of the polymerization reaction can be conveniently assayed by measuring the amount of light scattered by the solution, because light scattering increases as the polymer lengthens.

Polymerization occurs in three stages (Fig. 5.5). First, between the onset of conditions favoring polymerization and the first detected increase in polymer, a lag occurs. The lag reflects the need for an initial group of several subunits to associate correctly, forming a template for further assembly. This first stage of polymer assembly, the formation of a template, is called **nucleation**. The requirement for nucleation can be bypassed by adding small pieces of preformed polymer, often referred to as “seeds.”

During the second stage, **elongation**, templates formed during nucleation grow by endwise addition of subunits. The rate of elongation represents the difference between the rate of subunit addition and the rate of subunit loss. The rate of subunit addition is the product of the association constant (k_{on}) and the concentration of free subunits in solution; the rate of subunit loss equals the dissociation constant (k_{off}). Consequently, the rate of elongation is proportional to the

prevailing subunit concentration. Elongation continues until a plateau concentration of polymer is reached.

The third stage is a **steady state** in which a constant amount of polymer is maintained over time. The steady state is dynamic, the polymer gaining and losing subunits constantly. However, at steady state, the rate of subunit addition is balanced exactly by the rate of subunit loss (i.e., $k_{\text{on}}[\text{subunit}] = k_{\text{off}}$). Thus, steady state occurs when the concentration of subunits equals the ratio of the dissociation and association rate constants (i.e., $[\text{subunit}] = k_{\text{off}}/k_{\text{on}}$), the concentration known as the **critical concentration**. At concentrations less than this, polymer will not form spontaneously; at greater concentrations, the polymer will grow until the subunit concentration is depleted to the critical concentration.

5.3.2 Cytoskeletal polymers have an intrinsic polarity and hydrolyze nucleotides

Actin filaments and microtubules are polar structures because their protein subunits are asymmetrical. In polymer assembly, the asymmetric subunits line up end-to-end with a uniform orientation (Fig. 5.6A). The polarity thus conferred to the polymer means that each end has a different biochemical character. Therefore, each end of the polymer may have different rate constants for the assembly and disassembly reactions. In addition, each end of the polymer can be recognized specifically, so that cells may build polymer arrays with uniform polarity. The more dynamic end of the polymer is designated “plus” and the less active end “minus.” Note that in this context these terms do not indicate electrical charge; the adjectives *positive* and *negative* are seldom if ever used to refer to this polarity.

Actin binds and hydrolyzes ATP, whereas tubulin binds and hydrolyzes GTP. These nucleotides play an important role in

FIGURE 5.5 Diagram illustrating process and kinetics of polymerization. A solution of individual subunits is induced to polymerize at time zero. During nucleation (pink panel), subunits must associate to create a stable template that serves as a platform for further elongation. In this example, using actin filaments, a template is formed when three subunits associate, generating a trimer. Because several subunits must interact simultaneously to form a template, this process is kinetically slower than that of adding subunits to the ends of an extant polymer and results in a lag phase. During elongation (growth phase, blue panel), subunits are rapidly added to the ends of growing polymers. A steady-state phase (yellow panel) is reached when the rate of subunit addition ($k_{\text{on}}[S]$) is balanced exactly by the rate of subunit loss (k_{off}).

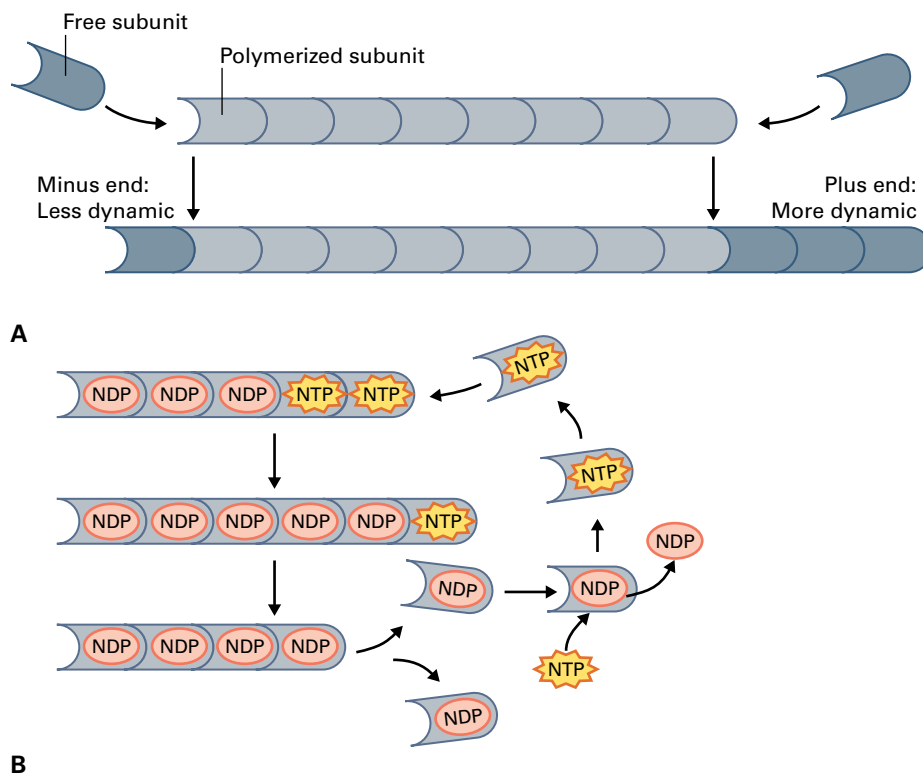

FIGURE 5.6 (A) Actin filaments and microtubules form by head-to-head addition of intrinsically polar subunits, giving the polymers a defined polarity and each end distinct biochemical properties. One end of the filament is more dynamic than the other end, having increased rates of both subunit addition and loss. The more dynamic end is called the “plus” end and the less dynamic end is called the “minus” end (these terms do not refer to electric charge). (B) Actin and tubulin each bind nucleotides. The soluble proteins have a high affinity for the triphosphate form (NTP), and NTP-bound subunits have a high affinity for the assembled polymer (i.e., $k_{on} S-NTP \gg k_{on} S-NDP$). After the subunit is incorporated into the polymer, the subunit’s nucleotide is hydrolyzed. This lowers the affinity of the subunit for the polymer and might promote depolymerization. Subunits usually disassemble in the NDP-bound form and must exchange this nucleotide for NTP before again binding to the polymer.

determining the properties of the polymers. The soluble subunit binds a nucleotide triphosphate (NTP), which greatly increases its assembly rate. This enhanced rate of assembly does not depend on energy from the γ -phosphate bond, because assembly is promoted equally by nonhydrolyzable nucleotide analogs. The γ -phosphate bond is hydrolyzed only after a subunit has bound to the polymer. The energy released by binding is stored in the polymer and used subsequently to enhance polymer dynamics, as described below. After a subunit dissociates, the bound nucleotide diphosphate (NDP) is rapidly exchanged for NTP, and the subunit is ready for another round (Fig. 5.6B). The involvement of nucleotides means that, in addition to the intrinsic difference between plus and minus polymer ends, each end may exist in at least two states, with subunits containing NDP or NTP. These different states extend the range of behavior possible for cytoskeletal polymers.

5.3.3 Differences in the biochemical properties of actin and tubulin give the polymers distinct dynamic behaviors

Soluble actin is a globular protein (sometimes termed *G-actin* in contrast to the polymeric or filamentous form called *F-actin*) of around 375 amino acids. Subunits polymerize into

a tightly helical filament, ≈ 8 nm wide (Fig. 5.7). For historical reasons having to do with the appearance of actin filaments when decorated with the protein myosin, the minus end is sometimes called the *pointed* end, and the plus end called the *barbed* end.

The subunits that assemble into microtubules are heterodimers of the globular proteins α - and β -tubulin (Fig. 5.8). The dimers associate to form a hollow structure 25 nm in diameter. Each member of the dimer contains a bound guanine nucleotide, but only the β subunit engages in GTP hydrolysis and GDP–GTP exchange. In the microtubule, tubulin dimers bind together at their sides and at their ends. The dimers lie in straight columns called protofilaments. Most microtubules have 13 protofilaments, but the number can vary from 11 to 16. The lateral bonds between tubulin dimers displace dimers in adjacent protofilaments by several nanometers toward one end. Thus, the lattice of subunits that makes up the microtubule wall has a helical character. The plus end of the microtubule corresponds to the β -tubulin end of the dimer.

Several features besides nucleotide specificity distinguish actin filament and microtubule polymerization. For actin, the lag time for nucleation is proportional to the third power of concentration, which suggests that nucleation requires the assembly of a trimer. For microtubules, the nucleation lag is proportional to a much higher power of concentration, as

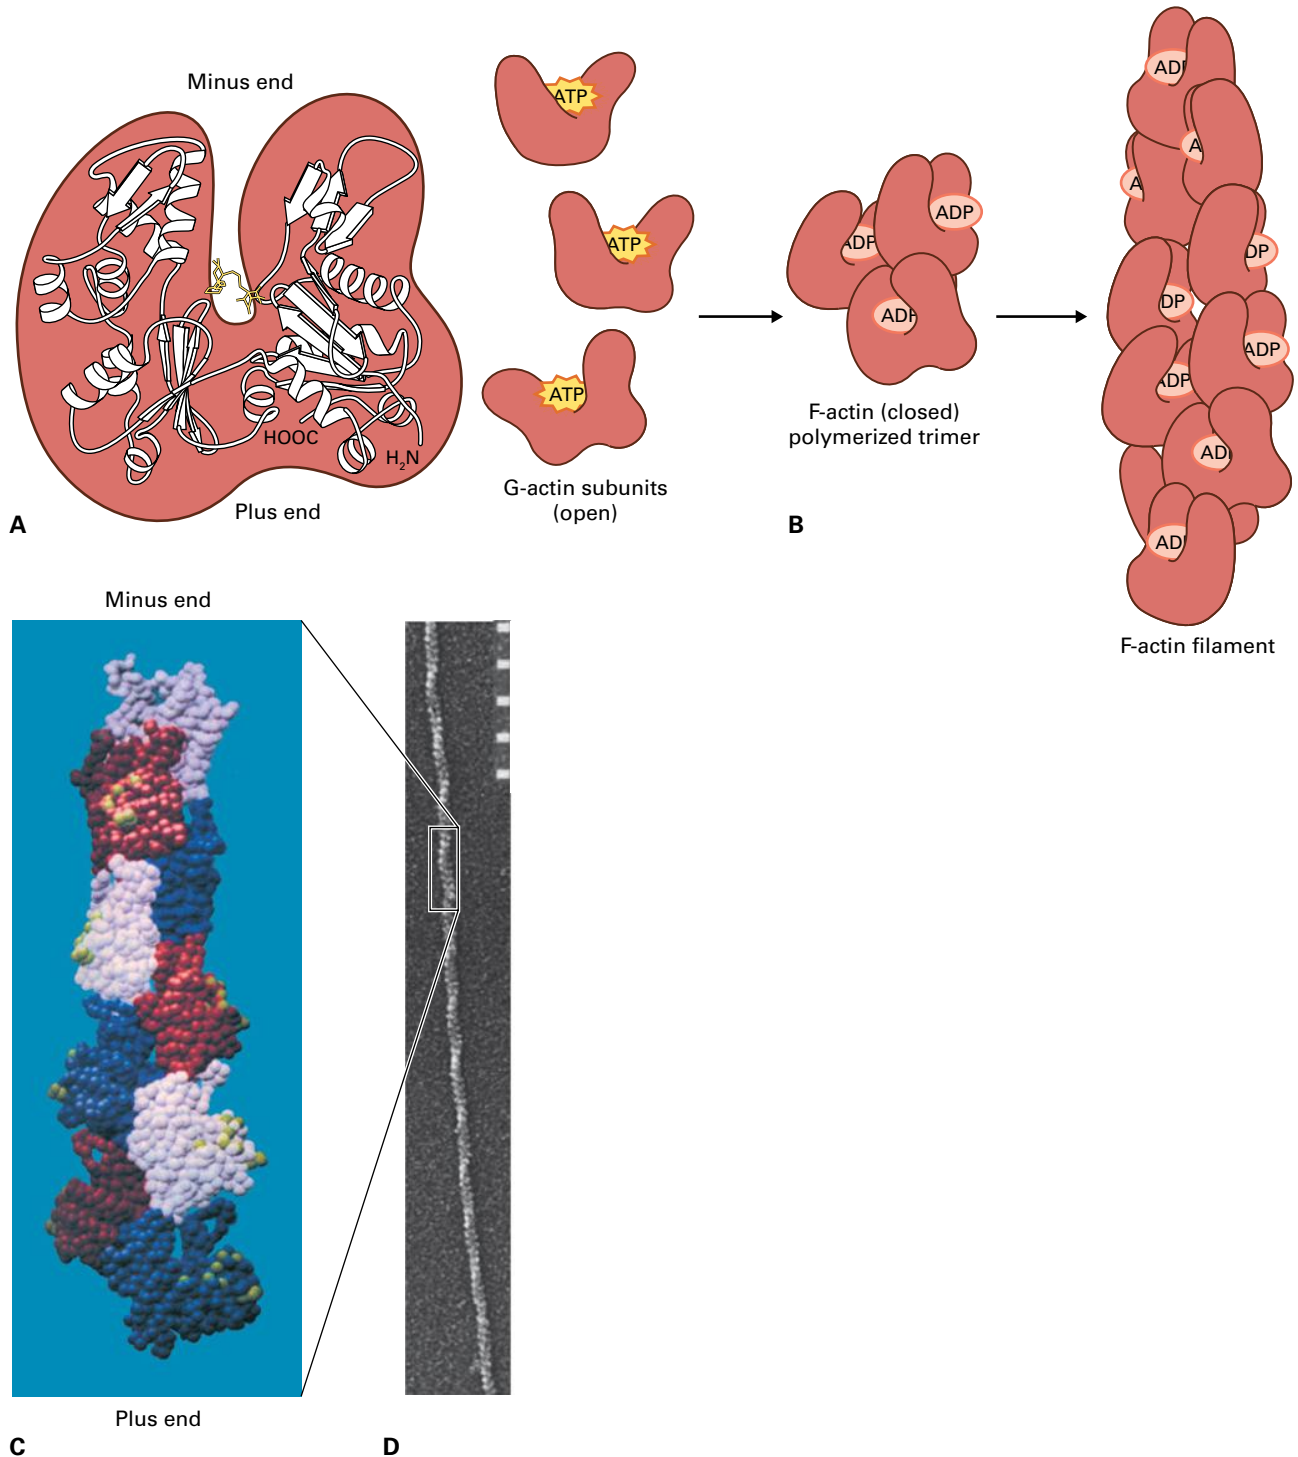

FIGURE 5.7 The structure of actin and actin filaments. (A) Ribbon model of a single actin molecule. The yellow structure in the middle is the bound ATP. (B) Diagrams of G-actin monomers, a nucleated F-actin trimer, and a short actin filament, emphasizing the “open” and “closed” conformations. In the polymerized form, the conformation changes to enclose the active site, preventing the loss or exchange of nucleotide. Staggered subunit associations give the polymer its helical character. (C) Three-dimensional model of an actin filament, in which each ball represents an amino acid. Note the different shapes of the plus and minus ends. (D) Actin filament assembled from purified actin and imaged by high-resolution scanning electron microscopy. The helical nature of the filament is visible. Scale divisions equal 25 nm. Source: (C) Holmes et al. (1999). *Nature* 347:44–49. (D) Y. Chen, University of Wisconsin.

would be expected if as many as 13 subunits must assemble to form a template. The critical concentration for assembly of actin is $\approx 0.2 \mu\text{M}$, very much lower than the concentration of actin typically found in cells (0.1–1 mM). Therefore, prevailing

concentrations seldom present a barrier to nucleation of actin filaments; instead, cells must prevent unwanted polymerization. Cells have evolved accessory proteins to sequester soluble actin and to control its polymerization into filaments (see

Section 5.4; Box 5.2). By contrast, the critical concentration for microtubule assembly is $\approx 10 \mu\text{M}$, only modestly below the usual cellular tubulin concentration ($\approx 20 \mu\text{M}$) and tubulin sequestration is usually not required.

Additionally, in the two types of polymer, nucleotide hydrolysis has different consequences. For actin, the presence of ATP at the plus (or barbed) end results in an assembly

rate far exceeding that at the minus (or pointed) end, where the actin subunits contain ADP. This difference underlies a type of dynamic behavior called **treadmilling**, which occurs when the prevalent concentration of free subunits supports growth at the plus end but results in shrinkage at the minus end. The net rate of change in polymer length can be exactly zero, during which subunits incorporated at the plus end will

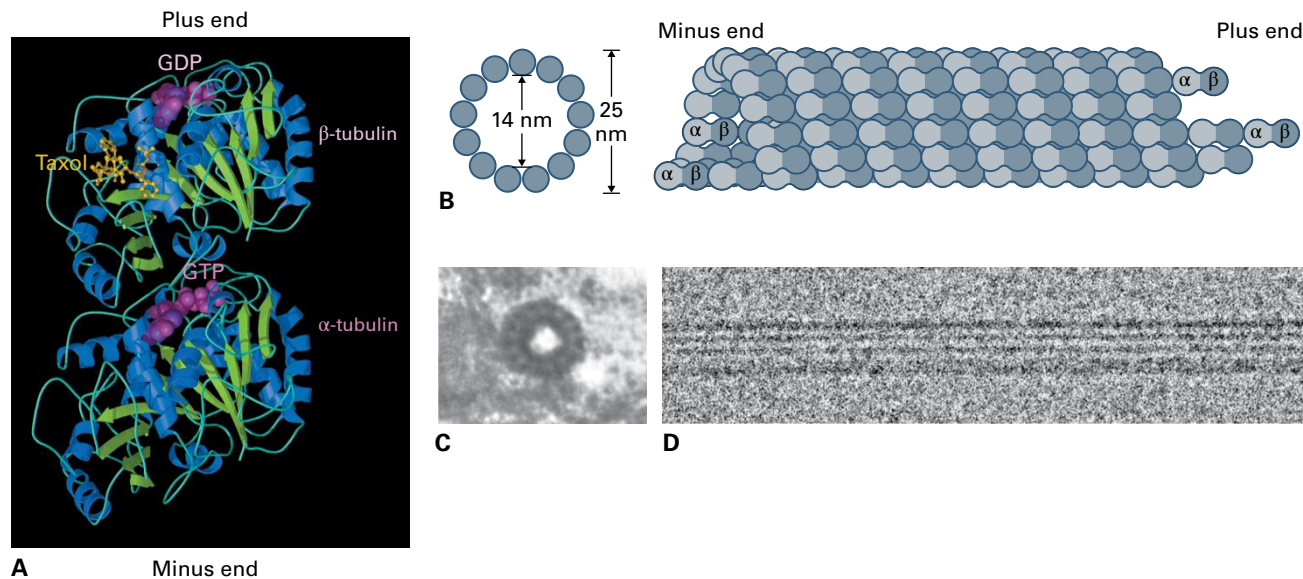

FIGURE 5.8 The structure of tubulin and microtubules. (A) Ribbon diagram of the tubulin dimer, resolved at 0.37 nm. Regions of the β -sheet structure are shown in green and the α -helix in blue. Also shown are the positions of bound nucleotide (purple) and of taxol (yellow; a compound that stabilizes microtubules and used in the structural determination). Note the overall similarity of structure between α - and β -tubulin. (B) Diagrams of a microtubule in cross-section and side view. The subunits of the microtubule, dimers of α - and β -tubulin, align head to tail in long parallel columns called protofilaments. The protofilaments are displaced longitudinally from one another, giving a helical character to the lattice of subunits, but the microtubule itself is linear. The α -tubulin is exposed at the minus end of the polymer, β -tubulin at the plus end. (C) Electron micrograph of a microtubule in cross-section from a plant cell, showing thirteen protofilaments. (D) Electron micrograph of a microtubule assembled from purified tubulin and viewed from the side. Unlike (C), this side view was prepared by using cryotechniques, without chemical fixation or staining with heavy metals.

BOX 5.2

On the trail of plant profilin—from sneezes to signals

If flowering plants make you sneeze, your allergy might be triggered by a fascinating, ubiquitous actin-binding protein called profilin. Medical research and plant cell biology, usually worlds apart, were united in 1991 by the discovery that patients with pollen allergies often synthesize antibodies against profilin, which is packed into pollen. The antibodies recognize profilin from a variety of plants, a finding that offered the first explanation for the nonselectivity of many pollen allergies. Even more intriguing, certain patients had antibodies against human profilin, implying the allergy is aggravated through

autosensitization. This finding has simplified diagnoses and is helping allergists evaluate preventative measures.

Beyond the etiology of allergy, the discovery of pollen as an abundant source of profilin was a boon for students of the plant cytoskeleton, enabling biochemical experiments. A small protein (10–17 kDa), profilin occurs in all cells, but its abundance increases 10- to 100-fold as pollen matures. Predicted amino acid sequences are typically 70–80% similar among plants, but when profilin sequences are compared across divergent taxa, the similarity drops to 20–40%. Despite sequence

divergence, profilin activity appears widely conserved. In fibroblasts, when profilin is overexpressed, the effects are identical, whether the encoding gene comes from a vertebrate or a plant. Furthermore, a profilin gene from maize (*Zea mays*) completely rescues a slime mold (*Dictyostelium discoideum*) mutant that lacks profilin. The similar activity of profilins from different sources might result from shared residues at both N- and C-termini and a similar three-dimensional structure. The ribbon diagrams (A) compare profilin from birch and acanthamoeba, a foraminifer. The conserved tertiary structure includes a core, six-stranded, antiparallel β -sheet, and the actin-binding domain, composed predominantly of the C-terminal α -helix (H3, blue) and the bottom three strands of the central sheet (β 4, β 5, and β 6, blue).

The first property of profilin to be characterized was its high affinity for soluble but not filamentous actin, which suggests that profilin sequesters actin monomers, releasing them locally, when and where the cell needs to

polymerize actin. Indeed, the name profilin was derived from “pro filamentous” actin, a term for sequestered actin that is otherwise competent to polymerize. The discovery of profilin in mature pollen fits this conception: mature pollen has few actin filaments but forms many within minutes of hydration. The ability of profilin to sequester actin is dramatically confirmed by microinjecting profilin into living *Tradescantia virginiana* stamen hair cells: the actin network is destroyed rapidly, thereby inhibiting cytoplasmic streaming (B) and cytokinesis. Presumably, profilin soaks up all of the actin monomers thus preventing new polymerization from balancing the ongoing depolymerization.

Since its discovery, activities reported for profilin have multiplied; these include stimulating nucleotide exchange, enhancing filament nucleation, interacting with regulatory subunits, and binding to membrane lipids. Thought to be important for profilin’s multi-tasking is a binding site recognizing uninterrupted stretches of

D

(C) Moss (*Physcomitrella patens*) gametophytes imaged with SEM. The control (top) has many thin branched protonemal filaments whereas when profilin expression is eliminated (bottom) cells are round, having lost the ability to polarize. Bars = 100 μ m (top) and 10 μ m (bottom). (D) Actin filaments imaged in control (top) and profilin RNAi (bottom) demonstrate that actin still polymerizes with reduced profilin but fails to be organized coherently.

the amino acid, proline, because polyproline stretches occur frequently in proteins that interact with profilin.

Which activity demonstrated in a test tube matters to a plant? Experiments with micro-injection (B) introduce the protein in super-abundance and thus the consequences might not be physiological. Progress toward elucidating key endogenous activities of profilin was made by taking advantage of the power of RNA interference in the moss, *Physcomitrella patens*. The moss gametophyte makes cellular filaments called protonemata, which grow by tip growth. Tip growing cells confine expansion to one region (the tip), giving rise to a slender, tube-like cell. Growth is confined to the tip by means of an extensive cellular polarization, long known to depend on actin. When protonemal cells express an RNAi construct that reduces if not eliminates

profilin, they become spherical (C) and their actin organization becomes random (D). These phenotypes are rescued by wild-type profilin but not by a profilin engineered to be unable to bind actin and only partially rescued by a profilin unable to bind polyproline. These results imply that profilin is activated locally to specify actin organization, rather than globally to regulate the total amount of filamentous actin; the results also point to the essentiality of profilin's actin binding compared to polyproline binding. Sneezes in autumn remind us how much we have yet to learn about this tiny but fascinating polypeptide.

“treadmill” through the polymer and eventually be released from the minus end (Fig. 5.9). Because the difference in assembly rate at the plus and minus ends is much larger for actin than for microtubules, treadmilling is presumed to be more common among actin assemblies. However, both polymers demonstrate this behavior.

Nucleotide hydrolysis gives rise to a different kind of behavior in microtubules, called **dynamic instability** (Fig. 5.10). Here, energy released by GTP hydrolysis accelerates depolymerization. Because GTP hydrolysis lags behind assembly, the growing ends of a microtubule will be rich in GTP-tubulin, a condition that stabilizes the microtubule lattice and favors growth. However, when the supply of tubulin dimers runs low, or when the rate of GTP hydrolysis accelerates, the end of the microtubule will contain few, or even no, GTP subunits. With only GDP subunits, the lateral bonds between protofilaments are strained. In this state, the protofilaments peel apart and initiate rapid disassembly, hundreds of times faster than the rate of growth. For a microtubule end, this transition from growing to shrinking is called *catastrophe*. Sometimes, the rapid disassembly stops, and growth resumes, a process called *rescue*. The mechanism for rescue is poorly understood, but might involve islands of GTP-tubulin remaining in the microtubule lattice.

5.4 Cytoskeletal accessory proteins

If actin filaments and microtubules are the cell's bones, then accessory proteins are the muscles, tendons, and nerves animating that skeleton. The different functions performed by polymers of the highly conserved proteins actin and tubulin are mainly determined by a suite of accessory proteins, less highly conserved or entirely novel. Key accessory proteins allow the cytoskeleton to work whereas many others bind

FIGURE 5.9 Treadmilling, a dynamic behavior observed in cytoskeletal polymers, is supported by nucleotide hydrolysis. Because the bound nucleotide is hydrolyzed after subunit polymerization, the substrates of the assembly reaction differ from the products of the disassembly reaction. Therefore, each end of the polymer may have different values of k_{on} and k_{off} and hence exhibit different critical concentrations. As a result, subunits may add preferentially at the plus end and be lost preferentially at the minus end without changing the length of the polymer. As shown in the diagram, subunits (orange) added at one end “treadmill” through the polymer and are released from the other end. Although the diagram illustrates actin, treadmilling occurs also in microtubules.

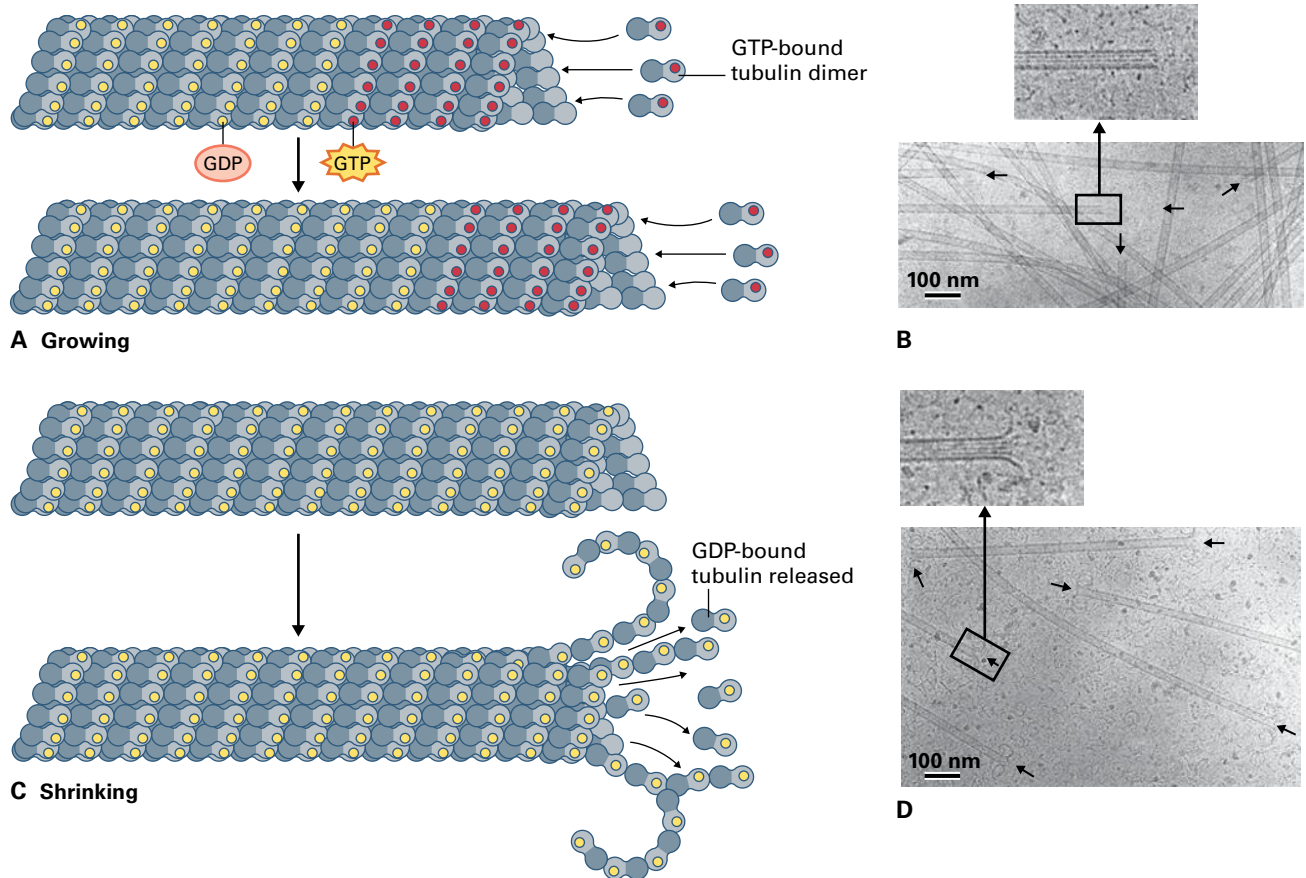

FIGURE 5.10 Model for microtubule dynamic instability. (A) Diagram of growing microtubules. Since hydrolysis of GTP usually lags behind polymerization of new subunits, the growing ends of microtubules are rich in subunits in which β -tubulin monomers bind GTP. Such microtubules are said to have a “GTP-cap.” In cells, the minus end of the microtubule is usually embedded in nucleating material, so GTP-caps are commonly considered only for the plus end. Note that the inert GTP bound to each α -tubulin is not shown. (B) Electron micrograph of growing microtubules. GTP-tubulin subunits pack into the microtubule lattice with minimal distortion, yielding straight ends for the growing microtubules (arrows; inset). (C) GTP hydrolysis causes a conformational change that tends to bend the protofilaments outward, weakening lateral contacts between dimers in adjacent protofilaments. In an intact microtubule, the GDP subunits in a protofilament are held in straight alignment by numerous lateral bonds to adjacent subunits and by the stability of the GTP cap. However, if the rate of polymerization decreases relative to the rate of hydrolysis, GTP subunits at the end become rare and the GDP subunits more readily assume their bent conformation. In this situation, the microtubule can undergo catastrophic depolymerization, during which subunits are released at a rate that far exceeds both the growth rate and the normal rate of subunit loss. (D) Electron micrograph of depolymerizing microtubules showing the protofilaments splaying outward (arrows; inset). Source: (B, D) Mandelkow et al. (1991). *J. Cell Biol.* 114:977–992.

and modify the characteristics of the polymer. Some of these proteins from plants have been implicated in human health (see Box 5.2).

5.4.1 Mechanochemical enzymes convert chemical energy into work

A pivotal type of accessory protein, mechanochemical enzymes, convert chemical energy to work, and are colloquially referred to as “motor proteins.” There are three super-families of motor proteins—**myosin**, **dynein**, and **kinesin** (Fig. 5.11)—all represented by large and diverse gene families. Fundamentally, these proteins allow force to be generated between a cytoskeletal polymer and another cellular element,

such as an organelle. Visualizing an organelle carried along a cytoskeletal polymer by a molecular motor invites comparison to a train carried along a track by a locomotive; however, a better comparison is to a person climbing a ladder using hands only. The climber has to grab the ladder, exert force to move at least as far as the next rung, and then let go of the ladder long enough to grab the next rung. To move along a cytoskeletal polymer, molecular motors work against thermal noise rather than gravity; they have high-affinity binding sites to grab the polymer, are built with long molecular lever arms to amplify a small conformational change driven by nucleotide hydrolysis into a large motion, and they alter the affinity for the cytoskeletal track in sync with the lever arm movement, thus allowing them to let go and rebind effectively.

Facing similar challenges, myosin, dynein, and kinesin share many features; having arisen eons ago, they differ in

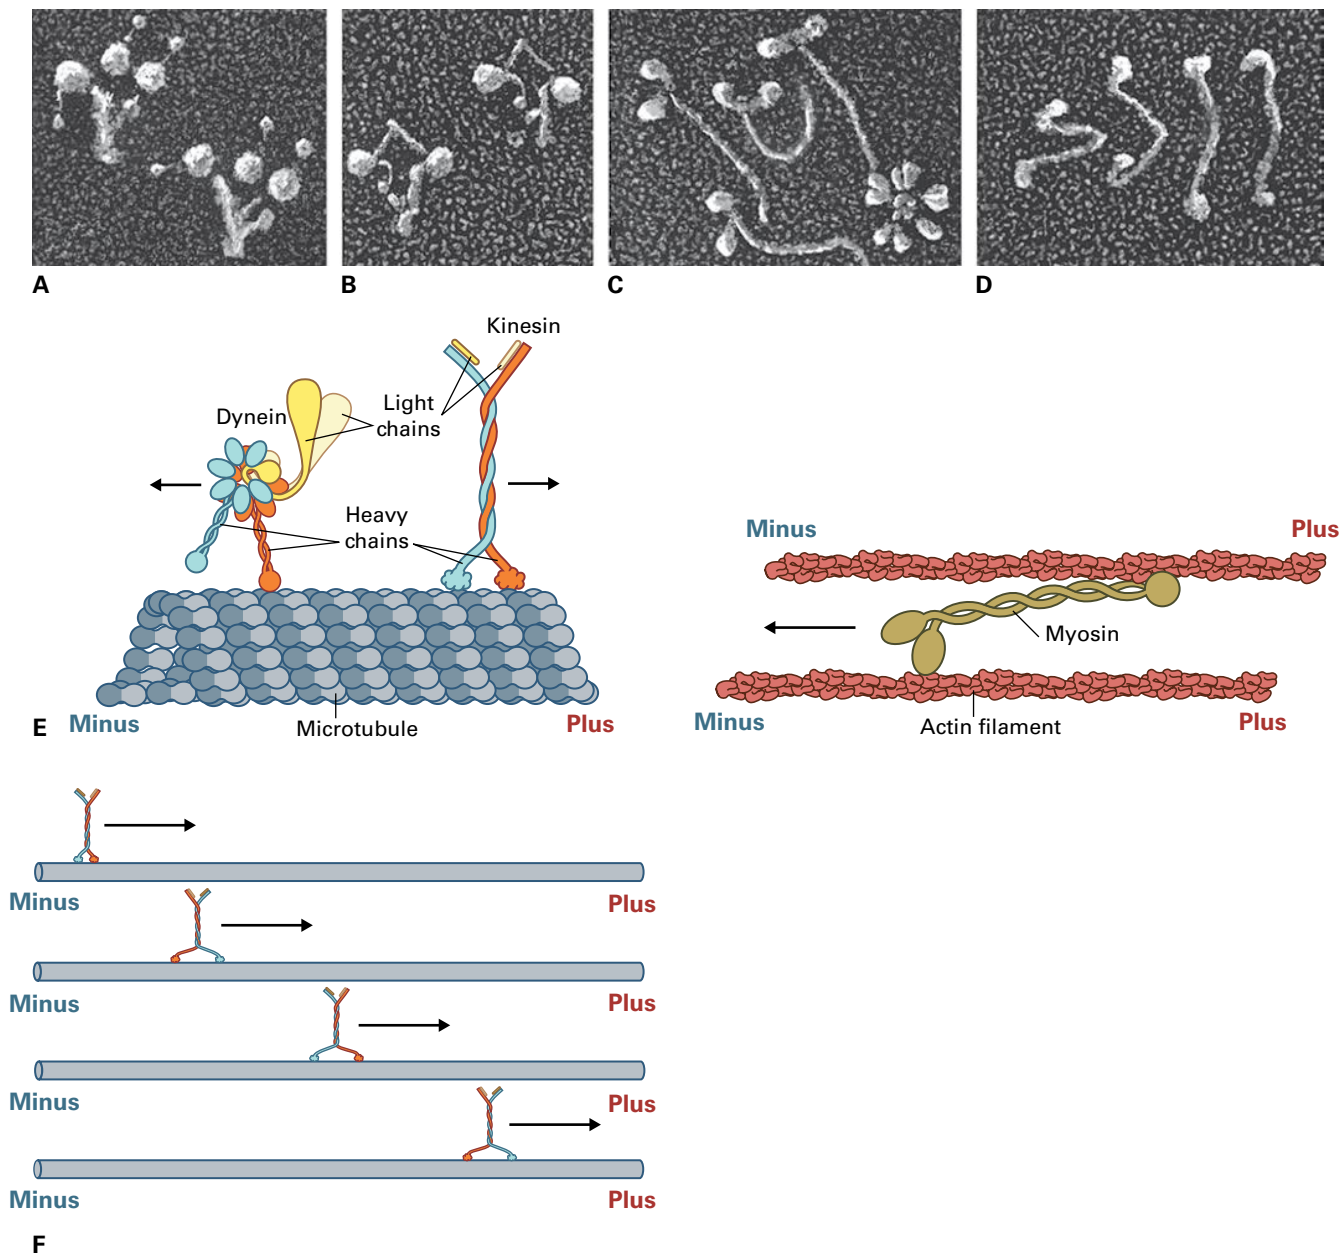

FIGURE 5.11 Motor proteins. (A–D) Electron micrographs of motor proteins. (A) The ciliary form of dynein has three spherical head domains. (B) The cytoplasmic form of dynein has two head domains. (C) Myosin II. The asterisk-shaped structure in the lower right of the image is an IgM antibody used to purify the myosin. (D) Kinesin. In this image, the motor domains at one end of the rod-shaped protein and the light chains at the other end are not distinguishable. (E) Diagrams of motor proteins. Though not homologous, myosin and kinesin share a similar structural organization, each containing a pair of heavy chains and several accessory light chains. The heavy chains form globular head domains and elongated tail domains. The head binds to the cytoskeleton, contains the ATP binding site, and produces most if not all of the force. The tail domain is responsible for binding the specific cargo. The light chains regulate the activity of the motor or modify its binding properties. Dynein has its “head” domain in the middle, with cargo-binding and microtubule-binding domains emerging as projections. Force is generated in the central domain and acts to rotate one projection relative to the other. (F) Schematic view of kinesin in action. Alternate binding by the two heads ensures that a head is almost always bound; hence, the motor with cargo can move along the microtubule for long distances before dissociating. Although this action is often likened to a biped walking, the two heavy chains are the same, not mirror images (as are left and right legs), and so the head rotates by 180° with each step to be in proper orientation for binding the microtubule. Source: (A–D) J. E. Heuser, Washington University of St Louis.

many others. They differ in which type of polymer they bind, what cellular cargo they transport, and the biochemical pathway they use to couple the changes in cytoskeletal affinity to steps of nucleotide binding, hydrolysis, and release. However all of them use ATP as their energy source. They all contain a

globular, force-producing domain that binds ATP and a rod-shaped “tail” domain that binds cargo as well as regulatory peptides. Furthermore, these motor proteins usually function as dimers, which allows one subunit to bind the cytoskeletal substrate while the other remains free to move to and bind the

next site on the polymer (Fig. 5.11F). In other words, this gives the motor two hands with which to climb the ladder. With two heads, a motor can travel along a cytoskeletal track for tens of microns without letting go, an attribute called **processivity**.

5.4.2 Myosin moves along actin; dynein and kinesin move along microtubules

Myosin, the first motor protein discovered, was identified as the force-producing enzyme of muscle; we now know that members of the myosin family are present in most, but not all, eukaryotic cell types, powering motility involving actin filaments (Fig. 5.12). In myosin, the globular force-producing domain, the “head,” also binds the actin substrate and force is developed by means of a long lever arm that connects head to tail (see Fig. 5.11E). With rare exception, myosins move to the plus end of the actin filament. Of the more than 20 different classes of myosin accepted to date, only two are present in plants, class VIII and XI, and these are unique to plants. Class XI myosin is similar to class V, which in animals and fungi plays a leading role in organelle motility. A class XI myosin isolated from the green alga, *Chara corallina*, holds the world’s record for motor protein speed ($60 \mu\text{m s}^{-1}$).

Historically the next motor protein discovered was dynein, identified as the protein responsible for movement of eukaryotic cilia (note, “cilia” as used here includes flagella, which have a similar structure; prokaryotic flagella are totally different). The motile component of the cilium, the **axoneme**, comprises nine doublet microtubules encircling a central pair of microtubules (Fig. 5.13). Dynein motors are deployed along one side of the doublet microtubules and reach out to and exert force on the next doublet. This is an example, by no means unique, where the motor protein is fixed in place and moves its cytoskeletal track. If our climber is standing on a rooftop holding a ladder, then their climbing action will lower it. In studies of axonemal dynein, the green alga, *Chlamydomonas reinhardtii*, has been instrumental. Dynein of several isoforms is precisely arrayed into axonemes, subject to exquisitely complex regulation, and generates the waveforms required for ciliary propulsion.

Most eukaryotic cells also contain a cytoplasmic dynein isoform, which is distinct from axonemal isoforms although closely related. As its name suggests, this isoform functions in the cytoplasm with prominent roles in organelle movement and in the mitotic spindle (see Section 5.9). Although cytoplasmic dynein is present in animals and fungi, it was apparently lost in an early ancestor of green plants and algae. Additionally, seed plants no longer make cilia and have lost

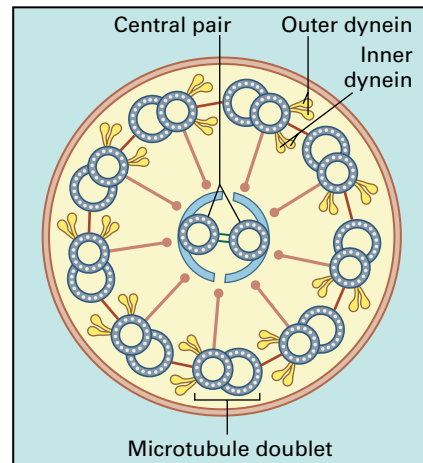

FIGURE 5.12 Myosin proteins interact with actin filaments, moving from the minus (pointed) end to the plus (barbed) end of the polymer. Myosin II proteins, such as those in muscle, have long rod-like domains that promote assembly into bipolar (head-to-tail) filaments. Myosin II filaments pull actin filaments with opposite polarity towards one another, mediating local contractions. Other myosin motors usually form dimers that can bind an actin filament or a membrane. Plants contain class VIII and XI myosin, which form two-headed (i.e., dimeric) motors. Force transduction by the myosin head might then (1) move an actin filament relative to another, (2) move a vesicle along an actin filament, or (3) move an actin filament along a membrane. These three arrangements apply as well to the microtubule motors, dynein and kinesin.

FIGURE 5.13 Electron micrograph showing a cross-section of a cilium from *Chlamydomonas reinhardtii*. The axoneme has a ring of nine microtubule-like structures called doublets surrounding a central pair of microtubules. Dynein is bound statically to one doublet and reaches out to the neighboring doublet and tries to move it. Because the doublets are anchored at their bases and also to the central pair, the action of the force exerted by dynein causes the cilium to bend.

Source: (micrograph) M. Hirono, University of Tokyo, Japan.

axonemal dynein. It is likely that some of the burdens lifted in animal cells by cytoplasmic dynein are shouldered in plants by kinesins (see below).

Dynein, whether axonemal or cytoplasmic, moves cargo to the minus end of the microtubule. It is a large polypeptide (>500 kDa), with its globular force-producing domain organized as a ring, and positioned in the middle of the molecule (see Fig. 5.11E). Two spokes emerge, one of which binds the microtubule and the other, longer and thicker, emerges on the other side of the ring and binds cargo and regulatory subunits. Force is generated by a contraction within the ring reducing the angle between the spokes. Dynein usually functions as a dimer, or even as a trimer, to increase processivity and perhaps to enhance scope for regulation.

Finally, the motor kinesin, although discovered third, is perhaps the best understood biochemically. Structurally, kinesin resembles myosin, with the globular head binding both ATP and microtubules and generating force by means of a lever arm connecting head to tail. In fact, kinesin and myosin might have evolved from the same ancestral peptide. Kinesins are diverse in most eukaryotes, with at least 14 classes defined, but have undergone particularly extensive radiation in plants, with *A. thaliana* containing 61 distinct kinesin genes, still a record among eukaryotic genomes, although poplar and rice (*Oryza sativa*) are close. Some classes of kinesin walk to the plus end (see Fig. 5.50 in Section 5.9.8) whereas others walk to the minus end. Plant kinesins, like those of animal cells, function in cell division and organelle motility; but we are just beginning to be able to assign functions to the multitude of plant kinesin motors.

5.4.3 Other accessory proteins bind, nucleate, or sever cytoskeletal polymers

Besides exerting force, accessory proteins help assemble, reinforce, and break down the cytoskeleton (Fig. 5.14). Knowledge about these accessory proteins comes mainly from studies on animals and fungi; in plants, some but not all of these proteins are present and new ones appear to have

FIGURE 5.14 Proteins that associate with the cytoskeleton have various functions, as illustrated here with actin filaments.

evolved. Dozens of such proteins exist, each with their own specialty. While unique in detail, the specialties can be categorized. Keep in mind that the following categorization refers to activity; some proteins have multiple activities.

A major distinction is between accessory proteins that interact with the monomer and the polymer. Proteins that

interact with monomers have two main activities, either to stimulate nucleotide exchange or to sequester the subunit. For example, **profilin** binds actin monomers and thereby lowers the concentration of subunits available for polymerization (see Box 5.2).

Accessory proteins that interact with polymer have three main activities: binding, nucleating, and severing (Fig. 5.14). All accessory proteins “bind” but the *binding protein* category refers to those that neither nucleate nor sever. Often the binding protein binds along the polymer (*side-binding*) and typically stabilizes it, exemplified by **tropomyosin** for actin and **MAP65** for microtubules, but some instead weaken the polymer lattice. An important subclass of binding proteins are those specific to one end of the polymer, often capping the polymer (*end-binding*). For example, the plus end of the microtubule is recognized specifically by the microtubule-associated protein, **EB1**, which remains at the plus end even as the microtubule grows and shrinks. Such proteins amplify the information contained in cytoskeletal polarity to generate or modify the polarity of the cell.

A large class of binding proteins is specifically crosslinking. This class includes proteins that link cytoskeletal elements to each other or to components of the cell, such as membranes, metabolic enzymes, or signal-transduction proteins. Proteins that crosslink one cytoskeletal polymer to another are of particular interest because the cytoskeleton nearly always is deployed as networks or bundles and these configurations require crosslinking for their formation and maintenance. The well characterized proteins of this class crosslink actin filament to actin filament or microtubule to microtubule, but newly discovered proteins, such as **anillin**, that link microtubules to actin filaments are attracting attention.

The structure of the cross-linking protein profoundly influences the type of network that forms. For example, **fimbrin** is a small, compact protein and has a pair of actin binding sites approximately 180° apart and therefore promotes the formation of tightly bundled actin filaments. Moreover, the binding sites on fimbrin are such that the two actin filaments have plus ends pointing in the same direction (so-called *parallel* polarity), ensuring that bundles form with uniform polarity. The uniformity supports movement in a single direction, as in cytoplasmic streaming (see Section 5.6.1). In contrast, **filamin** has a long and flexible region between actin-binding sites, which tends to promote a random, gel-like network. In addition to mechanical integrity, a gel-like network provides a path for transmitting a signal through the cell rapidly, because a mechanical disturbance initiated at one location in the gel can propagate through the network much faster than a chemical messenger can diffuse.

Nucleating proteins form a template from which the polymer can grow readily, overcoming the kinetic barrier to polymerization (see Section 5.3.1). For microtubules, **γ -tubulin**, a divergent member of the tubulin family, along with several other proteins forms a ring complex that serves as a base from which the $\alpha\beta$ -tubulin heterodimers assemble. For actin, nucleation is accomplished by a protein complex containing **ARP2/3**, and several other proteins; alternatively, actin may be

nucleated by **formins**. ARP2/3 nucleates filaments on existing actin filaments thereby forming a branched, mesh-like structure, whereas formin nucleates filaments on a membrane and tends to establish parallel filaments. By regulating the sites where nucleating proteins are deployed, the cell can control the sites from which cytoskeletal polymers emerge.

Severing proteins break down filaments. Although, as described (see Section 5.3), pure cytoskeletal polymers break down, the cell does not rely on spontaneous breakdown. Typical severing proteins bind anywhere on the filament and break it. An example of a protein that severs microtubules is **katanin** and one that severs actin filaments is **actin depolymerizing factor**. By creating free ends, severing proteins allow cytoskeletal arrays to be remodeled rapidly, for example promoting depolymerization or making easily translocated fragments. Some proteins break down cytoskeletal polymers from their ends, essentially by enhancing the rate for loss of subunits. Interestingly, several members of the kinesin class of motors have evolved to break down microtubules rather than to move cargo.

5.5 Observing the cytoskeleton: Statics and dynamics

To understand how the cytoskeleton works in a cell, we must go beyond reaction rate constants, genealogies, and catalogs of accessory proteins, and image the cytoskeleton within the cell. With few exceptions, the cytoskeleton in living cells is invisible through the light microscope. To increase its contrast, researchers can attach a fluorescent molecule (a **fluorophore**) to a cytoskeletal protein. Fluorescence offers high contrast because the light from the fluorophore is observed against a dark background. For this approach to succeed, the fluorophore must not alter the behavior of the protein and, likewise, subjecting the cell or organism to fluorescence microscopy must not alter its physiology.

5.5.1 Microinjection of labeled proteins was the first method used to image specific cytoskeletal polymers in living cells

The name “cytoskeleton” evokes a static, bony, armature, and this metaphor dominated early discussions of cytoskeletal function. Although clues were available to cytoskeletal dynamics—for example, from polarized-light microscopy—not until scientists imaged actin filaments and microtubules directly in living cells did the extraordinary dynamics of these polymers become widely appreciated.

Researchers found that a chemical fluorophore (e.g., fluorescein) could be conjugated covalently to tubulin without appreciably altering the biochemical properties of the protein. The labeled subunits, introduced into living cells

FIGURE 5.15 Schematic representation of fluorescent analog cytochemistry as applied to cytoskeletal polymers. A cell is microinjected with a small volume of a solution containing the protein of interest conjugated to a bright fluorescent molecule (a fluorophore). A short time later, fluorescent subunits (as well as native subunits) are incorporated into cytoskeletal structures, rendering them visible in fluorescence microscopy.

by microinjection, would incorporate into the native microtubules, rendering them visible with fluorescence microscopy (Fig. 5.15). Although this technique allowed microtubules to be observed in living animal cells in the 1980s, plant cells were more difficult to microinject because of their thick cell walls and large turgor pressures. In the 1990s, these obstacles were first overcome with stamen hair cells (Fig. 5.16), and soon thereafter in other cell types. In all cases, microtubule arrays were found to be extraordinarily dynamic, with the average individual microtubule half-life being about one minute.

For live imaging studies, actin filaments have also been tagged; however, in plant cells, all attempts have failed to introduce derivitized actin. An alternative has been to use a fluorescent conjugate of the small bicyclic peptide, phalloidin, which binds filamentous actin with high specificity and has been injected successfully into plant cells (Fig. 5.17; see Fig. 5.39). Nevertheless, not only can phalloidin affect actin filament behavior, it can become sequestered in vacuoles and be lost from the cell through plasmodesmata, hindering observations.

5.5.2 Fluorescent proteins have become reporters of choice for live cell imaging

Despite successes, the technical difficulty of microinjection slowed widespread adoption of this method. Instead, fluorescent proteins have become the reporters of choice for localizing proteins in living cells (see Fig. 1.27). Plants expressing labeled tubulin have been widely used and allow dynamics of microtubules to be followed in real time (Fig. 5.18). In contrast to labeled tubulin, where anomalous

behavior is minimal, labeled actin has proved problematic. As with chemical fluorophores (see Section 5.5.1), actin tagged with GFP functions poorly in plants, and instead actin-binding proteins are tagged. One promising approach has been to make a chimera between GFP and an actin-binding domain from fimbrin (Fig. 5.19). But even though some of these tagged proteins give rise to plants without apparent defects, the reporter's fluorescence shows the actin-binding protein, which is not necessarily contiguous with the entire actin cytoskeleton. Illustrating this, pollen tubes expressing one of three different tagged actin-binding proteins give three different staining patterns (Fig. 5.20).

5.5.3 Cryofixation offers the highest resolution images of the cytoskeleton

Beyond revealing dynamics, imaging a living cell appeals to our sense of wonder at cellular animation. Nonetheless, there are good reasons for imaging dead cells. Dynamics become a liability when the cell responds to being squeezed beneath a coverslip or irradiated with a laser. Light microscopy works best on objects within a few dozen micrometers of the coverslip; as distance increases, aberrations accumulate and obtaining informative images becomes increasingly difficult. Light microscopy also has limited resolving power, whereas electron microscopy, although having higher resolving power, is incompatible with liquid water and living cells. Therefore, to avoid unwanted cellular reactions, to image deep within a sample, or to take advantage of the resolution of electron microscopy, scientists have long relied on imaging dead cells, and they are likely to continue to do so for the foreseeable future.

FIGURE 5.16 Confocal fluorescence micrographs of a living stamen hair cell that was microinjected with tubulin purified from cow brain and derivatized with a fluorophore. These images represent the first use of fluorescent-analog cytochemistry to label the cytoskeleton in living plant cells. The disposition of microtubules is shown as the cell moves from (A) prophase through (B) prometaphase, (C) metaphase, (D) anaphase, (E) telophase, and (F) cytokinesis.

FIGURE 5.18 Green fluorescent protein (GFP) provides a powerful alternative to microinjection for labeling cytoskeletal structures. This example shows cortical microtubules imaged with confocal fluorescence microscopy in the hypocotyl of *A. thaliana*. The images were taken at 10-second intervals. At first glance the array looks static, but following individual microtubules shows that many of them are growing and shrinking dynamically. Source: S. Shaw, Indiana University.

For years, the way to kill a cell for microscopy, called fixation, was with alcohol. In the 1960s, after the introduction of an improved chemical fixation, based on glutaraldehyde, microtubules were imaged for the first time, a breakthrough that occurred with plant material. However, even the best chemical fixatives require minutes to halt the dynamic activities of cells. This is time enough for unnatural changes to occur while some cell components are fixed while others continue to move and react.

To overcome this problem, microscopists have turned to **cryofixation**. Samples are cryofixed by plunging them into a cryogenic liquid with a high heat capacity (e.g., propane) at a low temperature (-180°C). This removes heat from the sample so rapidly that insufficient energy remains to form ice (because ice expands, its formation damages the sample). The sample freezes in milliseconds, leaving little time for changes to occur. At ambient pressure, heat can be removed efficiently only from the outer 5–10 μm of the sample, restricting plunge freezing to single cells. However, using specialized apparatus, **high-pressure freezing** allows cryofixation under pressure, which prevents water crystallization for a considerable thickness (as much as 1–2 mm in favorable samples). Following cryofixation, the supercool water in the sample is exchanged with a solvent, such as acetone, at a temperature that is warmer (-80°C) but still too cold for formation of ice crystals. This exchange is called **freeze substitution**. Once the water is replaced with solvent, the sample can be processed for electron microscopy as usual.

Cryofixation halts all dynamic processes within milliseconds, the structures revealed often appear more life-like than those obtained with chemical fixation (Fig. 5.21). Recently, cryofixation has been used to address the problem of actin localization in the pollen tube. Contradictory images of actin in pollen tubes had been reported by different laboratories

and sometimes even by the same laboratory in different papers. Discordant images were likewise produced by living-cell reporters (see Fig. 5.20). Cryofixing pollen tubes followed by freeze-substitution and staining with anti-actin revealed two features of actin (Fig. 5.22). First, fine actin filaments fill the shank of the tube: the thick bundles previously reported probably represent a bundling induced by fixation. Second, a dense fringe of cortical actin subtends the apex. This unusual structure is believed to play a pivotal role in the process of tip growth.

5.6 Role of actin filaments in directed intracellular movement

In all cells, the cytoskeleton interacts with organelles to move them specifically or to prevent their moving by providing anchorage. In plant cells, organelles move mainly on actin, whereas in animal cells organelles mainly ride microtubules. There are exceptions, and in both kingdoms microtubules and actin are increasingly realized to cooperate to direct organelle traffic optimally. Curiously, a similar reversal occurs in cell shaping, which in animals is directed by actin but in plants by microtubules (see Section 5.7). These evolutionary role reversals underscore the idea that eukaryotes invented cytoskeletal polymers early and, as they subsequently evolved, used them with considerable modularity. Animals and plants represent just two branches of the eukaryotic tree—once this diversity is sampled more richly for cytoskeletal function, we should have a better context for understanding these global shifts in function.

FIGURE 5.19 The actin cytoskeleton can also be labeled with GFP reporters, albeit indirectly. These images are confocal fluorescence micrographs of various cell types in *A. thaliana* expressing a reporter containing GFP and sequences from the actin-binding protein, fimbrin. Dense networks of actin are seen in many cell types, including (A) the epidermis of a cauline leaf (the oval shapes are stomata), (B) a leaf vein, (C) cortical parenchyma of the root's elongation zone, and (D) a trichome. Source: E. Blancaflor, Noble Foundation, Ardmore, Oklahoma.

FIGURE 5.20 Actin reporters based on fluorescent actin-binding proteins label only a subset of actin structures. These are confocal fluorescence micrographs of lily pollen tubes expressing reporters using different actin-binding proteins. Each reporter gives rise a distinct pattern of "actin". Bar = 10 μ m.

5.6.1 Cytoplasmic streaming requires actin

Cytoplasmic streaming is the bulk movement of cytoplasm, literally streaming through the cell. Streaming is prominent in large, highly vacuolated cells (see Box Fig. 5.2A), such as the giant, algal internodal cells of the Characeae. The enormous size of these cells facilitated development of a pioneering model, allowing reactivation of motility with purified components (Fig. 5.23). In these cells, the cytoplasm is partitioned into a stationary layer in the cell cortex and an internal streaming layer, called the endoplasm. Near the boundary between layers lie long parallel bundles of actin filaments with uniform polarity. These bundles are firmly anchored to rows of chloroplasts, immobilized in the cortex by ramifying connections ultimately reaching the cell wall. The endoplasmic reticulum (ER) and other large organelles have myosin on their membranes, which drives organelle movement in a uniform direction, as specified by the polarity of the fixed actin filaments. The motion of the large organelles causes the entire endoplasm to flow.

Streaming in cells of land plants likewise involves myosin-bound organelles moving along actin filaments. Unlike the algal internodes, plant cells have dynamic actin so that

FIGURE 5.21 Comparisons of chemical and cryofixation. (A,B) Nomarski optics of sectioned *A. thaliana* roots prepared by (A) chemical fixation and (B) cryofixation. Note the coagulated cytoplasm in A compared to B, where the transvacuolar strands almost seem to remain under tension. Bars = 10 μm . (C–F) Transmission electron micrographs of tobacco (*Nicotiana tabacum*) roots comparing chemical fixation (C and E) with high-pressure cryofixation (D and F). Note the smooth membranes (arrow), spherical organelles (arrowheads) and dense cytoplasm present in the cryofixed sample (D). At higher magnification, the plasma membrane of the chemically fixed cell is distorted (E), whereas that of the cryofixed cell appears as a smooth bilayer (F). Bars = (C, D) 2 μm , (E, F) 25 nm.

streamlines meander as actin filaments rearrange. Nevertheless, the result is similar, a thorough mixing of organelles within the cytoplasm despite the massive vacuole. In cells without large vacuoles, organelles also undergo sustained movements along actin filaments but without causing bulk flow (i.e., streaming) within the cytoplasm (see Fig. 5.26B,C).

5.6.2 Sustained movement and anchoring of organelles depend on actin filaments.

By far the most well-studied organelle movements in plants are those of chloroplasts. In photosynthetic cells, as the light environment changes, chloroplasts move to absorb light optimally, maximizing absorption in dim light but minimizing absorption in bright light (Fig. 5.24). Light-induced movement of chloroplasts, and their subsequent anchorage, depends on actin filaments (Fig. 5.25). In some plants, a meshwork of actin filaments encases chloroplasts when they are anchored and this arrangement changes to a more linear pattern (“tracks”) when the chloroplasts are moving; however,

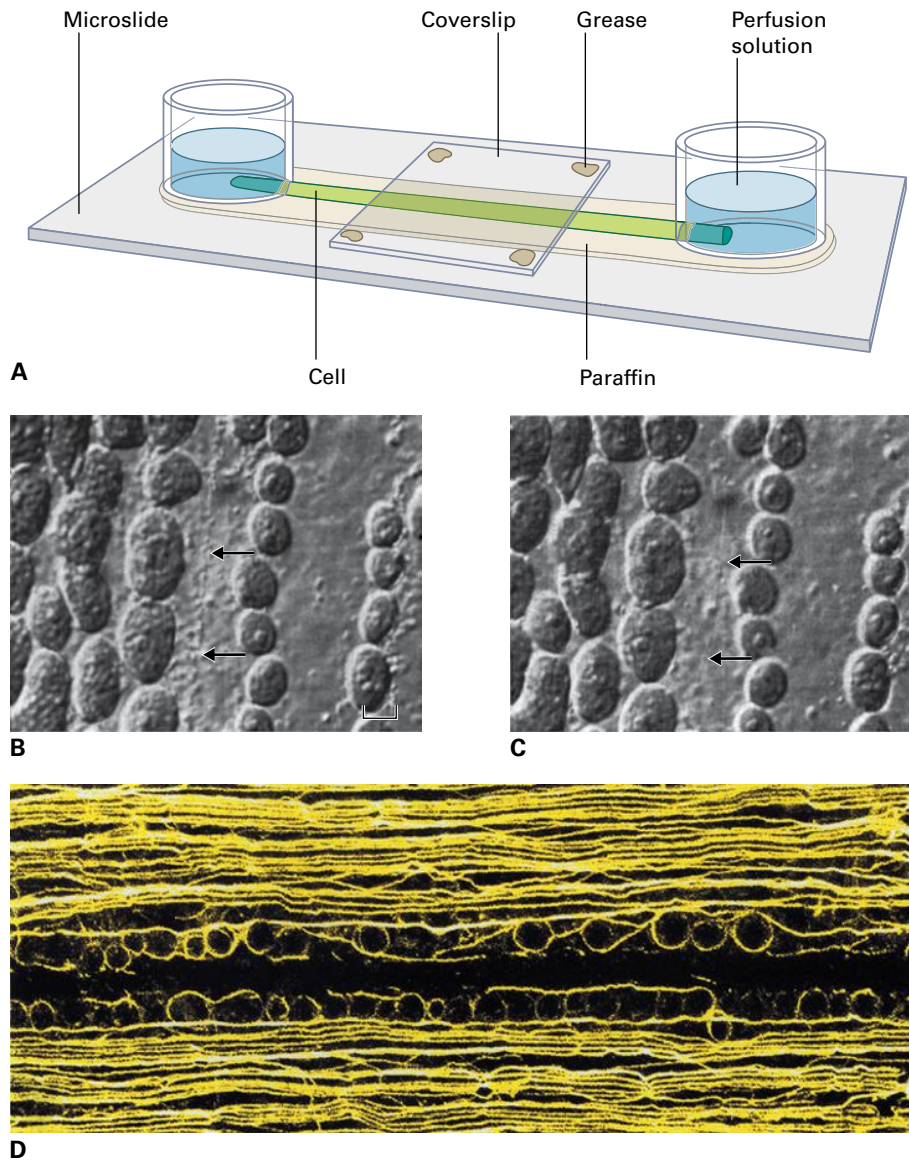

FIGURE 5.23 The giant internodes of characean algae were used in early functional studies of cytoplasmic streaming. (A) Perfusion chamber. An internode is placed on a microscope slide and each end of the cell is placed under a glass ring with a notch cut to accommodate the cell. The perfusion solution is placed in the rings, and the portion of the cell between the rings is covered with liquid paraffin. Under these conditions, intact cells continue to stream for more than a week. To begin an experiment, one severs the ends of the cell and perfuses through solution. This removes the central vacuole and much of the endoplasm; however, the cortical cytoplasm containing the chloroplasts and associated cytoskeletal elements remain. (B, C) Light micrographs of a perfused cell in the chamber. Arrows point to a bundle of actin filaments that has been dislodged from a nearby row of chloroplasts. In (B), the bundle is covered with small particles. In (C), a solution containing ATP was perfused through, which reactivates streaming, moving the particles along the bundle and out of the field of view. This movement is now known to be powered by myosin and to underlie cytoplasmic streaming in many plant cells. (D) Fluorescence micrograph showing a region of the cortical cytoplasm from a giant algal internode stained with fluorescent phalloidin to localize actin filaments (yellow). Files of chloroplasts are also visible beneath the bundles. Source: (B, C) Williamson. (1975). *J Cell Sci* 17:655–668. (D) G. Wasteneys, Australian National University, Canberra.

in other plants structural changes in the actin network are not observed. Given the importance of optimal light capture and the range of conditions where leaves photosynthesize, it should not be surprising that chloroplasts are moved by the actin system in more than one way. Plastid movements are also important in tissues that sense gravity; in these tissues, plastids (called amyloplasts because of their prominent starch grains) sediment in response to gravity. It is not known precisely

how the cell senses the direction in which the amyloplasts fall, but several lines of evidence point to the importance of an actin meshwork that surrounds these organelles.

The Golgi apparatus, ER, mitochondria, and peroxisomes, all move along actin filaments in plants, contrasting their microtubule-based movement in animal and fungal cells. Because actin filaments pervade the plant cytosol in a dense meshwork, even forming thin, membrane-covered protrusions

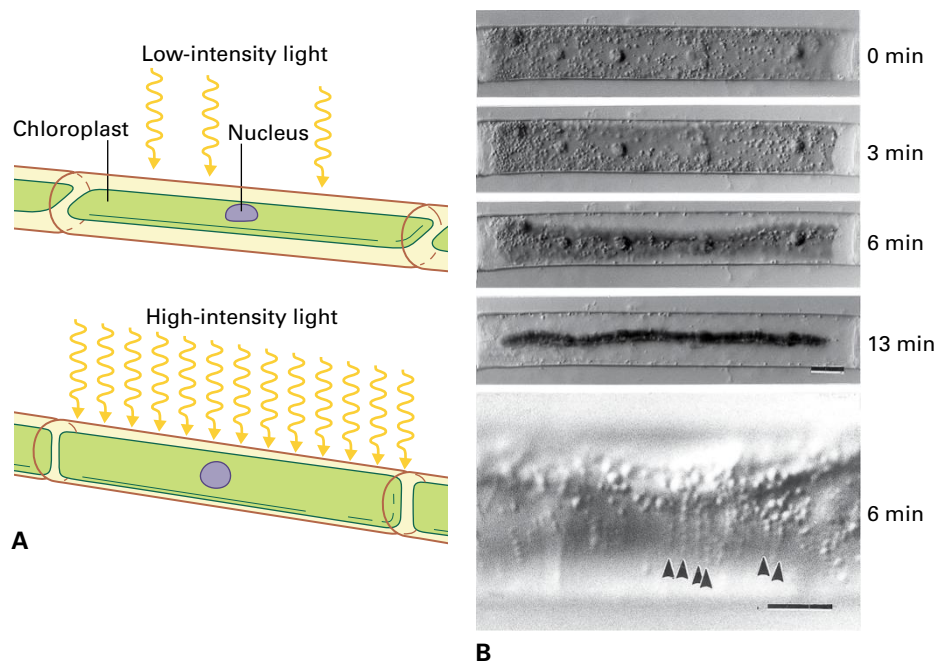

FIGURE 5.24 As shown in cross-sections through the leaf of *A. thaliana*, chloroplasts move to maximize or minimize their absorption of light. (A) Exposed to dim light, chloroplasts move to walls parallel to the leaf surface, and stay there, thus maximizing light absorption for photosynthesis. (B) Exposed to bright light, chloroplasts migrate to cell walls perpendicular to the leaf surface, thus minimizing light absorption and photodamage.

through the large central vacuole, organelles tracking actin thus are dispersed throughout the cell. The Golgi apparatus in animal cells is clustered beside the nucleus by means of minus-end-directed microtubule motor proteins that move the Golgi stacks toward the centrosome; whereas in plant cells, Golgi stacks move along actin filaments, albeit in a stop-and-go fashion, and are everywhere (see Fig. 1.27). In the cell cortex, the ER spreads out into a network of fine tubules connected by polygonal cisternae (see Fig. 1.16), an arrangement that depends on actin filaments anchored to the plasma membrane. Ribosomes and other structures for RNA processing also interact with actin filaments, an association attracting recent interest.

Plant mitochondria and peroxisomes also depend on actin to move, but interestingly these organelles also interact with microtubules, an interaction whose physiological relevance remains conjectural. Peroxisomes illustrate some

of the puzzling features of organelle motility. These organelles have a myosin isoform on their membrane and their location and movement closely follow actin filaments. However, peroxisomes tend to be static in leaf mesophyll cells, unlike Golgi or plastids, and the extent of their motility in other cells varies with cell type and development. Surprisingly, peroxisomes aggregate at cytokinesis around the forming cell plate in members of the genus *Allium* but Golgi remain dispersed, as do peroxisomes in numerous other genera, both monocot and eudicot (Fig. 5.26). No one knows why alliaceous peroxisomes aggregate so strikingly, nor why other organelles with actin-dependent motility are left behind. Evidently, cells have evolved layers of regulation to control which organelle moves where, and under what circumstances, regulatory mechanisms that are completely undiscovered.

FIGURE 5.26 Organelle motility. 5.6.3 Actin filaments participate in traffic to and from the plasma membrane

As described in Chapter 1, cells are congested with vesicular traffic, carrying membrane and soluble cargo from one organelle to another. The best-understood road runs from Golgi apparatus to plasma membrane, an outflow of material termed **secretion**. It is often assumed that secretory vesicles always move on actin filaments but this probably depends on cell type. Actin inhibitors do not always diminish rates of secretion measured biochemically, and given the proximity of Golgi bodies to the plasma membrane, a dedicated secretory “highway” is likely to be needed only in cell types that place particular demands on the secretory system, for example, root cap cells that secrete large volumes of slime to condition the rhizosphere.

Secretion is balanced by returning vesicles, going from plasma membrane to either Golgi or vacuole, an inflow of material called **endocytosis**. This pathway absolutely requires actin in animal and fungal cells; whereas, in plants, endocytosis can occur without actin, although rates and targeting are affected. In general, the role of actin in plant vesicle transport, both inward and outward, requires further study.

Two examples where actin filaments play an undisputed role in vesicle transport are in cells responding to pathogen attack and in tip-growing cells. Many pathogens initiate their attack by pushing against a cell, forming a structure called an **apressorium**. The plant cell responds to the pressure with a massive reorganization of both microtubules and actin filaments, with that of actin having been most clearly linked to a successful resistance. The actin filaments become focused on the apressorium and drive the accumulation of organelles and a localized cell wall thickening that hinders pathogen ingress (Fig. 5.27).

In pollen tubes, which grow by tip growth, actin filaments are polarized along the cell cortex to move secretory vesicles (and organelles) toward the tip and are polarized in the center of the tube to move endocytic vesicles (and organelles) away from the tip (Fig. 5.28). The vesicles associate with actin filaments and have myosin in their membranes. The high rates of relative expansion sustained by tip-growing cells require delivery of a large quantity of wall precursors without interruption. Moreover, streaming is *less* sensitive to the disruption of the actin cytoskeleton than is growth itself, an observation that has been interpreted as indicating a requirement for actin beyond vesicle transport to the tip. The exact roles of the actin cytoskeleton in inward and outward vesicle trafficking await their Mendel.

FIGURE 5.27 Actin filaments help plants resist infection by pathogens. In this example showing cotyledon epidermal cells before (left) and 1 day after infection with powdery mildew (right), actin filaments, labeled with a GFP actin-binding protein, in the infected cell form a radial array focused on the infection site (asterisk). This configuration is thought to support the formation of wall thickening making it more difficult for the pathogen to enter the cell. Bar = 20 μm .

5.7 Cortical microtubules and expansion

Whereas actin stars in intracellular motility with microtubules supporting, the casting is reversed in the process of diffuse growth (so-called when growth occurs throughout the cell). Diffuse-growing plant cells usually expand faster in one direction than in another, that is, anisotropically. Anisotropic expansion underlies the plant's ability to make cylindrical stems, flat leaves, not to mention a petal shaped like a bee (made by certain orchids to lure pollinators). Anisotropic expansion depends on microtubules; when they are inhibited, the rate of increase in volume remains constant but the anisotropy of expansion decreases, often becoming isotropic.

5.7.1 An array of cortical microtubules controls the anisotropy of expansion

A dense array of microtubules lies just inside the plasma membrane of interphase plant cells, in the cortical cytosol (see Fig. 5.18). These so-called **cortical microtubules** are found in nearly all plant cell types although they are broken down during mitosis. In immunofluorescence light micrographs, the array looks like a single structure, encircling the cell; however, in electron micrographs, the array is resolved into a series of short (<10 μm), partially overlapping microtubules (Fig. 5.29). The microtubules within the array run mostly parallel one another and are close to and often touching the plasma membrane. The orientation of cortical microtubules was originally thought to be uniform per cell, but we now know that orientation can differ on different walls of a single cell. In elongating cells, their net orientation is perpendicular to the direction of most rapid expansion, an orientation that is referred to as “transverse.” As elongation stops, transverse microtubules reorient to form helices around the cell, which is the typical orientation for non-growing cells.

A major function of the cortical array is to influence the direction of cellulose microfibril deposition, which in growing cells specifies the direction of maximal cell expansion (see Chapter 2). Except in tip-growing cells (such as pollen tubes and root hairs), the alignment of the cellulose microfibrils parallels that of the microtubules (Fig. 5.30). Cellulose microfibrils parallel the underlying cortical microtubules when protoplasts regenerate a cell wall. Both cellulose and microtubules become oriented in helices as cells mature, with a helical arrangement of cellulose microfibrils providing plywood-like reinforcement for the wall. Cellulose microfibrils also parallel the microtubules in developing secondary walls. When cell wall thickenings form in tracheids, the banded deposition of cellulose is preceded by a bundling of cortical microtubules. Finally,

FIGURE 5.29 A map of the cortical array of microtubules from a cell in the root of *Azolla pinnata*, based on reconstructions from serial sections examined with electron microscopy. The double-headed arrow represents the direction of maximum expansion rate.

when microtubules are lost, either by experimental treatment with inhibitors or naturally, as in the leaf sheath cells of certain bulb-forming monocots, cellulose microfibrils are usually deposited with less organization and expansion is no longer as anisotropic.

Although such evidence makes it clear that cortical microtubules influence the orientation of cellulose, the mechanism behind this influence has not been discovered. Furthermore, microtubules might also influence other attributes of cellulose microfibrils, for example, their strength or their integration within the cell wall, both properties being important for expansion anisotropy. The strength of the microfibril could be influenced by proteins binding the microtubule that keep the cellulose synthase running optimally, like the coal-car behind a locomotive. Microfibril integration could be influenced by transmembrane proteins that bind microtubules with their cytosolic domains and, with their extracellular domains, promote reactions that integrate cellulose microfibrils into the cell wall fabric. Combining live-imaging and structural analysis of the cell wall is beginning to let us evaluate these possibilities and discover new ones.

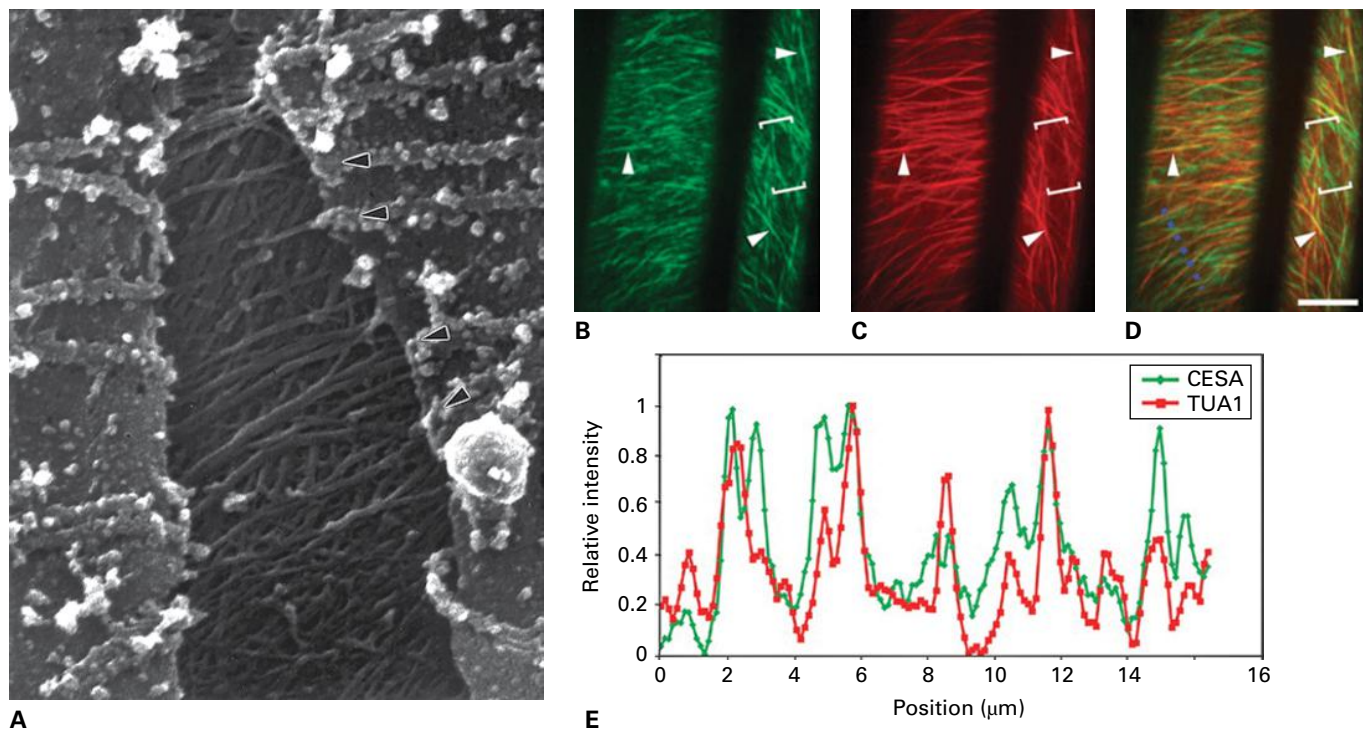

FIGURE 5.30 Cellulose microfibrils parallel cortical microtubules. (A) Field-emission scanning electron micrograph of the interior of an onion root cell, looking toward the cell wall. Shown is the cortical cytoplasm on either side of a tear in the plasma membrane through which the cell wall is visible. The orientation of cortical microtubules (arrowheads) can be seen to parallel the direction of many of the microfibrils in the cell wall. (B–E) Live cell imaging of *A. thaliana* hypocotyls expressing fluorescently tagged tubulin (C, red) as well as cellulose synthase tagged with a yellow fluorescent protein (B, green). At a single time, the cellulose synthase labeling is point-like; the image (B) was made by summing consecutive frames so that the movement of the point becomes a line, defining the trajectory of motion (arrowheads in B). D merges both green and red signals into a single image, in which overlap of green and red appears yellow. Bar = 10 μm . The graph (E) plots the intensity of the green and yellow signal along the purple dotted line (in D). The cellulose synthase trajectories closely parallel the underlying microtubules, as seen by the many yellow lines in D and the correlated intensity profiles (E). Source: (A) Vesik et al. (1996). *Protoplasma* 195:168–182. (B–E) Paredez et al. (2006). *Science* 312:1491–1495.

5.7.2 Cortical microtubules collaborate with actin filaments in cell shaping

In contrast to the roughly cylindrical or polyhedral shapes of most plant cells, certain cell types are marvels of miniature sculpture. These shapes are carved by actin filaments and microtubules working together. Well-studied examples are leaf epidermis and mesophyll, which are highly sinuous at maturity (Fig. 5.31). In both cell types, microtubules and actin are deployed complementarily. In mesophyll, microtubules form thick bands here and there and actin filaments are enriched between the bands. Importantly, the microtubule bands form back-to-back in neighboring cells. In an epidermal cell, actin filaments are enriched within outward bulges whereas microtubules form preferentially within inward bulging regions; because an outward bulge of one cell is an inward bulge of its neighbor, microtubules and actin filaments have alternating deployments in neighboring cells. Within a cell, the mechanisms driving this complementary deployment are being actively investigated and apparently involve feedback in which actin filaments bind proteins that destabilize microtubules, and vice versa.

The complementary deployment of these systems contributes to cell shaping although this is clearer for mesophyll than for epidermis. In mesophyll, cells separate between expanding lobes, a separation that creates the airspaces essential to

FIGURE 5.31 The cytoskeleton is involved in producing complex cell shapes, as exemplified by spongy mesophyll and epidermal pavement cells. In mesophyll (left), microtubule bands (blue) girdle the cell while actin patches (red) form between microtubule bands; importantly, microtubule bands form opposite each other in neighboring cells, as do the actin patches. The microtubule bands cause congruent wall reinforcement (green) whereas the actin patches promote expansion, giving rise to lobes and cavities, and hence to the characteristic sponginess of mesophyll. However, in epidermis (right), actin patches and microtubule bands alternate between neighbors. This organization partitions the periclinal cell wall into regions of high and low expansion rate, and the lobes reflect this underlying variation.

photosynthesis. The microtubule bands cause the underlying cell wall to thicken, thereby restricting expansion, while the actin filaments, perhaps by promoting secretion, locally enhance expansion; in concert, this pushes cells apart by growth at the lobes with air spaces forming where the cells are restricted (Fig. 5.31). In contrast, epidermal cells remain fully contiguous. Therefore, a lobe reflects an overlying area of rapid expansion rate (over an actin-rich region) adjacent to a region of slow expansion rate (over a microtubule-rich region). In these cells with elaborate shapes, as well as others such as trichomes and guard cells, antagonistic roles of microtubule and actin systems are being discovered and elucidated.

5.7.3 The cortical array is organized by a mechanism that separates nucleation and orientation

The mechanism that organizes the cortical array is an outstanding problem in plant cell biology. Virtually all known microtubule arrays, whether plant, animal, or fungal, are organized with respect to a prominent structure, such as the centrosome or the basal body, that houses the γ -tubulin complexes responsible for nucleating microtubules (see Section 5.3). By controlling where microtubules can form, these organizing structures determine the position of microtubules as well as their polarity (the minus end is at the nucleating site). The plant cortical array forms diffusely, with neither prominent organizing structures nor defined patterns of microtubule polarity. The cortical array contains γ -tubulin complexes, scattered throughout the array and supporting microtubule nucleation (Fig. 5.32). The nucleated microtubules often form at an acute angle to the original microtubule, giving rise to diverging microtubules, which are organized subsequently into the parallel alignment desired by the cell. Evidently, for the cortical array, the processes of nucleation and organization are distinct.

The problem of organizing the microtubules can be usefully broken down into three steps: (a) a signal must specify a direction, (b) that signal must be perceived by some cellular components and transmitted to the microtubules, and (c) the microtubules themselves must line up accordingly. The signal providing a polarity cue (step a) could be mechanical, electrical, or chemical. The transduction mechanism (i.e., perception, step b) is widely thought to involve a transmembrane protein or protein complex, in which the extracellular domain “senses” the signal, and the cytosolic domain constrains microtubule behavior. Behavior (i.e., the response, step c) can include specific interactions between microtubules, moving microtubules into correct alignment with a motor protein or treadmilling, and selectively stabilizing those microtubules that happen by chance to form at the correct angle. Cortical microtubule behavior is known to be affected

B

C

D

FIGURE 5.32 The formation of the cortical array can be studied *in vitro*. Microtubules form *de novo* when fragments of the plasma membrane are incubated in a cell extract. The extract contains $\alpha\beta$ -tubulin as well as γ -tubulin nucleating complexes, but new microtubules form only when the membrane fragment retains cortical microtubules. (A) Transmission electron micrograph showing microtubules nucleated along the side of an existing microtubule (circles). Bar = 200 nm. (B–D) Fluorescent micrographs showing microtubules (B) and γ -tubulin (C), and overlay (D). The γ -tubulin binds all along microtubules and is present at branch points (arrows in the merged image). Bar = 5 μm . It is believed that, in cells, continuous turnover of cortical microtubules is supported by γ -tubulin complexes binding to an existing microtubule, nucleating a microtubule, detaching after a while from that microtubule, and then binding another microtubule to repeat the process. Source: Murata et al. (2005). *Nature Cell Biol* 7:961–968.

by interactions between microtubules, as well as by signal transduction elements, such as protein phosphorylation (Fig. 5.33; see Chapter 18). However, we are far from understanding the means whereby the plant lines up its cortical microtubules in a particular direction.

5.8 The cytoskeleton and signal transduction

Only connect. This motto was coined as advice for humanity; it also applies to cellularity. The cytoskeleton—large, pervasive, and filamentous—connects the cell. This connectivity means that the cytoskeleton is more than a substrate for motility; additionally, the cytoskeleton forms a compartment, providing a restricted space, and the cytoskeleton responds to mechanical forces. These related features of cytoskeletal function are subsumed here under the heading of *signal transduction* and described below. Ultimately, the machinery of signal transduction, such as G-proteins and kinases (see Chapter 18), is modulated, but specific pathways will not be elaborated here.

5.8.1 The cytoskeleton acts as a metastable compartment

Among the types of proteins discovered to bind the cytoskeleton, a large class are enzymes. Some of these are involved in metabolism, some are involved in protein translation, and many are regulatory. We do not fully understand the reasons for such associations, or even if they are functional rather than accidental, but there is a case for functionality. Several glycolytic enzymes localize to microtubules, apparently taking advantage of **metabolic channeling**, a term that describes the product of one enzyme being channeled to the next enzyme, for which it is a reactant (Fig. 5.34). Channeling occurs because propinquity limits diffusion to an effective surface as opposed to a volume, and diffusion in two dimensions is faster than in three.

In view of channeling, the cytoskeleton and its bound proteins can be thought of as a cellular compartment, albeit less restricted than the inside of a vesicle. However, as the cell responds to a change in its environment, the cytoskeleton often disassembles within minutes, freeing the contents of the cytoskeletal compartment to acquire new associations. Reassembly happens soon thereafter, often bringing about new

FIGURE 5.33 Protein phosphorylation plays a role in microtubule organization. (A) Cortical microtubule arrays in a growing region of the *A. thaliana* root have transverse orientation. (B) Cortical arrays in a similar region of a root treated with staurosporine, an inhibitor of protein kinases, are organized aberrantly within each cell. Inset is at higher magnification. (C) Cortical microtubules in the growing hypocotyl with transverse orientation. In the *A. thaliana* tonneau2 (*ton2*) mutant (D), the arrays become disorganized on a tissue level, with different orientations in different cells. The *TON2* gene encodes a protein phosphatase. Bars in C and D = 50 μm . Source: (A, B) Baskin & Wilson (1997). *Plant Physiol.* 113: 493–502. (C, D) Camilleri et al. (2002). *Plant Cell* 14:833–845.

orientations or structures. Insofar as much of the cytoskeleton is within the cortical cytoplasm, these widespread changes affect plasma-membrane components disproportionately. Responses to aluminum, salt, cold, and water deficit, among others, have been shown to include transient depolymerization of cytoskeletal elements and concomitant changes in signaling, such as elevated levels of cytosolic calcium or increased activities of regulatory enzymes. As an example, the opening and closing of stomata requires complex changes to both actin and microtubules, and actin filaments have been implicated in the gating of the potassium channels that potentiate guard cell movements. Just as the opening of an ion channel can change a cell's membrane potential by tens of millivolts, thereby changing the status of the plasma membrane throughout the cell in

FIGURE 5.34 Metabolic channeling might occur when the enzymes for a sequence of reactions bind to a microtubule. This makes it easier for the product of the first reaction to diffuse to the active site for the second reaction. The same principle occurs in multi-subunit complexes, such as pyruvate decarboxylase (see Chapter 22), in which several individual enzymes aggregate into a superstructure, again enhancing diffusional coupling between successive active sites.

seconds, so too depolymerizing actin filaments or microtubules affects the cytoplasm throughout the cell. We are only beginning to understand the role of the cytoskeleton as a labile repository of information.

5.8.2 The cytoskeleton is connected to the cell wall

Unable to see, hear, or smell, plants rely widely on sensing mechanical forces. When the wind blows or the caterpillar chews, the plant vibrates; as rain and drought change water status, turgor pressure and cell wall stress respond in step; when the plant grows, the cell wall deforms. To sense these changes, the plant cell might relay the mechanical status of the wall to the cytoskeleton, a relay requiring connection points. In principle, attachment to the cell wall would amplify the range of mechanical perturbations that the cell could sense (Fig. 5.35).

Certainly, the cytoskeleton is anchored to the cell wall. This has been inferred from static images where cross-bridges extend from the cytoskeleton into the membrane (Fig. 5.36) and also from experiments. When intact cells are lysed, turgor pressure completely expels the contents of the cell, except for a skein of cortical microtubules and subtending patches of plasma membrane affixed to the wall. Similarly, when protoplasts settle on a slide and are lysed, the slide retains fragments of plasma membrane (“ghosts”) with cortical microtubules; however, when protoplasts are treated briefly with a protease prior to lysis, microtubules are lost, presumably because the protease degrades a transmembrane attachment protein that binds both slide and microtubules.

The plasma membrane is also attached to the cell wall. This has been demonstrated by placing cells in a solution that is sufficiently hypertonic to cause the cell to shrink to a volume smaller than the space enclosed by the cell wall, a process called **plasmolysis**. In plasmolyzed cells, the protoplast seldom becomes spherical but remains stuck to the wall in

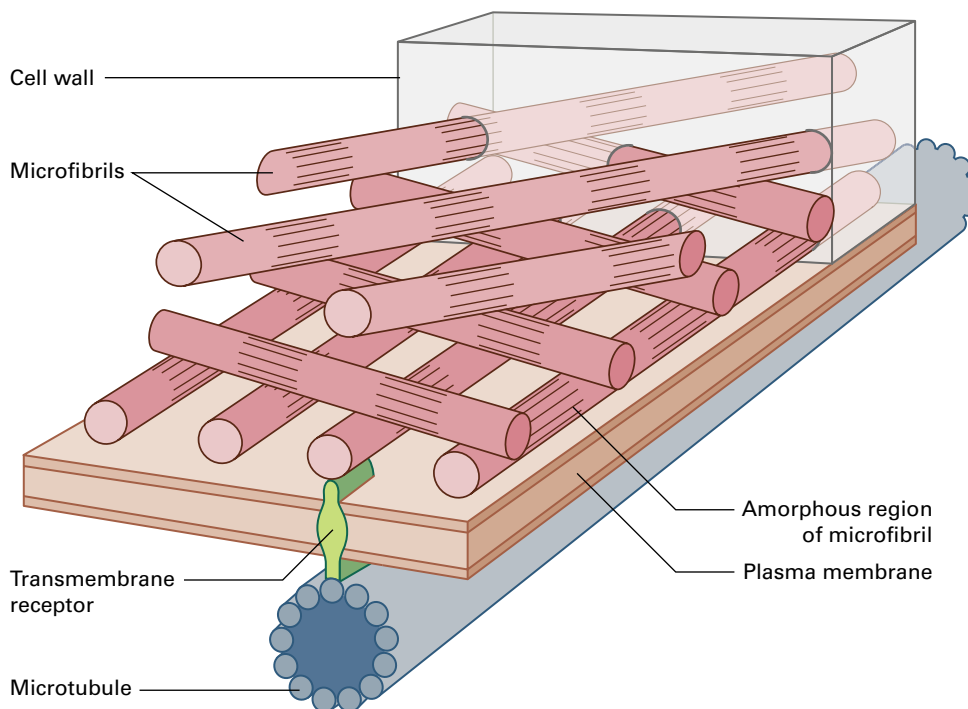

FIGURE 5.35 Schematic view of how mechanical information may be sensed at the plasma membrane. This cutaway view of the cell wall illustrates a putative relationship between cellulose microfibrils, receptors in the membrane, and cortical microtubules. Amorphous regions on the microfibrils (or on other wall polymers) are deformed by the substantial tensions generated by turgor pressure. Receptors that span the plasma membrane have two binding sites: At their extracellular domain they bind the deformed regions of the microfibrils, and at their cytosolic domain they bind microtubules (or other cytoskeletal polymers). Changes in the mechanical loading will change the extent of deformation of the microfibril, which in turn could increase or decrease its binding affinity to the receptor. As with conventional receptors (e.g., for hormones), occupancy of the receptor's extracellular binding site determines the activity of its cytosolic site. The cytosolic site could have kinase activity and participate in signal transduction directly, or it could affect the behavior of cytoskeletal polymers. We can even imagine this relationship working in reverse, where the extracellular binding site influences reactions in the cell wall based on the status of the microtubules.

FIGURE 5.36 Field-emission scanning electron micrograph of the cortex of a tobacco hypocotyl cell. The cell has been lysed, ejecting the cytoplasm but leaving behind the plasma membrane (note the geometrical lattice of a forming clathrin-coated vesicle (white arrowhead; see Chapters 1 and 4) and microtubules, apparently cross-bridged to the membrane (e.g., black arrow). Scale divisions = 50 nm. Source: T. Baskin, University of Massachusetts, Amherst.

many regions. Often, the wall and protoplast are linked by a large number of thin, membranous strands, called Hechtian strands, after the botanist who described them in the 1910s (see Fig. 1.13). We don't know whether the attachment sites revealed through concave plasmolysis and Hechtian strand formation are the same as those that anchor the cytoskeleton to the cell wall, but they are likely to represent at least an overlapping set.

5.8.3 Probing the functionality of attachment sites leaves open the involvement of the cytoskeleton

What is the function, if any, of the attachment between cytoskeleton and cell wall? The relevance of such specialized attachment sites is suggested by analogy to animal cells, in which transmembrane receptor proteins, called **integrins**, physically link the actin cytoskeleton to the extracellular matrix and mediate signal transduction based on the status of that linkage. Integrins

are a large and complex family of plasma-membrane receptors that form connections needed for cell adhesion and locomotion, as well as for the bidirectional flow of information between cytoplasm and extracellular matrix. Integrins bind a variety of proteins in the extracellular matrix that contain a tripeptide, RGD (in the one-letter amino acid code). Consequently, exposing cells to small peptides containing RGD breaks connections between integrin and extracellular matrix and allows their relevance to be assayed, often with striking results.

That plants contain integrins was initially suggested by antibodies against integrins recognizing plasma-membrane proteins, as well as by RGD peptides disrupting various processes, including embryogenesis, gravity sensing, acclimation to salt stress, pollen tube growth through the pistil, and pathogen resistance. However, plant genomes contain sequences recognizable by similarity as homologues neither to integrins nor to their extracellular matrix ligands, although an RGD-containing protein, secreted by a pathogen and used to promote infectivity through disrupting plant cell adhesion, has been argued to be a homolog of an integrin ligand based on structural similarity rather than sequence. Furthermore, a plant plasma-membrane protein that binds RGD has been identified as being a serine/threonine receptor kinase of the lectin class and hence not homologous to integrins.

While attachment sites between cell wall and membrane are clear in plants, and both actin and microtubules undoubtedly participate in the cell's response to mechanical perturbation, in the absence of recognizable integrins any linkage between those sites and the cytoskeleton is undefined. There have been only a few studies of the plant cytoskeleton as affected by RGD peptides, and these have produced contradictory results. In addition to providing physical connections, it is logical that these attachment sites constitute conduits through which information about the cell's surroundings flows between cell wall and cytoskeleton (see Fig. 5.35). A grand challenge for the future will be to detect this information flow and to decipher its meaning.

5.9 Mitosis and cytokinesis

Every cell on earth was formed by division. **Mitosis** describes the physical separation of replicated chromosomes into two new nuclei. **Cytokinesis** describes the physical division of one cell into two. Mitosis and cytokinesis are accomplished by elaborate molecular machines constructed from the cytoskeleton: the **mitotic spindle**, which separates chromosomes, and (in plants) the **phragmoplast**, which builds the new wall between daughter cells. Comparing plants and animals, cytoskeletal machines for mitosis are largely the same whereas those for cytokinesis are distinct (Fig. 5.37). In both kingdoms, mitosis and cytokinesis represent the capstone function of the cytoskeleton. To grasp how these machines work, we need to know how the cytoskeletal structures are assembled and how forces are exerted to move chromosomes or to separate newly formed cells.

Mitosis and cytokinesis occur during a short phase of the cell cycle, called the M phase (see Chapter 11) and generally the processes are linked, with the spindle giving rise to the phragmoplast. However, the linkage is facultative; mitosis can occur without cytokinesis, forming multi-nucleated cells, and cytokinesis can happen long after the mitotic spindle has disassembled. In animal cells, the cytoskeletal involvement in cytokinesis begins in metaphase, whereas in plants, cytokinesis begins in prophase (part of M phase) or even earlier. Perhaps because cell walls are immobile and all but permanent, the plant cell takes pains to build them in the right place.

5.9.1 The preprophase band defines a cortical division site, which defines the placement of the new cell wall

The major cytoskeletal structure involved in orienting the cell wall built between dividing cells is the **preprophase band**, a ring of actin filaments and microtubules that encircles the cell just inside the plasma membrane (Fig. 5.38; see Fig. 5.45). Despite its name, the band is mature and functional in prophase, although it sometimes initiates earlier. The preprophase band forms at the site where the cell plate will eventually join the parent wall. Initially, the band is wide and rather loosely organized; as prophase continues, the band narrows and nearly all of the actin filaments and microtubules become closely parallel. Around the time of nuclear envelope breakdown, the polymers of the preprophase band depolymerize. This removes all microtubules from the cortical cytoplasm, whereas actin filaments remain in the rest of the cortex and are depleted, but not eliminated from the location previously occupied by the preprophase band (Fig. 5.39). The complete depolymerization of preprophase band actin and microtubules is surprising because it is only as telophase ends, long after the preprophase band polymers have vanished, that its former location is zeroed-in on by the edges of the enlarging phragmoplast, thus ensuring that the forming cell plate fuses with the parental wall at the right place.

We now believe that the preprophase band somehow modifies the underlying membrane or cell wall (or both) to establish the **cortical division site**, which is recognized subsequently by the edges of the phragmoplast. The preprophase band (or cortical division site) also plays a role in orienting the mitotic spindle; however, the phragmoplast edges can find the cortical division site even when the spindle has been considerably displaced, for example, by centrifugation, implying that orienting the spindle is a function for the band distinct from defining the placement of the new cell wall. In addition to guidance, the cortical division site might also promote a seamless integration of daughter and parental walls (Fig. 5.40).

How the preprophase band establishes the division site is obscure, as is how that site carries out its functions; however, there are some clues. A microtubule-associated protein, TANGLED, colocalizes with preprophase band microtubules but then remains at the division site thereafter (Fig. 5.41).

(C) Prophase, (D) metaphase, and (E) anaphase of the same cell. (F) Telophase of another cell. Actin filaments are depleted from the cortical division site (arrowheads) but remain elsewhere in the cortex. (A–E) A focal plane at the cell cortex; (F) a mid-plane. Source: (A–F) Cleary et al. (1992). *J Cell Sci* 103:977–988.

We do not know its biochemical function but loss of tangled activity gives rise to plants in which cell divisions are somewhat misoriented, suggesting that TANGLED participates in cortical site function.

A cortical division site forms in cells that divide with specific orientation but is generally absent from cell types

where the division plane is inconsequential, cell types such as free endosperm, callus, and male and female gametophytes. Despite being nonessential for division per se, the preprophase band continues to tantalize researchers with its accurate forecast of cell plate placement and subsequent disappearing act.

FIGURE 5.40 Time-lapse light micrographs at 1-minute intervals during cell plate formation in a living stamen hair cell. The cell plate undulates as it forms; a short time after the plate reaches the parent wall (77 to 81 minutes), the undulations vanish abruptly. The cortical division site may condition the wall for subsequent events involving cell plate fusion. Scale division = 10 μm .

FIGURE 5.42 Formation of the phragmosome. When highly vacuolated cells divide, such as the parenchyma cell sketched here, first the nucleus migrates to the center of the cell and the cytoplasm coalesces in the plane of the future cell wall. This sheet-like accretion of cytoplasm is called the phragmosome (orange), which might provide a conduit for the growing cell plate. Construction of the cell plate (dark red) begins at the cell center and must move outward through the vacuole to reach the parent cell wall. Top row shows the cell from the top and bottom row from the side.

5.9.2 Division in large, vacuolated plant cells places unusual demands on the cytoskeleton

Usually, division is the business of shoot and root meristems (see Chapter 11), which contain densely cytoplasmic cells, little wider than the spindle itself; however cells of the secondary meristem, the cambium, are far larger. Furthermore, fully differentiated cells in plants are readily induced to divide, for example, by wounding or hormonal treatment, and such cells often reach dimensions of hundreds or even thousands of micrometers. Building a cell plate across a full grown cell is a Herculean task for the phragmoplast, taking for example an entire day to partition a 2-mm vascular cambium cell, longer than the entire cell cycle of a typical meristem cell.

Cytoskeletal involvement in the division of large, vacuolated cells begins well before prophase. Probably during S phase, the nucleus migrates to a central position in the cell, a migration that depends on both actin and microtubules. In certain cells, the cortical division site is marked by a thick ring of cytoplasm rich in actin filaments and depending on them for formation. However, the most conspicuous structure that forms in dividing vacuolated cells is the **phragmosome**.

The phragmosome (not to be confused with the phragmoplast) is a thin, reticulated layer of cytoplasm that forms in the plane of the future cell wall. The phragmosome contains both actin and microtubules and can be nearly a continuous sheet or a just a few strands. The phragmosome forms as the nucleus attains its central position, perhaps by means of the coalescence of the cytoplasmic, cytoskeleton-rich strands that support its migration (Fig. 5.42). Subsequently, at the periphery of the phragmosome, the preprophase band forms. Experiments show that once a phragmosome is present, reprogramming the plane of division becomes difficult. Specific functions for the phragmosome are not clear.

It appears to anchor the nucleus at its central position and to help program the division site. In addition, a popular idea is that cytoskeletal elements within the phragmosome help the phragmoplast forge a coherent path through large vacuolar spaces.

5.9.3 The mitotic spindle comprises balanced forces and rapid microtubule turnover

The structure and general properties of the mitotic spindle are well conserved among eukaryotes. The spindle consists of hundreds to thousands of microtubules as well as their associated proteins. Other components are actin filaments and membrane-bound organelles derived from the ER. The mitotic spindle has two poles, which define not only the sites where the separated chromosomes will finally arrive but also the spindle's bipolar organization. Microtubules radiate away from each pole with their minus ends toward the nearest pole and their plus ends away (Fig. 5.43). Some microtubules run from the pole to specialized sites of attachment on the chromosomes, called kinetochores (see Section 5.9.6), whereas others extend from the pole for various lengths. Some of the latter meet and interact at the spindle equator with microtubules emanating from the opposite pole, forming a zone of overlap that stabilizes the spindle structure (see Box Fig. 5.3A).

The structure of the spindle is maintained by opposing forces. In general terms, forces at the midzone pushing outward are balanced by forces at the poles pushing in. Despite these forces, microtubules in the spindle are highly dynamic, with half-lives on the order of 1 minute. Kinetochores are longer lived but still turn over many times during mitosis. Many microtubules also undergo treadmilling (see Section 5.3.3), in which microtubule subunits are added at the kinetochore and

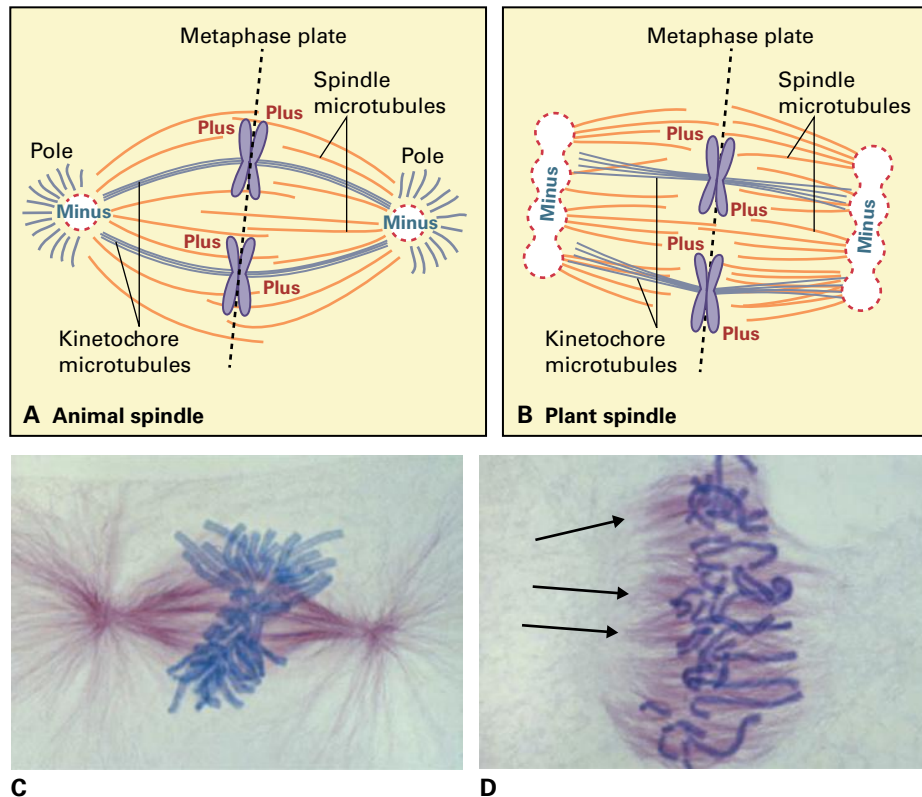

FIGURE 5.43 Comparison of the mitotic spindle in cells of animals and plants. (A, B) Schematic. Both spindles are at metaphase. The plane occupied by the chromosomes (the equator, or metaphase plate) is a plane of symmetry for the spindle. Each half-spindle contains a pole, kinetochore microtubules (prominent bundles of microtubules that run from the kinetochore up to or near the pole), and many spindle microtubules, some of which enter the area occupied by the other half-spindle but never penetrate as far as the opposite pole. The minus ends of most microtubules are near the poles, whereas the plus ends grow away from the poles. In animal cells, the poles are tightly focused at the centrosome, whereas in plant cells, the poles are a group of subsidiary foci. (C–D) Bright-field micrographs of metaphase spindles from (C) a newt (*Taricha granulosa*) lung epithelial cell and (D) endosperm of the plant, *Haemanthus katherinii*. DNA is blue and microtubules are reddish brown. The newt spindle has focused poles and prominent kinetochore bundles typical of animal spindles whereas the endosperm spindle is barrel-shaped. However, although lacking an overall polar organizing center, numerous subsidiary foci of microtubules are present (arrows). Source: (C, D) Wadsworth & Khodjakov. (2004). *Trends Cell Biol* 14:413–419.

are lost at the pole. Treadmilling creates a coherent **flux** of tubulin dimers moving through the spindle, from kinetochore to pole. Underscoring the complexity of the spindle, microtubule turnover and flux are themselves able to generate forces and the motor proteins must be able to exert forces against microtubules even while the polymers assemble and disassemble.

5.9.4 A major difference between the spindles of animals and plants is assembly

Eukaryotes invented the spindle early in their evolution and for the most part mitosis in plant, fungal, and animal kingdoms is similar, but differences do occur. A fundamental difference between animal and plant mitotic spindles is in the manner of assembly. Animal cells have two known pathways for spindle assembly. The first discovered (and best understood) pathway involves **centrosomes** (Fig. 5.44). At interphase, the centrosome is adjacent to the nucleus and nucleates a radial array of microtubules; during S phase it replicates, and during prophase the replicated centrosomes separate to form two radial arrays

of microtubules (each often called an aster) that become the spindle poles (Fig. 5.44E). The second pathway involves chromatin. Here, spindles form in a process in which the condensed chromosomes nucleate randomly oriented microtubule bundles and the bipolar organization of the mature spindle subsequently emerges as the divergent microtubules coalesce, apparently bundled and focused by dynein along with other proteins. Although discovered in oocytes where centrosomes are absent, we now know that a chromatin-mediated spindle assembly pathway operates alongside of the centrosome pathway, presumably to ensure a well-built spindle.

In interphase plant cells, most microtubules are part of the cortical array but some radiate from the nuclear envelope, nucleated there by proteins that are related to constituents of the animal centrosome, including γ -tubulin. In prophase, cortical microtubules disappear, except for those in the preprophase band (see Section 5.9.1) and spindle assembly starts with myriad microtubules polymerizing on the nuclear envelope. Soon, these microtubules radiate from foci on opposite sides of the nucleus that define the future poles of the mitotic spindle. This structure is called the **prophase spindle** (see Fig. 5.26A, Fig. 5.45H).

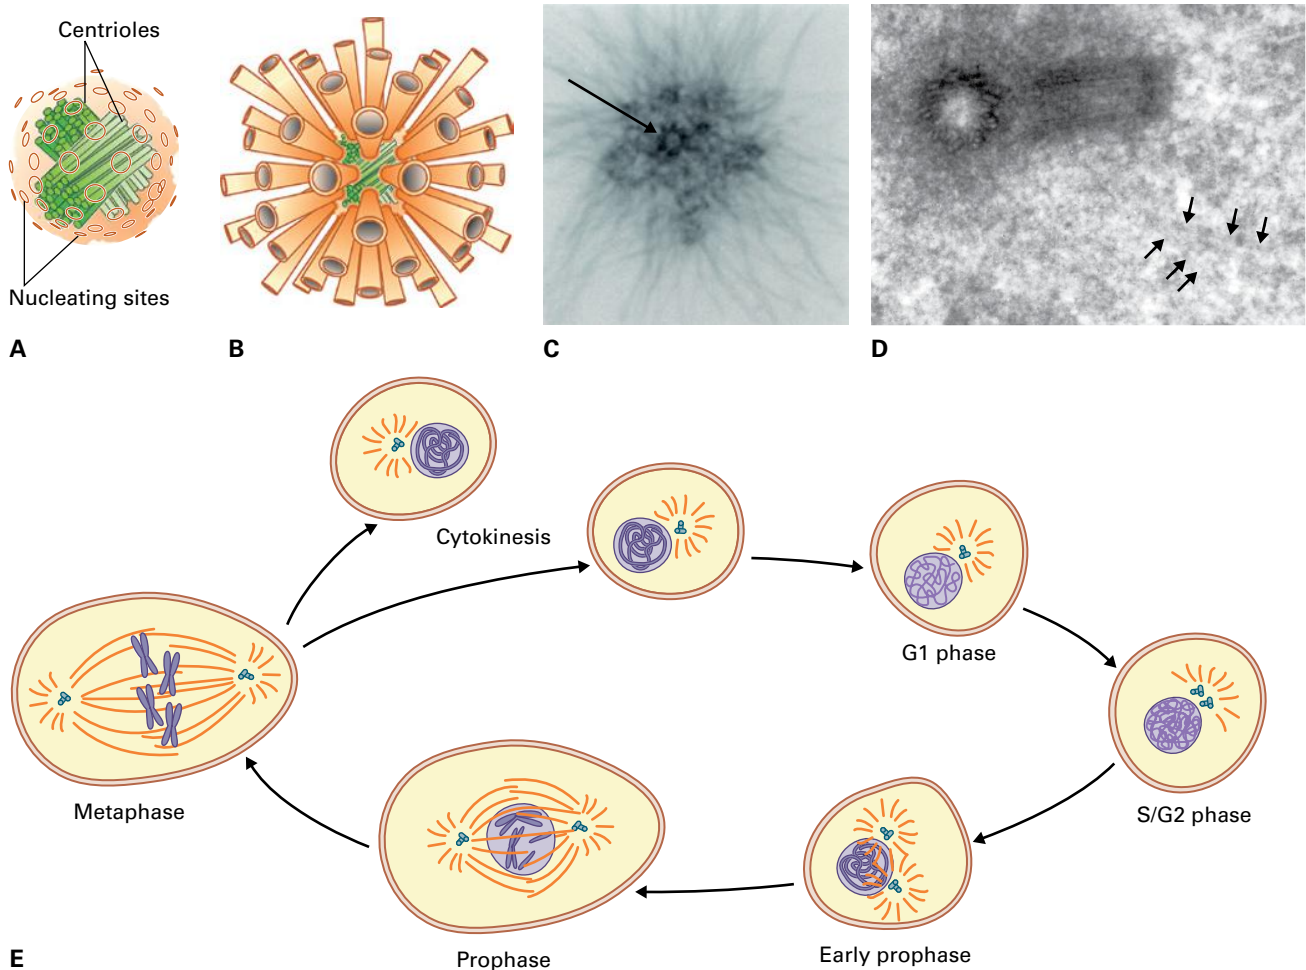

FIGURE 5.44 *The animal centrosome.* (A–B) Schematics. The centrosome comprises a pair of centrioles, oriented at right angles, surrounded by a protein-rich matrix of indeterminate structure, termed pericentriolar material. One component of this material is γ -tubulin, which along with other proteins forms ring-shaped templates that play a role in nucleating microtubules. (C) Electron micrograph of an isolated centrosome from *Drosophila melanogaster*. One of the centrioles is just visible as a dark ring near the center of the pericentriolar material (arrow). (D) Electron micrograph through a centrosome from a mouse embryo. A pair of dark centrioles is seen with (faint) radiating microtubules (arrows). (E) The centrosomal cycle of an animal cell. The pair of centrioles duplicates during S phase, but the two pairs remain closely associated in a single complex. In early prophase, the complex splits, forming two separate centrosomes, each nucleating a radial array of microtubules, called an aster. As prophase continues, the centrosomes separate further and define the two poles of the mitotic spindle, which forms between them. By the end of mitosis, when the chromosomes have reached the poles, each daughter nucleus reforms near the centrosome. After cytokinesis, each new cell inherits a single centrosome. Source: (C) Moritz et al. (1995). *J Cell Biol* 130:1149–1159. (D) H. Schatten, University of Missouri, Columbia.

Lacking centrosomes, plant cells cannot use the centrosome-mediated pathway. Moreover, the bipolar organization of the plant spindle is typically established before nuclear envelope breakdown, ruling out the involvement of chromatin. Evidently plants assemble their spindle by a pathway that is at least partially distinct from those of other eukaryotes.

Some evidence on how the plant spindle forms implicates the preprophase band. In plant suspension cultured cells, which divide haphazardly, some of them divide without making a preprophase band. When the band is present, spindle bipolarity emerges during prophase as usual, but interestingly when the band is absent, a bipolar spindle forms after nuclear envelope breakdown, perhaps by the chromatin-mediated pathway described above. That the preprophase band appears to participate in the pathway of spindle organization underscores the importance of the cortical division site. Because

the band bisects the position of the nucleus, usually by early in prophase, the band is sited ideally to enforce bipolarity on the myriad microtubules polymerizing along the surface of the nuclear envelope, perhaps by stimulating turnover of those microtubules in the middle of the nucleus (i.e., nearest to the band).

5.9.5 The structure of the plant and animal spindle pole is superficially different but fundamentally the same

For many years, a notable difference between plant and animal spindles was said to be the structure of the mitotic spindle pole. Animal spindle poles contain centrosomes and

FIGURE 5.45 Confocal fluorescence micrographs of fixed wheat (*Triticum aestivum*) root cells, showing the assembly of the mitotic spindle. Microtubules are green and yellow, DNA is blue. (A–D) The preprophase band develops from the coalescence of cortical microtubules before or during prophase. (E–H) The prophase spindle forms around the nuclear envelope. In late prophase (G, H), the preprophase band disassembles. (I–K) The mitotic spindle forms after breakdown of the nuclear envelope as the poles spread laterally and kinetochores capture bundles of spindle microtubules. Source: (A–K) Gunning & Steer. (1996). *Plant Cell Biology: Structure and Function*. Jones and Bartlett, Sudbury, MA.

are tightly focused, whereas in plant cells, the mitotic spindle pole lacks centrosomes and is usually broad (see Fig. 5.43). The tight focus of the animal mitotic spindle pole was formerly ascribed to centrosomes, but poles are focused in oocytes and in somatic cells when centrosomes are removed surgically; what is more, poles become unfocused, despite centrosomes, when specific motor proteins are inhibited. Furthermore, the plant spindle pole is well focused during prophase, and the broad poles found at other phases, in fact, contain subsidiary microtubule foci (“little poles”) linked by interdigitating microtubules. Because this resembles the canopy of a conifer forest, this organization is described as *fir-tree-like*. Although unfocused as a whole, each fir-tree top represents a focused structure. We now know that polar focusing, whether in broad or narrow spindles, is determined mainly by activity of minus-end directed motor proteins and cross-bridging proteins. In animals, a notable role is played in polar focusing by cytoplasmic dynein (see Section 5.4.2), a

role that in plant cells has presumably been usurped by a minus-end directed kinesin.

5.9.6 Chromosomal movements at mitosis are similar in plant and animal cells

At the end of prophase, the nuclear envelope breaks down, and spindle microtubules begin to interact with chromosomes. The main sites of interaction are **kinetochores**, which form on each sister chromatid at opposite sides of the paired centromeric region (Fig. 5.46). For correct attachment of chromosomes to the spindle, each kinetochore must bind microtubules from only one spindle pole, and sister kinetochores must bind microtubules from opposite poles; mechanisms to resolve inappropriate associations rely on balancing

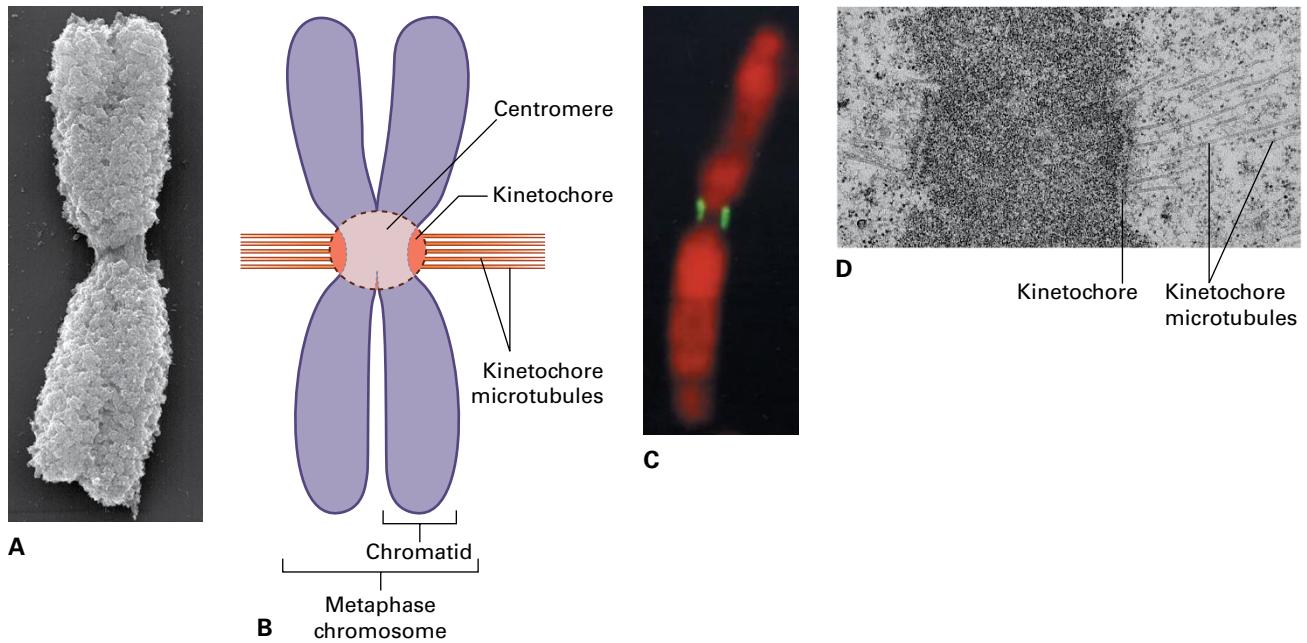

FIGURE 5.46 The kinetochore. (A) Classical studies of genetics and cytology identified a chromosomal region that lacked genes and recombined infrequently as the location where sister chromatids attach to each other. This region, termed the centromere, can often be discerned in light micrographs as a constriction of the chromosome and is clear in this scanning electron micrograph of a plant metaphase chromosome. (B) The centromeric region of the chromosome is now known to mediate attachment of the mitotic spindle to the microtubules by virtue of a protein-rich plaque that forms at each sister centromere, called the kinetochore. The kinetochore binds to the plus ends of microtubules. (C) The kinetochore is a flat, plate-like structure. A Barking deer (*Muntiacus muntjak*) chromosome in metaphase is shown double-labeled for DNA (red) and for several kinetochore proteins (green). Two distinct kinetochores are visible, one for each chromatid. (D) Electron micrograph through the centromeric region of a chromosome at metaphase, showing both kinetochores. Note the layered structure of the kinetochore and the microtubules terminating there. A kinetochore typically binds 30–50 microtubules but, depending on its size, might bind just one or more than 100.
 Source: (A) R. Martin, Gerhard Wanner, University of Munich, Germany. (C) Van Hooser & Brinkley. 1999. *Methods Cell Biol* 61:57–80. (D) K. McDonald, University of California, Berkeley.

the tension forces across the two sister kinetochores. These usually are resolved during the 10–30 minutes of prometaphase but even one persisting bad attachment will arrest the cell in metaphase.

Chromosomes move mainly in two phases of mitosis, prometaphase and anaphase (see Fig. 5.37). At prometaphase, the chromosomes congress, moving from the random positions they held when first captured by the mitotic spindle to gather at the spindle midzone, termed when the chromosomes arrive, the **metaphase plate**. At anaphase, the replicated sister chromatids, previously held together by the cohesin complex, uncouple synchronously and move apart. Chromosomes move toward the poles (**anaphase A**) and the poles themselves move apart (**anaphase B**). Anaphase A is powered by forces exerted cooperatively on the kinetochore fiber; forces are exerted at the kinetochore, at the poles, and even from within the spindle. Anaphase B is powered by pulling forces exerted on each spindle pole from outside the spindle or pushing forces exerted by microtubule motor proteins on microtubules of opposite polarity (i.e., emanating from opposite spindle poles) located in the zone of overlap in the middle of the spindle (Box 5.3). The force generating mechanisms overlap and current research efforts are directed toward understanding where the forces originate and how they are regulated.

5.9.7 Plants have evolved a unique structure, the phragmoplast, for cytokinesis

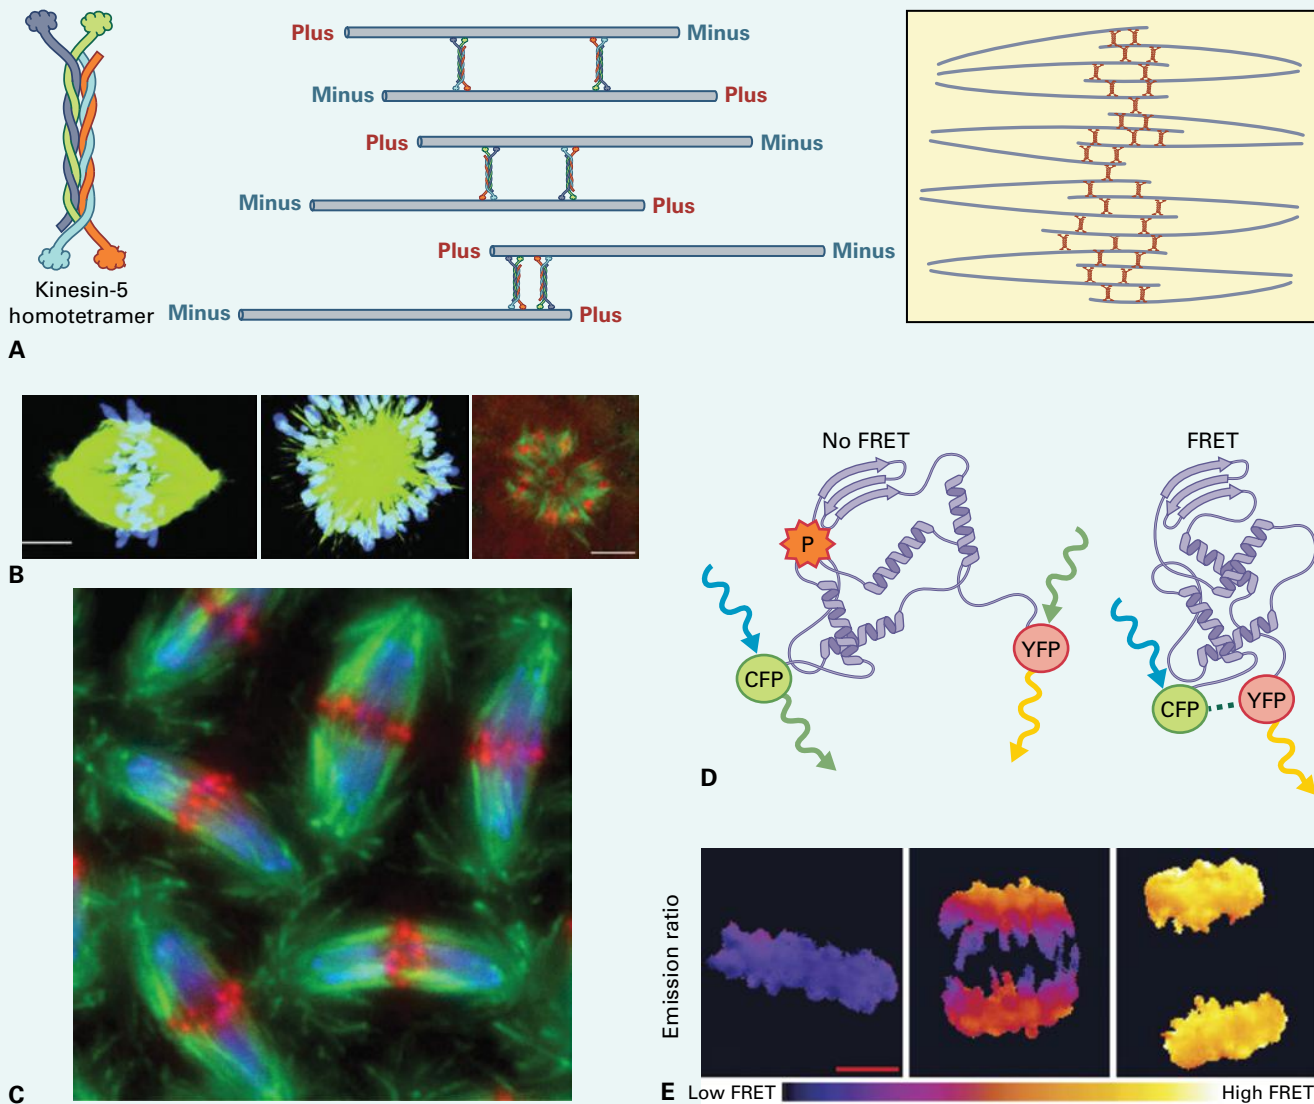

An animal cell physically pinches itself in two, whereas a plant cell erects a partition, in the form of a new cell wall. To divide, animal cells have evolved a cytokinetic organelle called the **contractile ring**, a band of actin filaments encircling the cell in the future plane of division, anchored to the plasma membrane (see Fig. 5.37). The contractile ring contains myosin, which pulls together adjacent, antiparallel actin filaments, shortening the circumference of the ring and squeezing the cell in two. We also know that some motile animal cells can divide by each half of the cell crawling in opposite directions, somewhat like the medieval punishment of being pulled apart by horses, but here too the cell periphery controls the process. In fungi and algae, construction of the new wall also typically begins at the edges and moves to the center, analogous to the animal contractile ring. In contrast, plants begin construction on the new wall within the cell (between the two daughter nuclei) and the process expands to reach the edges (see Fig. 5.37). The phragmoplast contains actin and myosin as well as microtubules, and both cytoskeletal systems contribute to function

Holding the middle ground: the power at the spindle midzone

Watching a cell divide, one is struck by symmetry. At prophase, the preprophase band encircles the nucleus neatly around its equator. At metaphase, chromosomes come to rest in the middle of the spindle, precisely. After that, the cytokinetic apparatus bisects the spindle, exactly along the mid-plane. How is this symmetry established? The preprophase band helps orient the prophase spindle, the mitotic spindle in animal cells helps orient the contractile ring, and yet these structures are separated

spatially by many micrometers. How does information from one structure propagate through the cell to another?

We are far from answering such questions but an important clue has been provided by special behavior of the zone of microtubule overlap in the spindle mid-plane. In both plants and animals, the zone of overlap is stabilized in part by kinesin-5 motor proteins. This type of kinesin forms a tetramer, organized so that each pair of heads binds a microtubule of opposite polarity, as

(A) Schematics of kinesin-5 arrangements. (B) Inhibiting kinesin-5 causes mono-polar spindles, exemplified by a vertebrate cell exposed to a chemical inhibitor of kinesin-5 (left, center: tubulin = green; DNA = blue) and by a plant cell mutant for KIN5c (right: tubulin = green; DNA red). (C) Passenger proteins (red) are dropped off at the spindle midzone during metaphase where they remain through cytokinesis. This image shows spindles in a *Drosophila* embryo (tubulin = green; chromosomes = blue). (D) The FRET sensor consists of an Aurora-B phosphorylation site placed between two domains incorporating fluorescent protein tags. When phosphorylated, the fluorescent proteins are held apart; when dephosphorylated, the fluorescent proteins come within FRET range, detectable as YFP emission given CFP excitation. (E) The FRET sensor targeted to chromosomes reveals phosphorylation is high (low FRET) when the chromosomes are at the midzone (left) and low when they are at the poles (right), with a gradient of phosphorylation in between (middle). Depositing an active kinase at the spindle midzone communicates this position to the surrounding cytoplasm. Bars = 5 μm .

present in the spindle midzone (A). When kinesin-5 function is inhibited, either chemically or genetically, the midzone fails and a mono-polar spindle results (B). In humans, a chemical inhibitor, monastrol, specific to this motor, is in clinical trials as a cancer therapeutic agent because of its specificity for dividing cells.

The spindle midzone is important not only for holding the halves of the spindle together but also because it defines the mid-plane of the mitotic apparatus. Kinesin-5 is a plus-end-directed motor. When the tetramer binds a pair of microtubules of opposite polarity, by walking to the plus ends of each, but not falling off, it produces a pair of microtubules of opposite polarity linked by a small region of overlap at their plus ends. The overlapping microtubules or the motor protein itself can serve as a binding site for other proteins, which thereby accumulate at the middle of the spindle. Certain proteins that accumulate there are called passenger proteins: during interphase and prophase, they bind chromatin, but when chromosomes reach the metaphase plate, these passengers disembark at the spindle midzone, where they remain for the remainder of mitosis and cytokinesis (C). One of these passengers is a kinase, aurora B. Is it just taking a ride?

Aurora B is active. This kinase actually signals the position of the spindle mid-plane, according to an ingenious piece of biosensor engineering. The engineered sensor combines two fluorescent proteins (YFP and CFP) separated by a flexible linker and a short sequence that is phosphorylated by aurora B specifically (D). The sensor operates based on the principle of fluorescence resonance energy transfer (FRET): when two fluorophores are side by side, energy can resonate from one to the other so that energy exciting one can be emitted by the other. In this case, exciting CFP when YFP is close enough for resonance yields emission characteristic of

YFP. The ratio of emission from CFP and YFP quantifies the efficiency of energy transfer. This efficiency decreases with the sixth power of distance: even relatively small increases in distance lead to an essentially complete loss of energy transfer. With the phosphorylation site interposed between the fluorophores, the energy transfer efficiency becomes a function of phosphorylation by aurora B. The final step was to add a sequence to target the sensor to a specific cellular component; for instance, a histone sequence incorporates the sensor into chromatin. Following transformation of a vertebrate cell line with a construct encoding the sensor, phosphorylation due to aurora-B kinase can be observed in living cells on a specific cellular component.

The sensor reveals a striking phosphorylation gradient, centered at the midzone (E). The gradient is driven by aurora-B and in this instance functions to site the contractile ring in relation to the spindle. It is irresistible to extrapolate this mechanism to other processes related to the midzone. The ability of the preprophase band to modify behavior of microtubules at the nuclear equator, the force exerted on metaphase chromosomes being strongest in the spindle midzone, the ability of the phragmoplast to recruit new sets of overlapping microtubules at its periphery in precise alignment, all follow plausibly from the output of a localized kinase. The challenge now is to find those signals, elucidate their formation, and put together a complete picture of the forces and fluxes that divide the chromosomes and cleave the cell.

although microtubules play the lead. The phragmoplast and the contractile ring are structurally so dissimilar it is difficult to visualize a common ancestor.

5.9.8 The phragmoplast initially forms between the separating chromosomes at late anaphase and then expands centrifugally to reach the parental cell wall

As the phragmoplast begins to form, residual microtubules in the spindle midzone are joined by abundant, newly polymerized microtubules emanating from the poles and reforming nuclei (Fig. 5.47). Initially, the phragmoplast mid-plane is defined by a narrow band, where microtubules emanating from each nucleus overlap. Soon thereafter,

the band narrows until microtubules no longer overlap. Ultimately, a gap forms between microtubules as the new cell plate coalesces. Actin filaments also assemble into the phragmoplast, following the microtubules and generally parallel to them (Fig. 5.48). Both actin and microtubules have their plus ends at the phragmoplast mid-plane, meaning that nucleation occurs at or near the nuclei and new polymers grow toward the mid-plane.

The phragmoplast forms in the center of the cell between reforming nuclei. It then grows centrifugally toward the cell edges. As it grows, new microtubules are recruited to the periphery and lost from the interior, so that soon the phragmoplast attains a ring-like structure (Fig. 5.49). Initially, microtubules are long, reaching most of the way from nucleus to midzone but as the phragmoplast matures, microtubules become progressively shorter, losing any connection to the nuclear envelope. A progressive shortening also happens to

FIGURE 5.47 Microtubule organization in the phragmoplast, as shown by fluorescence micrographs of phragmoplast microtubules from different plant cell types. (A–D) Fixed wheat root cells, with microtubules in green or yellow and DNA in blue. (E–H) Living *T. virginiana* stamen hair cells microinjected with labeled neural tubulin. (I–L) Living tobacco BY-2 cells with the GFP-tubulin signal shown in red. (M, N) Fixed endosperm cells of *H. katherinii*. The phragmoplast begins to form at late anaphase (A, E, I, M), as interzonal microtubules of the spindle are joined by newly polymerized microtubules at the equator. By telophase (B, F, J), the organization of the phragmoplast is well established: The plane of the forming cell wall is defined by a line where microtubules meet. Soon a gap between microtubules appears as the cell plate is deposited. As telophase progresses, phragmoplast microtubules tend to shorten, and disappear from the central region, forming an annulus of overlapping microtubules that expands centrifugally, eventually reaching the parental wall (C, D; G, H; K, L; N).

Murata, National Institute for Basic Biology, Okazaki, Japan. (M–N) Smirnova et al. (1995). *Cell Motil Cytoskel* 31:34–44.

actin filaments, but they are generally retained in the center (see Fig. 5.48). Microtubules and actin in the phragmoplast are highly dynamic, with half-lives for microtubules recorded to be on the order of 1 minute. The dynamic state of these polymers presumably facilitates phragmoplast growth, although the mechanism behind the ordered expansion is not known.

One of the first plant microtubule motor proteins to be characterized biochemically, a member of the kinesin-5 family and a relative of the motor protein that holds the spindle midzone together (see Box 5.3), was purified from isolated phragmoplasts (Fig. 5.50). This protein might be responsible for microtubule translocation observed *in vitro* in the phragmoplast or for stabilizing the bipolar arrangement of microtubules in the phragmoplast, plausible functions for a

kinesin-5 motor. Many other kinesins have been implicated in phragmoplast structure and function, largely on the basis of mutant phenotypes. However, we do not understand what orchestrates the activities of all of these motors into a harmonious performance.

5.9.9 The phragmoplast coordinates the deposition of polysaccharide for the new wall

Both microtubules and actin filaments within the phragmoplast coordinate the intense secretory activity needed to build the cell plate. The phragmoplast harbors swarms of

FIGURE 5.48 Confocal fluorescence micrographs of actin filaments, labeled with fluorescent phalloidin, in the phragmoplast of living stamen hair cells. Actin filaments do not form as obvious an annular structure but instead tend to remain present throughout the forming cell plate. The persistent dark band at the equator indicates that actin filaments never overlap significantly across the equator.

vesicles and membranous organelles (Fig. 5.51). Vesicles deliver proteins and polysaccharides to the nascent cell wall and deliver plasma membrane to the growing cell plate. Additionally, vesicles return from the cell plate to the Golgi apparatus, removing excess membrane and recycling cell

wall components. While some vesicles might move diffusively, most of this motility is powered by motor proteins bound to the vesicle membrane. Actin might also be directly involved in membrane fusion machinery, as is known for yeast, but this remains to be defined for plants.

FIGURE 5.50 The phragmoplast contains the first microtubule motor protein to be purified and characterized from plants, tobacco kinesin-related protein of 125 kDa (TKRP125), a member of the kinesin-5 family. (A) TKRP125 purified from the tobacco phragmoplast moves microtubules toward their minus ends. The purified protein was used to coat one surface of a microscopic observation chamber and was allowed to bind fluorescently labeled microtubules, prepared with a small region of heightened fluorescence marking their minus ends (arrowheads). ATP was added to the chamber and images captured at successive intervals (time is given in seconds; the arrow marks a fixed reference location). The microtubules move minus-end first, which is equivalent to a protein moving cargo toward the plus end of an anchored microtubule. (B) The motor protein is abundant in the spindle midzone. Here, an anaphase mitotic spindle from a tobacco cell has been triple-labeled to show DNA (blue), microtubules (green), and TKRP125 (red). The orange color in the spindle midzone, where the phragmoplast is forming, results from co-localization of microtubules and TKRP125. In this location, the motor is poised to help cement the microtubule overlap in the phragmoplast mid-plane. Source: (A) Asada & Shibaoka. (1994). *J Cell Sci* 107:2249–2257. (B) T. Asada, Osaka University, Japan.

FIGURE 5.51 The phragmoplast teems with vesicles for cell plate construction. (A) Fluorescence micrograph of a vacuolated suspension-cultured tobacco cell at telophase, stained with a membrane marker, indicating the abundant membranous material throughout the phragmoplast and the forming cell plate. The right-hand panel is an enlargement of the forming cell plate. (B) Electron micrograph prepared by high-pressure cryofixation of an early stage phragmoplast (section is parallel to and at the mid-plane) showing the abundance of vesicles and membranes. Microtubules can be seen in cross-section (arrowheads), as can the unusual, tubular, membrane extensions (arrows), believed to be associated with endocytosis. Source: (A) Gunning & Steer. (1996). *Plant Cell Biology: Structure and Function*. Jones and Bartlett, Sudbury, MA. (B) Samuels et al. (1995). *J Cell Biol* 130:1345–1357.

Membrane structures within the phragmoplast have been comprehensively imaged through electron tomography on material prepared by high-pressure cryofixation and the following model has been proposed (Fig. 5.52). In the initial stage of cell plate formation, an aggregation of vesicles with tubular extensions coalesce to form the **tubulovesicular network**. These tubules are long, thin, and curved and are surrounded by a protein-rich “fuzzy” matrix. This membranous network occurs at the phragmoplast midzone, where microtubules are abundant: first in the center of the cell where the phragmoplast forms, and then moving out to the periphery. After this stage, the continued delivery of vesicles and synthesis of polysaccharides widens the tubules to form an interwoven membranous layer, the **tubular network**. At this point, microtubules and the fuzzy matrix are lost. The network gradually loses reticulation, passing through a stage called the fenestrated sheet, and eventually becomes continuous. Each of these stages is associated with deposition of specific polysaccharide components of the cell plate. Interestingly, in a growing phragmoplast, all of these stages are present—the earliest being found at the periphery, and later ones succeeding progressively toward the center.

FIGURE 5.52 Model showing the succession of membrane states in the developing phragmoplast. Initially, the region surrounding the zone where former spindle microtubules meet and overlap is called the fuzzy matrix and is rich in small vesicles which begin to fuse in the mid-plane. This forms the tubulovesicular network, where the volume of the membrane compartments at the mid-plane increases (forming tubules and cisternae) still surrounded by the fuzzy matrix. Continued secretion results in larger sheet-like cisternae forming, still with many tubular projections, called the tubular network, and the loss of the fuzzy matrix. Cisternae coalesce further to form the fenestrated sheet and eventually the mature cell plate. Note that as the phragmoplast grows, all of these stages can be found starting at the edge and moving to the center.

Summary

In plants, the cytoskeleton comprises filamentous protein polymers of two types: actin filaments, and microtubules. Actin filaments and microtubules are not only skeletal but also “muscular”; they are responsible for the movements of cytoplasm and organelles. Actin filaments and microtubules are dynamic, turning over continually. These polymers are also polar in the sense of having different biochemical properties at each end. Their dynamic behavior and polarity are enhanced by free energy from the hydrolysis of nucleoside triphosphates. The biochemical properties of cytoskeletal polymers themselves appear to be widely conserved among eukaryotes. The different functions of the cytoskeleton, whether among cell types or taxa, are mediated by accessory proteins, which assemble, disassemble, bundle, sever, cap, cross-link, or move the polymers. In plants, actin filaments play starring roles in organelle movement. Microtubules are important for cell polarity and for controlling the anisotropy of expansion.

The cytoskeleton provides the machinery that separates the replicated chromosomes at mitosis and that

partitions the daughter cells at cytokinesis. Mitosis depends on the mitotic spindle, a structure built largely from microtubules. Spindle microtubules interact with chromosomes at the kinetochore, a specialized protein-rich region that forms at the centromere. The dynamic properties of the microtubules, the architecture of the spindle, and force-generating proteins participate jointly in chromosome movement. The importance of each may vary at different phases of mitosis and in different cell types. Cytokinesis depends on cytoskeletal structures to ensure the appropriate orientation of the cell’s new wall and to build it. During interphase, the phragmosome, a raft of cytoskeletal-rich cytoplasmic strands, often forms in the plane in which cell division will take place. In prophase, the preprophase band, a ring of microtubules and actin filaments, usually marks the location where the new cell plate will later fuse with the parental cell wall. During cytokinesis itself, the phragmoplast, a structure built from microtubules and actin filaments, orchestrates the intense secretory activity needed to build the forming cell plate and guides the growing cell plate to the parent cell wall.

CELL REPRODUCTION

Introduction

The nucleic acids—deoxyribonucleic acid (DNA) and ribonucleic acid (RNA)—are polymers that can store and transmit genetic information. The blueprints for the biochemical machines that manufacture living organisms are encoded in the DNA molecules that make up the **genome** of the cell. During **transcription**, sequences of DNA serve as templates for the synthesis of RNA. Certain RNAs provide structural scaffolds in riboprotein complexes, others are important regulatory molecules that govern gene expression, and yet others, called messenger RNAs (mRNAs), are decoded by ribosomes during **translation** (see Chapter 10). The information in the translated sequences of mRNA specifies the amino acid sequence of proteins that ultimately contribute to the phenotypic characteristics of the organism. When cells divide, DNA **replication** generates a duplicate set of genetic instructions for the new cell (Fig. 6.1). DNA replication and repair are important processes because the survival of the individual organism depends on the stability of its genome. However, long-term survival of a population can be promoted by the genetic variation that results from changes in the DNA blueprints of its individual members.

Living cells store genetic information in the form of double-stranded DNA. In contrast, viral genomes consist of either double- or single-stranded nucleic acids and contain either DNA or RNA. The genomes of viruses are generally small and encode only a few of the proteins required for viral propagation. To replicate their nucleic acids and multiply, viruses must, therefore, exploit the biochemical machinery of

a host cell. For example, when an RNA virus infects a cell, the cellular machinery can translate the viral RNA directly into protein, or it can use the viral genome as a template and synthesize complementary RNAs for subsequent translation. Some RNA viruses encode reverse transcriptase, an enzyme that uses RNA as a template for DNA synthesis. Once this enzyme has catalyzed the **reverse transcription** of a DNA copy of the viral RNA genome, the transcriptional and translational machinery of the host cell produce the other components necessary for virus multiplication (Fig. 6.1).

6.1 Composition of nucleic acids and synthesis of nucleotides

6.1.1 DNA and RNA are polymers of purine and pyrimidine nucleotides

DNA and RNA are long, unbranched polymers composed of four types of building blocks, called **nucleotides**. Each nucleotide comprises a purine or pyrimidine base, a pentose sugar, and a phosphate group (Fig. 6.2). The ribonucleotides in RNA contain ribose, a sugar with the chemical formula $(\text{CH}_2\text{O})_5$. The deoxyribonucleotides that make up DNA contain 2-deoxyribose, from which the hydroxyl group linked to C-2 has been removed. Reactive 2'-hydroxyl groups make RNA much less stable than DNA, particularly in alkaline solutions.

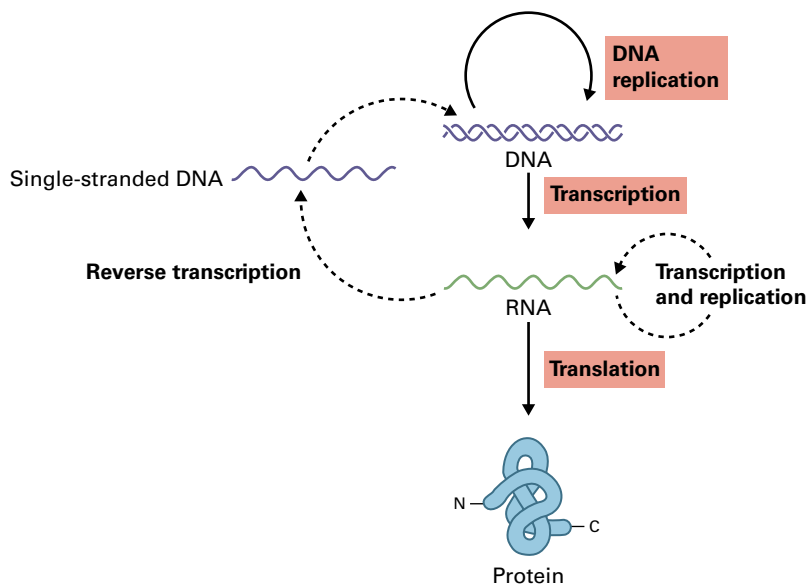

FIGURE 6.1 In living organisms, genetic information is stored in genomes of double-stranded DNA. Single-stranded RNA is transcribed from this DNA template. Some RNA molecules encode instructions for the synthesis of specific proteins. Others participate in RNA processing or translation of RNA sequences into proteins. In contrast, viral genomes are varied; different viruses encode the genetic information required for their amplification in either single-stranded or double-stranded genomes that contain either DNA or RNA. The dotted lines indicate pathways involved in the reproduction of single-stranded RNA and single-stranded DNA viruses.

FIGURE 6.2 The chemical components of nucleic acids. (A) The purine bases adenine and guanine are present in both DNA and RNA, as is the pyrimidine base cytosine. The pyrimidine base thymine is present in DNA. Uracil replaces thymine in RNA. (B) RNA nucleotides contain the pentose sugar ribose. DNA contains a less reactive pentose, 2-deoxyribose. In nucleosides and nucleotides, the carbons of the pentose sugar are numbered 1' to 5', as shown here. (C) A nucleoside comprises a purine or pyrimidine base and a pentose sugar. A nucleotide is a nucleoside in which C-5' is linked to one, two, or three phosphate groups by a phosphoester bond.

FIGURE 6.3 The pathway of de novo pyrimidine nucleotide synthesis. Orotate, the first product with a complete pyrimidine ring, reacts with 5-phosphoribosyl-1-pyrophosphate (PRPP) to form the nucleotide orotidine 5'-monophosphate (OMP). Decarboxylation of OMP produces UMP. CTP is synthesized from uridine 5'-triphosphate (UTP) by amination; the probable amino donor is glutamine. Alternatively, cytidine 5'-monophosphate is synthesized from UMP (not shown). UDP, uridine 5'-diphosphate.

Each nucleic acid includes four nitrogenous bases: two purines and two pyrimidines. DNA contains the purines adenine and guanine, and the pyrimidines cytosine and thymine. RNA also contains adenine, guanine, and cytosine, but thymine is replaced with another pyrimidine, uracil. Unusual or modified bases are also found in some ribonucleic acids, particularly transfer RNAs (tRNAs, see Section 6.7.3).

6.1.2 Plant cells synthesize pyrimidine and purine nucleotides de novo as well as by way of salvage pathways

The de novo synthesis of pyrimidine nucleotides begins with a series of six reactions that make up the orotic acid pathway. The pyrimidine orotate is produced from simple molecules: CO_2 , aspartate, and the amide group of glutamine (Fig. 6.3). Once synthesized, orotate is joined to 5-phosphoribosyl-1-pyrophosphate (PRPP), and is subsequently modified to form the ribonucleotides uridine triphosphate (UTP) and cytidine triphosphate (CTP). In plants, all enzymes required for pyrimidine nucleotide biosynthesis are found in plastids, which are thought to be the primary site of cellular pyrimidine biosynthesis.

Purine nucleotide synthesis in plants is not well understood but is thought to proceed by a pathway defined in other organisms. Whereas the pyrimidine orotate is first synthesized as a free base and then linked to PRPP by an N-glycosidic bond, purine nucleotides are synthesized directly from PRPP by sequential addition of purine moiety precursors: glycine, CO_2 , amide groups from aspartate and glutamine, and methenyl and formyl tetrahydrofolates (Fig. 6.4). Unlike pyrimidine biosynthesis, purine nucleotide synthesis is thought to occur in the cytosol.

Deoxyribonucleotides are derived from the corresponding ribonucleotides. The ribose moiety of the ribonucleotide is reduced by ribonucleotide reductase. The enzyme thymidylate synthase catalyzes the formation of deoxythymidine 5'-monophosphate (dTMP) by transferring a methyl group from methenyl tetrahydrofolate to the C-5 of deoxyuridine 5'-monophosphate (dUMP). Because the thymidylate synthase reaction is the only intracellular source of de novo dTMP, this enzyme is essential for maintaining a balanced supply of the four deoxynucleotide triphosphates required for DNA replication. The enzyme also has an important role in regulating the concentration of deoxyuridine nucleotides, which must be kept low to prevent incorporation of these nucleotides into DNA. Indirect evidence suggests certain plants (e.g., *Lemna major*) may contain an alternative pathway that methylates deoxycytidine 5'-diphosphate and deaminates the resulting product to yield deoxythymidine 5'-diphosphate.

The catabolism of nucleotides in plants is not well understood. DNA or RNA is first hydrolyzed to oligonucleotides by deoxyribonucleases or ribonucleases, respectively. The oligonucleotides are further hydrolyzed by phosphodiesterases to yield mononucleotides, which are then hydrolyzed by nucleotidases

and phosphatases to yield nucleosides. The free nucleosides and bases that are formed during the breakdown of nucleotides can be converted back to nucleotides by way of salvage pathways. Unlike the de novo pathways of purine and pyrimidine synthesis, which are well established and thought to be similar in animals and plants, the salvage pathways of nucleotide biosynthesis are less understood and more diverse. These pathways have received considerable attention following the discovery that some diseases in animals and humans result from deficiencies in salvage pathway enzymes (Box 6.1).

Most salvage pathways of nucleotide biosynthesis fall into one of two principal categories. The first is a one-step pathway catalyzed by phosphoribosyltransferase (Reaction 6.1). This reaction is reversible in the presence of pyrophosphatase, which is found in the plastids but not the cytosol of plant cells (see Chapter 13).

Reaction 6.1 Phosphoribosyltransferase

The second type of salvage pathway requires two steps that are catalyzed by nucleoside phosphorylase (Reaction 6.2) and nucleoside kinase (Reaction 6.3), respectively. The latter reaction is irreversible.

Reaction 6.2 Nucleoside phosphorylase

Reaction 6.3 Nucleoside kinase

Not all of the possible reactions suggested by the two pathways above occur in vivo. For example, while the nucleoside cytidine is present in plants, the free base cytosine has not been observed. Although certain deoxynucleosides can be salvaged by comparable reactions, experimental analysis has focused primarily on thymidine metabolism.

6.1.3 Nucleic acids are composed of nucleotides linked by phosphodiester bonds

In a nucleic acid, nucleotides are linked together in a polynucleotide chain. Covalent phosphodiester bonds join the 5' carbon of one nucleotide to the 3' carbon of the next, forming a sugar-phosphate backbone to which the four bases are attached (Fig. 6.5A). The directional nature of these bonds means that a linear nucleotide chain has two distinct ends with different biochemical characteristics. The 5' end of a nucleic acid usually has a free phosphate group, and the 3' end is typically hydroxylated. By convention, polynucleotide sequences are written 5' to 3', from left to right (Fig. 6.5B).

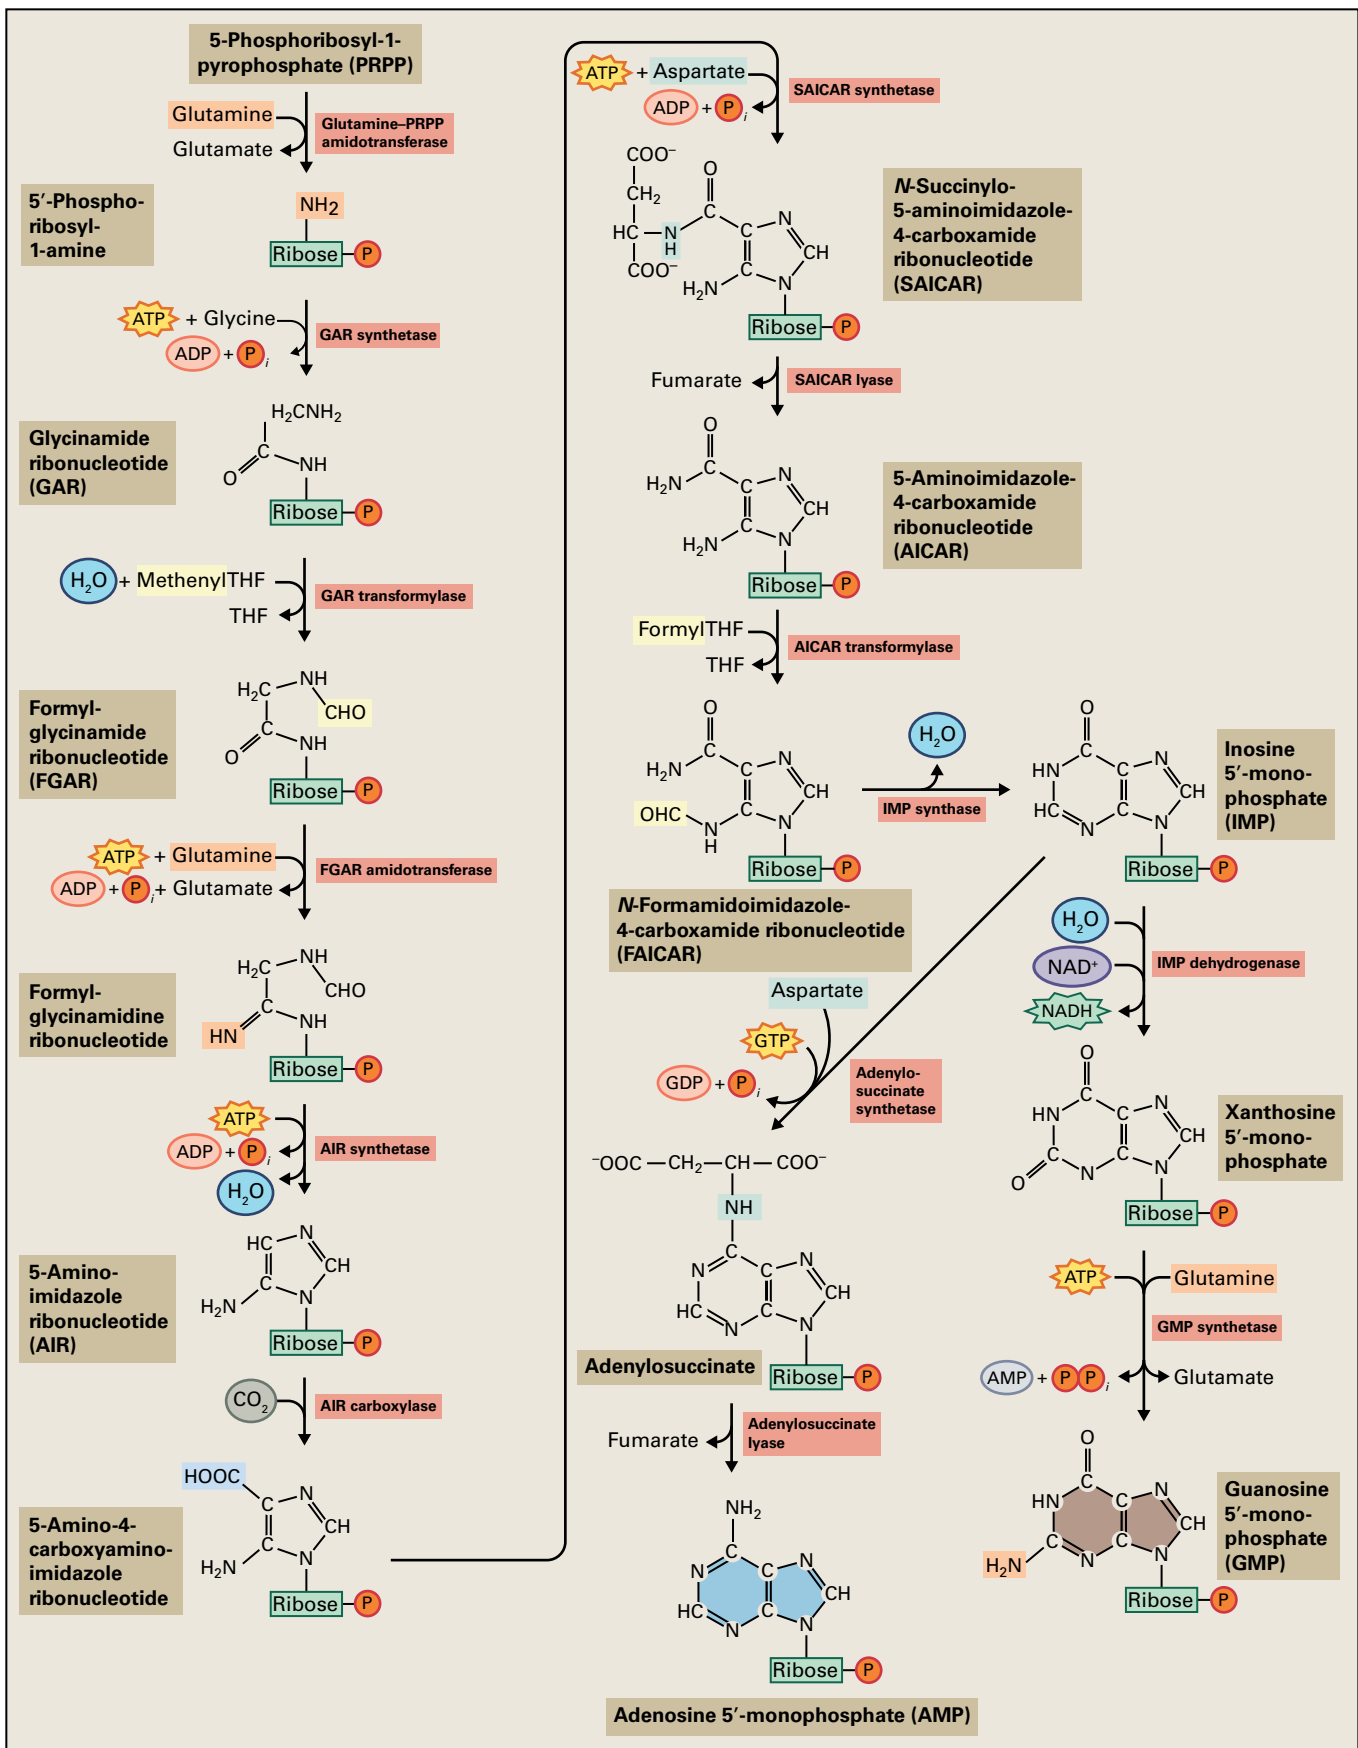

FIGURE 6.4 The pathway of de novo purine nucleotide synthesis. In contrast to de novo synthesis of pyrimidine nucleotides, in which the nitrogenous base is formed prior to ribosylation, purine nucleotide synthesis modifies PRPP to create inosine 5'-monophosphate (IMP), the first product with a complete purine ring. Both AMP and GMP are derived from IMP. To generate AMP, first an aspartate is added to IMP, and then the carbon skeleton of the amino acid (fumarate) is removed, resulting in a net amination. IMP is oxidized and then aminated by glutamine to create GMP. THF, tetrahydrofolate.

BOX
6.1

Defects in the salvage pathways of nucleotide biosynthesis are associated with diseases in humans

The importance of the salvage pathways of nucleotide biosynthesis is illustrated by the severity of the diseases that result from deficiencies in salvage pathway enzymes. For example, **Lesch–Nyhan syndrome**, a severe genetic disorder that occurs mostly in boys, is caused by lack of functional hypoxanthine-guanine phosphoribosyltransferase (HGPRTase), which catalyzes the condensation of hypoxanthine and PRPP. The inability to use PRPP results in its accumulation, which in turn stimulates glutamine-PRPP amidotransferase, thereby causing the overproduction of purine nucleotides. Oxidation of the excess purines results in the production of high concentrations of uric acid and affects especially the central nervous system, which may reflect the brain's particular dependence on the

salvage pathways. Symptoms of the disease include mental retardation, poor coordination, and self-mutilating behavior.

Reduced activities of purine-nucleoside phosphorylase and adenosine deaminase affect the development and function of both T cells and B cells, causing a severe human immunodeficiency disease. Purine nucleoside phosphorylase deficiency results in a large accumulation of dGTP in T cells, which most likely is toxic during T-cell development. Adenosine deaminase deficiency leads to accumulation of deoxyadenosine in T cells, which has a negative effect on the activity of ribonucleotide reductase and thereby lowers the concentration of other deoxynucleotide triphosphates. The basis for B-cell toxicity is less understood.

The predominant form of DNA is a double-stranded, double helical structure formed from two separate polynucleotide chains by specific pairing of bases. Hydrogen bonds form between a larger, purine base on one chain (A or G, respectively) and a smaller, pyrimidine base on the other chain (T or C, respectively). A–T pairing involves two hydrogen bonds, whereas G–C pairing involves three hydrogen bonds (Fig. 6.6). The free energy that drives the hybridization of two single strands to form a duplex DNA results from the overall increase in entropy that occurs when the hydrophobic bases are moved from an aqueous environment into the center of the duplex. (Although duplex formation decreases the entropy of the nucleotide chains, it increases the entropy of the surrounding water molecules.) The two chains are antiparallel, such that the sugar–phosphate backbones of the two strands are oriented in opposite directions. The 5' and 3' ends of the genomes of single-stranded DNA viruses are typically linked by a phosphodiester bond, resulting in a circular molecule.

Most cellular RNA is single stranded, although the nucleotide chain often folds locally. The resulting domains generally contain stems, double-stranded regions that contain both “Watson–Crick” base pairs (i.e., G–C and A–U), many types of atypical base pairs (e.g., G–U, U–U, G–A, etc.), and terminal, single-stranded loops. These domains then associate with each other through various types of specific tertiary interactions. As a result, RNAs can assume very compact structures.

6.2 Replication of nuclear DNA

Before a cell can divide, it must produce a new copy of each of its chromosomes. In eukaryotic cells, chromosomes are made up of **chromatin**, a filamentous complex of DNA and

proteins (see Chapter 9). Considering the long DNA molecules are tightly packaged into DNA–protein complexes, it is not surprising that the replication of DNA involves a large number of enzymes and regulatory proteins. Replication of nuclear DNA has been studied extensively in bacteria, yeast, and mammalian cells. Regulation of this process during the eukaryotic cell cycle is discussed in more detail in Chapter 11.

In all organisms, DNA replication involves three stages: initiation, elongation, and termination. In eukaryotes, the ends of the linear chromosomes are also modified to prevent DNA loss during subsequent rounds of replication. This section focuses on the general enzymology of nuclear DNA replication in eukaryotes. The prevailing view is that this process is very similar in all eukaryotes, although some of the regulatory mechanisms of DNA replication in plants may be tailored to their unique developmental and physiological functions.

6.2.1 Nuclear DNA synthesis begins at discrete origins of replication and requires complex cellular machinery composed of many proteins

Nuclear DNA replication occurs during the S phase of the cell cycle (see Chapter 11) and is a highly regulated process. Replication initiates simultaneously at a number of specific sites, termed **origins of replication** (Fig. 6.7). The identification of eukaryotic chromosomal replication origins has been most successful in the budding yeast *Saccharomyces cerevisiae*, where a specific sequence of 200 base pairs (bp)—called the autonomously replicating sequence (ARS)—is the minimal sequence requirement for the initiation of chromosomal DNA replication. In mammalian cells, initiation of DNA

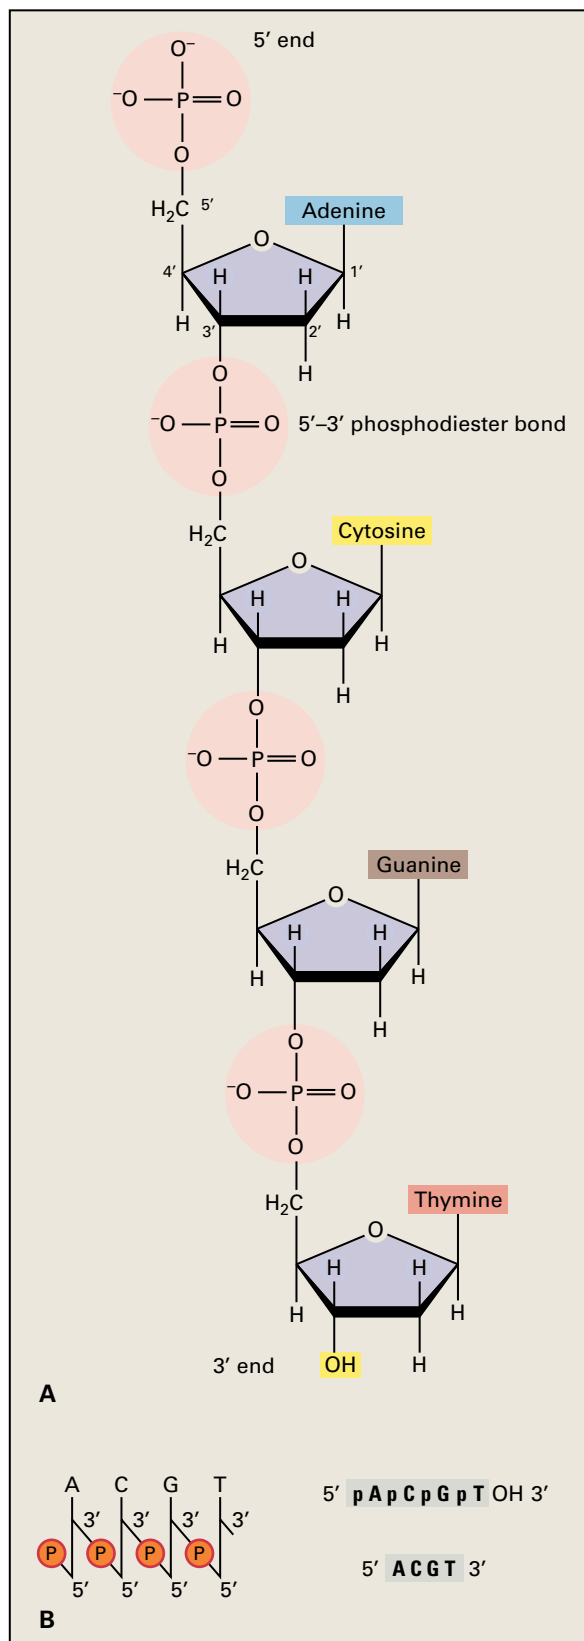

FIGURE 6.5 (A) A polynucleotide chain of DNA. The alternating sugar-phosphate polymer forms the backbone of the polynucleotide chain. In RNA, a 2'-hydroxyl group replaces the 2'-hydrogen. (B) Representations of nucleic acids are drawn 5' to 3', from left to right. In most cases, nucleic acid sequences are presented in a format that does not include symbols for the sugar-phosphate backbone (lower right).

replication occurs in specific regions that are more than 10,000 bp (i.e., 10 kilobases, or kb) apart. The minimal sequence that constitutes the DNA replication origin in these regions is still unknown. Specific replication origins have not been identified in plants.

Many possible origins of replication exist in the chromosome, but not all function in every cell. The segment of DNA that is replicated from a single origin is termed a replicon. In plant cells, for example, a typical replicon is 50–70 kb in length. *Triticale*, a hybrid allohexaploid grain, has replicons of about 22 kb. In contrast, the parent plants (rye and wheat) have replicons of 50 to 60 kb. Apparently, replication origins that remain silent in the cells of the parental species can become active in *Triticale*. Experiments with synchronized cell populations have also shown that not all replication origins on a given chromosome are activated at the same time when DNA replication is initiated during S phase. Origins of replication are activated (“fire”) in a reproducible order. The timing of firing at a given origin is tightly regulated by the cell and may depend on the state of condensation of the chromatin in which the replication origin resides (see Section 6.2.4).

The activation of replication origins during S phase is now understood best in yeast and mammalian cells (see Chapter 11). DNA replication initiates as the chromatin structure unfolds. The two DNA strands separate at an AT-rich region and replication-specific proteins bind to the DNA (Fig. 6.8). Because the DNA double helix is very stable under normal conditions, specific ATP-dependent enzymes, called DNA helicases, must catalyze strand separation at the origin and ahead of the replication fork. Following DNA helicase activity, replication protein A (RP-A) binds to single-stranded DNA and stabilizes its structure. As DNA replication proceeds, DNA topoisomerases remove supercoils that form in front of the replication fork (Box 6.2).

6.2.2 Nuclear DNA replicates semi-conservatively and semi-discontinuously

As DNA replication proceeds from the replication origin, a multienzyme complex that contains **DNA polymerase** catalyzes the addition of deoxyribonucleotides to the 3' end of a template-bound nucleic acid. Thus, DNA synthesis proceeds in the 5' to 3' direction, while the template strand is read 3' to 5', creating an asymmetric structure at the replication fork (Fig. 6.8). DNA polymerases can only add nucleotides to a pre-existing chain (**primer**) and are not active unless a primer with a free 3' hydroxyl is hydrogen bonded to the DNA template being replicated. Primers are synthesized by specific ribonucleotide polymerases, called DNA primases, which initiate primer synthesis with a purine ribonucleotide.

As a result of the asymmetric structure of the replication fork, DNA synthesis is **semi-discontinuous**. Addition of nucleotides to one strand of newly synthesized DNA is continuous. This **leading strand** begins at a single primer,

FIGURE 6.6 The DNA double helix. Two DNA strands associate when their complementary bases pair. Three hydrogen bonds link cytosine and guanine, whereas only two hydrogen bonds form between thymine and adenine. The two DNA strands are antiparallel, running from 5' to 3' in opposite directions.

FIGURE 6.7 DNA replication initiates at specific DNA sequences, called origins of replication, which are spaced apart in the DNA. Each origin produces two replication forks that move in opposite directions until they meet replication forks initiated at neighboring origins. The parental DNA strands are shown in blue, the newly synthesized strands in red.

and the other **lagging strand** is synthesized in short, discontinuous segments of DNA called Okazaki fragments, each of which requires its own primer (Fig. 6.8). To produce a continuous DNA strand from the many fragments of the lagging strand, a special DNA repair system that includes a specific ribonuclease, RNase H, removes the RNA primer and replaces it with DNA. Another enzyme, DNA ligase, joins the 3' end of the new DNA fragment to the 5' end of the downstream DNA fragment. Since both strands of nuclear DNA serve as templates for DNA synthesis, the replication products each contain one original and one newly synthesized

complementary strand. This type of DNA replication is termed **semi-conservative** (see Fig. 6.7).

Three principal DNA polymerase holoenzymes that replicate nuclear DNA have been identified in the nuclei of eukaryotes, including plants: α , δ , and ϵ . DNA polymerase α often dissociates from the template and, therefore, does not synthesize long chains of nucleotides, but two of its four subunits have DNA primase activity. DNA polymerase α , therefore, is thought to function primarily as a primase in lagging strand DNA synthesis (Fig. 6.8). After DNA polymerase α dissociates from the template, a primer terminus is exposed.

FIGURE 6.8 Schematic representation of the organization of the eukaryotic DNA replication fork, showing discontinuous replication of the lagging strand. The model shown in this figure is based primarily on research in yeast. A complex containing helicase and two molecules of DNA polymerase carries out the coordinated synthesis of both the leading strand and the lagging strand. Topoisomerase acts ahead of the replication fork to remove the supercoils generated by unwinding the DNA (see Box 6.2). The leading DNA strand is lengthened continuously towards the fork as nucleotides are added. In contrast, the lagging DNA strand is synthesized in discrete segments, called Okazaki fragments. As leading strand synthesis progresses and the fork opens, priming sites on the lagging strand template are exposed. Following synthesis of a short RNA primer by primase, DNA polymerase α adds nucleotides to the new fragment until its 3' end reaches the primer of the adjacent fragment. Gaps are produced by the concerted action of FEN-1 nuclease, which cleaves between the RNA primer and the new DNA strand, and RNase H, which degrades the RNA primers. The gaps are filled by DNA polymerases δ/ϵ , and the lagging DNA strand fragments are joined by DNA ligase. PCNA (proliferating cell nuclear antigen) is a protein cofactor of the DNA polymerase complex. RP-A (replication protein A) binds to and stabilizes single-stranded DNA.

A multisubunit replication factor complex binds the terminus, facilitating the assembly of a functional DNA polymerase δ or ϵ complex to complete the synthesis of the Okazaki fragment. In contrast to DNA polymerase α , DNA polymerases δ and ϵ remain tethered to the DNA template by PCNA (proliferating cell nuclear antigen), an essential protein cofactor of the DNA polymerase complex that forms a ring-like structure around the DNA. For pedagogical reasons, most of the components involved in DNA replication are shown as individual complexes in Fig. 6.8. These proteins, however, cooperate to form a large, multisubunit complex of replication machinery at the replication fork. In addition, DNA replication occurs at discrete foci in the nuclei of mammalian cells. Called replication centers, these foci may contain as many as 100 replication forks.

DNA replication proceeds with remarkably high fidelity, producing on average only one error for every 10^9 base pairs replicated. Mismatch repair and the $3' \rightarrow 5'$ exonuclease function of DNA polymerases δ and ϵ maintain this high fidelity. DNA polymerases are self-correcting enzymes that remove their own polymerization errors during replication. Separate, intrinsic $3' \rightarrow 5'$ exonuclease activities enhance fidelity by a process called **proofreading**. These enzymatic activities can clip mismatched nucleotides from the 3' end of the newly synthesized strand. DNA polymerase α lacks this $3' \rightarrow 5'$ exonuclease activity, but demonstrates high fidelity nonetheless. The lack of proofreading by DNA polymerase α may be compensated for by the removal of the RNA primers and the few deoxyribonucleotides polymerized by the enzyme, followed by DNA mismatch repair (see Section 6.3.4).

In double-stranded DNA, approximately 10 base pairs correspond to one complete turn about the axis of the double helix structure. As DNA replication begins, the DNA double helix must unwind to expose the leading and lagging strand templates. When one section of the molecule is underwound, the regions proximal and distal to it become overwound, thereby creating supercoils (Fig. 6.B2, left panel). The DNA ahead of the replication fork would have to rotate rapidly to remove these supercoiled regions and allow DNA replication to proceed. DNA in circular molecules or chromosomes, however, is not free to rotate. Instead, DNA topoisomerases remove (or in some cases add) supercoils to maintain favorable DNA topologies and allow DNA replication to continue. The electron micrograph shows a supercoiled circular DNA molecule (A) and a relaxed circular DNA molecule (B) for comparison.

During replication of circular DNA molecules such as the chloroplast genome (see Section 6.5.4), the oppositely oriented replication forks eventually collide to yield two catenated (linked) circles of double-stranded DNA (see middle panel of diagram and structure C in the electron micrograph). In addition to removing supercoils, DNA topoisomerases are also required for separation of the interlocked circular replication products (see right panel of diagram).

Two classes of DNA topoisomerase that can attach covalently to a DNA phosphate, type I and type II, are

found in both prokaryotes and eukaryotes. Topoisomerase I causes a single-strand break (or nick) in a DNA duplex by breaking a phosphodiester bond. Topoisomerase II creates transient double-strand breaks. Cleavage of the phosphodiester bonds is reversible and rapid, and it does not require additional energy. Topoisomerase I can only remove supercoils from DNA, whereas topoisomerase II (also called DNA gyrase) can either add or remove supercoils and can either catenate or decatenate circular duplex DNA molecules. Genetic analysis of topoisomerase function in yeast has shown topoisomerase II is essential for cell growth and division. In addition to decatenating the products of replication, this class of enzymes participates in chromosome condensation during mitosis and meiosis, constitutes a major component of the chromosome scaffold and nuclear matrix, and may also play a role in the structure of the DNA matrix complex.

The topoisomerases found in plant nuclei resemble their yeast and animal counterparts. A type I enzyme isolated from chloroplasts, however, is more similar to prokaryotic topoisomerase I, which is consistent with the prokaryotic origin of this organelle (see Section 6.5.1). Topoisomerases of types I and II have also been found in the mitochondria of mammals and trypanosome, but not in plant mitochondria.

6.2.3 Unlike prokaryotic DNA, eukaryotic chromosomes have ends that are protected by telomeres

Termination occurs in regions where newly synthesized DNA strands from two replication origins meet. In the *Escherichia coli* chromosome, specific sequences near the termination region, called *Ter* sites, arrest new strand synthesis in one direction. The newly synthesized strand from the other direction passes through the *Ter* site, and homologous recombination (see Section 6.4.2) occurs between the two newly synthesized strands. A similar mechanism may operate in eukaryotes, as DNA sequences resembling *Ter* sites have been found in yeast.

As described above, DNA polymerases require nucleotide primers to initiate DNA replication. If a priming site is located at the end of a linear chromosome, this short DNA segment would remain unreplicated after the primer is degraded and would not be available during the next round of DNA replication. As a result, a short segment of the chromosome would be deleted during each round of DNA replication. Normally, however, such deletions do not occur and chromosome length remains stable because chromosomes terminate in special sequences of DNA called **telomeres**. These sequences, which are similar in all eukaryotic cells, consist of multiple tandem repeats of a short DNA sequence—TTAGGG in humans and TTTAGGG in *Arabidopsis* (Fig. 6.9).

An enzyme called telomerase recognizes the G-rich strand of the telomere and extends the 3' end of chromosomal DNA by adding new repetitions of the telomeric sequence. All known telomerases contain specific RNA molecules that are part of the enzyme complex and serve as the complementary template for the telomeric repeat unit (Fig. 6.10). After telomerase has copied several telomere repeats from its integral RNA template, the complementary C-rich DNA strand is synthesized. The telomeric repeats may serve as a primer site for chain elongation, allowing DNA polymerase to complete the unfinished strand.

Telomerase was discovered in the protist *Tetrahymena* and has also been isolated from yeast and animals. Plant chromosomes have highly conserved telomeric sequences, and telomerase activity has been found in plants, suggesting plant telomeres are maintained by mechanisms similar to those identified in other eukaryotes.

<i>Trypanosoma</i>	TTAGGGTTAGGGTTAGGGTTAGGG
<i>Arabidopsis</i>	TTTAGGGTTTAGGGTTTAGGG

FIGURE 6.9 Telomeres are simple, repeated DNA sequences found at the ends of eukaryotic chromosomes. Despite the evolutionary divergence of eukaryotic organisms, the repeated sequences of telomeric DNA are remarkably conserved.

6.2.4 The timing of nuclear DNA replication is tightly regulated, although the mechanisms involved are not well understood

All chromosomal DNA replicates during the S phase of the cell cycle, but the timing of replication of a DNA segment depends in part on the structure of the chromatin region in which the DNA segment resides. The chromatin that remains in a highly condensed conformation during the interphase of the cell cycle is called **heterochromatin**; replication of DNA in segments of heterochromatin occurs very late in S phase. Studies in the budding yeast *S. cerevisiae* have also revealed the DNA located near telomeres is replicated late in S phase, whereas the DNA associated with centromeres (see Chapter 9) is replicated earlier. A telomere-associated ARS replicates sooner if relocated to another site on the chromosome. Similarly, if small segments of telomeric DNA sequence are inserted into a chromosome near an origin of replication that initiates DNA replication early, activation of the origin is delayed. In contrast, DNA segments that are actively transcribed are located in **euchromatin**, regions of the chromosome in which the chromatin is less condensed. These DNA segments are replicated early during S phase, suggesting gene expression can affect the timing of DNA replication. For example, genes that are transcribed constitutively in all cells replicate early, whereas genes that encode proteins with tissue-specific functions are replicated early in cells that express the genes but late in cells where they are inactive. Together, these observations suggest the DNA sequence of the replication origin does not necessarily dictate replication timing—other regulatory elements probably control initiation of DNA replication.

6.3 DNA repair

6.3.1 Damage to DNA can result in mutations

DNA molecules are constantly subjected to physical and chemical stresses in vivo. Oxygen, ultraviolet (UV) light, alkylating agents, and radicals all can cause random changes in the DNA sequence. These changes can result from strand breaks, chemical modification of bases, and incorporation of mismatched bases during replication. Common types of DNA changes include the formation of pyrimidine dimers, alkylation of bases, and deamination of bases (Fig. 6.11). If left uncorrected, spontaneous and induced DNA changes would rapidly alter the DNA sequence. For example, spontaneous deamination of cytosine to uracil is estimated to occur at a rate of 100 bases per genome per day. During replication, uracil would permanently change the DNA sequence at this

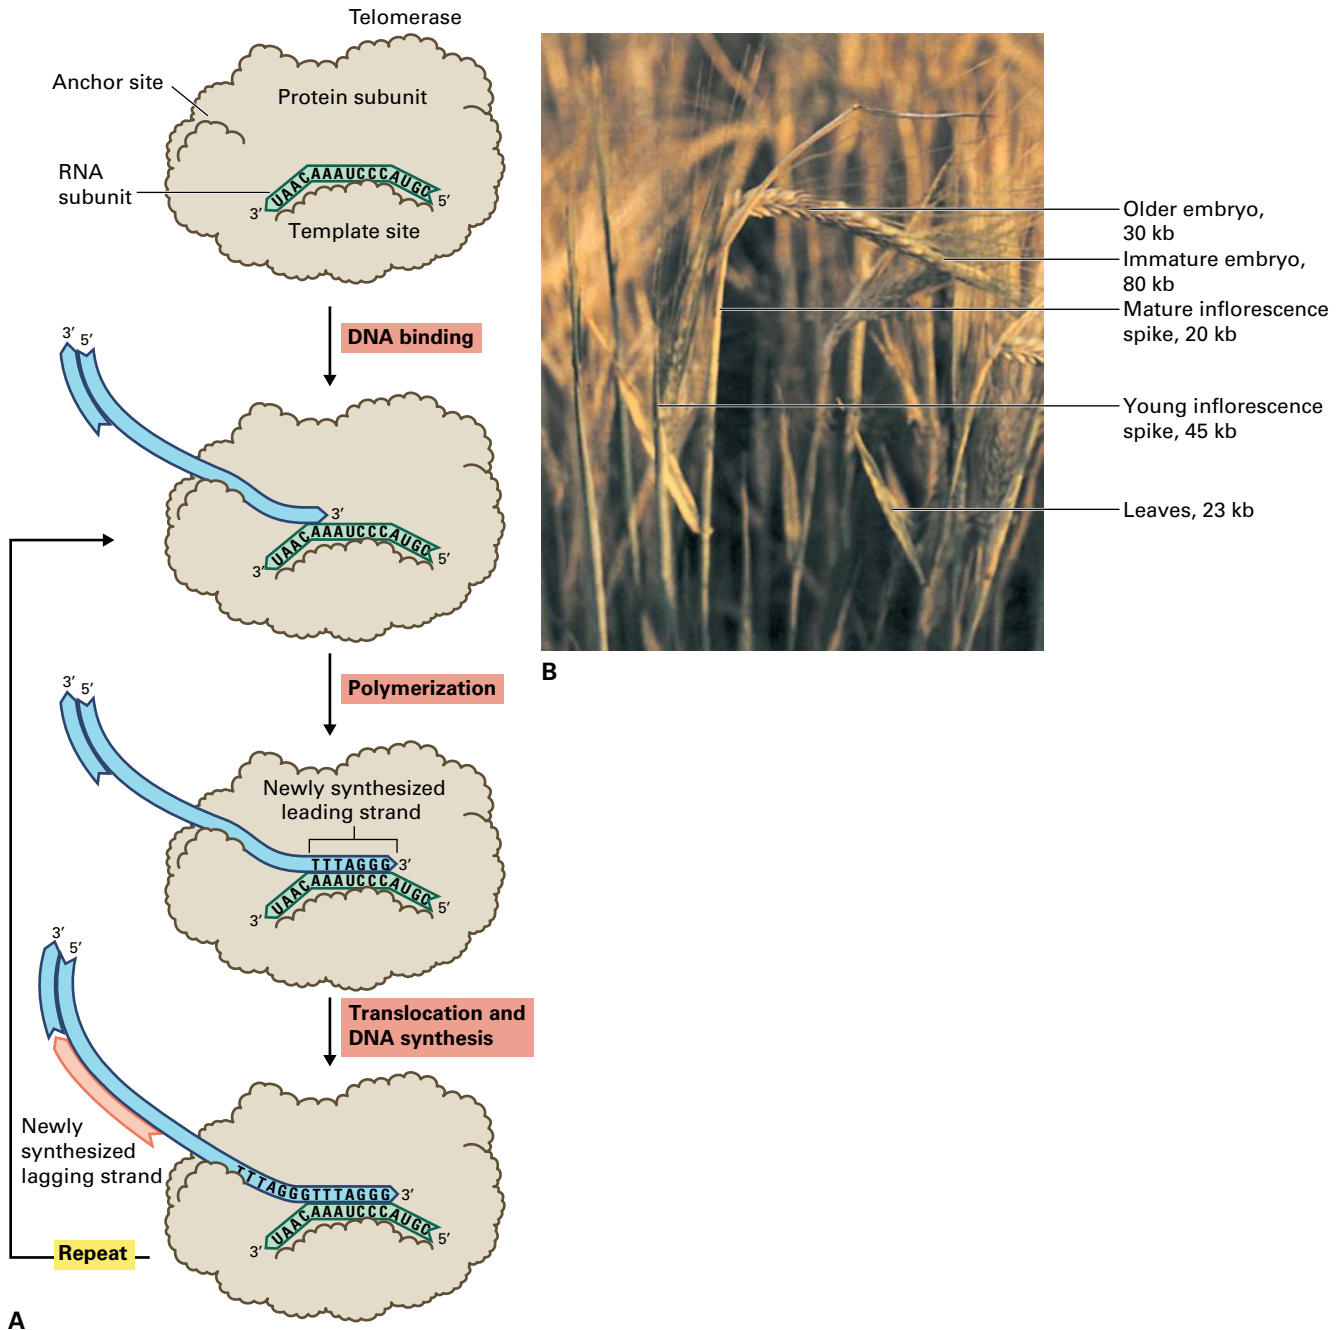

FIGURE 6.10 (A) Elongation of telomeres. Telomerase recognizes the overhanging 3' telomere sequences of the chromosome. An RNA molecule that is complementary to the telomeric DNA is part of the telomerase enzyme complex. The overhanging DNA of the leading strand hybridizes with the telomerase RNA and is elongated by telomerase, which uses the RNA as a template. Telomerase then translocates to the end of the leading strand. Primase and DNA polymerase subsequently elongate the lagging strand of telomere DNA. (B) Telomere length does not remain constant during development. The length of the telomeres of barley chromosomes varies among different organs and developmental stages. Source: (B) Shippen & McKnight (1998). *Trends Plant Sci.* 3:126–129.

site by pairing with adenine instead of guanine. Most DNA changes occur in sequences that do not encode genes; such events are therefore inconsequential. However, the possibility that DNA damage may result in mutations that disrupt the function of essential enzymes or structural proteins poses a significant risk to the cell. Several efficient DNA repair mechanisms have evolved to protect organisms against the potential deleterious effects of mutations.

6.3.2 Pyrimidine dimers, which are caused by UV-B, are repaired using visible light or UV-A

UV light can fuse pyrimidines to create cyclobutane dimers (Fig. 6.11) and pyrimidine(6 → 4)pyrimidinone dimers. Plants and humans incur approximately equal amounts of

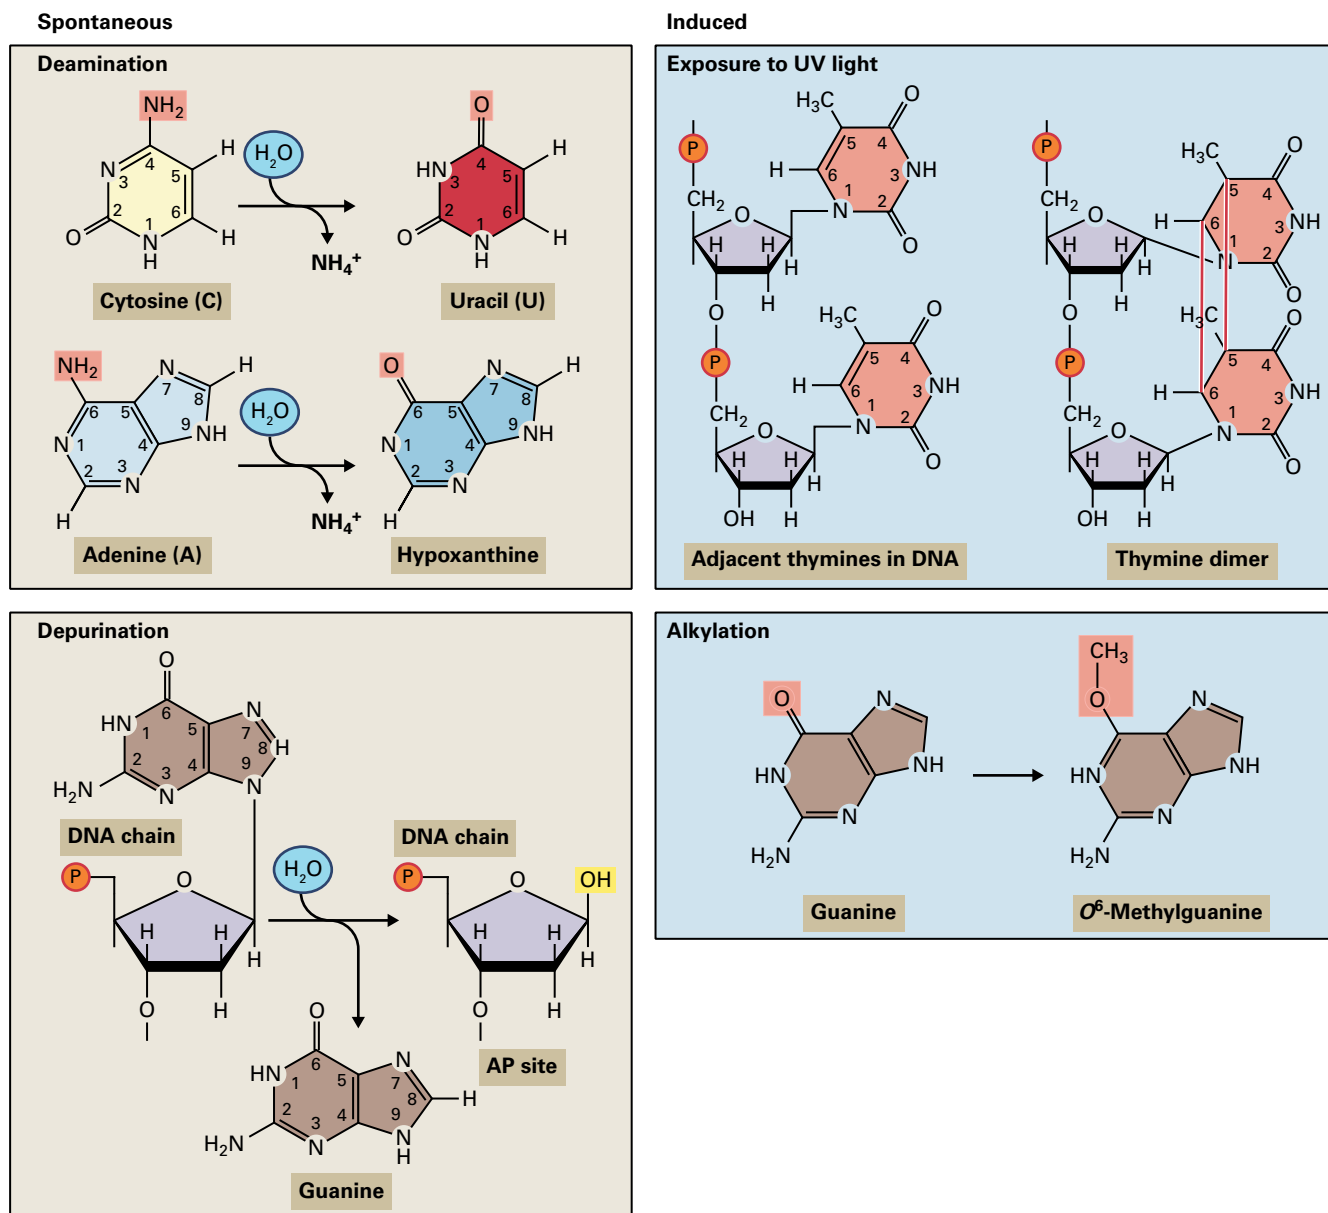

FIGURE 6.11 Chemical reactions that cause DNA mutations can either occur spontaneously or be induced by radiation or chemicals. One major type of spontaneous DNA damage results from deamination of the bases cytosine or adenine. Depurination, another type of spontaneous event, forms an apurinic (AP) site in the DNA. UV light induces the formation of pyrimidine dimers between adjacent pyrimidine bases. Alkylation of DNA bases results in the addition of methyl groups (or sometimes ethyl groups, not shown) at various positions in the ring structure.

DNA damage from the UV-A (320–400 nm) and UV-B (280–320 nm) wavelengths of sunlight. In bacteria and plants, some UV-induced mutations can be reversed by high-energy wavelengths of visible light or by UV-A. This conversion is called **photoreactivation** and is catalyzed by photolyases, enzymes that absorb radiant energy of wavelengths 300–600 nm and convert cyclobutane dimers to pyrimidine monomers (Fig. 6.12). In plants, the activation of certain photolyases is regulated by light and mediated by the photoreceptor phytochrome (see Chapter 18). A photolyase required for repair of pyrimidine(6 → 4)pyrimidinone dimers has been identified in *Arabidopsis* and wheat (*Triticum* spp.). This photolyase appears to be expressed constitutively.

6.3.3 Excision repair mechanisms can remove either individual bases or longer nucleotide chains

Two major pathways have been identified for DNA excision repair: **base excision repair** and **nucleotide excision repair**. In base excision repair, the chemically modified base (e.g., uracil, 5-methylcytosine, or 3-methyladenine) is first removed by a DNA glycosylase that is specific for that type of DNA lesion. The action of DNA glycosylase results in an apurinic or apyrimidinic (AP) site with an intact sugar–phosphate backbone. Next, an AP endonuclease cleaves a phosphodiester bond at

FIGURE 6.12 Photolyases catalyze the repair of pyrimidine dimers. The enzyme uses energy from visible light to break the carbon–carbon bonds that join adjacent pyrimidine residues, such as UV-induced thymine dimers.

FIGURE 6.13 The base excision repair pathway. In the pathway shown in this figure, a uracil formed by deamination of cytosine is removed from the sugar–phosphate backbone of the DNA strand by DNA glycosylase. AP endonuclease recognizes the resulting AP site and cleaves the DNA strand at that site. Deoxyribose phosphodiesterase then removes the remaining deoxyribose molecule. DNA polymerase and ligase repair the gap, restoring the cytosine/guanine base pair.

the AP site, and a pathway that includes several enzymes then repairs the resulting nick. First, DNA deoxyribose phosphodiesterase removes the deoxyribose-phosphate molecule. Next, repair polymerase (DNA polymerase β in animal and yeast cells) adds a single nucleotide to the 3' end of the DNA strand at the gap. Finally, DNA ligase seals the nick (Fig. 6.13). Plant homologs of the yeast genes that encode proteins involved in base excision repair have been isolated, and their gene products can excise specific DNA damage products in vitro.

The second pathway, nucleotide excision repair, involves the DNA replication machinery. This repair pathway can remove DNA damage that distorts the DNA double helix, including various pyrimidine dimers created by UV light. In eukaryotic cells, nucleotide excision repair removes and replaces a DNA fragment approximately 30 bases long. A multienzyme complex that recognizes the distortion in the DNA cleaves the damaged strand on both sides of the lesion. The oligonucleotide is then removed by DNA helicase. The resulting gap is repaired by DNA polymerase δ or ϵ and closed by DNA ligase (Fig. 6.14). With few exceptions, these activities have been identified in plants, and mutant plants defective in light-independent DNA repair have been identified. The mutations are located in genes that are homologous to human genes required for nucleotide excision repair, indicating plants utilize the same repair pathways identified in other eukaryotes.

6.3.4 Mismatch repair corrects errors made during DNA replication

In *E. coli*, adenine residues in the palindromic sequence GATC are methylated shortly after DNA replication. If DNA polymerase introduces an error during DNA replication that results in a mismatched base pair, repair occurs before methylation, when the newly synthesized DNA strand is unmethylated and the two strands can be distinguished (Fig. 6.15). This repair requires the function of three proteins that form a complex: MutS recognizes and binds to the base mismatch, MutH binds to DNA at the hemimethylated GATC sites and cleaves the unmethylated (newly synthesized) strand, and MutL binds to MutS and MutH and is required for the final repair steps. The combined action of additional proteins, namely the UvrD helicase and exonucleases, results in the removal of the damaged DNA strand beginning at the MutH cleavage site. The resulting gap is filled by DNA polymerases and sealed by DNA ligase.

Mismatch repair is a highly conserved mechanism that appears to function similarly in eukaryotes and bacteria. Several homologs of the bacterial *mutS* and *mutL* genes have been found in the genomes of yeast and mammals, and a *mutS* homolog is also present in human mitochondrial DNA. The mechanism that allows the bacterial MutS–MutL–MutH complex to discriminate between the parental and newly synthesized strands of DNA is not known in eukaryotes, in which GATC methylation has not been detected and *mutH*

FIGURE 6.14 Nucleotide excision repair of a pyrimidine dimer. The nucleotide excision repair pathway utilizes the DNA replication machinery to remove large distortions in the DNA double helix, such as pyrimidine dimers induced by UV light. Damaged DNA is first recognized by endonucleases and cleaved (red arrows). The oligonucleotide that contains the damaged bases is then excised after helicase unwinds the DNA at this site. DNA polymerase and ligase repair the resulting gap.

homologs have not been identified. Families of eukaryotic genes that are homologous to *mutS* and *mutL* arose before the evolutionary divergence of animals, plants, and fungi. Homologs of these two genes have been cloned from several plants, suggesting this type of mismatch repair system is similar in all eukaryotic cells.

6.3.5 Error-prone repair allows DNA polymerase to read through damaged sites on the template

If during DNA replication the DNA polymerase complex encounters damage in the template strand, the enzyme complex bypasses the damaged site and continues DNA synthesis. This process is potentially mutagenic because the DNA polymerase does not repair the damage but instead inserts adenine nucleotides at the gap regardless of the original DNA sequence that would otherwise result at the damaged site.

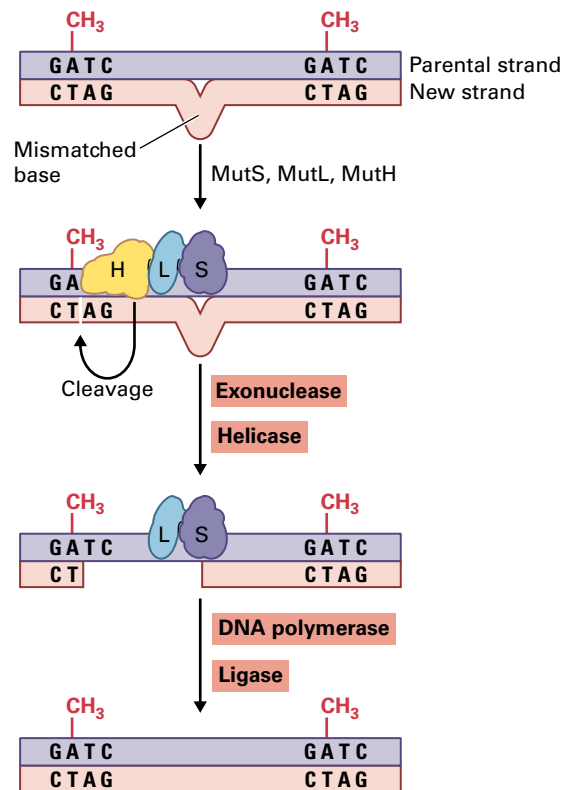

FIGURE 6.15 Mismatch repair in *Escherichia coli*. A complex of three proteins—MutH, MutL, and MutS—recognizes mismatched bases introduced by DNA polymerase into the newly synthesized, unmethylated DNA strand. MutH cleaves the new DNA strand opposite the methylated site. The damaged DNA is then removed by the combined action of helicase and exonuclease. DNA polymerase and ligase subsequently repair the gap.

In bacteria subjected to potentially lethal conditions, such as extensive UV irradiation, this **error-prone repair** mechanism, also called **translesion replication**, is activated. In *E. coli*, the proteins UmuC and UmuD bind to DNA polymerase and alter the stringency of nucleotide incorporation. Adenines are inserted into the newly synthesized strand at the lesion site irrespective of the sequence of the parental DNA strand. If the damaged sites are thymidine dimers, the newly synthesized DNA is not mutated. However, cytosine dimers result in mutations at the lesion sites. Although this type of repair can generate a large number of mutations, it may allow the cells to survive extensive DNA damage. A similar bypass mechanism has been identified in yeast. The products of the *umuC* gene family are required for dimer bypass and include proteins active in both error-prone and high fidelity repair mechanisms. A gene homologous to one member of the *umuC* gene family, the human XP-V gene, has been identified in plants.

6.3.6 Extensive DNA damage can also be repaired by homologous recombination

When DNA damage is extensive or affects a longer stretch of nucleotides, an alternate repair pathway can be induced as well. In recombination repair (Fig. 6.16), DNA polymerase stops

FIGURE 6.16 Post-replication repair. When the DNA replication machinery encounters an unrepaired lesion (e.g., a pyrimidine dimer), DNA polymerase can bypass the block and reinitiate at a downstream site. The resulting gap in the newly synthesized DNA strand is then repaired by recombination with the undamaged parental strand. DNA polymerase and ligase fill the resulting gap in the previously intact parental DNA. The pyrimidine dimer can later be removed by excision repair (not shown) to produce two intact, double-stranded DNA molecules.

replication when a lesion is encountered in the parental (template) strand. DNA replication resumes at the next priming site on the template, which may be several hundred nucleotides downstream from the damaged site. The discontinuity, or daughter strand gap, in the newly synthesized strand is then repaired by homologous DNA recombination with the complementary parental strand using specific recombination enzymes (see Section 6.4.2). DNA polymerases and DNA ligase repair the resulting gap in the complementary parental strand.

6.4 DNA recombination

6.4.1 DNA recombination plays an important role in both meiotic cell division and evolution

Although accurate DNA replication and repair are crucial for genetic stability in individuals, the long-term survival of a species as a whole is also influenced by genetic variation that

FIGURE 6.17 Two types of homologous DNA recombination produce different results. Crossover between two molecules of double-stranded DNA results in the reciprocal exchange of DNA sequences (left panel). Gene conversion involves a nonreciprocal transfer of a nucleotide sequence from one double-stranded DNA molecule to another. The donor sequence (purple) remains unchanged while the recipient sequence (pink) loses genetic information (right panel).

allows its members to adapt to changing environments. **Genetic recombination** of DNA has an important role in evolution because it rearranges DNA sequences to generate new combinations of DNA molecules. The novel genes that result can yield new types of RNAs and proteins and, therefore, new phenotypes. Furthermore, during meiotic cell division, DNA recombination can produce genetically distinct gametes and thereby promote the production of varied genotypes, which are acted on by environmental factors in the process of natural selection. The mechanisms involved in genetic recombination are related to DNA replication and repair. DNA recombination events are not rare; they have been observed in all classes of living organisms and in viruses.

6.4.2 Homologous recombination occurs between long nucleotide sequences that are similar

Three types of DNA recombination mechanisms have been identified: homologous recombination, site-specific recombination, and illegitimate recombination. Homologous recombination requires the DNA sequences involved to have regions that are substantially similar (i.e., homologous). The frequency of recombination generally increases with the length of the homologous DNA segments. The mechanisms used in homologous recombination can be inferred from the structure of the products (Fig. 6.17). When no information encoded in the two DNA duplexes is lost during the exchange of sequences by **crossover**, the recombination event is termed reciprocal. Nonreciprocal recombination, or **gene conversion**, results when one DNA duplex donates sequence information rather than exchanging it. Three molecular models—single-strand annealing, double-strand break repair, and one-sided invasion—have been proposed to explain the particular products of specific DNA recombination events as well as the general finding that double-strand DNA breaks enhance homologous recombination rates (Fig. 6.18).

1 Single-strand annealing model**2 Double-strand break repair model****3 One-sided invasion model**

FIGURE 6.18 Three models of homologous recombination. The donor DNA is purple, the recipient DNA pink. In the single-strand annealing model (1), a double-strand break must occur in both DNA duplexes (A). Exonucleases remove nucleotides beginning at the double-strand breaks and expose single-stranded homologous regions (B). The complementary single strands of DNAs anneal to each other (C), followed by the removal of the nonhomologous DNA overhangs and gap repair (D). This recombination mechanism is nonconservative, because only one chimeric DNA duplex can survive. In the double-strand break repair (DSBR) model (2), the recombination event initiates with a double-strand break in one of two DNA duplexes (A). After the double-strand break is enlarged by exonucleases (B), the overhanging 3' ends of the DNA bind to complementary sequences on the other duplex and act as primers for DNA repair synthesis (C). The remaining gaps are repaired using the intact donor DNA as a template (D). The branched DNA molecules resulting from this process resolve into one of two possible combinations (E). DSBR is a conservative recombination mechanism because both DNA duplexes participating in the recombination event are restored. In the one-sided invasion model (3), a double-strand break in the acceptor DNA (A) is enlarged by exonucleases (B). One of the two resulting 3' ends invades a complementary DNA sequence on an intact DNA duplex (C). DNA synthesis lengthens the invading strand. (D) Illegitimate recombination occurs upstream from the double-strand break, resulting in gene conversion (E).

Plant breeding practices applied by humans over the course of thousands of years to select for desired traits in crop species have, in fact, been utilizing homologous recombination. Recent advances in molecular breeding techniques and transgenic plant technologies (see Box 6.3 and Box 6.4) are providing insights into the processes that underlie meiotic and somatic DNA recombination events in plants. The double-strand break repair model (Fig. 6.18) may explain the recombination events that occur during meiosis in plants. The single-strand annealing model (Fig. 6.18) best describes the extrachromosomal recombination events that can occur at a low frequency in somatic plant cells when plasmid DNA molecules that contain overlapping parts of a specific reporter gene are transferred into plant cells and

recombine to restore an intact reporter gene. Naturally occurring extrachromosomal DNA molecules, such as the transferred DNA (T-DNA) of *Agrobacterium tumefaciens* (see Chapter 21) or viral DNAs show a similar recombination behavior.

6.4.3 Some proteins involved in homologous recombination have been identified in plants

Homologous recombination in both meiotic and mitotic cells requires the function of many gene products. Of these, the yeast proteins RAD51 and DMC1 are well characterized.

**BOX
6.3****Gene targeting is a powerful technology for investigating gene function**

Homologous recombination, the integration of transfected DNA molecules into homologous sequences of genomic DNA, has many possible applications for manipulating the plant genome. It has been used extensively to analyze the function of genes in yeast and mouse cells. The moss *Physcomitrella patens* has been developed into a plant model system over the last two decades (see figure). Its haploid gametophyte produces filamentous protonema and the leafy gametophore. In the haploid genome of the moss, homologous recombination is the normal pathway of DNA integration, and gene targeting experiments in this organism are generating insights into gene function. In the cells of angiosperms, homologous recombination between transfected DNA and homologous sequences within the genome occurs at a lower frequency than illegitimate

recombination (see Section 6.4.5). Site-specific mutagenesis using novel restriction enzymes (see Section 6.4.6) has become a promising way of targeting and enhancing this process.

Source: R. Reski, University of Freiburg.

**BOX
6.4****Site-directed mutagenesis using novel restriction enzymes**

Hybrid nucleases can be expressed in plant cells to generate site-specific double-stranded breaks in genomic DNA. These nucleases can be used to either replace a target DNA sequence (knock-in) or disrupt the open reading frame (ORF) of the target (knockout). For knock-in experiments, the nuclease is used with a DNA donor template that contains an engineered sequence for the nuclease's target gene; this facilitates repair by homologous recombination and results in replacement of the target DNA sequence with the engineered sequence. For knockout experiments, the nuclease is expressed without a donor DNA template, which causes imperfect repair by nonhomologous end-joining mechanisms and perturbs the targeted DNA sequence, often disrupting the ORF.

The hybrid nucleases typically comprise two protein subunits that dimerize at their nuclease domains to generate a functional enzyme. Each subunit has a DNA-binding domain fused to the nonspecific cleavage domain of the FokI endonuclease. Several methods have been developed for the construction and selection of the DNA-binding domains that target the hybrid nucleases to specific DNA sequences. The most commonly used hybrid nucleases (see Fig. 6.B4) are zinc-finger nucleases (ZFNs) and transcriptional activator-like effector nucleases (TALENs).

ZFNs contain eukaryotic transcription factor zinc-finger DNA-binding motifs that bind to specific DNA sequences (see Chapter 9). To create a ZFN, three or more 25-amino acid zinc-finger peptides are fused to the FokI endonuclease cleavage domain. Each peptide can bind to specific nucleotide triplets via the zinc-finger's interchangeable seven-amino acid recognition helix.

Three fused zinc-finger regions provide specificity to bind to a unique 9-bp sequence. ZFN dimers are context-dependent, so specific binding to a DNA sequence requires cooperative binding of the fingers and subunits. This means that not all sequences can be efficiently targeted and that, prior to their use, thorough screening and testing of the combined binding affinities is required.

Like the ZFNs, the DNA-binding domains of TALENs are also fused with cleavage domains from the FokI endonuclease (see Fig. 6.B4). The difference is in the DNA-binding domains. For TALENs the binding domain, called a TALE, is a central domain that typically holds 15 to 30 single-repeat monomers, each of 34 amino acid residues. The monomers are highly conserved with the exception of a hypervariable region at amino acid positions 12 and 13. The hypervariable regions bind to specific nucleotides, the repeat-variable diresidues (RVDs). There are four classes of RVDs determined by their hypervariable region. For example, an RVD with the following diamino acid residues will bind to these specific nucleotides NI = adenosine (A), HD = cytosine (C), NG = thymine (T), NN = guanine (G) or adenosine (A). TALENs appear to be more reliable and more specific than ZFNs, most likely due to the fact that because each RVD binds to a single nucleotide whereas ZFNs bind to DNA codons.

ZFNs and TALENs hold great promise as tools for targeted gene replacement and disruption. Substituting the nuclease domains with other enzymatic activities may also become powerful tools for regulating gene expression through epigenetic modifications, such as DNA methylation.

RAD51 is required for both mitotic and meiotic recombination, while DMC1 is expressed and active only during meiosis. Both are homologous to the *E. coli* protein RecA, which plays a central role during homologous recombination in bacteria. RecA catalyzes the strand transfer reaction, allowing single-stranded DNA to invade a DNA duplex at a homologous region (Fig. 6.19). In the presence of RP-A, which binds to single-stranded DNA, RAD51 and DMC1 also catalyze strand transfer. Strand transfer activity is required by all three mechanisms of homologous recombination (see Fig. 6.18).

A number of plant genes that share homology with *recA* have been identified, some of which may encode proteins that function in the chloroplast. Homologs of RAD51 have been cloned from several plants, including *Lilium*, *Arabidopsis*, rice (*Oryza sativa*), wheat (*Triticum* spp.), and maize (*Zea mays*). Interestingly, expression of this gene is activated after treatment of plants with X-rays, suggesting somatic DNA recombination is induced by DNA damage. Plant proteins homologous to RecA or RAD51 most likely function in homologous recombination. A cDNA homologous to DMC1 has been isolated from *Arabidopsis*. DCM1 and RAD51 colocalize during some stages of meiosis in *Lilium*; these proteins may act cooperatively in the alignment and pairing of complementary DNA strands during homologous recombination. Both proteins are attached to chromatin loops during the leptotene and zygotene stages of meiosis, and are associated with the synaptonemal complex during pachytene (Fig. 6.20).

6.4.4 Site-specific recombination involves enzymatic activities and defined DNA loci

Another mechanism of DNA exchange that occurs in *E. coli*, called **site-specific recombination**, occurs at specific loci, does not require long regions of homologous DNA, and is independent of RecA. The experimental system in which

FIGURE 6.19 The role of RecA in strand transfer. The *Escherichia coli* protein RecA is a 38-kDa monomer that binds to single-stranded DNA by a cooperative and stoichiometric mechanism. The resulting nucleoprotein complex aggregates with double-stranded DNA in triple-stranded DNA complex in which the nucleotide bases do not pair. This complex facilitates invasion of the single-stranded DNA and complementary pairing of base. Strands are subsequently exchanged. A stable heteroduplex region forms and functions as a template for branch migration (not shown).

FIGURE 6.20 The LIM15 protein of *Lilium* participates in the formation of the synaptonemal complex during meiosis. The synaptonemal complex may provide the structural framework for recombination events mediated by protein complexes at the recombination nodule.

FIGURE 6.21 Integration of λ phage into the *Escherichia coli* chromosome involves site-specific recombination between the *attP* sequence of the phage genome and the *attB* sequence of the bacterial genome. The recombination is catalyzed by an integrase.

site-specific recombination is best characterized is the integration of bacteriophage λ into the *E. coli* chromosome. Two proteins and a shared DNA sequence are necessary and sufficient for λ integration. The proteins are a phage-encoded recombinase activity (integrase) and a host-encoded DNA-binding protein (IHF). The sequence requirement is a 31-bp palindrome that is present in both phage DNA and the host chromosome (Fig. 6.21).

Site-specific recombination also occurs in eukaryotes. For example, the 2μ plasmid of budding yeast encodes a recombinase (FLP) that is required for site-specific recombination at inverted repeats during DNA replication (see Section 6.5.4). In mammalian B and T cells, the rearrangement of immunoglobulin genes results from site-specific recombination. Although site-specific recombination events in the plant nucleus have not been identified, this process appears to be important during replication of plasmid DNA and the rearrangement of many plant mitochondrial genomes (see Sections 6.5.4 and 6.5.5).

6.4.5 Illegitimate recombination does not require long segments of homologous DNA

Recombination events that do not fall under any of the categories described above are generally referred to as **illegitimate recombination**. Several models for this type of DNA recombination have been proposed; some of these proposed mechanisms involve short sequences of homologous DNA, but others do not require any DNA homology. In *E. coli*, two mechanisms of illegitimate recombination are particularly well characterized: one is a homology-dependent process catalyzed by RNA polymerase, the other a homology-independent reaction catalyzed by DNA gyrase (topoisomerase II). Although illegitimate recombination does not appear to be a general mechanism in yeast, some gene products that participate in this type of DNA recombination have been identified.

Recombination products that cannot be explained by typical meiotic or somatic homologous DNA recombination mechanisms are often observed in plants. Illegitimate recombination models are often used to explain these novel recombinants. If this assumption is correct, plant genomes appear to experience illegitimate recombination more frequently than

they do homologous recombination. Since integration and excision of transposable DNA elements (see Chapter 9) and insertion of *Agrobacterium tumefaciens* T-DNA into plant chromosomes (see Chapter 21) do not require significant DNA homology, these events are often considered illegitimate recombination as well.

6.5 Organellar DNA

One of the major features by which eukaryotic cells differ from prokaryotes is the presence of various subcellular organelles (see Chapter 1), including the mitochondria (present in almost all eukaryotes) and plastids (present only in plants and algae). Plastids perform a wide variety of anabolic reactions that include photosynthetic carbon reduction (see Chapter 12), synthesis of amino acids (see Chapter 7), and fatty acid production (see Chapter 8). Plant mitochondria engage in respiration (see Chapter 14) and act in concert with other organelles to perform photorespiration (see Chapter 14) and gluconeogenesis (see Chapters 10 and 14).

Among the organelles of eukaryotic cells, plastids and mitochondria are unique because they possess their own genetic systems and protein synthesis machinery. In different taxa of algae and plants, transmission of these organelles (and thus of their genomes) varies, but is typically uniparental. Since the discovery almost 40 years ago that plastids and mitochondria contain DNA, much of the molecular research

has focused on the structure and function of the organellar genomes. We now know that the genomes in plastids and mitochondria encode a small number of genes for proteins that function in the organelles, as well as components for the maintenance of their own genetic system. Expression of organellar genomes is under the tight control of the nuclear genome, but regulatory mechanisms have also evolved in plants that coordinate the expression of nuclear, plastid, and mitochondrial genes for proteins that function in the cytoplasmic organelles.

6.5.1 During evolution, chloroplasts and mitochondria originated from endosymbiotic bacteria

Plastids and mitochondria share many traits with free-living prokaryotic organisms. For example, the organization of organellar and bacterial genomes is similar. Likewise, chloroplasts carry out photosynthesis in much the same way as cyanobacteria. Comparison of ribosomal RNA (rRNA) sequences from organelles and certain free-living prokaryotes suggests plastids share a common ancestor with modern cyanobacteria, and mitochondria with modern proteobacteria. This RNA evidence supports the **endosymbiont hypothesis**, that chloroplasts and mitochondria probably evolved from prokaryotes that were engulfed by protoeukaryotic cells during the origin of the eukaryotic lineage (Fig. 6.22). Extant

FIGURE 6.22 Eukaryotes probably evolved from endosymbiotic associations between different prokaryotic organisms. A comparison of ribosomal RNA (rRNA) sequences suggests plant plastids share a common ancestor with modern cyanobacteria, such as the free-living *Synechococcus lividus*. Mitochondrial rRNA sequences of extant eukaryotes share greatest homology with members of the α -group of the proteobacteria, which includes several genera of intracellular parasites (e.g., *Agrobacterium*, *Rhizobium*, and *Rickettsia*). The electron micrograph shows *Rickettsiella popilliae* cells within a blood cell of its insect host.

Source: Madigan et al. (1997). Brock Biology of Microorganisms, 8th ed. Prentice Hall, Upper Saddle River, NJ.

symbioses between photosynthetic organisms and nonphotosynthetic hosts lend additional support to the endosymbiont hypothesis. For example, the biflagellate protist *Cyanophora paradoxa* acquires an endosymbiotic cyanobacterium, called a cyanelle, which functions as a chloroplast and provides the host cell with photosynthetically reduced carbon. Other examples are marine nudibranchs (sea slugs) that feed on algae. These animals can incorporate the algal chloroplasts into their own tissue and maintain the foreign organelles for nearly two months, receiving nourishment from plastid photosynthesis. Considering these contemporary examples, it is not difficult to envision that endosymbiotic events gave rise to oxygen-tolerant, photosynthetic eukaryotes.

Neither the chloroplasts nor the mitochondria of contemporary organisms can exist autonomously outside of the eukaryotic cell. During evolution, most of the DNA once present in the organelles was transferred to the nuclear genome. This process of gene transfer is ongoing. Some organellar DNA sequences resemble the **operons** of prokaryotes, in which genes encoding proteins that function in a common pathway or assemble into a complex are clustered together. Some sequences in the plastid genome are similar to the corresponding operons in cyanobacteria, including some regulatory elements, gene clusters (e.g., the *rpl23* operon), and ATPase subunit genes (*atp*). In general, however, some transcriptional and a majority of post-transcriptional regulatory factors in plant organelles are novel, and show no relationship to those in bacteria.

6.5.2 The structure of the plastid genome is conserved among plants

The plastid genome is composed of a single, circular chromosome of double-stranded DNA that typically comprises four segments (Fig. 6.23A): a large region of single-copy genes (LSC), a small region of single-copy genes (SSC), and two copies of an inverted repeat that separate the single-copy regions (IR_A and IR_B, respectively). However, other modes of plastid DNA organization have also been found. Plastid DNA is generally homogeneous within a given plant species, although in genomes that contain IR regions, plastid DNA often consists of two groups of molecules differing in the relative orientation of the single-copy regions. In the same way that all somatic cells in an organism possess the same set of nuclear genes but may express those genes in different combinations, all plastids in a single plant contain identical genetic material but may differ in developmental fate and metabolic activity.

The plastid DNAs of different plant and algal species vary greatly in length. The chlorarachniophyte alga *Bigeloviella natans* has one of the smallest known plastid genomes of any photosynthetic eukaryote, 69 kb. In contrast, the chlorophyte alga *Floydiella terrestris* is 521 kb. Most plastid genomes, including those of tobacco, maize, rice, and *Marchantia*, range in size from 120 to 160 kb

and share similar gene distribution and organization (Fig. 6.23B). Some of the size variation observed among land plant plastid genomes can be accounted for by changes in the length of the IR region, which ranges from 0.5 to 76 kb. The presence or absence of IR regions in plastid DNA has been used to categorize plastid genomes. Most plants contain IR regions but the plastid genomes of certain legumes, conifers, and algae lack them. It is likely that IR regions existed in the plastids of the common ancestor of plastids, and that one IR region was lost in some legumes and conifers during evolution.

6.5.3 Plastids contain both plastid-encoded and nuclear-encoded gene products

Complete sequences are available for the chloroplast genomes of more than 200 plants, including tobacco, maize, rice, and pine, and the mitochondrial genomes of more than one dozen plant species. Most plastid DNAs contain all the genes for plastid rRNAs and a full complement of genes for plastid tRNAs. They include, however, only about 100 single-copy genes, and most encode proteins required for photosynthetic functions (Table 6.1). Although the functions of most plastid-encoded proteins have been identified, a few open reading frames (ORFs) in the plastid genome have unknown functions. Chloroplast transformation technologies developed in tobacco (*Nicotiana tabacum*) and the unicellular alga *Chlamydomonas* are, however, providing powerful approaches for investigating these genes. Interestingly, the plastid genomes of nonphotosynthetic plants (e.g., *Rhizanthella gardneri*) are small (50–73 kb) and have lost many of the genes required for photosynthesis. In contrast, algal plastid genomes are generally larger than the plastid DNAs of plants and contain many additional genes not found in plant plastids. For example, the red alga *Porphyrta purpurea* contains 70 novel protein-encoding plastid genes; in plants, these genes are found in the nuclear genome.

Many genes in the plastid genome are organized into **polycistronic** transcription units, that is, clusters of two or more genes that are transcribed by RNA polymerase from a single promoter. Some of these resemble prokaryotic operons (Fig. 6.24), although unlike prokaryotic operons, plastid genomes also contain polycistronic transcription units composed of functionally distinct genes. Often, mRNA from genes encoding proteins that are required during photosynthesis can be detected in nonphotosynthetic plastids, such as amyloplasts in root or chromoplasts in red tomato fruit (see Chapter 1). Apparently, these mRNAs are not translated into functional proteins. These findings and others have established that post-transcriptional regulation plays a significant role in the regulation of plastid gene expression.

While the plastid genome encodes several of the RNAs and proteins involved in translation of organellar mRNA, most of the genes that encode proteins required for photosynthesis are found in the nuclear genome. As discussed above,

TABLE 6.1 Genes identified in complete plastid genome sequences.

Gene products	Gene acronym	Plants		Algae	
		Photosynthetic plants	<i>Epifagus</i> *	<i>Euglena</i>	<i>Porphyra</i> [†]

rRNA	rrn	4	4	3	3
tRNA	trn	30–32	17	27	35
Ribosomal protein	rps, rpl	20–21	15	21	46
Other		5–6	2	4	18
Photosynthesis					
Rubisco and complexes of the thylakoid membrane system	e.g., <i>rbcL</i> , <i>psa</i> , <i>psb</i> , <i>pet</i> , <i>atp</i>	29–30	0	26	40
NADH dehydrogenase [‡]	<i>ndh</i>	11	0	0	0
Biosynthesis and miscellaneous functions		1–5	2	1	40
Number of introns		18–21	6	155	0

**Epifagus* (beechdrops) is a nonphotosynthetic, parasitic flowering plant.

[†]*Porphyra* is a red alga.

[‡]The plastid genome of black pine does not encode genes for NADH dehydrogenase.

FIGURE 6.24 The *psbB* operon of plant plastids exemplifies the typical organization of plastid genes into operons similar to those of prokaryotic genomes. Operons are transcribed into polycistronic mRNAs that often encode several related gene products. In the case of the *psbB* operon, the *psbN* gene encoded by the opposite strand appears to be transcribed as a monocistronic mRNA that encodes only one gene product.

many genes present in the progenitor organelle were probably transferred to the nucleus during evolution. For example, the enzyme required for CO₂ fixation, ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), is a multiprotein complex with two types of subunits. The gene for the smaller subunit (*RBCS*) is found in the nucleus, whereas the gene for the larger subunit (*rbcL*) is present in the plastid genome (see Chapter 12). This distribution of genes between the nuclear and plastid genomes is typical of proteins that participate in the assembly of photosynthetic protein complexes. For example, photosystems I and II contain proteins encoded in both the nuclear and plastid genomes, as does the cytochrome *b₆f* complex and the plastid ATP synthase (see Chapter 12). Chloroplasts and other types of plastids contain many important biochemical pathways for which all of the enzymes are

encoded in the nuclear genome, translated in the cytoplasm, and transported into the plastids (see Chapter 4).

6.5.4 The mechanism of plastid DNA replication is not well understood

Usually each chloroplast contains many copies of its circular genome, often as many as 150. However, the copy number of plastid genomes can vary widely with the developmental stage and the type of plastid. A large number of DNA molecules in chloroplasts probably reflects a high demand for expression of proteins active in photosynthesis, because substantially fewer DNA molecules are found in root amyloplasts and other nonphotosynthetic plastids. Our understanding of

FIGURE 6.25 The double rolling-circle model was first developed to describe the amplification of the yeast 2μ plasmid, but also serves as a model for the replication of chloroplast DNA. The small red arrows indicate the direction of DNA synthesis. During double rolling-circle replication, a single initiation event produces two replication forks with opposite orientations. A site-specific recombination catalyzed by FLP recombinase reorients the forks so they move in the same orientation. A second recombination event returns the replication forks to their initial, opposing orientations, allowing the forks to meet and replication to terminate. The resulting replication product is a long concatameric DNA from which monomers can be generated by FLP-mediated recombination or other recombination mechanisms. These concatameric DNA molecules have been observed in plastids.

the regulation of plastid DNA replication is limited, but it is established that DNA replication in organelles is mostly independent of DNA replication in the nucleus. Plastid DNA amplification appears to be regulated by the frequency of DNA replication initiation, either in synchrony with the cell cycle in rapidly dividing cells, or by a cell cycle-independent mechanism during cellular differentiation. The process of plastid DNA replication is probably similar to the double rolling-circle model that describes the replication of the 2μ plasmids of budding yeast (Fig. 6.25). In these plasmids, as in the plastid genome, replication origins and site-specific recombination sites are located within long inverted repeats.

Electron microscopic analysis of DNA replication intermediates has been used to map the replication origins of plastid DNAs in some plants. In *Oenothera* and tobacco (*N. tabacum*), DNA replication begins at specific origins in the IR regions, near the gene for the 16S rRNA. Although pea (*Pisum sativum*) and *Euglena* do not have IR regions, the replication origin still appears to be close to the rRNA genes, suggesting the rRNA operon has retained DNA sequences that interact with the DNA replication machinery to initiate replication. However, in the chloroplast DNAs of *Oenothera*, pea, maize, and tobacco, displacement or D-loops have been observed at multiple sites. The presence of more than two D-loops, replicative intermediates, in which the unidirectional synthesis of a single new strand displaces one parental strand, suggests plastid genomes may

contain DNA replication origins in addition to those associated with the rRNA operon.

DNA sequences available from several different plants indicate all the enzymes and regulatory proteins essential for plastid DNA replication are encoded in the nuclear genome. Specific enzymatic activities, including DNA polymerases, primase, topoisomerases, and helicases, have been detected in plant plastids; their function in replication is under investigation. DNA sequences in the chloroplast genomes of *Chlamydomonas* and *Porphyra* share homology with the *E. coli* genes *dnaA* and *dnaB*, which encode proteins that function in DNA replication and repair. The presence of these sequences in chloroplast DNA suggests the mechanisms of plastid DNA replication are similar to those of *E. coli*.

6.5.5 The size and arrangement of plant mitochondrial genomes are highly variable

Plant mitochondrial genomes, which range from about 200 kb in *Oenothera* and *Brassica* to over 10 Mb in *Silene conica*, are the most variably sized genomes in any group of organisms. Part of this variability results from an unusual accumulation of noncoding DNA sequences in the regions between genes (Fig. 6.26). Surprisingly, in *Arabidopsis* the nuclear genome is more information dense than the mitochondrial genome:

FIGURE 6.26 The map of the mitochondrial genome of maize (*Zea mays*) is based on a hypothetical master circle DNA molecule that contains all of the mitochondrial genes. Although the mitochondrial DNA in maize is considerably larger than the chloroplast DNA, it contains fewer genes. Several inverted and direct repeat DNA sequences (shown in blue, green, and magenta boxes on the inner circle) have been identified that participate in recombination events to produce the small subgenomic circular DNA molecules shown in Figure 6.27.

coding regions make up less than 10% of the 367-kb mitochondrial DNA, and 60% of the genome contains no characterized information. Unlike much of the noncoding intergenic DNA in the nuclear genome, plant mitochondrial intergenic regions are not made up of repetitive DNA sequences. In stark contrast, animal mitochondrial genomes are compact (about 16 kb) and essentially lack noncoding intergenic sequences.

Plant mitochondrial genomes sometimes exist as circular DNA molecules of variable size. Sequence analysis suggests the smaller DNA circles, called **subgenomic circles**, are derived from a larger circle, and the combined DNA sequence content of subgenomic circles can account for the entire mitochondrial genome. The subgenomic circles of maize (*Zea mays*) mitochondrial DNA are typical of this type of mitochondrial genome organization (Fig. 6.27). The largest possible maize mitochondrial circular DNA molecule, the **master circle**, would encode the complete set of mitochondrial genes. However, the master circle DNA has never been isolated; in fact, it is conceivable this large circular DNA molecule does not exist. Several short regions of different repeated DNA sequences that are distributed throughout the maize mitochondrial genome participate in the recombination events

that form subgenomic DNA circles. These direct and inverted DNA repeat sequences probably shield the functional genes from deleterious rearrangements. Formation of subgenomic DNA circles has been observed *in vivo*. It remains to be established whether some or all subgenomic DNA circles replicate independently or whether they can be generated only from the hypothetical master circle. Recombination and fragmentation of plant mitochondrial DNA is not universal: The linear genome of *Chlamydomonas* and the circular genomes of *Marchantia* and white mustard (*Brassica hirta*) are homogeneous and do not appear to form subgenomic DNA circles.

6.5.6 The genetic content of the mitochondrial genome is conserved among plant species

The unicellular green alga *Chlamydomonas* was the first photosynthetic organism whose mitochondrial DNA was fully sequenced and the genome organization elucidated (Fig. 6.28). Complete nucleotide sequences of mitochondrial

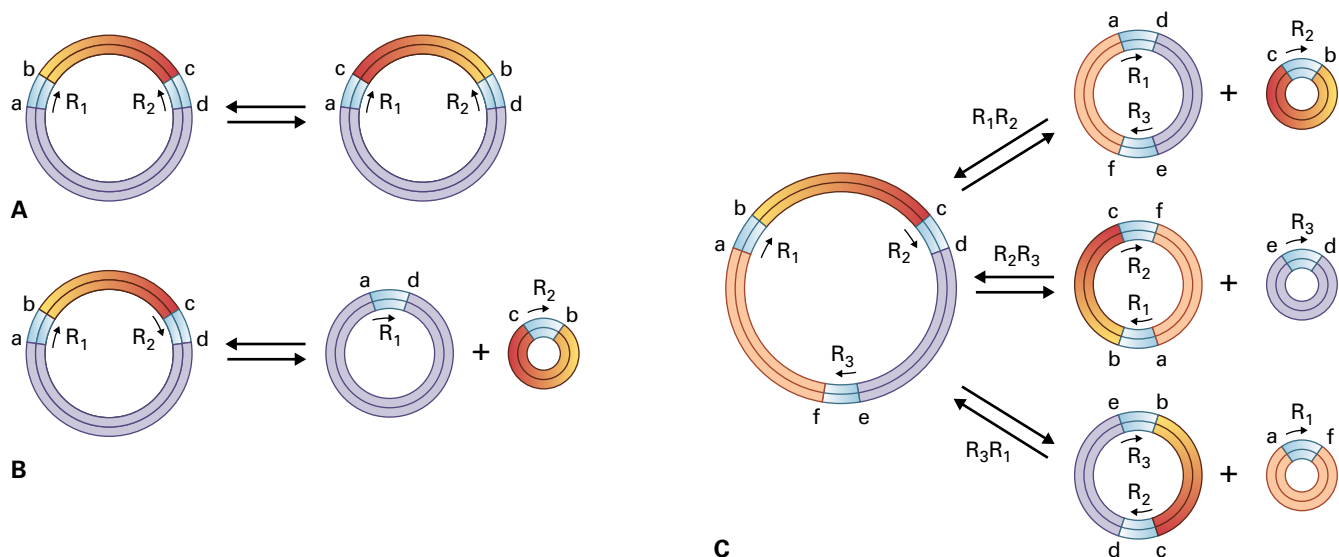

FIGURE 6.27 Homologous recombination occurs at repeated DNA sequences within the plant mitochondrial genome. The DNA repeats can be either direct or inverted; their orientation influences how a recombination event reorganizes the genome. Three hypothetical master circle DNAs are shown, as are some of the subgenomic circles they can generate (A) Recombination between one pair of inverted repeats yields two isomeric forms of the master circle DNA. (B) Recombination between one pair of direct repeats yields two subgenomic circles. (C) Three distinct recombination events can occur in a master circle containing a three-copy direct repeat. Each possible recombination event produces a different pair of subgenomic circles.

Gene content of *Chlamydomonas* mitochondrial DNA

	Gene	Gene product
Protein-coding genes	<i>cob</i>	Apocytochrome
	<i>coxI</i>	Cytochrome oxidase subunit I
	<i>nad1, nad2, nad4, nad5, nad6</i>	Subunits of NADH dehydrogenase
	<i>rnl</i>	Reverse transcriptase-like reading frame
rRNA genes	L ₁ – L ₈	Segments encoding large subunit of rRNA
	S ₁ – S ₄	Segments encoding small subunit of rRNA
tRNA genes	W	Tryptophan tRNA
	Q	Glutamine tRNA
	M	Methionine tRNA (elongator, not initiator)

FIGURE 6.28 The mitochondrion of *Chlamydomonas* contains a linear DNA duplex of 15.8 kb. The genome contains eight genes that code for proteins. One striking and unique feature is the scrambled arrangement of rRNA gene segments. Both LSU and SSU rRNA genes are discontinuous. Throughout a 6-kb region, segments encoding specific rRNA domains are interspersed with one another and with intact genes that encode protein and tRNA. The rRNA-coding segments are numbered S1 through S4 and L1 through L8, according to the 5' to 3' order in which the homologous segments occur in the 16S and 23S rRNAs of *Escherichia coli*, respectively. The mtDNA encodes only three tRNAs, necessitating import of numerous tRNAs from the cytoplasm. The ends of the genome are characterized by terminal inverted repeats with single-stranded 3' extensions. These extensions, which are identical in sequence (not complementary), exclude the possibility of genome cyclization or the formation of concatamers.

BOX
6.5**Mitochondria in all eukaryotes are likely derived from the same endosymbiotic event**

At one time, it was thought that only plant mitochondrial DNA contained a 5S rRNA gene, which is absent from the mitochondrial genomes of animals, fungi, and algae. This observation, combined with the striking differences in the size of mitochondrial DNA in plants, led to the hypothesis that plant mitochondria may have a separate evolutionary origin from the mitochondria of other eukaryotes.

When the mitochondrial genome of the green alga *Prototheca* was sequenced, however, it was found to contain a gene for 5S ribosomal RNA. Also encoded by

the mitochondrial DNA of *Prototheca* is a set of genes for ribosomal proteins similar to those encoded by the mitochondrial genome of liverwort (Marchantiophyta), but absent from that of *Chlamydomonas*. These findings challenge the proposal that mitochondria originated separately in different eukaryotic taxa. Instead, they suggest a complex pattern of gene loss from a commonly inherited mitochondrial genome. Further DNA sequence analysis of mitochondrial genomes from divergent algae and plants has confirmed the evolutionary links shared by the mitochondrial DNAs of all eukaryotic organisms.

TABLE 6.2 Types of genes identified in the maize mitochondrial genome.

Gene products	Gene abbreviations	Function
rRNAs	rrn18, rrn26, rrn5	Protein synthesis
tRNAs	trn	Protein synthesis
Ribosomal proteins	rps, rpl	Protein synthesis
NADH dehydrogenase	nad	Respiratory electron transport
Cytochrome c oxidase	cox	Respiratory electron transport
Apocytochrome	cob	Respiratory electron transport
F ₀ F ₁ -ATPase proteins	atp	ATP synthesis

genomes are now available for over 65 species of plant and algae, including *Arabidopsis*, *Marchantia*, the green alga *Prototheca* (Box 6.5), and the red alga *Chondrus*. Although plant mitochondrial DNAs are complex and variable in size, they all contain essentially the same genetic information. Mitochondrial genomes do not code for many genes, as most of the enzymes required for DNA replication, transcription, and translation are encoded by the nucleus. The products of genes encoded in the mitochondrial genome participate predominantly in oxidative respiration, ATP synthesis, or mitochondrial translation (Table 6.2).

6.5.7 Homologous DNA sequences found in more than one plant genome suggest extensive movement of DNA between genomes

DNA sequencing projects revealed that mitochondrial genomes of plants contain nucleotide sequences homologous to sequences in chloroplast DNA (Fig. 6.29). In addition, sequences of mitochondrial and chloroplast DNA were found in nuclear genomes. These discoveries indicated the possibility of DNA transfer between organelles and nuclei, and the name “promiscuous DNA” was coined to describe a DNA sequence that occurs in more than one of the three genetic systems of eukaryotic cells—the nuclear, mitochondrial, and plastid genomes. To date, many types of promiscuous DNA segments have been reported in yeast, fungi, animals, and plants.

Promiscuous DNA sequences may be relics of extensive DNA transfer between progenitor organelles and nuclei. These transfers occurred over a long time span and provide insights into the evolution of plants. For example, the *tufA* gene, which encodes the plastid protein synthesis factor EF-Tu, is a plastid gene in algae but a nuclear gene in plants. The transfer of *tufA* from the plastid to the nuclear genome was probably an early event during the evolution of the Charophyceae more than 500 million years ago. Another example is *rpl21*, a gene that encodes the plastid ribosomal protein L21. This gene is present in the plastid genome of liverwort and the nuclear genomes of angiosperms. Thus, *rpl21* was probably transferred to the nuclear genome some time after the divergence of nonvascular plants and flowering plants. The *rpl22* gene for the plastid ribosomal protein L22 may represent an even later transfer event because it is present in the plastid DNA of all plants except legumes, in which it is a nuclear gene.

FIGURE 6.29 Comparison of mitochondrial and chloroplast DNA sequences from rice (*Oryza sativa*) reveals the extent of promiscuous DNA. The colored triangles and boxes shown on the chloroplast genome (inner circle) represent DNA sequences that have been transferred to the mitochondria and inserted at different sites in the mitochondrial DNA (outer circle). It is interesting to note that mitochondrial DNA sequences have not been found inserted into the chloroplast genome, suggesting DNA transfer may be unidirectional, or the chloroplast may have an effective mechanism to protect itself against invading DNA molecules.

6.6 DNA transcription

The nuclear and organellar genes discussed in previous sections contribute to the function of individual cells and the development of the multicellular organism. Expression of these genes must be regulated for cells to respond to changes in their environment and coordinate their activities within the tissues that make up complex organisms. Particularly in the nucleus, the organization of genes into chromatin and chromosomes is an important aspect of their regulation. However, **DNA transcription**, the synthesis of RNA on the DNA template, constitutes the primary control step.

The transcription from DNA to RNA is performed by DNA-dependent RNA polymerases. Subsequent modification of the resulting RNAs is discussed later in this chapter. This section briefly reviews the types of DNA-dependent RNA polymerases found in the nuclei and organelles of plants. The control of transcription by these RNA polymerases and associated regulatory proteins is described in Chapter 9.

6.6.1 Five nuclear RNA polymerases each transcribe different types of RNAs

Eukaryotic nuclei contain three classes of DNA-dependent RNA polymerases, called RNA polymerases I, II, and III (Table 6.3). RNA polymerases bind to and initiate transcription at specific sites on the chromosome, termed **promoters** (see Chapter 9). Although bacterial RNA polymerases can begin transcribing at promoters in the absence of additional

TABLE 6.3 The nuclear DNA-dependent RNA polymerases of plant cells.

Polymerase	Location	Products
I	Nucleolus	25S, 17S, and 5.8S rRNAs
II	Nucleoplasm	mRNAs, pri-miRNAs, U1, U2, U4, U5,
III class 1	Nucleoplasm	5S rRNA
III class 2	Nucleoplasm	tRNAs
III class 3	Nucleoplasm	U3; U6; other small, stable RNAs
IV	Nucleoplasm	Transcripts from transposon and repeat elements that are processed into siRNAs
V	Nucleoplasm	Short transcripts from intergenic noncoding (IGN) regions

proteins, eukaryotic RNA polymerases must interact with specific proteins called transcription factors to initiate transcription (Fig. 6.30).

Nuclear RNA polymerases are complex enzymes that contain two large subunits (125–220 kDa) and several smaller subunits. Five of the smaller subunits are common to all

three RNA polymerases. As a result of these structural similarities, the three nuclear RNA polymerases share several functional properties, including the requirement for accessory proteins to initiate transcription correctly at cognate promoter regions.

FIGURE 6.30 Comparison of eukaryotic and prokaryotic RNA polymerases reveals these enzymes differ in complexity. Eukaryotic RNA polymerase II (RNAPII) is a multisubunit complex that requires several accessory proteins and regulatory protein complexes for promoter recognition at the TATA box region. In contrast, prokaryotic RNA polymerases, typified by *Escherichia coli* RNA polymerase, consist of four core subunits (α , α , β , and β') and regulatory σ subunits. The increased complexity of the eukaryotic RNA polymerase II reflects the regulation of nuclear transcription by numerous signals (see Chapters 7 and 18). TFI, transcription factors for RNA polymerase II.

The largest subunit of RNA polymerase II has a C-terminal domain that contains multiple repeats of the consensus sequence Tyr-Ser-Pro-Thr-Ser-Pro-Ser. A regulatory protein complex called transcription factor II H (TFIIH), which interacts with RNA polymerase II following recruitment of the enzyme to the promoter, contains a protein kinase that can phosphorylate Ser and Thr residues in the C-terminal domain. This phosphorylation is thought to release RNA polymerase II from its association with the promoter-initiation complex and allow the enzyme to begin synthesis of the mRNA from the template strand of the DNA.

Though many details of the mechanisms by which the three nuclear RNA polymerases initiate transcription in yeast and mammalian cells are known, additional regulatory proteins remain to be discovered. Plant RNA polymerases I, II, and III are similar to those of other eukaryotes. Moreover, genetic and biochemical data suggest the initiation of transcription in plants is controlled by regulatory mechanisms that resemble those in yeast and mammals. In plants, two other RNA polymerases (IV and V) produce RNAs for the epigenetic regulation of gene expression (Table 6.3).

6.6.2 Plastids contain multiple DNA-dependent RNA polymerases

The principal RNA polymerase of plastids resembles that of *E. coli*, which has five core subunits— α ($\times 2$), ω , β , and β' —and one of several regulatory σ subunits. Chloroplast DNA contains genes that encode proteins similar to the *E. coli* subunits α , β , and β' that can form an enzyme complex in the plastid (Fig. 6.31). Several genes for σ -like subunits have also been identified in the nuclear genomes of plants. In a current model, plastid and nuclear gene products combine to form an *E. coli*-like plastid RNA polymerase required for the transcription of plastid genes.

As would be expected for genes transcribed by the plastid-encoded, prokaryote-type RNA polymerase, most chloroplast genes have regions proximal to their transcription initiation

FIGURE 6.31 Plant chloroplasts have two types of RNA polymerases. The existence of plastid genes encoding proteins similar to subunits α , β , and β' of the *Escherichia coli* RNA polymerase, combined with biochemical analyses, suggest the presence of a prokaryotic-type chloroplast RNA polymerase (right). Genes for σ -like subunits have been identified in the nuclear genomes of many plants, indicating that both plastid and nuclear genomes cooperate in the regulation of chloroplast transcription. The plastid-encoded RNA polymerase recognizes chloroplast promoters that contain typical “-10” and “-35” prokaryotic consensus sequences. Recent results suggest chloroplast genes can also be transcribed by a nuclear-encoded, single-subunit RNA polymerase that resembles the RNA polymerases of bacteriophage T3 and T7 (left). When specific inhibitors of translation protein synthesis are used to block protein synthesis in the chloroplast, the nuclear-encoded RNA polymerase activity continues to transcribe chloroplast genes. The promoter sequences recognized by this novel type of RNA polymerase are not well understood.

sites that often contain DNA sequences similar to the *E. coli* “-10” and “-35” consensus promoter motifs. Analysis of these DNA sequences by mutagenesis has shown the RNA polymerase recognizes this *E. coli*-type chloroplast promoter during initiation of transcription. However, subsequent investigations of chloroplast transcription in the presence of inhibitors of plastid protein synthesis, combined with analysis of mutants defective in chloroplast-localized protein synthesis, revealed transcriptional activity was reduced but not abolished when the *E. coli*-type RNA polymerase was impaired. Plastids must, therefore, import a nuclear-encoded RNA polymerase that functions alongside the *E. coli*-type RNA polymerase. This novel RNA polymerase, which resembles the single-peptide RNA polymerases of bacteriophage T3 and T7, recognizes promoter regions that differ in DNA sequence from the conserved “-10” and “-35” consensus promoter motifs. The nuclear-encoded enzyme is active in all plastid types (e.g., etioplasts, chromoplasts, and amyloplasts). Results suggest constitutive gene transcription of the plastid genome maintains chloroplasts and nonphotosynthetic plastids.

6.6.3 The genes of plastids and mitochondria can have multiple promoters

Unlike nuclear genes, which typically have one promoter that is recognized by RNA polymerase, transcription of many plastid genes and operons is initiated either at multiple promoters or at multiple sites. One example of this is the dicistronic *atpB*-*atpE* transcription unit (Fig. 6.32). Transcription of many plastid genes, especially of those encoding proteins involved in photosynthesis, is regulated by the developmental program and environmental factors, such as changing light conditions. Overall transcriptional efficiency can be controlled by adjusting the number of active promoters or by altering promoter strength, and plastids appear to utilize both these mechanisms. Certain mitochondrial genes also have multiple promoters that may control their differential expression. It is not known whether the different types of plastid RNA polymerases or the cofactors for these enzymes are involved in either promoter selection or control of transcription initiation at multiple sites.

FIGURE 6.32 Multiple promoters direct transcription of the *atpB*-*atpE* gene cluster in tobacco (*Nicotiana tabacum*) chloroplasts. The *atpB* and *atpE* genes encode the β and ϵ subunits of ATP synthase, and their coding regions overlap each other by a few nucleotides. There are five transcription initiation sites (P1 through P5), indicated by red arrows. Four of the transcription initiation sites contain “-10” and “-35” consensus sequence motifs, but the sequence around the -290 site (P3) has no such motifs.

6.7 Characteristics and functions of RNA

RNA is the primary product of gene expression and has essential roles in protein synthesis and other cellular functions. Coding mRNAs are central to protein synthesis, and other, noncoding RNAs are involved in guiding mRNA processing and degradation. Ribosomal RNA (rRNA) molecules form complex three-dimensional structures that combine with polypeptides to create ribosomes, the organelles responsible for protein synthesis (see Chapter 9). Ribosomes serve as a platform for reading mRNAs, which carry the instructions that dictate the amino acid sequences of proteins. Transfer RNAs (tRNAs) act as adapters to translate the codons of mRNA (specific three-nucleotide sequences) into particular amino acids (see Chapter 10).

In addition to its roles in protein synthesis, the versatile RNA molecule has biochemical properties that allow it to function as a genome or as a catalyst. One such characteristic is the ability of RNA to self-replicate, which is key to the evolutionary success of many RNA viruses that infect eukaryotic cells (see Chapters 10 and 21). Another trait is the ability of RNA to catalyze the breakage and formation of covalent bonds between nucleotides (e.g., during RNA splicing, see Section 6.8). Some RNA molecules can assume specific structures that cause particular chemical groups in one or more of its constituent nucleotides to become highly reactive. These RNAs, often referred to as **ribozymes**, can catalyze the cleavage and rejoining of polynucleotide chains. Some RNAs, such as the small nuclear RNAs (snRNAs) and the RNA component of telomerase (see Section 6.2.3), are found in eukaryotic nuclei and participate in RNA processing and DNA replication. The following sections discuss the different types of RNAs found in eukaryotic cells and their functions in plants.

6.7.1 RNAs are classified according to their function and size

When bulk RNA is extracted from cells, it consists of a complex mixture of polynucleotide chains that vary in lengths. RNA molecules are commonly designated according to the

FIGURE 6.33 The separation of RNA species by zone centrifugation. A solution containing a mixture of RNA molecules is loaded onto the top of a sucrose gradient (typically ranging from 2.5% to 15% sucrose) and centrifuged at high speed. When subjected to strong gravitational field, large RNA molecules sediment more rapidly than small RNA molecules. After centrifugation, sequential fractions are collected from the bottom of the centrifugation tube and the amount of RNA in each fraction is determined by measuring UV absorption at 260 nm (A_{260}).

FIGURE 6.34 Comparison of plastid 23S rRNAs from various organisms with the 23S rRNA of *Escherichia coli* reveals differences in organization. The 23S rRNA of *E. coli* is 1904 nucleotides long. The 4.5S rRNA encoded by the plastids of plants (shown in red) is homologous to the 100 nucleotides at the 3' end of the *E. coli* 23S rRNA. The *Chlamydomonas reinhardtii* chloroplast genome contains 7S and 3S rRNAs (shown in red) that are homologous to the 5' end of *E. coli* 23S rRNA. In contrast, the plastid-encoded 23S rRNA of *Euglena* is continuous, as are those of cyanobacteria and several algae (not shown).

sedimentation coefficient, measured in Svedberg units (S, or 10^{-13} seconds). Three main RNA fractions (23S to 25S, 16S to 17S, and 4S RNA) can be separated by zone sedimentation (Fig. 6.33). The 23S to 25S and 16S to 17S fractions contain rRNAs, while the 4S fraction includes tRNAs and small non-coding RNAs. Most of the RNAs in these three classes are relatively stable molecules that can be detected easily using agar gel electrophoresis and ethidium bromide staining. In contrast, mRNAs are far less abundant in the cell and typically make up only 1–2% of the total cellular RNA. Molecules in this class of RNA, which vary considerably in size and stability, do not separate as a discrete fraction when subjected to zone sedimentation or gel electrophoresis.

6.7.2 The bulk of cellular RNA is ribosomal

All ribosomes consist of a large subunit and a small subunit. The small ribosomal subunit contains only one type of rRNA molecule (small-subunit rRNA), whereas the large subunit contains one long rRNA molecule (large-subunit rRNA) and one or more short rRNA molecules. Plants, algae, and photosynthetic protists each contain three classes of ribosomes: cytoplasmic, plastid, and mitochondrial. The short 5.8S rRNA is unique to cytoplasmic ribosomes and associates with 25S rRNA. Interestingly, the 5.8S rRNA is homologous to sequences in the 5' end of *E. coli* 23S rRNA. Plastid 23S rRNAs

resemble those of *E. coli* and cyanobacteria, both in sequence and length (Fig. 6.34), although it is broken into shorter RNA chains in some plants or algae. Plant mitochondrial ribosomes also contain a short 5S rRNA molecule, which is absent in animal mitochondria. Prokaryotic rRNAs typically contain methylated nucleotides, up to 10 in 16S rRNA and up to 20 in 23S rRNA, but little is known about the methylation states of plant and animal rRNAs because their sequences have been deduced from their genes.

Both small and large rRNAs fold into complex secondary structures (Fig. 6.35). Comparisons of rRNA sequences from many different organisms and organelles suggest the secondary structures of rRNAs are highly conserved despite considerable sequence divergence among organisms. The proposed structures receive additional support from experimental analysis, because many regions that are predicted by comparative analysis to form intramolecular base pairs also resist digestion by RNases and chemical reagents that degrade single-stranded RNA.

6.7.3 Plant cells contain three distinct sets of transfer RNAs

The second type of abundant RNA, tRNA, makes up most of the 4S RNA fraction in a whole-cell rRNA extract (see Fig. 6.34). Acting as adapters, tRNAs bind specific amino

A Tobacco plastid 16S rRNA

II. Central domain

B Tobacco plastid 23S and 4.5S rRNAs

FIGURE 6.35 Ribosomal RNAs can fold into complex secondary structures by pairing of complementary sequences. (A) The predicted secondary structure of tobacco plastid 16S rRNA reveals four major domains (I to IV). The structure of the tobacco 16S rRNA is based on the model for the structure of *Escherichia coli* 16S rRNA. (B) Secondary structure predictions for tobacco plastid 23S and 4.5S rRNAs also reveal a conserved organization with six major domains (I–VI). Domain V is the principal site of tRNA binding to the 50S subunit.

FIGURE 6.36 The cloverleaf representation of wheat germ tRNA^{Phe}, the first plant tRNA to be sequenced. The structures of the modified nucleotides that occur at specific positions in plant tRNAs are shown. The four arms are named for their structure and function. The acceptor stem consists of a stem of nucleotide base pairs that extends to an unpaired CCA sequence at the 3' end. The T ψ C loop is named for its pseudouridine residue (ψ). The anticodon, which varies among different tRNAs, constitutes the three nucleotides that interact with mRNA during translation (see Chapter 9). The D-loop is named for its dihydrouridine residue (D). A notable feature of all tRNA molecules is the presence of modified (or unusual) bases.

FIGURE 6.37 The cytoplasmic initiator $tRNA^{Met}$ of bean (left) is typical of eukaryotic cytoplasmic tRNAs. In contrast, the plastid initiator $tRNA^{Met}$ (right) resembles those of prokaryotes. Initiator tRNAs, which are distinct from elongator $tRNA^{Met}$, have certain unique features. All cytoplasmic initiator tRNAs contain the sequence $A\psi C$ instead of $T\psi C$ in the $T\psi C$ loop. Although the plastid $tRNA^{Met}$ has the typical $T\psi C$ sequence, its 5' nucleotide is unusual in that it cannot base pair to the acceptor stem.

acids and base pair with defined mRNA codons, facilitating the translation of nucleic acid sequences into polypeptides (see Chapter 10). A particular tRNA can accept only one of the 20 standard amino acids, but in most cases several different tRNA species, called isoaccepting tRNAs, bind the same amino acid. All tRNAs sequenced fit the cloverleaf model (Fig. 6.36). The conserved primary and secondary structures that characterize this class of molecules make purification of individual tRNA species difficult. In plants, the cytoplasm, plastids, and mitochondria each contain a unique population of tRNAs.

While mammalian mitochondrial DNA encodes all the tRNA genes necessary for translation, mitochondria from plants and many other organisms lack a full set of tRNA genes. Mitochondrial import of tRNAs from the plant cytoplasm was first suggested by the findings of hybridization experiments in which genes encoding some mitochondrial tRNAs were detected in nuclear DNA. Direct evidence was subsequently obtained from transgenic potato (*Solanum* spp.) plants that expressed a nuclear tRNA gene from bean. The bean tRNA could be detected in both the cytoplasm and the mitochondria of the transgenic potato plants. The mechanism of mitochondrial tRNA import remains unknown. In *Arabidopsis*, a single base mutation of $tRNA^{Ala}$ blocks both its aminoacylation and import, suggesting that aminoacyl-tRNA synthetases (see Chapter 10) participate in tRNA import into plant mitochondria. In contrast to mitochondrial DNA, the plastid genome of most plants encodes approximately 30 species of tRNAs (see Table 6.1), which are generally assumed to be sufficient for translation of proteins within the organelle. However, the chloroplast DNA of the nonphotosynthetic parasitic plant *Epifagus* contains only 17 tRNA genes (see Table 6.1). Translation in *Epifagus* plastids must therefore involve tRNAs of nuclear origin, suggesting that plastids may also be able to import tRNAs.

Plant cytoplasmic tRNAs are similar in sequence to those found in the cytoplasm of yeast and other eukaryotes, but many plastid tRNAs have attributes that are typically prokaryotic

(Fig. 6.37). Consistent with their mixed origin, some plant mitochondrial tRNAs resemble those of prokaryotes, while others resemble those found in plant cell cytoplasm.

6.7.4 Cytoplasmic mRNAs are modified extensively after transcription

Messenger RNAs encode the amino acid sequences of proteins. The number of distinct mRNA species in a given cell, which can exceed tens of thousands, is comparable to the number of different proteins present in the cell. As discussed above, mRNAs constitute no more than 1–2% of total cellular RNA. Consistent with the range of molecular masses observed for polypeptides, mRNAs vary in length from a few hundred to several thousand nucleotides. In addition, mRNAs are generally more labile than rRNAs and tRNAs, although the turnover rate for some mRNAs is quite slow. Since individual mRNA species are usually of low abundance and, therefore, cannot be visualized directly by staining a gel with ethidium bromide, their detection requires hybridization with labeled probes of complementary DNA.

A typical cytosolic mRNA consists of five distinct regions (Fig. 6.38):

- a “cap” structure at the 5' end
- a 5'-untranslated region
- the protein coding region
- a 3'-untranslated region
- a polyadenylic acid tract added to the 3' end

The 5' of the mRNA is first modified, or “capped,” by addition of a 7-methylguanosine nucleotide (m^7G). In the nucleus, shortly after the mRNA emerges from the RNA polymerase complex, a guanosine residue is joined to the 5' nucleotide by way of a triphosphate bridge. The N-7 of the guanine is subsequently methylated (Fig. 6.39). The 5' cap

FIGURE 6.38 Structure of a typical mature, nuclear-encoded, eukaryotic mRNA. Most mature mRNAs have 5' and 3' untranslated regions (UTRs) that often contain cis-regulatory sequences involved in the regulation of translation or mRNA stability. Specific regulatory sequences in the 3'-UTR are recognized by poly(A) polymerase, which synthesizes the addition of a polyadenylic acid tail at the 3' end.

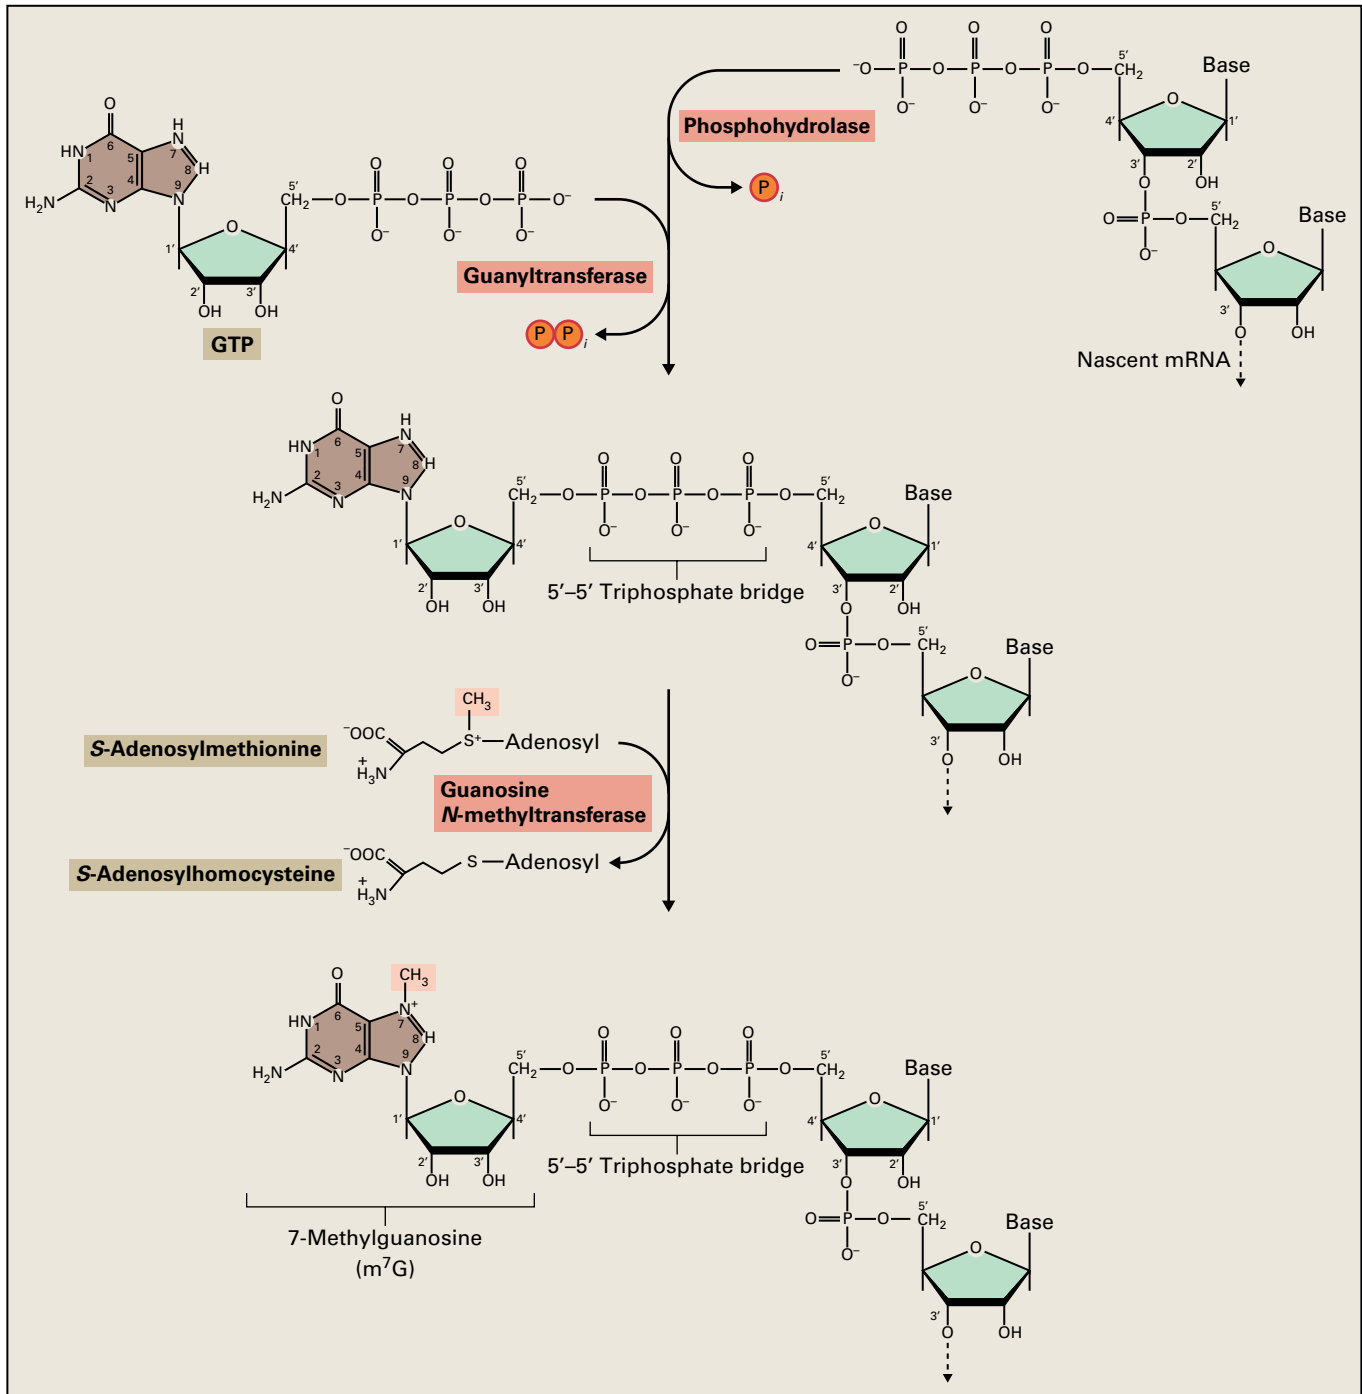

FIGURE 6.39 5' cap formation. The first nucleotide in an mRNA transcript, usually an A or a G, retains its 5' triphosphate group. Phosphohydrolase cleaves a phosphate from the 5' terminal residue of the mRNA. The subsequent reaction of the 5' triphosphate of a GTP and the 5' diphosphate of the mRNA, catalyzed by guanylyltransferase, releases pyrophosphate and generates a 5'-triphosphate-5' nucleotide linkage. Guanine methyltransferase then transfers a methyl group from S-adenosylmethionine to the 7 position of the guanine residue.

plays an important role during the initiation of translation (see Chapter 10) and also seems to protect the mRNA from degradation during its synthesis.

The coding region, which is the nucleotide sequence translated into the amino acid sequence, begins with an initiation codon (usually AUG), and ends with a termination codon (UAG, UAA, or UGA). The sequence between start and stop codons constitutes an ORF (see Chapter 10). It is flanked by 5' and 3' untranslated regions (UTRs) that are highly variable in length. Consequently, the length of an mRNA does not always correlate with the length of the amino acid sequence it encodes. The precise function of the 5' and 3' UTRs is poorly understood for many mRNAs, but often these regions contain RNA sequences that can form secondary structure and interact with proteins that regulate transport, translation, and stability of the mRNA.

Most cytoplasmic mRNAs contain a 3' sequence of polyadenylic acid. This poly(A) tail is not encoded in the DNA, but is added post-transcriptionally before the mRNA is exported from the nucleus to the cytoplasm. An enzyme complex that includes an endonuclease and poly(A) polymerase recognizes a signal sequence (5'-aa meta-3') near the 3' end of the transcript, cleaves the pre-mRNA downstream from the signal, and adds 20–250 adenosine residues to the 3' end. The poly(A) tail facilitates export of the mRNA from the nucleus, stabilizes the mRNA against exonucleolytic degradation, and appears to have a role in the initiation of translation.

The structure of plastid and mitochondrial mRNAs differs from that of cytoplasmic mRNA. The organellar mRNAs lack both the 5' cap and 3' poly(A) tail (Fig. 6.40). As a result of differences in post-transcriptional RNA processing, mitochondrial mRNAs commonly retain the 5' triphosphate group, while the 5' ends of most plastid mRNAs are monophosphorylated. Similar to prokaryotic mRNAs, the 5'- and 3'-UTRs of most organellar mRNAs can form stem-loop structures that have regulatory and stabilizing functions. These RNA structures often interact with proteins and serve as signals that affect the processing, translation, and degradation of the mRNA. A small fraction of plastid mRNA contains a short poly(A) segment or A-rich tract at the 3' end. These poly(A) sequences are added to plastid mRNAs after endolytic cleavage at a 3' sequence and at internal sites within the transcript. Unlike the poly(A) tail of

FIGURE 6.40 Structure of a typical mature chloroplast mRNA. Chloroplast mRNAs resemble prokaryotic mRNAs and are not modified at the 5' end. The mRNAs usually end in a 3' stem-loop structure that appears to be important for the processing and stability of the transcript.

cytoplasmic mRNAs, the 3' polyadenylate sequences of plastid mRNAs appear to promote efficient degradation of the modified mRNA fragment.

6.7.5 Eukaryotic cells contain different classes of small RNAs

The majority of small RNAs in a plant cell have extremely important roles and can be divided into two main classes. One class comprises small nuclear RNAs (snRNAs) and small nucleolar RNAs (snoRNAs) of 60–300 nt in length. The other class is made up of very small (20–24 nt) RNAs that are generated from longer primary RNAs by Dicer-like endonucleases.

Small nuclear and small nucleolar RNAs (snRNAs and snoRNAs) are critical components of the small ribonucleoproteins snRNPs and snoRNPs that play essential roles in the maturation of mRNAs and rRNAs, respectively. They are numbered from U1 onward, reflecting the chronological order of their discovery. Most are found in the nucleolus and are, therefore, designated snoRNAs (small nucleolar RNAs). Several snRNAs contain unique 5' cap structures as well as nucleotides that are methylated or modified. Most of the snRNAs in snRNPs are involved in splicing (removal) of intervening noncoding regions that from the precursor mRNA in the nucleus (see Section 6.8.2). Other snRNAs (e.g., U7) participate in processing of the 3' terminus of histone pre-mRNA, which lacks a poly(A) tail. Most of the snoRNAs in the nucleolus, the site of transcription of ribosomal RNA genes (see Chapter 9), are involved in the processing of rRNA precursors. Although not all homologs of yeast and animal snRNA and snoRNA species have been identified in plants, the similarity of RNA processing mechanisms among all eukaryotes suggests the undetected ones likely exist.

6.7.6 Small regulatory RNAs derived from dsRNA mediate gene silencing

Small, 20–25-nt RNAs were first discovered in plants in which introduced transgenes were being silenced, and in plants infected with viruses. These **small RNAs** contained sequences from the “invading” transgene mRNA or viral genomic RNA. Because these RNAs are short and interfere with the expression of the gene or survival of the virus, they are called short interfering RNAs (siRNAs), and the process in which they act is called RNA interference (RNAi).

siRNAs are made by **Dicer-like (DCL) endonucleases**, which cleave long double-stranded (ds)RNAs that have themselves been generated either by host RNA-dependent RNA polymerases (RdRPs) or viral RdRPs (see Section 6.8.7). siRNAs are usually 21 nt long, and one strand of the DCL-generated duplex RNA is loaded on to another endonuclease called **Argonaute (AGO)**, which in turn uses it as a guide to find target RNAs (Fig. 6.41). The siRNA-guided AGO is the main component of an **RNA-induced silencing complex**

FIGURE 6.41 In the basic mechanism of RNA interference, double-stranded RNA is recognized by a Dicer-like (DCL) endonuclease, which cleaves it into 21 nt RNA duplexes. One of the duplex strands, termed a short interfering (si) RNA, is loaded onto the Argonaute (AGO) endonuclease, which uses it to recognize single-stranded (ss) RNAs with a complementary sequence. AGO cleaves the cognate ssRNA in the middle of the target region.

(RISC), which cleaves its target RNA and diminishes expression of the transgene or replication of the virus.

The mechanism that produces and utilizes siRNAs is related to pathways that produce and use four other classes of 20–25-nt RNAs (see Section 6.8.7 and Fig 6.42). These pathways produce microRNAs (miRNAs), trans-acting siRNAs (tasiRNAs), natural-antisense siRNAs (natsiRNAs), and heterochromatic siRNAs (hcsiRNAs). All four small RNA types are methylated at their 3' nucleotide to protect them from polyuridylation and degradation. miRNAs range in size from 20 to 24 nt, tasiRNAs and natsiRNAs are predominantly 21 nt long, and hcsiRNAs are 24 nt in length. The differences in their sizes reflect the different DCL enzymes that produce them.

All eukaryotes encode miRNAs. Over 350 miRNAs have been identified in *Arabidopsis*, and almost 2000 in humans. Because of the wide distribution of miRNAs across species and the ongoing discovery of new members, their current nomenclature is inconsistent. A central miRNA registry (<http://www.mirbase.org>) provides a new number from its

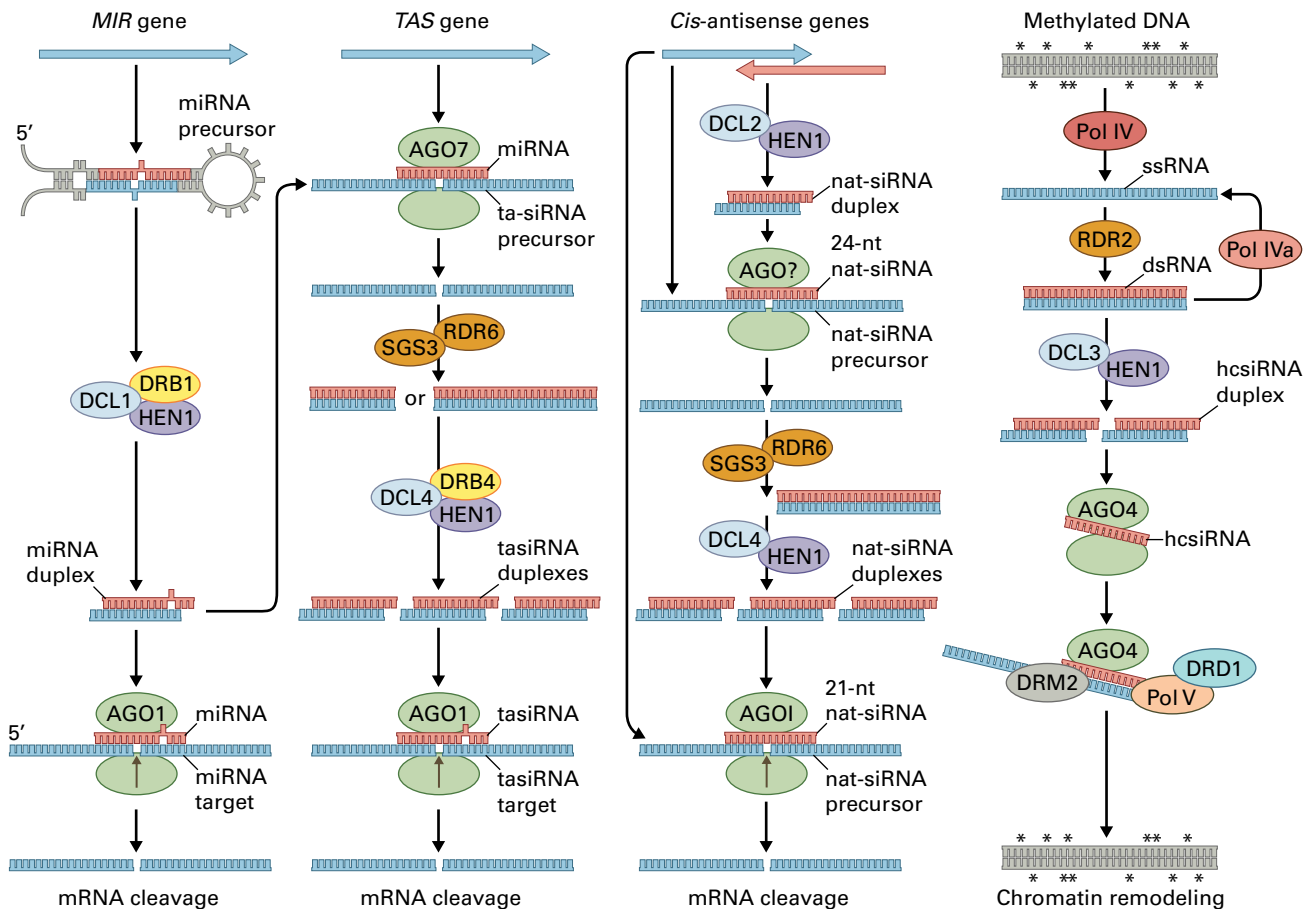

FIGURE 6.42 In *Arabidopsis*, four different Dicer-like (DCL) endonucleases produce small RNAs to direct a number of different pathways. DCL1 generates microRNAs (from imperfect hairpin-like RNA precursors) that regulate development-associated genes. DCL2 and 4 produce siRNAs (from perfect dsRNA from replicating RNA viruses) for viral defense, and DCL3 produces hcsiRNAs (from dsRNA from transposons and other genomic sequences) to target chromatin repression. The pathways are intertwined, sharing some common or similar components, such as RNA-dependent polymerases, double-stranded RNA binding proteins, and Argonaute (AGO) endonucleases. Two other pathways produce tasi- or natsiRNAs, which are involved in regulating plant development and responses to environmental stress.

FIGURE 6.43 Plants and animals produce microRNAs by DCL enzymes cleaving imperfect hairpin-like RNA precursors. The miRNA is shown in red. The compartments in which the processing steps occur are different between plants and animals, as is the method of directed gene repression. In plants, the mRNAs of the target genes are cleaved by miRNA-directed Argonaute (AGO), whereas in animals the AGO operates by translational repression. In the photographs, the top *Arabidopsis* mutant plant has a defective DCL1 protein and shows a severely distorted developmental phenotype. The bottom *Arabidopsis* plant has a wild-type DCL1 gene and shows normal inflorescence development.

ascending register to each newly discovered miRNA, regardless of the species from which it was discovered. The first plant miRNA recorded in the registry was its 156th miRNA, and it came from *Arabidopsis*, so it is called *AtmiR156*. Ten different loci in the *Arabidopsis* genome encode this miRNA, so the miRNA from each locus is differentiated by an alphabetic suffix (i.e., *AtmiR156a* to *AtmiR156j*).

Overall, hundreds of genes are regulated by miRNAs, which downregulate their expression levels in different tissues or at different times. In some cases, miRNAs control developmental transitions and responses to environmental stresses, and in others they provide sharp, tissue-specific expression boundaries. In contrast to animal miRNAs, which act by translational repression, plant miRNAs operate mostly by cleaving the mRNA of the target gene (Fig. 6.43).

Like miRNAs, tasiRNAs and natsiRNAs downregulate gene expression by directing AGO-mediated cleavage of target gene mRNAs. In *Arabidopsis*, tasiRNAs are generated from only four template RNAs, and their main function is to regulate the expression of auxin response factors. In contrast, there are more than 2000 potential natsiRNA-targeted

Arabidopsis genes. The principal role of natsiRNAs is thought to be the provision of an additional layer of gene regulation in response to environmental stresses.

The most abundant DCL-produced small RNAs in plants are hcsiRNAs. They are produced from and act upon transposons, repeated elements, and the heterochromatic regions of the plant genome. Unlike mi-, si-, tasi-, and natsi-RNAs, the 24-nt hcsiRNAs do not regulate gene expression by cleavage of mRNAs. Instead they operate by inhibiting transcription (see Section 6.8.7) by recruiting histone modifiers and DNA methyltransferases to their target regions in the chromosome. hcsiRNA-directed chromatin remodeling protects the genome from the deleterious effects of mobile transposons. It is increasingly implicated in short-term epigenetic alterations in response to environmental stresses and in determining the developmental fate of a cell.

In addition to snRNAs, snoRNAs, and the DCL-generated small RNAs, other types of small, stable RNA molecules have also been identified (Table 6.4). RNase P, an enzyme required for processing tRNAs, contains an integral RNA component. The 7SL RNA of the signal recognition

TABLE 6.4 Small RNAs in plants.

Type	Names	Location	Proposed function
Small nuclear RNAs (snRNAs)	U1, U2, U4 through U9, U11, U12,	Nucleoplasm	Pre-mRNA splicing
	U7	Nucleoplasm	Histone pre-mRNA processing, poly(A) addition
Small nucleolar RNAs (snoRNAs)	U3, U8, U13 through U40	Nucleolus	Pre-rRNA processing
Short interfering RNAs (siRNAs)	siRNA	Cytoplasm	Virus defense
MicroRNAs (miRNAs)	miR156 to miR5666	Cytoplasm	Regulation of development and stress responses
Trans-acting siRNAs (tasiRNAs)	siR255 to siR1778	Cytoplasm	Regulation of auxin response factors
Natural-antisense siRNAs (natsiRNAs)	natsiRNA	Cytoplasm	Gene self-regulation
Heterochromatic siRNAs (hcsiRNAs)	hcsiRNA	Nucleus	Epigenetic regulation
Other small RNAs	RNase P	Nucleoplasm, plastids, mitochondria	Pre-tRNA processing
	7SL	Cytoplasm	Protein transport

particle functions in conjunction with proteins during the transport of proteins into the endoplasmic reticulum (see Chapter 4).

6.8 RNA processing

Although transcription is a complex and highly regulated step in the expression of a gene, it represents only the first in a series of events necessary to produce a functional RNA. RNA can be modified extensively, but most primary transcripts in eukaryotic cells must also be processed to yield mature RNA products. The coding regions of many eukaryotic genes are interrupted by sequences that do not appear in the mature RNA. The primary transcripts synthesized by RNA polymerases, therefore, include stretches of RNA that contribute to the final gene product (**exons**) and noncoding, intervening sequences that must be removed before the RNA can function (**introns**). In the case of pre-mRNAs transcribed from genes containing introns, the intron sequences must be removed to produce an mRNA molecule that codes directly for the protein. The process by which the introns are excised from a pre-rRNA and the exons are rejoined to yield the mature RNA sequence is called **RNA splicing**.

6.8.1 Introns are found in RNAs encoded in all three genomes of plant cell

Introns have been found in most classes of genes and occur in the nuclear, chloroplast, and mitochondrial genomes. However, the number of introns and frequency of intron-containing genes varies among plant species and organelles. For example, 155 introns account for 40% of the plastid genome of *Euglena*, whereas the chloroplast DNA of the red alga *Porphyra* lacks introns entirely. Most protein-coding genes in the plant cell nucleus contain one or more introns, but some, such as the maize (*Zea mays*) zein gene, do not. It is not unusual for some members of a gene family to have multiple introns and other members to contain none. No introns have been reported in 5.8S and 5S rRNA genes or in any of the plant snRNA genes.

Most introns can be classified into four general categories based on their structural features and the mechanisms by which they are spliced (Table 6.5). Nuclear pre-mRNA introns are the most prevalent type. In mammalian genes, these introns are highly variable in length, ranging from less than 100 nt to 100 kb, but they are typically shorter in plant genes. Nuclear pre-tRNA introns, which are found only in a subset of nuclear tRNA genes, are usually short and distinct from mRNA introns. Group I and II introns, which are classified

TABLE 6.5 The four major types of introns.

Type	Structural features		
	Length (nucleotides)	Splice sites	Occurrence
Nuclear pre-mRNA	>70	G↓GU...AG↓N*	Nuclear mRNAs
Nuclear pre-tRNA	11–13	not conserved	Nuclear tRNAs
Group I-type	>200	U↓N...G↓N	Plastid tRNA, rRNA, and mRNAs
Group II-type	<200 to >400	N↓GYGCG...AY↓N†	

*Minor classes of nuclear pre-mRNA introns contain the splice site sequence N↓GC...AG↓U and N↓AU...AC↓N, in which N represents any nucleotide.

†Y represents a pyrimidine nucleotide.

according to their primary and secondary structures, occur in the mitochondrial genomes of fungi, as well as in plant mitochondria and plastids. A fifth category of introns, Group III, was identified in the genus *Euglena*, in which more than 100 examples of this type of intron are now known.

6.8.2 The introns of plant nuclear pre-mRNA tend to be AU-rich and have conserved sequences at their splice junctions

Introns in plant pre-mRNAs vary considerably in length—from 70 nt to well over 7 kb—but most range from 80 to 140 nt. A minimum length is required for efficient splicing of these introns, because introns of less than 70 nt are rarely found in protein-coding genes. In contrast to the introns in the nuclear genes of animals, plant nuclear pre-mRNA introns tend to be enriched for adenosine and uridine ribonucleotides. In dicots, these introns contain 70% A-U base pairs on average. The composition of the pre-mRNA introns of monocots is 60% A-U on average, although some contain as few as 30% A-U base pairs.

The nucleotide sequences surrounding each exon–intron junction are highly conserved. In almost all plant nuclear mRNA introns, the boundary sequences at the 5′ splice site (donor site) and the 3′ splice site (acceptor site) consist of 5′ GU and AG 3′; this characteristic is known as the GU-AG rule. In rare instances, the intron splice site sequences are 5′ GC...AG 3′ or 5′ AU...AC 3′. An additional structural element, the branch site, is usually located 20–40 nt upstream from the 3′ splice site. During intron excision, the 5′ end of the intron binds to an adenine residue at the branch site, forming a lariat (Fig. 6.44). A conserved branch site sequence, UACUAAC is found in yeast introns, but this sequence is not strictly conserved in plant or mammalian introns. The branch site adenine in the conserved sequence has been underlined.

Unlike the case with animals, it has been difficult to obtain from plant tissues an *in vitro* splicing system that faithfully

reproduces the *in vivo* pre-mRNA splicing reaction. However, the fundamental mechanism of pre-mRNA splicing in plants probably resembles that of mammals and yeast, because all of the conserved elements present in plant introns, that is, the 5′ and 3′ splice sites and the branch site, are similar to those found in the introns of mammals and yeast.

6.8.3 The position of nuclear tRNA introns is conserved, but their sequences are not

Introns in eukaryotic nuclear tRNA genes are short (11–60 nt). The 5′ splice site is located one nucleotide distal to the anticodon. There is no conserved sequence at the splicing junctions, but the introns contain a sequence that is complementary to the anticodon of the tRNA. Nuclear tRNA splicing is best understood in yeast. An *in vitro* pre-tRNA splicing system from wheat germ has provided a model for nuclear pre-tRNA splicing in plants, which is similar to that in yeast cells (Fig. 6.45).

6.8.4 Group I introns can self-splice and act as mobile genetic elements

Group I introns are distributed in the mitochondria of yeasts and other fungi, the nuclear rRNA genes of certain unicellular eukaryotes (e.g., *Tetrahymena*), and the organellar genes of plants. Group I introns are ribozymes (RNA molecules with catalytic activity) and reflect the presumed importance of RNA-catalyzed splicing reactions early in evolution. Group I intron sequences, which fold into complex secondary structures, begin the splicing reaction by binding and activating a G nucleotide. The 3′-hydroxyl of the activated G attacks the 5′ splice site group and catalyzes the cleavage of the phosphodiester bond at that site, releasing an exon (Fig. 6.46A). The 3′-hydroxyl of the free exon then attacks the 3′ splice site to release the intron and ligate the exons. Some self-splicing group I introns remain today, for example in the nuclear

FIGURE 6.44 Steps in the intron splicing of nuclear pre-mRNA. Pre-mRNA intron splicing occurs within a large ribonucleoprotein complex, called the spliceosome, which assembles on pre-mRNA. The spliceosome contains the snRNAs U1, U2, the U4/U6 complex, and U5, which are associated with small ribonuclear proteins (snRNPs), and non-snRNP protein factors. The splicing reaction is initiated by the nucleophilic attack of the 2'-hydroxyl group of the branch site adenosine on the 3' → 5'-phosphodiester bond at the 5' splice site. The 5' guanosine of the exon-intron boundary and the branch site adenosine together form a 2' → 5' phosphodiester bond, generating the lariat intermediate and releasing the 5' exon. Splicing is completed with a second nucleophilic attack by the 3'-hydroxyl group of the 5' exon on the phosphodiester bond at the 3' splice site, which ligates the exons and releases the intron lariat.

rRNA genes of *Tetrahymena* (where they were first discovered) and in certain chloroplast and mitochondrial genes.

Several group I introns, including the intron of the plastid 23S rRNA gene from *Chlamydomonas reinhardtii*, are mobile genetic elements. In a process known as “intron homing,” these mobile introns are transmitted with high frequency to the progeny of genetic crosses between parents that have the intron and parents that do not. All mobile introns encode a DNA endonuclease that specifically recognize the intron-less allele and generates a double-strand break in the DNA near the insertion or “homing” site. This break is thought to initiate the replicative integration of the intron into the intron-less allele.

6.8.5 Group II introns and nuclear pre-mRNA introns share the same splicing mechanism

Group II introns are found in fungal mitochondrial genes, as well as in plant mitochondrial and plastid genes (see Box 6.6). Although group II introns differ significantly from nuclear pre-mRNA introns in their structure, they do share certain common features. Group II introns follow the GU-AG rule: the

sequences at their 5' and 3' splice sites resemble those of nuclear pre-mRNA introns and contain a conserved branch site adenine. This finding indicates the group II introns and nuclear pre-mRNA introns have a common evolutionary origin and share the same splicing mechanism. Some of the group II introns in yeast mitochondria self-splice in vitro, using a particularly reactive A residue in the intron sequence as the attacking group for the formation of the lariat structure (Fig. 6.46B). Autocatalytic splicing has not been observed in Group II introns from plant plastids or mitochondria, suggesting these introns require additional factors for efficient splicing.

6.8.6 Precursor RNAs are processed extensively to create functional RNA molecules

Most eukaryotic genes are transcribed as precursor RNA (pre-RNA) molecules, which are then processed into shorter RNA species (mature RNAs). Extensive processing and modification are highly regulated, critical aspects in the production of functional RNA forms. Only certain species of small, stable RNAs that are transcribed by RNA polymerase III do not undergo extensive processing.

FIGURE 6.45 The splicing pathway of pre-tRNA. An endonuclease cleaves the pre-tRNA at both ends of the intron (red arrows). This results in the formation of a cyclic 2',3'-phosphate group at the 3' end of the 5' tRNA segment, as well as a free 5'-hydroxyl group at the 5' end of the 3' tRNA segment. The cyclic phosphate group is cleaved to form a 2'-phosphate group. After the free 5' hydroxyl of the 3' tRNA segment is phosphorylated, both halves of the tRNA are joined by an RNA ligase. A 2'-phosphatase removes the 2'-phosphate group to yield the mature spliced tRNA.

The transcription units in the nuclear rRNA gene cluster that encode the 17S, 5.8S, and 25S rRNA molecules are transcribed by RNA polymerase I into a single, long precursor molecule. The rRNA precursor molecule then undergoes a series of cleavage and methylation steps to yield mature the 17S, 5.8S, and 25S rRNA molecules (Fig. 6.47). The 5.8S rRNA is derived from the same RNA intermediate as the 25S rRNA; the bases of these two RNA products remain paired even after the intergenic RNA spacer sequences have been removed. Transcription of the 5S rRNA from the corresponding nuclear genes is independent and is catalyzed by RNA

polymerase III. This cytoplasmic 5S rRNA is unusual in that it requires no processing.

All four plastid rRNA molecules are encoded as a polycistronic transcription unit that also includes the two tRNA genes encoding tRNA^{Ile} and tRNA^{Ala}, each of which contains an unusually long intron. Following a complex processing pathway involving specific nucleases, the precursor RNA is then cleaved into 16S, 23S, 4.5S, and 5S rRNAs (Fig. 6.48). Once removed from the polycistronic RNA, the cleaved tRNA precursors are also processed and their introns are spliced to produce functional tRNA^{Ile} and tRNA^{Ala} molecules. Ribosomal

FIGURE 6.46 Self-splicing mechanisms remove Group I- and Group II-type introns. Splicing of Group I introns is initiated when a guanosine molecule or its 5' phosphorylated derivative binds to an intron sequence. The 3' OH group of the bound guanosine attacks the phosphate group at the 5' splice site, cleaving the phosphodiester bond at that site. The 3' OH at the end of exon 1 reacts with the phosphate at the 3' splice site, ligating the two exons and releasing a linear intron that is subsequently circularized (not shown). In contrast, the mechanism of group II introns self-splicing resembles splicing of nuclear pre-mRNAs, but does not involve the formation of a spliceosome (see Fig. 6.44).

BOX 6.6

Certain Group II introns of plant organelles are removed by a *trans*-splicing mechanism

Splicing reactions are typically intramolecular and join exons from a single transcript (*cis*-splicing). However, splicing events discovered in plant chloroplasts and mitochondria involve two or more RNA molecules (*trans*-splicing). The tobacco (*Nicotiana tabacum*) chloroplast *rps12* gene (see Fig. 6.46B) is organized as two separate loci in the genome. Each locus produces an independent transcript: one encodes exon 1, and the other encodes the RNA product exon 2-intron-exon 3. Following transcription, *trans*-splicing joins exons 1 and 2; exons 2 and 3 are spliced in *cis* after removal of the intron. The *Chlamydomonas* chloroplast *psaA* gene (see Fig. 6.46B) is another example of a discontinuous gene in which

three exons are encoded by three separate loci in the genome. In this case, two *trans*-splicing events generate the mature mRNA from three different transcripts.

In angiosperm mitochondria, the *nad1*, *nad2*, and *nad5* genes are also discontinuous, and their transcripts require *trans*-splicing to produce functional mRNAs. In contrast, the *nad2* and *nad5* genes in the mitochondrial genomes of ferns are continuous, and their introns are spliced in *cis*. These continuous genes are thought to be the ancestral genes that gave rise to the discontinuous genes of flowering plants. The unique *trans*-splicing mechanism may have co-evolved with the angiosperm genes as the latter were cleaved into separate transcription units.

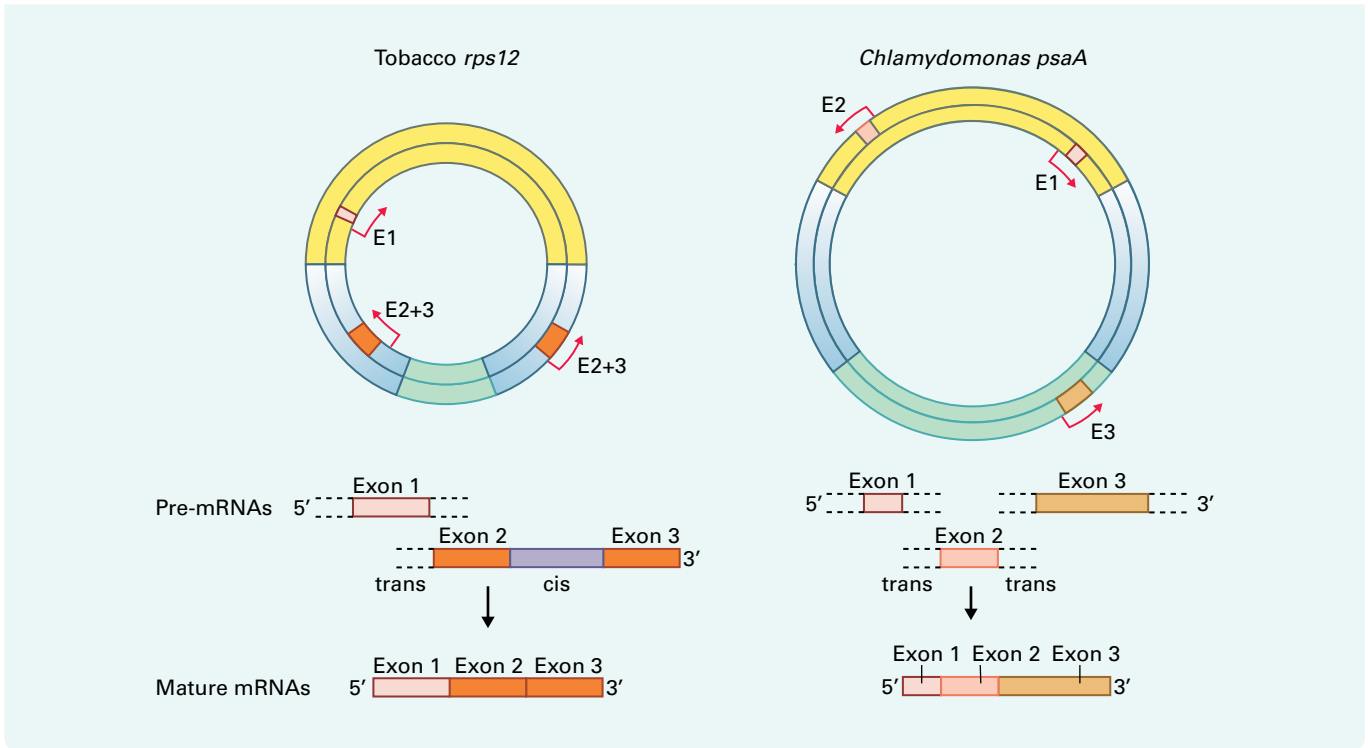

FIGURE 6.47 Processing of the nuclear-encoded 45S rRNA precursor molecule produces three mature rRNAs. The 17S, 5.8S, and 25S rRNAs are derived from a common precursor rRNA molecule by processing reactions that require several RNases. During processing, the 25S and 5.8S rRNAs become hydrogen bonded and remain paired after the processing is complete.

RNAs and tRNAs in plant mitochondria are also extensively processed from precursor molecules.

Unlike 5S rRNA, the tRNAs encoded by clusters of nuclear genes are transcribed by RNA polymerase III into precursor molecules that contain additional sequences at both the 5'

and 3' ends. These extra sequences are then removed by specific nucleases, followed by the addition of three nucleotides, CCA, to the 3' end. As discussed earlier, some tRNA precursors also contain introns that are spliced during processing to produce the functional tRNA molecule (see Fig. 6.45).

FIGURE 6.48 Processing of chloroplast pre-rRNA from plants. Unlike nuclear-encoded rRNAs, the chloroplast rRNA operon also encodes two tRNAs in the spacer regions that separate the 16S and 23S rRNA. These tRNAs are interrupted by long introns (approximately 1 kb) and require both processing and splicing to produce the mature tRNAs.

FIGURE 6.49 (A) A mature microRNA (indicated by red lines) is precisely cleaved from its primary transcripts by Dicer-like1 (DCL1) endonuclease. (B) The microRNA is excised as a 21-nt duplex made up of the miRNA (red line) and its partner miR* strand (blue line). The DCL1 cleavage sites are indicated by the arrows. When excised, the duplex RNA molecule has a 19-nt overlap between the strands and two nucleotide 3' overhangs.

6.8.7 RNA transcripts are processed into small regulatory RNAs

The small RNAs that regulate endogenous gene expression by guiding specific mRNA degradation and chromatin modification are processed from long double-stranded or self-

complementary single-stranded RNA molecules. Each of the four types of endogenous regulatory small RNAs are generated by a Dicer-like (DCL) endonuclease (Fig. 6.43). In plants there are four types of DCLs (DCL1-DCL4). DCL1 cleaves a miRNA duplex out of a hairpin-like single-stranded transcript (Fig. 6.49A). This transcript is made by DNA-dependent

RNA polymerase II from *MIRNA* genes that reside in the intergenic regions of the genome. DCL1 specifically cleaves a 21-nt duplex from the hairpin-RNA with a staggered cut at each end to produce two nucleotide 3' overhangs. The tasi-, natsi-, and hcsiRNAs are cut by other DCLs from dsRNA molecules synthesized by **RNA-dependent RNA polymerases** (RdRPs) from single-stranded templates. The same cytoplasmic RdRP produces dsRNA for tasi- and natsiRNA production, but is recruited to the tasiRNA template by a specific miRNA, and by a DCL2-produced small RNA for the natsiRNA template. The dsRNA precursor for hcsiRNA production is generated in the nucleus by a different RdRP acting on a transcript made by DNA-dependent RNA polymerase IV. No matter which DCL or which dsRNA or hairpin-like RNA substrate is being acted upon, the DCL excises a duplex of dsRNA from the substrate and transfers only one strand of the duplex of the Argonaute (AGO) endonuclease. In the case of miRNA production the loaded strand is the miRNA and the discarded strand is called the miR* or passenger strand (Fig. 6.49B). The cleavage of target mRNAs guided by mi-, tasi-, and natsi-RNAs is predominantly mediated by AGO1. The recruitment of histone modifiers and DNA methyltrans-

ferases guided by hcsiRNAs is mediated by AGO4, which has a binding but not cleaving activity. The current model is that intergenic repeat regions of the genome have short transcripts produced by DNA-dependent DNA polymerase V which somehow remain associated with their template DNA and are accessible for recognition by hcsiRNA-loaded AGO4. This provides a way of recruiting the epigenetic modifiers to the appropriate genomic location (Fig. 6.43).

6.8.8 Some plastid mRNAs are polycistronic

Since the chloroplast genome of most plants contains about 150 genes, but only about 60 transcription units, it is likely most plastid mRNAs are first synthesized by chloroplast RNA polymerase into polycistronic mRNAs. While polycistronic bacterial mRNAs can be translated without further processing, polycistronic chloroplast mRNAs are first cleaved and processed to create monocistronic mRNAs (Fig. 6.50). The significance of this difference between bacterial and chloroplast

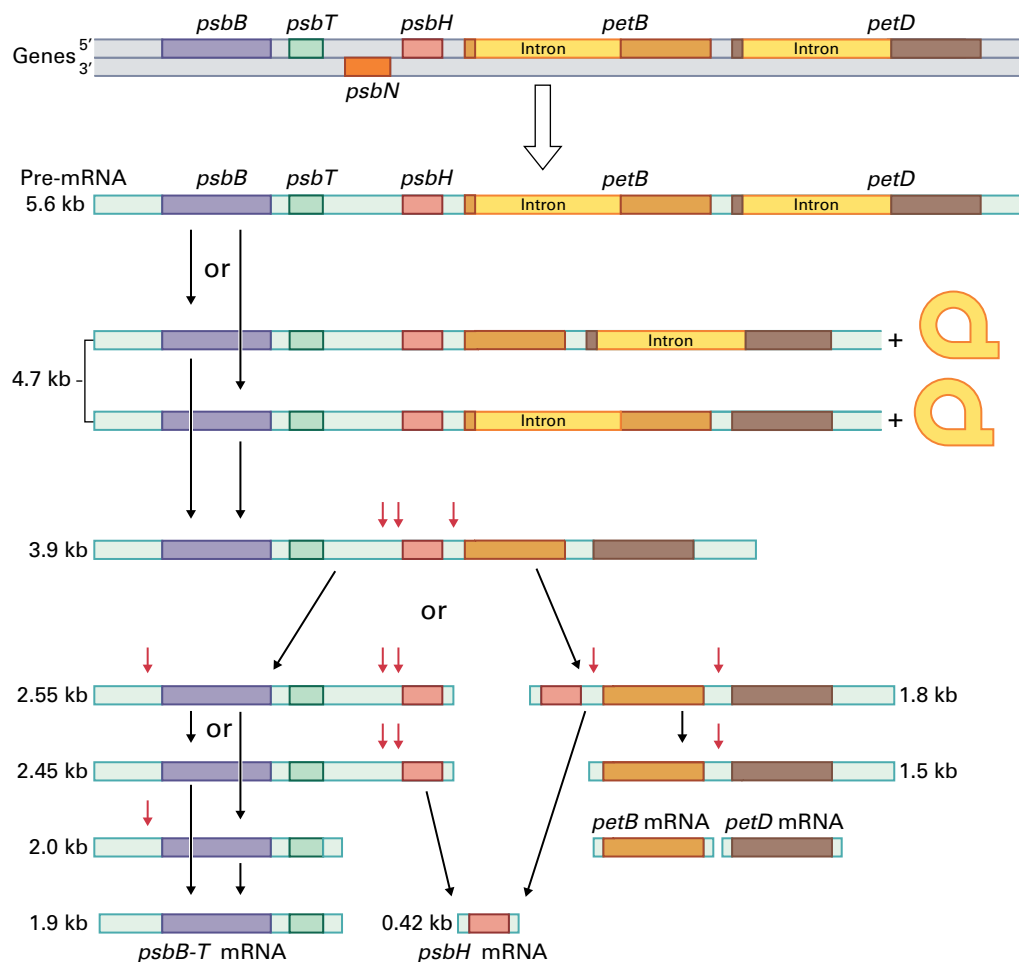

FIGURE 6.50 The transcript from the *psbB* operon in plant plastids is a typical example of the complex processing and splicing reactions that are required to cleave the polycistronic mRNA precursor into mature monocistronic mRNAs that can be efficiently translated. Black arrows indicate possible alternative processing steps, and red arrows indicate cleavage sites that have been experimentally confirmed. The *psbN* gene is encoded by the opposite DNA strand and, therefore, is not part of the polycistronic transcript.

polycistronic mRNAs is not well understood, although analysis of mutants that lack chloroplast functions has shown that, in some cases, processing is required for plastid mRNA translation. This suggests some details of the mRNA translation process in plastids differ from those in prokaryotes. With the exception of some closely linked genes, plant mitochondrial protein-coding genes are transcribed into monocistronic mRNAs.

6.8.9 RNA editing occurs in transcripts from plant organelles

RNA editing alters the protein-coding sequence of some mRNAs. This type of processing was first discovered in transcripts from mitochondrial genes of a trypanosome, in which the sequence of the RNA differs from the corresponding DNA sequence. Since then, RNA editing has been found in a number of different genetic systems, including plant mitochondria and chloroplasts.

Two types of RNA editing mechanisms alter primary transcripts: (a) insertion or deletion of nucleotides and (b) nucleotide conversion (i.e., modification or substitution), such as C to U (Table 6.6). Nucleotide insertion and deletion editing was first examined in the mitochondria of trypanosomes (Fig. 6.51A) and the slime mold *Physarum*, where transcripts are often extensively edited by insertion of long stretches of U. Short RNA molecules, called guide RNAs, contain the information required for editing. The guide RNAs are complementary to the edited portions of the mature mRNA. These guide RNAs contain short poly-U sequences at their 3' end that donate the Us inserted during editing by a mechanism that resembles RNA splicing.

Nucleotide conversions, which occur in transcripts of plant mitochondria and chloroplasts, mammals, viruses, and lower eukaryotes, result in less dramatic changes to the mRNA sequence. Multiple site-specific conversions from C to U (or, rarely, U to C) occur in primary transcripts from

both plastid and plant mitochondrial genomes (Fig. 6.51B). The frequency of RNA editing is organelle and gene specific, and the distribution of editing sites appears to be random. In mitochondria, C to U conversion occurs in nearly all protein-coding regions of transcripts. The total number of editing sites per genome has been estimated at 1,200 in wheat (*Triticum*) mitochondria, but only about 30 in the chloroplasts of flowering plants.

Editing of certain plant organellar mRNAs is essential for translation of a correct protein. Most nucleotide conversions change the first or second nucleotide in a codon, thereby altering the amino acid sequence of the protein (Fig. 6.52). Usually the amino acid change results in translation of a more highly conserved protein, as predicted by comparing the DNA sequence of a given gene and its edited mRNA transcript with DNA sequences for the same gene from organisms that do not edit mRNA. In rare cases, RNA editing occurs at the third codon position. Often, as a result of redundancy in the genetic code, such editing is silent and does not modify the predicted protein (see Chapter 9).

Editing can also shorten ORFs predicted from DNA sequences or produce new ORFs. The editing of glutamine codons (CAA and CAG) and the arginine codon (CGA) yields termination codons (UAA, UAG, and UGA), thereby introducing a premature termination of the ORF in both mitochondria and plastids. These edited stop codons generally convert the predicted C-terminal extension of a protein to the conserved protein size. Likewise, a threonine codon (ACG) can be converted to AUG. C to U editing can thus create both an initiation and a termination codon within the same transcript, producing a new ORF. These examples demonstrate that genomic DNA sequencing alone is not always sufficient to predict the products of organellar genes.

Editing processes in plant mitochondria and chloroplasts share certain features: C to U conversion and strong preferences for second codon positions and certain codon transitions. Furthermore, common sequence motifs around the editing sites are found in the transcripts of both organelles. These

TABLE 6.6 Occurrence of RNA editing.

Type	Organism	Organelle	Transcript	Modification

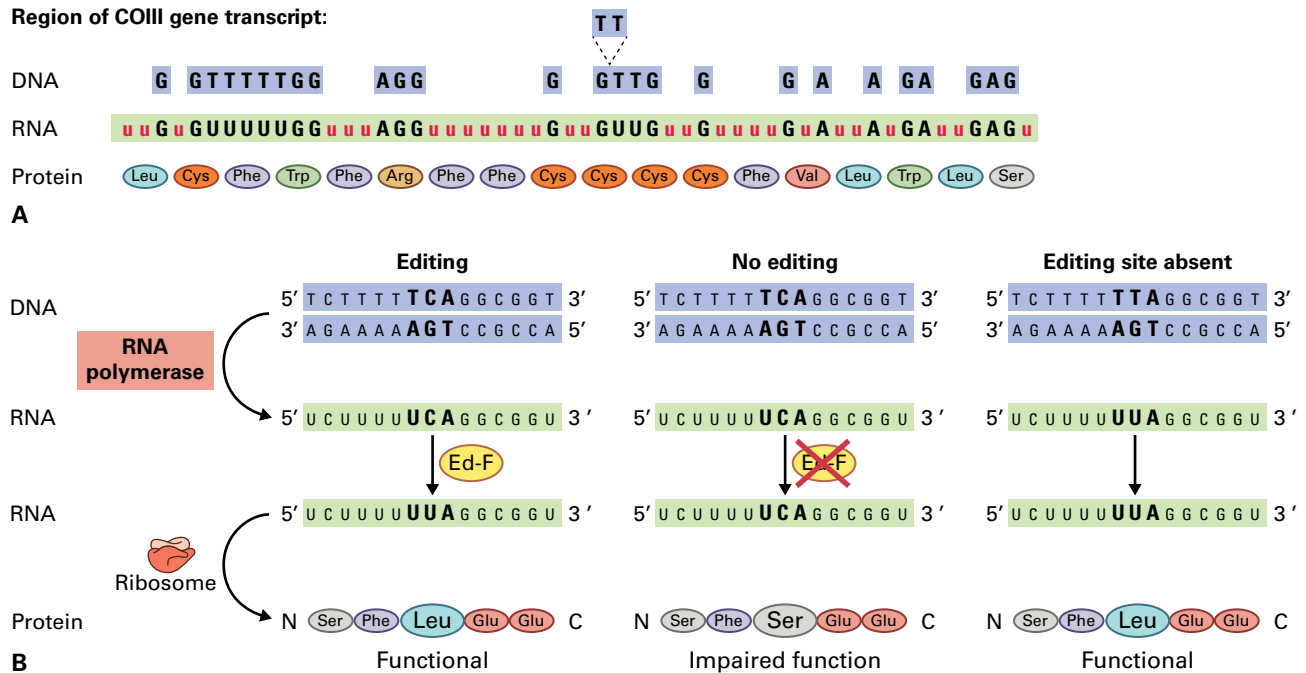

FIGURE 6.51 RNA editing in protein-coding regions of mitochondrial transcripts from the protozoan *Trypanosoma brucei*. (A) Comparison of the DNA sequence (purple) and RNA sequence (green) for the mitochondrial cytochrome oxidase III reveals striking differences. The RNA sequence is made considerably longer than the DNA sequence as the result of RNA editing, in this case the insertion of long stretches of Us. The protein encoded by the edited, mature mRNA has an amino acid sequence resembling the consensus sequence of cytochrome oxidase III proteins. The information required for RNA editing is provided by guide RNAs (not shown), which are complementary to portions of the edited mRNA. (B) RNA editing in chloroplasts of land plants changes specific cytidines into uridines on the RNA level. Often, editing affects TCA-serine codons and converts them into UUA-leucine codons (left panel). Nonediting of an editing site (middle panel) leads to defects usually resembling loss-of-function mutants of the gene whose transcripts remain unedited. Whether amino acids specified by nonedited codons are incorporated into the peptide chain, as depicted here, has not been thoroughly investigated yet. The absence of an editing site, for example a T being present already on the level of DNA (right panel), does not lead to a mutant phenotype.

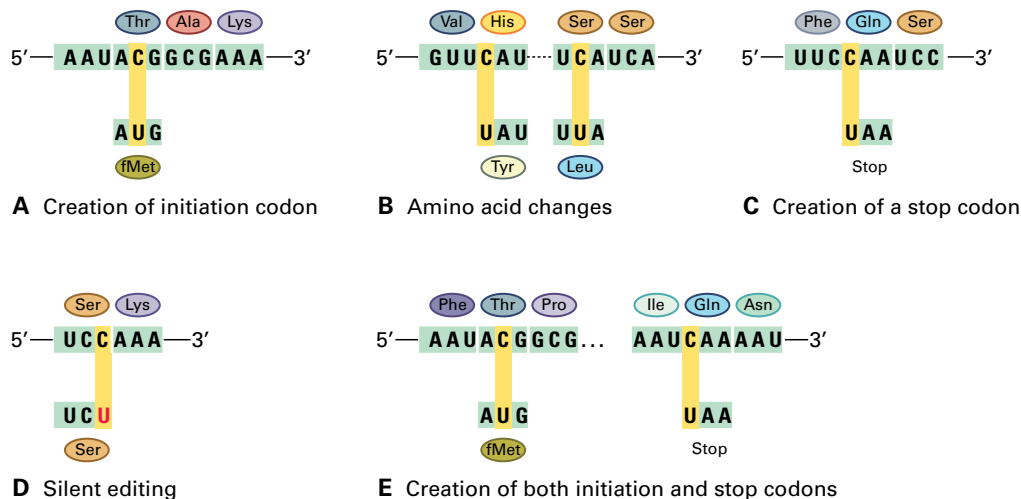

FIGURE 6.52 Several types of mRNA editing involving base substitutions can significantly alter the polypeptide products encoded by the RNA sequences. Base substitutions can produce translation initiation codons (A), result in amino acid changes (B), or create a stop codon (C), possibly leading to premature termination of translation. Certain base substitutions within coding regions may not alter the amino acid sequence (D), whereas others may introduce initiation and stop codons that result in a new open reading frame (E).

similarities suggest editing systems in chloroplast and mitochondria share components and perhaps mechanisms, although it is likely organelle-specific factors are also required. RNA edit-

ing in chloroplasts does not require translation, indicating that all protein components necessary for editing are encoded by the nuclear genome and imported into the chloroplast.

Summary

Genetic information is encoded in the nucleotide polymer of DNA. The DNA molecule is a double-stranded helix of two complementary strands of nucleotides that form hydrogen bonds between A-T and G-C base pairs. The genetic information is duplicated during DNA replication when DNA polymerases synthesize a new complementary nucleotide polymer, using each of the two parental strands in the double helix as templates. Although DNA is a stable molecule, it sometimes suffers damage from UV light or chemicals, or errors introduced by DNA polymerase during replication. If not repaired, this damage can cause mutations. Several repair mechanisms function to remove damaged nucleotides or incorrectly paired bases. Exchange of genetic information between DNA molecules in chromosomes is an important mechanism that drives evolution and establishes diversity among organisms. Exchange of genetic information occurs during recombination, when double-stranded DNA molecules are broken and rejoined with different DNA molecules. Before the genetic information stored in DNA can be expressed into a collinear

sequence of amino acids in proteins, it must be transcribed into RNAs by multiprotein enzyme complexes called RNA polymerases. Plants contain the three well-known types of eukaryotic nuclear RNA polymerase and an additional two that are involved in RNA-directed epigenetic regulation. Chloroplast (and probably mitochondrial) genes are transcribed by prokaryote-type RNA polymerases, which reflects their evolutionary origin. Most RNAs transcribed by RNA polymerases must undergo extensive processing before they can function in the translation of proteins, the formation of ribonucleoprotein complexes such as ribosomes, or the guidance of mRNA degradation systems. The protein-coding regions of many genes are also interrupted by noncoding sequences, called introns, which must be spliced out to produce functional RNAs. In some cases, the genetic information contained in genes differs from the information found in their corresponding RNAs, which have nucleotides added, deleted, or substituted. This RNA editing usually restores cryptic DNA information to produce proteins with evolutionary conserved amino acid sequences.

Amino Acids

*Gloria Coruzzi, Robert Last,
Natalia Dudareva, and
Nikolaus Amrhein*

Introduction

Amino acids are compounds that contain both an amino group and a carboxyl group, and the term “amino acid” is usually associated with one of the 20 “proteinogenic” amino acids that are incorporated into proteins during translation (Fig. 7.1 and see Chapter 10). In addition to these, plants also make several hundred structurally diverse, nonproteinogenic amino acids with no obvious roles in protein synthesis. The proteinogenic amino acids are L- α -amino acids of the general structure R-C α H(NH₂)COOH, with the exception of proline, which is a cyclic secondary amino acid.

In addition to their role in protein synthesis, amino acids perform essential functions in both primary and secondary plant metabolism. Some amino acids serve to assimilate nitrogen (N) and transport it from sources to sinks, and others serve as precursors to phytohormones, such as indoleacetic acid and ethylene (see Chapter 17), or to an immense variety of secondary compounds involved in the interaction of plants with their abiotic and biotic environments (see Chapters 21 and 22). Traditionally, many amino acid biosynthetic pathways were investigated by researchers interested in plant secondary metabolism; most were originally uncovered in microorganisms and found to be phylogenetically conserved between bacteria, fungi, and plants. Thus, investigation of these pathways in plants appeared to provide few opportunities for original research on topics such as the reaction mechanisms of the respective enzymes.

The progress, however, in plant molecular biology and genome research has allowed questions specific to these pathways in plants to be addressed, such as the regulation of the

expression of the isoenzymes involved in amino acid metabolism and their compartmentation, allosteric regulation, and specific functions. These investigations have revealed that amino acid biosynthesis and degradation are dynamic processes controlled by metabolic, environmental, and developmental factors. This chapter highlights examples in which combined molecular, biochemical, and genetic approaches have helped to define the pathways and uncover regulatory mechanisms of amino acid biosynthesis in plants. Knowledge of amino acid biosynthesis in plants has implications for applied research, because several enzymes of amino acid biosynthesis are targets for herbicide action, and a number of genes have been targets in the metabolic engineering of transgenic crop plants.

7.1 Amino acid biosynthesis in plants: research and prospects

7.1.1 Amino acid biosynthesis pathways in plants have been inferred largely from microbial pathways

The carbon skeletons used by plants for amino acid biosynthesis are derived from only a handful of intermediates of glycolysis, photosynthetic carbon reduction, the oxidative pentose phosphate pathway, and the citric acid cycle (Fig. 7.1).

Carbon metabolite	Amino acid derivative(s)

FIGURE 7.1 Organic acid products of glycolysis, the citric acid cycle, and the Calvin-Benson cycle provide the carbon skeletons from which 19 of the 20 standard amino acids are synthesized. Not shown is erythrose 4-phosphate, a substrate in the synthesis of all three aromatic amino acids, and ribose 5-phosphate, a substrate in both histidine and tryptophan synthesis (see Fig. 7.2). Histidine is a special case, because formation of the carboxyl group is the last step in its biosynthesis. In this scheme, amino acids are arranged in relation to their respective common organic acid precursor. In textbooks of biochemistry, you usually find amino acids arranged with respect to side chain hydrophobicity. Both the one- and three-letter codes, respectively, are indicated.

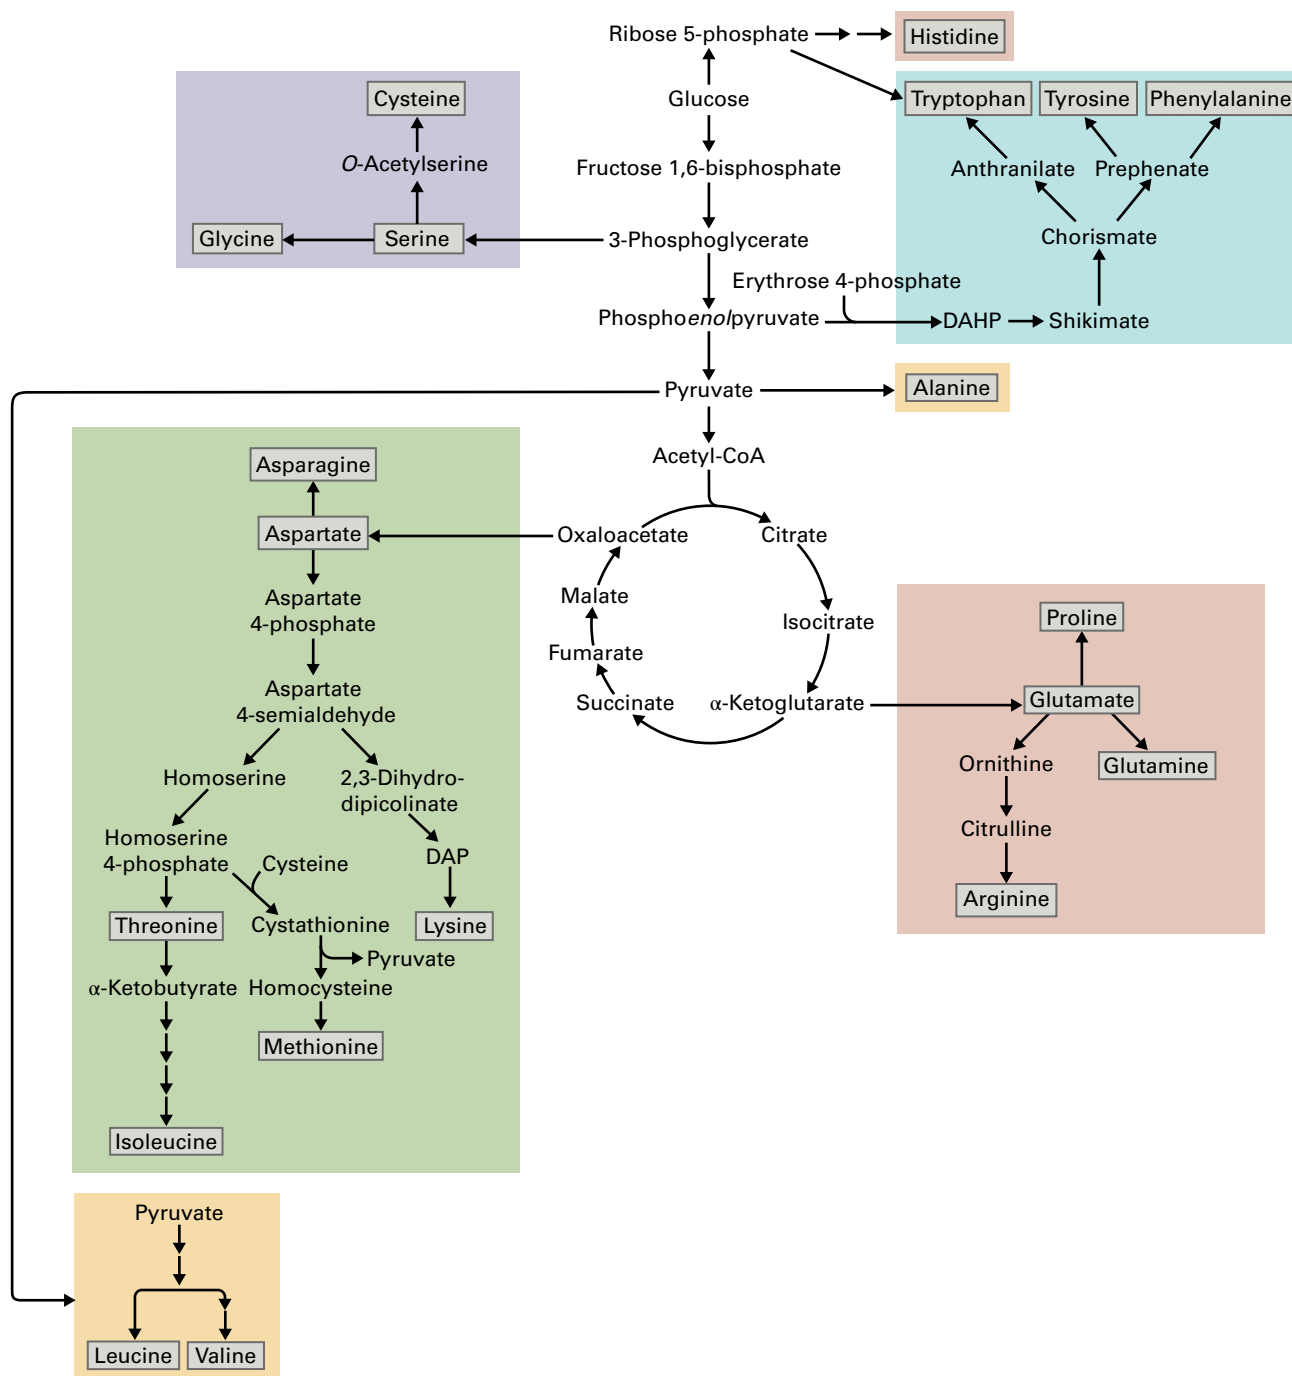

FIGURE 7.2 Overview of the biosynthesis of the 20 proteinogenic amino acids in plants. Biosyntheses of serine, glycine, and cysteine are referred to in Chapters 14 and 16, respectively. Alanine is derived from the glycolysis intermediate pyruvate in a single transamination step. Ribose-5-phosphate is produced in the oxidative pentose phosphate cycle.

The pathways generally accepted for amino acid biosynthesis in plants (Fig. 7.2) have been inferred in large part from those defined for bacteria and fungi, and these were identified through the combined use of auxotrophic mutants, isotopically labeled precursors, enzyme studies, and the analysis of the corresponding genes. Historically, the isolation of comparable amino acid biosynthesis mutants in plants was hampered by several factors, including gene redundancy and problems associated with supplementing auxotrophs.

It is not known whether plants use all the enzymatic pathways and control points observed in bacteria and yeast, as some variation also exists within these microorganisms. Indeed, plant amino acid biosynthetic pathways demonstrate levels of complexity not found in microbes. Whereas bacteria possess small genomes and lack organelles, plants may contain multiple genes for each step in a pathway, and sequential or even identical steps may occur in distinct subcellular compartments. In addition, although a number of plant **amino**

acid transporters have been identified, the mechanisms controlling the intra- and intercellular transport of amino acids and their intermediates are poorly understood. Furthermore, it is impossible to predict the *in vivo* function of an **isoenzyme** based solely on *in vitro* biochemistry. Plant extracts often contain mixtures of isoenzymes that do not coexist in the same organelle or even cell type within a plant tissue; therefore, the *in vitro* flux measurements used to define rate-limiting steps in the biosynthetic pathways of unicellular organisms have limited significance for study in multicellular plants.

In recent years, however, several different types of **genetic screens** have identified plant mutants in amino acid biosynthetic enzymes. Additionally, genes homologous to those known to be involved in amino acid biosynthesis, metabolism, and transport in other organisms can be identified in the increasingly available number of sequenced genomes, and their function *in vivo* can be examined using genetic approaches. Though investigations of amino acid biosynthesis mutants in plants have centered on *Arabidopsis*, progress in genomics, transcriptomics, proteomics, and metabolomics now allows extension of these investigations to crop plants, weeds, medicinal plants, or other species of interest in phylogenetic or ecological contexts.

7.1.2 Amino acid pathways in plants are targets for basic and applied research

Uncovering the features of amino acid biosynthesis unique to plants should stimulate both fundamental and applied research. One goal is to understand the genes that control growth-limiting processes (e.g., the assimilation of inorganic nitrogen into amino acids) and the factors that regulate the synthesis of plant

secondary compounds from amino acid precursors. Such studies should also provide a framework for manipulating amino acid biosynthesis pathways in transgenic plants. For example, enzymes in several pathways have been identified as targets for herbicides, and in some cases, the genes encoding these enzymes have been used for engineering herbicide resistance (see Box 7.1). Eventually, insights from amino acid biosynthesis research may also provide enhanced crop resistance to osmotic stress (see Chapter 22), improved food protein composition, and production of pharmaceutically useful compounds. Therefore, the structural and regulatory genes controlling amino acid biosynthesis in plants are of interest not only to biochemists, but also to agricultural biotechnologists.

7.2 Assimilation of inorganic nitrogen into N-transport amino acids

The acquisition of N-containing ions, predominantly **nitrate**, and their conversion to the fully reduced form of inorganic nitrogen, that is, the **ammonium ion**, are described in Chapter 16. Here, we consider the entry of the reduced nitrogen into the amide and amine nitrogen of amino acids.

The initial assimilation products, mainly glutamate and glutamine, fulfill immediate functions as substrates in protein biosynthesis, but they also function in N-transport and readily donate nitrogen to the biosynthesis of amino acids, nucleobases, and a host of other N-containing compounds. Alternatively, nitrogen assimilated into glutamate and glutamine may be incorporated into aspartate and asparagine.

FIGURE 7.3 Concentrations of free amino acids in light- and dark-adapted *Arabidopsis*, determined by high-performance liquid chromatography. Aspartate, glutamate, asparagine, and glutamine constitute 70% of total free amino acids. Asparagine concentrations are induced dramatically in dark-adapted plants, whereas glutamine concentrations increase in the light. These light-induced reciprocal changes in concentrations of asparagine and glutamine reflect the distinct natures of these amino acids. Glutamine, a metabolically very reactive amino acid, is preferentially synthesized in the light, whereas asparagine, which is relatively inert, is preferentially synthesized in the dark. Asparagine carries more nitrogen atoms per carbon atom than does glutamate and so is a more economical compound to transport nitrogen when carbon skeletons are limiting (in the dark). Increased concentrations of glycine in light-adapted plants result from photorespiration, which produces glycine as a byproduct.

Aspartate is a metabolically reactive amino acid that serves as the nitrogen donor in numerous **aminotransferase** reactions and is the precursor of a large family of amino acids (see Fig. 7.2); asparagine, on the other hand, is relatively inert and serves primarily as a nitrogen transport and storage compound. Glutamate, glutamine, aspartate, and asparagine are the major amino acids translocated in the phloem, but also the xylem, of most species, including corn (*Zea mays*), pea (*Pisum sativum*), and *Arabidopsis*. Total amino acid concentrations in the phloem are in the range of 100–200 mM and are about tenfold lower in the xylem. Tissue and phloem concentrations of these transported amino acids are not static; they are modulated by factors such as light (Fig. 7.3) and nutritional or developmental stage.

The following sections focus on the enzymes that synthesize N-transport amino acids: **glutamine synthetase** (GS), **glutamate synthase** (GOGAT), **glutamate dehydrogenase** (GDH), **aspartate aminotransferase** (AspAT), and **asparagine synthetase** (AS) (Fig. 7.4). These enzymes are involved in the **primary assimilation** of inorganic nitrogen from the soil as well as in the reassimilation (**secondary assimilation**) of free ammonium within the plant. In plants, ammonium is released from organic compounds during several metabolic processes, including the **deamination of amino acids** during either seed germination or the formation of phenylpropanoid compounds (e.g., lignins), and, in particular, photorespiration in green tissues. Unlike animals, plants do not excrete nitrogenous wastes: the liberated ammonium must be reassimilated to support plant growth. **Photorespiratory ammonium release** (see Chapter 14) may exceed primary nitrogen assimilation by a factor of ten, so a plant unable to recycle ammonium would quickly suffer from severe ammonia toxicity.

7.2.1 The GS/GOGAT cycle is the principal nitrogen assimilation pathway in plants

GS catalyzes the ATP-dependent assimilation of ammonium into glutamine, using glutamate as a substrate, and it functions in a cycle with **GOGAT** (glutamine-2-oxoglutarate aminotransferase), which catalyzes the reductive transfer of the amide group from glutamine to **α -ketoglutarate** (2-oxoglutarate), forming two molecules of glutamate (Fig. 7.5). In the coupled reactions of GS and GOGAT, α -ketoglutarate is reductively aminated to form glutamate, and ATP is hydrolyzed. In fact, GS transfers the terminal phosphoryl group of ATP first to glutamate to form **γ -glutamyl phosphate**, and the activated carboxyl group of this compound then reacts with ammonia to form glutamine. The **GS/GOGAT cycle** is considered the principal route of **ammonium assimilation** in plants.

Distinct isoenzymes of both GS and GOGAT have been identified in all plant species examined. The two GS isoenzymes, GS1 and GS2, have been localized to the cytosol and

chloroplast, respectively (Fig. 7.6), but GS2 has also been detected in mitochondria of *Arabidopsis*. The mechanism by which GS2 is directed to either organelle (e.g., through splice variants or alternative use of initiation codons) is unknown, but the mitochondrial GS2 would ensure that ammonia released from glycine during photorespiration is immediately recaptured. Either of two alternative shuttles, an **ornithine-citrulline shuttle** (see Section 7.6.4) or a **glutamine-glutamate shuttle**, may move toxic ammonia in bound form from the mitochondria to the chloroplasts. GS1 is encoded by a small multigene family, and the expression profiles and physicochemical properties of the isoforms differ (see below).

The two major classes of plant GOGAT enzymes are a **ferredoxin-dependent GOGAT** (Fd-GOGAT, found also in cyanobacteria) and an **NAD(P)H-dependent GOGAT** (NAD(P)H-GOGAT); the eubacterial enzyme is NADPH dependent. Subcellular fractionation and identification of plastid-targeting sequences have shown that both Fd-GOGAT and NADPH-GOGAT are plastid localized (Fig. 7.6). Some proteins in the latter class are more active in the presence of NADH than NADPH and are, therefore, termed NADH-GOGAT, which are expressed preferentially in nonphotosynthetic tissues, such as roots.

GS has a high affinity for ammonium and so can operate at the low ammonium concentrations present in living cells (K_m 3–5 μ M). Labeling studies that trace the fate of $^{15}\text{NH}_4^+$ confirm that the label is incorporated primarily into the amide group of glutamine and then appears in the amino group of glutamate (see Fig. 7.5) and other amino compounds, including glutamine. The addition of GS inhibitors, for example, the glutamate analogs **methionine sulfoximine** or **L-phosphinothricin** (MSO or L-PPT, respectively; Fig. 7.7), inhibit, but do not completely block labeling of the amide group of glutamine and the amino group of glutamate. GS transfers the phosphate group from ATP to MSO, and the phosphorylated product forms an irreversible dead-end complex with the enzyme. This complex has been used to determine the intermediate state structure of GS1 from maize (*Zea mays*) after formation of **γ -glutamyl phosphate** (see above). Maize GS1 has a unique homodecameric structure of \approx 400 kDa, whereas bacterial GS are homododecamers. **Phosphinothricin** (also known as **glufosinate**) forms a dead-end complex with GS as well and is used as an herbicide. Another GS inhibitor is **tabtoxinine- β -lactam** (Fig. 7.7) which is produced by plant pathogenic *Pseudomonas syringae* as a phytotoxin. The GOGAT inhibitor **azaserine** (a glutamine analog) blocks incorporation of the radiolabel into glutamate. These results, among others, support the hypothesis that the majority of inorganic nitrogen is assimilated through the GS/GOGAT pathway in plants.

At first glance, the GS/GOGAT pathway with its two coupled reactions and energy consumption looks unnecessarily complicated in comparison with the alternative direct reductive amination of α -ketoglutarate by **glutamate dehydrogenase**, but as discussed in Section 7.2.4, this is not the case.

FIGURE 7.5 The glutamine synthetase–glutamate synthase (GS/GOGAT) pathway is thought to be the principal mechanism of primary and secondary ammonium assimilation. Sites of action are shown for several enzyme inhibitors. Fdx, ferredoxin.

FIGURE 7.6 Isoenzymes of glutamine synthetase (GS) are present in both the plastids (GS2) and the cytoplasm (GS1). Fdx, ferredoxin.

7.2.2 Molecular and genetic studies demonstrate that cytosolic and chloroplast GS isoenzymes perform distinct roles in vivo

GS1 and GS2 can be separated by ion-exchange chromatography and so can be assayed and studied individually from plant extracts. Although the biochemical properties of these enzymes do not differ significantly when assayed in vitro, GS1 and GS2 have distinct physiological functions in vivo. GS2 is the predominant isoenzyme in leaves, where it may function both in primary ammonia assimilation and the reassimilation of photorespiratory ammonia. **Cytosolic GS1** isoenzymes are present at low concentrations in leaves and at higher concentrations in roots, suggesting this isoenzyme has a role in primary assimilation in roots. In some nitrogen-fixing legumes, nodule-specific cytosolic GS isoenzymes (termed GS_n) assimilate nitrogen fixed by rhizobia (see Chapter 16).

Gene expression analyses carried out in various model and crop plants have revealed specific spatial, developmental, and seasonal patterns for GS1 and GS2. The gene encoding GS2 is expressed in mesophyll cells, whereas the genes for GS1 isoenzymes appear to be expressed specifically in phloem, suggesting that the chloroplast (and perhaps mitochondrial) and cytosolic GS isoenzymes perform distinct functions in vivo. The phloem-specific GS1 likely synthesizes glutamine for long-distance nitrogen transport, whereas GS2 in mesophyll cells is involved in primary nitrogen assimilation (in chloroplasts) or

FIGURE 7.7 Methionine sulfoximine, phosphinothricin, and tabtoxinine- β -lactam are inhibitors of glutamine synthetase. Phosphinothricine is part of the tripeptide bialaphos, an antibiotic produced by certain streptomycetes, and tabtoxinine- β -lactam is part of the dipeptide tabtoxin produced by the plant pathogen *Pseudomonas syringae*.

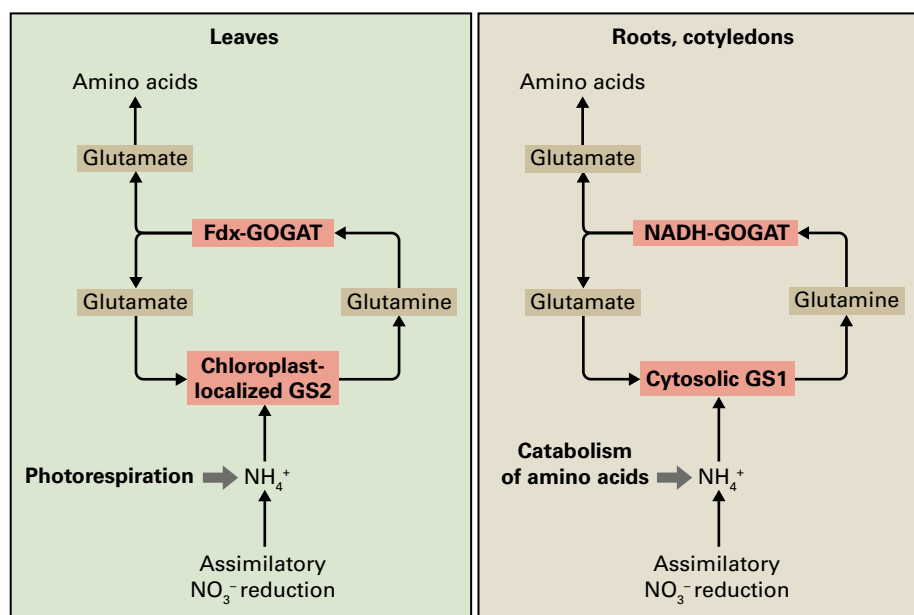

FIGURE 7.8 NADH-dependent and ferredoxin-dependent isoenzymes (NADH-GOGAT and Fd-GOGAT, respectively) of GS play different physiological roles in plant metabolism.

the reassimilation of **photorespiratory ammonium** (in chloroplasts and mitochondria). Mutants in chloroplast GS2 display a conditional lethality: they die in air (0.03–0.04% CO₂) but grow in a 1% CO₂ atmosphere that suppresses photorespiration. Thus, the chloroplast/mitochondrial GS2 enzyme is responsible for reassimilating ammonium released by mitochondrial photorespiration. GS1 is unable to compensate for the loss of GS2 function in leaf mesophyll cells of GS2 photorespiratory mutants, but it can take over its function in primary ammonia assimilation.

7.2.3 Mutants indicate a major role for Fd-GOGAT in photorespiration

GOGAT enzymes are flavoproteins containing iron–sulfur (Fe–S) clusters. Eubacterial NADPH-GOGAT has a basic ($\alpha\beta$) subunit structure, in which the **glutamine amidotransferase** activity releases the first glutamate and ammonia. The ammonia is then channeled through a **tunnel** within the α subunit to the oxoglutarate-binding site, where an iminoglutarate is formed. The iminoglutarate is then reduced to the second glutamate; electrons from NADPH arrive from the β

subunit via Fe–S clusters and flavin mononucleotide (FMN). Eukaryotic GOGAT enzymes consist of a single polypeptide chain, which in case of NADH-GOGAT seems to have evolved through a fusion of the α and β subunits, while Fd-GOGAT shares similarity only with the α subunit.

In *Arabidopsis*, **Fd-GOGAT** is encoded by two genes (*GLU1* and *GLU2*), and NADH-GOGAT by a single gene (*GLT*). Unlike the situation with GS, all GOGAT isoforms are located exclusively in plastids. Fd-GOGAT is the predominant GOGAT isoenzyme in leaves and accounts for as much as 95–97% of total leaf GOGAT activity. In contrast, the NADH-GOGAT isoenzyme is present in low amounts in leaves, but it constitutes the predominant isoenzyme in non-photosynthetic tissues such as roots, where it has the same expression pattern as GS1. These organ-specific distribution patterns suggest a major role for Fd-GOGAT in primary nitrogen assimilation and photorespiration in leaves, whereas NADH-GOGAT may function predominantly in primary assimilation in the roots (Fig. 7.8). Light (mediated in part by phytochrome), carbon (in particular sucrose), and nitrogen signals, such as nitrate and ammonium, interact in the complex regulation of both Fd- and NADH-GOGAT (Fig. 7.8).

FIGURE 7.9 Proposed role of Fd-GOGAT in primary nitrogen assimilation and in assimilation of ammonium produced as a byproduct of photorespiration. *gls* (Fd-GOGAT) mutants of Arabidopsis demonstrate a chlorotic phenotype when grown in air (0.03–0.04% CO_2), but can tolerate growth in a 1% CO_2 atmosphere that suppresses photorespiration. Source: Photographs: Coschigano et al. (1998). Plant Cell 10:741–752.

The importance of Fd-GOGAT in photorespiration can be seen in the *Arabidopsis gluS* mutants of *GLU1*, in which leaf Fd-GOGAT activity is reduced to less than 5% of wild-type levels (the low amounts of NADH-GOGAT activity detected in wild-type plants remain unaffected). All Fd-GOGAT-

deficient mutants have a conditional lethal phenotype: they are chlorotic when grown in atmospheric conditions and are rescued when photorespiration is suppressed (1% CO_2) (Fig. 7.9). This indicates that primary ammonia assimilation is intact, due to the low level of GOGAT activity (<5% of the total activity)

provided by expression of *GLU2* and *GLT*. On the other hand, NADH-GOGAT deficiency in the *Arabidopsis* mutant (*glt1-T*) has only a weak phenotype (in particular, reduction in glutamate levels), and this is not related to impaired photorespiration because the phenotype persists in the presence of 1% CO₂.

7.2.4 Evidence suggests GDH plays primarily a catabolic role

GDH, an enzyme present in nearly all organisms, can catalyze both the synthesis and catabolism of glutamate. In the forward direction, GDH catalyzes the **reductive amination of α -ketoglutarate** using NAD(P)H; in the reverse reaction, it catalyzes the **oxidative deamination of glutamate**, with NAD(P)⁺ as oxidant, to yield α -ketoglutarate and ammonium (Fig. 7.10). Plants contain two classes of GDH enzymes: an **NADH-dependent GDH** found in the mitochondria, and an **NADPH-dependent GDH** in the chloroplast.

GDH was long thought to represent a primary route of ammonium assimilation in plants because it is also present in microbes grown in ammonium-rich media. However, the discovery of the GS/GOGAT cycle in plants argued against a major role for GDH in ammonium assimilation. GDH has a high K_m for ammonium (10–80 mM), whereas tissue concentrations of ammonia typically range 0.2–1.0 mM. Furthermore, experiments in which ¹⁵NH₄⁺ is fed to plants indicate a precursor-product relationship between glutamine and glutamate, consistent with primary nitrogen assimilation by GS/GOGAT (see Section 7.2.1). Additionally, treatment of plants with the GS inhibitor MSO (see Fig. 7.7) prevents incorporation of ammonium into glutamate and glutamine, even though both GDH

activity and ammonium concentrations remain high in the treated plants. The high K_m of GDH for ammonium and its mitochondrial localization suggested this enzyme might instead be involved in reassimilating the large amount of photorespiratory ammonium released in mitochondria; however, screens for mutants in photorespiration did not identify GDH mutants, so any role that GDH plays in photorespiration is probably minor.

It is generally accepted that the primary role for GDH *in vivo* is in **glutamate catabolism**, for example, in darkness to provide carbon skeletons to fuel the citric acid cycle, or in germinating seeds and senescing leaves, when rates of amino acid catabolism are high (see Chapters 19 and 20). Under these conditions, GDH transcripts and enzyme activities are both upregulated. GDH may, however, play an anabolic role under certain conditions. GDH activity is induced in plants exposed to high concentrations of ammonium, likely as a detoxification mechanism, and possibly under salt stress, when there is a high demand for glutamate-derived proline (see Section 7.6.2), indicating a limited assimilatory role for GDH under conditions of ammonium toxicity (Fig. 7.10).

Energetic considerations may reveal why the GS/GOGAT pathway is preferentially, or almost exclusively, used for ammonia assimilation: in the net reactions catalyzed by GDH and GS/GOGAT, respectively, α -ketoglutarate is reductively aminated to glutamate. The GS/GOGAT reaction consumes ATP, while the GDH reaction does not. Hydrolysis of ATP ensures that glutamate formation in the GS/GOGAT reaction is irreversible, while the equilibrium is unfavorable for glutamate in the GDH reaction.

At least two genes encode GDH in plants, *GDH1* and *GDH2*. As GDH has a hexameric structure, a total of seven isoforms of the holoenzyme can be formed, and these can be separated electrophoretically: the two homohexamers of GDH1 and GDH2, and a total of five GDH1/2 heterohexamers,

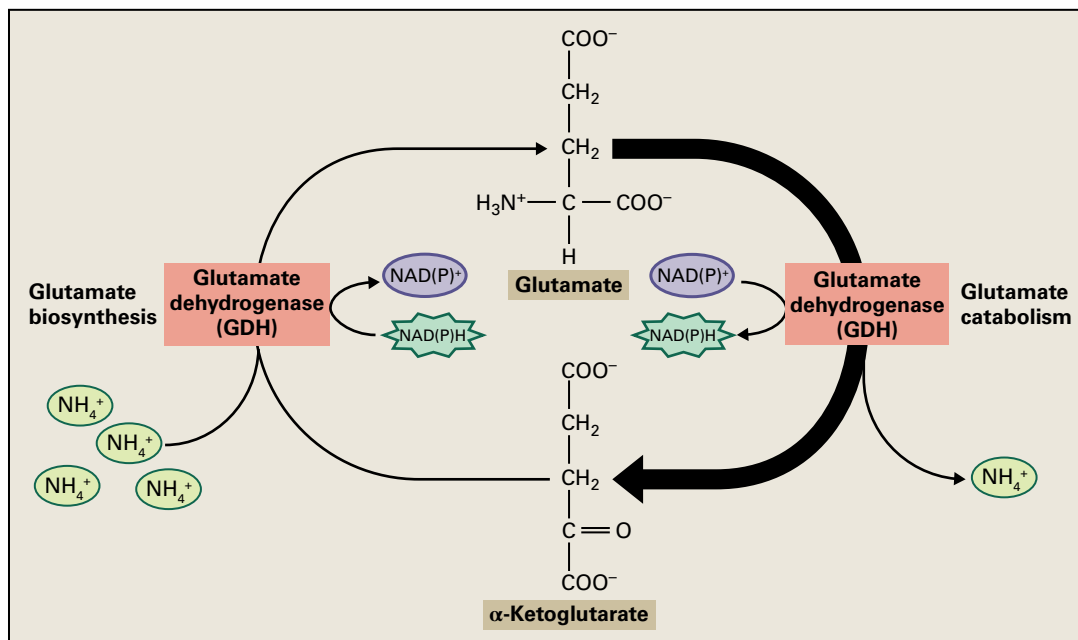

FIGURE 7.10 GDH is thought to function primarily in glutamate catabolism (deamination), but may produce glutamate when ammonium concentrations are high, primarily as a detoxification mechanism.

provided *GDH1* and *GDH2* are coexpressed in the same cells. The *gdh1* mutant of *Arabidopsis* displays an impaired growth phenotype under conditions of excess inorganic nitrogen (nitrate + ammonium; Fig. 7.11). The *gdh1/gdh2* double mutant is particularly sensitive to prolonged dark periods, during which plants suffer carbon starvation. Thus, the main function of GDH appears to be the provision of the C₅ carbon skeleton (α -ketoglutarate) of glutamate.

7.2.5 Studies of mutant plants have defined the isoenzymes that control nitrogen assimilation into the N-transport amino acid aspartate

After its initial assimilation into glutamine and **glutamate**, nitrogen can be distributed to many other compounds by **transaminases** or **aminotransferases** (AT). Because glutamate-utilizing transaminations regenerate α -ketoglutarate, these reactions permit primary assimilation to continue in the absence of de novo α -ketoglutarate synthesis. In particular, synthesis of **aspartate** regenerates the carbon skeletons required for further nitrogen assimilation by transferring an

FIGURE 7.11 *gdh1-1* mutant seedlings can grow in the absence of inorganic nitrogen (B), but their growth is inhibited (A) by high nitrogen concentrations (20 mM ammonium plus 40 mM nitrate). Source: Melo-Oliveira et al. (1996). Proc. Natl. Acad. Sci. USA 93:4718–4723.

amino group from glutamate to **oxaloacetate**. Note that two electrons are transferred with the amino group, thus in the course of the transamination the donor of the amino group is oxidized and the recipient of the amino group is reduced. In this way, **aspartate amino transferase (AspAT)** plays a key role in nitrogen assimilation in plants (see Fig. 7.4).

In addition, aspartate is active in the transport of carbon and nitrogen within and between cells. In some C₄ plants, aspartate mobilizes carbon and reducing equivalents from the mesophyll to bundle sheath cells (see Chapters 12 and 14). In C₃ plants, the **malate–aspartate shuttle** allows transfer of reducing equivalents from mitochondria and chloroplasts into the cytoplasm (see Chapter 14 for detailed discussion of a similar malate–aspartate shuttle in mitochondria).

AspAT, the best characterized aminotransferase in plants, plays a central role in both aspartate synthesis and catabolism (Fig. 7.12). AspAT, also known as **glutamate:oxaloacetate aminotransferase (GOT)**, is a **pyridoxal phosphate**-dependent enzyme, like all transaminases (Fig. 7.13). The ability of AspAT to interconvert these important carbon and nitrogen compounds places it in a key position to regulate plant metabolism.

In line with the fact that aspartate is used to transfer carbon, nitrogen, and reducing equivalents between intracellular compartments, isoenzymes of AspAT have been localized to four cellular compartments: the cytosol, mitochondria, chloroplasts, and peroxisomes. In *Arabidopsis*, the entire gene family of AspAT isoenzymes has been characterized, and mutants of the two major AspAT isoenzymes (cytosolic AAT2 and plastid AAT3) have been identified. The *aat2* mutant plants are small, and they have greatly reduced content of free aspartate in the light and decreased asparagine content in the dark. It appears that aspartate produced during the day under control of AAT2 is converted to asparagine in the dark. The function of AAT3 has not been defined, because the *aat3* mutant has no visible phenotype. This is likely due to the activity of a recently identified nuclear-encoded novel prokaryotic-type AAT (PT-AAT) that is localized to chloroplasts in *Arabidopsis*, rice (*Oryza sativa*), and pine (*Pinus* sp.). It has been proposed, but needs to be substantiated, that AAT3 is primarily involved in shuttling reducing equivalents, while PT-AAT provides aspartate for the biosynthesis of the **aspartate-derived amino acids** threonine, lysine, and methionine, which occurs in the plastid (see Section 7.4.1). The lack of a visible phenotype of the *aat3* mutant plants is, therefore, likely due to the presence of PT-AAT.

FIGURE 7.12 Aspartate aminotransferase catalyzes the reversible transamination of oxaloacetate by glutamate to yield α -ketoglutarate and aspartate.

FIGURE 7.13 Pyridoxal phosphate mechanism/Schiff base formation. The deamination half-reaction catalyzed by a transaminase is diagrammed from left to right. In the case of AspAT, the L-amino acid substrate at left is glutamate, and the α -keto acid product at right is α -ketoglutarate. Note the carbanion (in the brackets) is formed by deprotonation of the α -C of the bound amino acid, and the pyridinium N serves as an electron sink driving the formation of the quinonoid intermediate. Reprotonation gives rise to a ketimine, which is then hydrolyzed to form the α -keto acid and pyridoxamine phosphate. The subsequent amination half-reaction reverses the steps from right to left. For AspAT, the α -keto acid substrate at right is oxaloacetate, and the L-amino acid product to the left is aspartate. Pyridoxal phosphate also participates in racemization and decarboxylation of amino acids (not shown), forming similar carbanion and quinonoid intermediates.

7.2.6 Light represses the biosynthesis of asparagine, an amino acid used for N-transport and storage

Amidation of aspartate by glutamine or ammonia yields asparagine, an inert amino acid used to store nitrogen and transport it from sources to sinks. Asparagine is the major nitrogenous compound detected in the phloem of several legumes, with concentrations as high as 30 mM. Crystallized out of **asparagus** extracts almost 200 years ago, asparagine was actually the first amino acid discovered. In the early 1800s, it was already known that this compound, which gives the distinct flavor to white asparagus, increases in the dark, while the formation of woody tissue is suppressed in this condition. Thus, etiolated asparagus is both tasty and soft. Asparagine is converted to **acrylamide** (a compound that is of concern as a carcinogen) during the heating of starchy food to high temperatures, as in the frying of French fries and potato chips.

The enzymology of asparagine biosynthesis in plants has been complicated by the instability of the enzyme.

In prokaryotes, separate genes, *asnA* and *asnB*, encode structurally distinct ammonium- and glutamine-dependent **asparagine synthetases** (ASs), respectively, whereas in plants, only genes encoding glutamine-dependent AS have been identified. The plant AS catalyzes the ATP-dependent transfer of the amido group from glutamine to aspartate, generating glutamate and asparagine (Fig. 7.14A). Note that AS releases pyrophosphate (PP_i) from ATP, so the activated intermediate in the amidation reaction is the adenylate, that is, **aspartyl AMP**, rather than the respective phosphate, as in the case of glutamine biosynthesis (see Section 7.2.1). Thus two energy-rich bonds are eventually cleaved in the amidation of aspartate. Although glutamine is the preferred substrate for nearly all of the AS enzymes studied in plants, some evidence indicates that ammonium-dependent asparagine synthesis may also occur (Fig. 7.14B). K_m values for ammonium, however, are more than 10-fold higher than in the case of glutamine

FIGURE 7.14 Asparagine synthetases from plants preferentially use glutamine as a nitrogen donor (A), but can catalyze the assimilation of inorganic nitrogen when ammonium is plentiful (B).

synthesis, and tracer studies with $^{15}\text{NH}_4^+$ have shown that glutamine is labeled efficiently, so the direct amidation of aspartate does not appear to occur at significant rates in vivo unless plants may encounter toxic concentrations of ammonium.

The genes encoding AS in *Arabidopsis* are differentially expressed: AS encoded by *ASN1* appears to be primarily involved in nitrogen mobilization during seed germination and in nitrogen remobilization in senescing leaves, while the enzyme encoded by *ASN2* is involved in nitrogen remobilization under stress conditions.

7.2.7 Light and carbon metabolism regulate the assimilation of nitrogen into amino acids

The incorporation of inorganic nitrogen into the assimilatory amino acids glutamate, glutamine, aspartate, and asparagine is a dynamic process that is regulated by external factors, such as light, and by internal stores of carbon and nitrogen metabolites. As early as the 1850s, studies showed that asparagine concentrations are dramatically influenced by light in several plant species (see Section 7.2.7). Later, it was found that the asparagine content of phloem exudates and the amount of AS enzyme activity are negatively regulated by light or by sucrose, and they increase during dark adaptation, while glutamine shows the opposite behavior (see Fig. 7.3).

Expression of the genes controlling assimilation of inorganic nitrogen into amino acids is subject to control by both

light and metabolic factors. For example, genes for **nitrate reductase** and **nitrite reductase** are induced by light and by sucrose (Chapter 16). Similarly, light upregulates the expression of genes involved in ammonium assimilation into glutamine and glutamate, particularly that of chloroplast GS2 and Fd-GOGAT. By contrast, light represses the expression of genes for AS. In all three cases, this transcriptional regulation is mediated, at least in part, by the plant photoreceptor **phytochrome** (Chapter 18). Additionally, the light-driven synthesis of carbohydrates also affects the expression of genes involved in nitrogen assimilation. Sucrose or glucose can at least partially substitute for light in inducing the expression of genes for GS2 or Fd-GOGAT, as demonstrated in tobacco (*Nicotiana tabacum*) and in *Arabidopsis*. In contrast, sucrose represses the expression of AS genes when supplied to dark-adapted maize explants or to whole *Arabidopsis* plants. The effects of sucrose on GS/AS gene expression can be antagonized by amino acids. Sucrose induction of GS expression is repressed by amino acids, whereas amino acids relieve sucrose repression of AS gene expression.

Based on the reciprocal effects of carbon and organic nitrogen on the expression of GS2 and ASN1, a metabolic control model has been proposed (Fig. 7.15). In this model, GS2 expression is induced by light or when carbon skeletons required for ammonia assimilation are abundant. Thus, in the light, nitrogen is assimilated and transported as metabolically reactive **glutamine**, a substrate in numerous anabolic reactions. In contrast, ASN1 expression is induced when darkness prevents photosynthetic carbon reduction, or when concentrations of organic nitrogen are high relative

FIGURE 7.15 Synthesis of glutamine and asparagine is sensitive to light and to the availability of reduced carbon. Expression of plastid-localized GS is upregulated by light or sucrose, promoting formation of the metabolically reactive nitrogen donor, glutamine. AS is inhibited by light or sucrose, and this inhibition can be released by increasing the concentration of amino acids in plant tissues. Darkness promotes AS expression and enhances synthesis of the inert nitrogen storage compound, asparagine. Note that asparagine represents a more efficient use of reduced carbon than glutamine does: Both amino acids bind two nitrogen atoms, but glutamine contains five carbon atoms, asparagine four.

to those of carbon. Thus, under conditions of low carbon availability or high organic nitrogen, plants direct assimilated nitrogen into inert **asparagine**, which has a higher N:C ratio than glutamine and, therefore, can transport and store nitrogen more efficiently when carbon skeletons are limiting.

7.3 Aromatic amino acids

All living cells require the **aromatic amino acids** phenylalanine, tryptophan, and tyrosine for protein biosynthesis. In plants, the aromatic amino acid pathways also provide precursors for the production of numerous aromatic primary and secondary metabolites, such as plant hormones (the auxin, indole-3-acetic acid, and salicylic acid), pigments (anthocyanins), volatiles, defensive phytoalexins (see Chapter 21), feeding deterrents (tannins), UV protectants (flavonoids), signal molecules (isoflavonoids), bioactive alkaloids, and structural components (lignin, suberin, and cell wall-associated phenolics) (Fig. 7.16; see also Chapter 24). The importance of these pathways in plants is underscored by the fact that about 30% of the fixed carbon can flow through the common aromatic amino acid pathway, largely to make **lignin** (Chapters 2 and 24). Owing to their pharmacological and biological activities, aromatic amino acid-derived plant natural products are widely used in medicine (e.g., condensed tannins and morphine) and as food supplements (e.g., flavonoids and tocopherols) (see Chapter 24). The aromatic amino acid pathways are absent in animals; the enzymes of these pathways, therefore, became

targets for the development of antibiotics against human and animal pathogens and plant herbicides.

7.3.1 Synthesis of chorismate constitutes the common aromatic amino acid pathway

Chorismic acid, the final product of the **shikimate pathway**, is the last common precursor in the synthesis of the three aromatic amino acids (**phenylalanine**, **tryptophan**, and **tyrosine**) as well as **p-aminobenzoic acid** (a precursor for the C_1 carrier tetrahydrofolate), the electron transport cofactor phyloquinone, other naphtho- and anthraquinones (see Chapters 12 and 14), and **salicylic acid** (see Chapter 17). Plastids have a prominent function in this biosynthesis, because a full set of the shikimate pathway enzymes has been localized to these organelles, while the occurrence of a full set of extraplasmidial shikimate pathway enzymes has not been proven.

The seven-step synthesis of **chorismate** via the shikimate pathway (Fig. 7.17) begins with the condensation of two intermediates of carbohydrate metabolism, **phosphoenolpyruvate** (PEP) from glycolysis and **erythrose 4-phosphate** from the pentose phosphate pathway (Chapter 13). This reaction is catalyzed by **3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP) synthase**. Based on the absence or presence of certain domains in the protein as well as amino acid sequence similarity, DAHP synthases have been classified into two types (type I and II) with less than 10% sequence identity. *E. coli* DAHP synthase belongs to the **type I DAHP synthase** family with molecular masses less than 40 kDa. Type II enzymes (≈ 50 kDa)

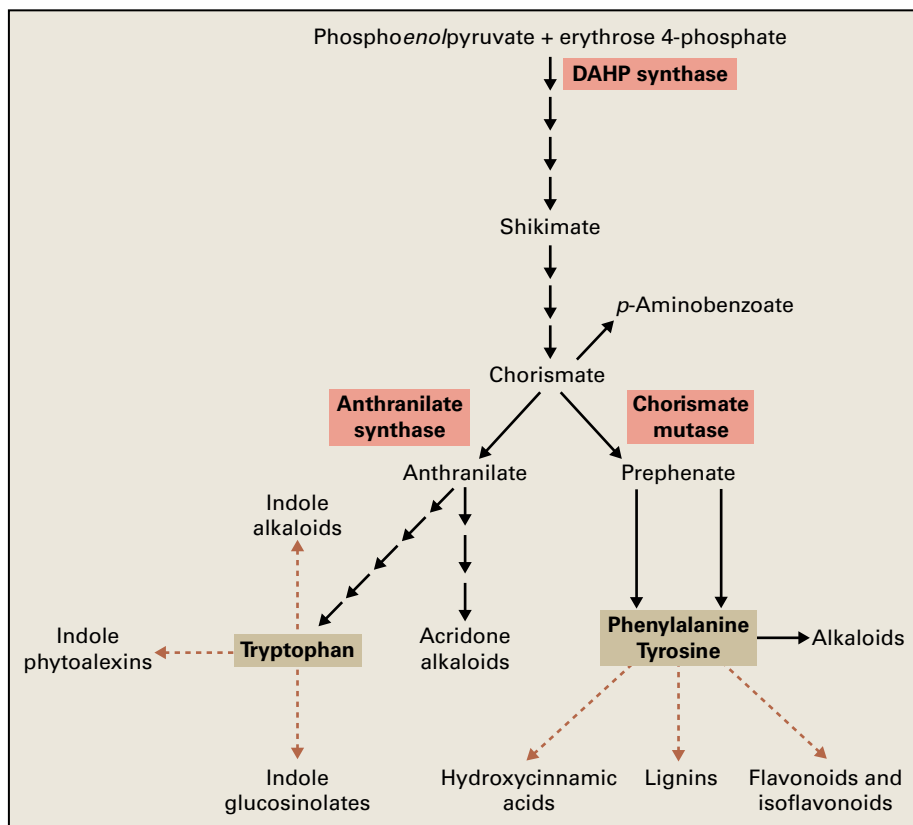

FIGURE 7.16 Synthesis of the aromatic amino acids in plants. In addition to their functions in proteins, phenylalanine, tyrosine, and tryptophan serve as precursors for the synthesis of numerous primary and secondary metabolites.

were first identified in plants, but were later also identified in some microorganisms. As more sequenced genomes became available, it appeared the **type II DAHP synthase** family contains a subset of plant enzymes that are clustered within a more divergent set of microbial enzymes.

High-resolution protein crystal structures have been determined for both types of enzymes and revealed similarities in tertiary structure and function between them. In fact, all DAHP synthases have a core $(\beta/\alpha)_8$ barrel monomer structure, and the key residues that interact with phosphoenolpyruvate and the required divalent metal ion (Mn^{2+}) are conserved and positioned almost identically in both types, despite their minimal sequence identity. This common active site architecture and chemistry suggest that type I and type II enzymes evolved from a common ancestor. Type I and II DAHP synthases appear to differ in the possession of peripheral small domains (type II) that decorate the core $(\beta/\alpha)_8$ fold and are responsible for **aromatic amino acid-mediated allosteric regulation**.

In contrast to microbial enzymes, plant DAHP synthases are not feedback-inhibited by any of the aromatic amino acids, with the possible exception of those from maize and pea, which are feedback inhibited by tryptophan and tyrosine, respectively. Given that plant DAHP synthases contain domains that in microorganisms function as aromatic amino acid-binding elements, the correct conditions or combinations of aromatic amino acids that affect plant DAHP synthase activity may not have been found yet. Despite the divergence

in their primary sequence and differences in regulatory properties, the plant enzyme can substitute for a defective *E. coli* or yeast enzyme and restore prototrophy.

Plants appear to contain two DAHP synthase genes (*DAHPS1* and *DAHPS2*) that are differentially expressed, suggesting they have distinct functions in vivo. *DAHPS1* is strongly induced in response to wounding and pathogen infection, whereas *DAHPS2* is constitutively expressed. In addition to plant DAHP synthases, which require Mn^{2+} as cofactor, a Co^{2+} -dependent DAHP synthase activity has been detected in the cytosol of several plant tissues. However, the corresponding protein has not been isolated; hence, its substrate specificity is unknown. Likewise, the corresponding gene(s) have not been identified, and the physiological function of this activity is currently unknown.

The second enzyme of the shikimate pathway, **3-dehydroquinate synthase**, catalyzes the cyclization step to a cyclohexane ring, which eventually becomes the benzene ring of the aromatic amino acids (see Fig. 7.17). The activity requires Co^{2+} and NAD^+ as cofactors (even though the overall reaction is redox neutral), and the plant enzyme has a K_m of 25 μM for DAHP. The conversion of DAHP to 3-dehydroquinate by the plant enzyme likely proceeds through the same five consecutive steps identified in the reaction sequence of the bacterial enzyme: alcohol oxidation, β -elimination of inorganic phosphate, carbonyl reduction, ring opening, and intramolecular aldol condensation. The crystal structure of a bacterial 3-dehydroquinate synthase revealed that the enzyme performs

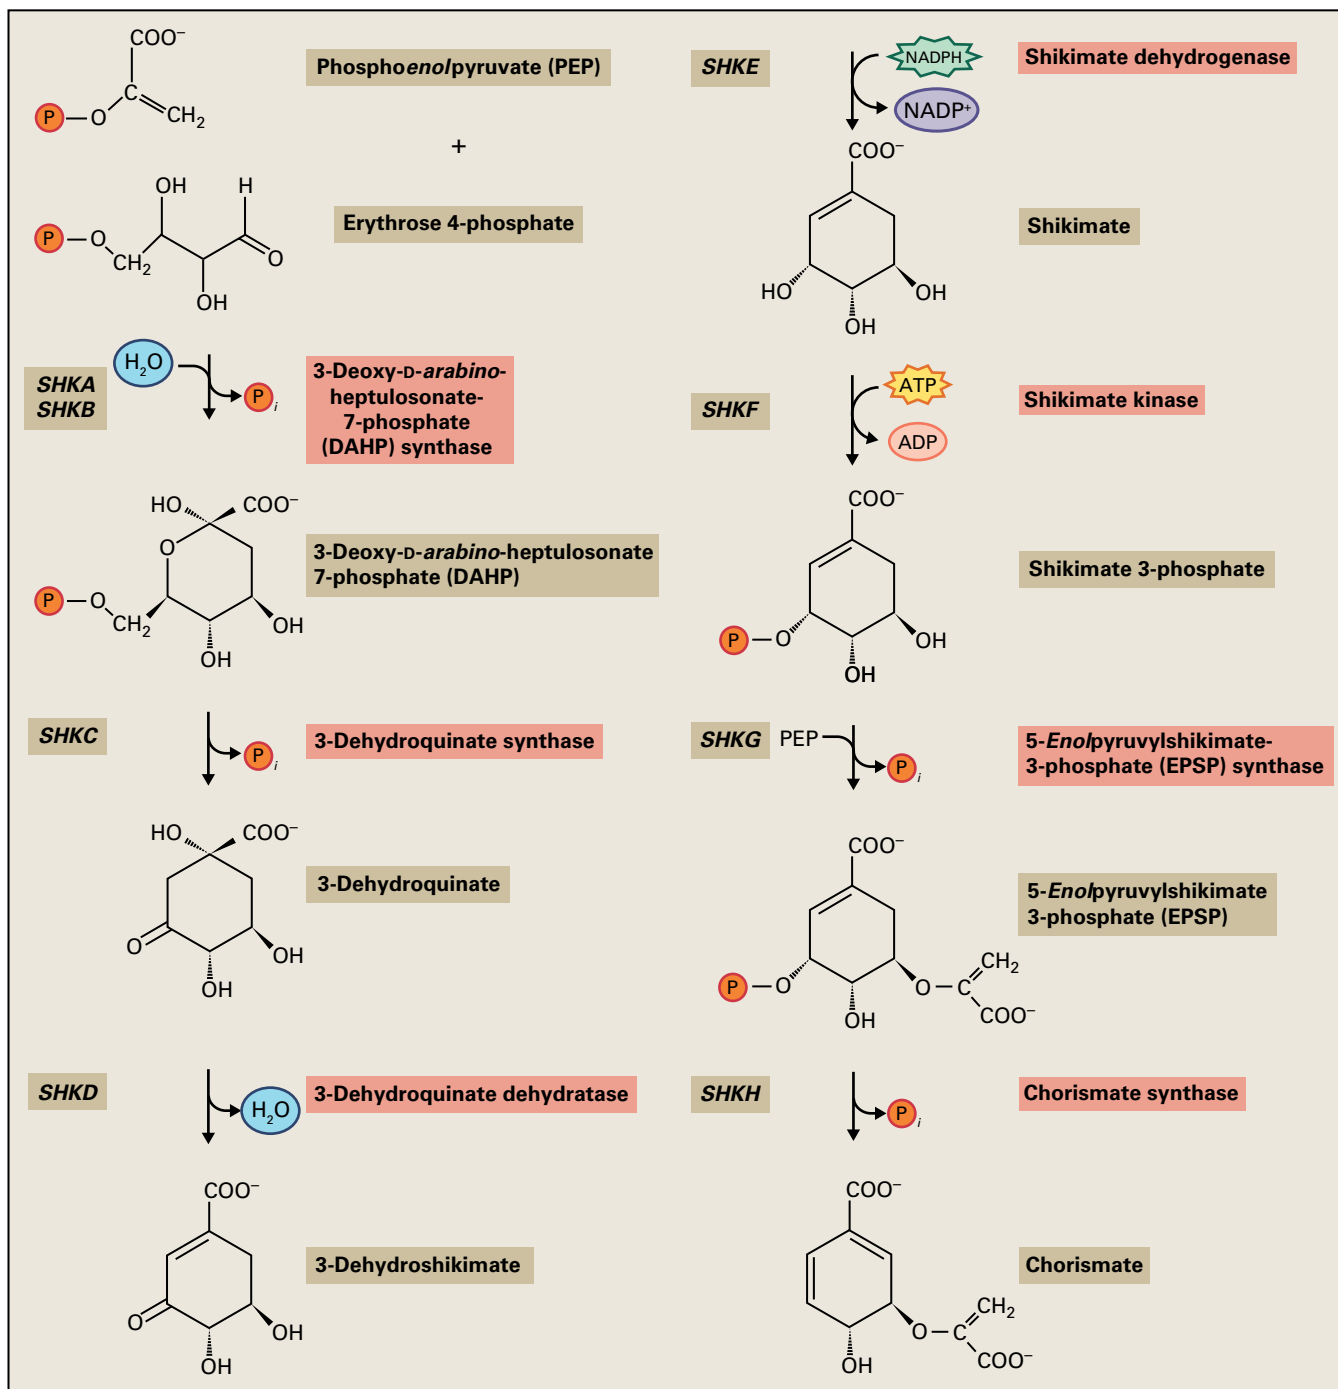

FIGURE 7.17 Chorismate biosynthesis from phosphoenolpyruvate and erythrose 4-phosphate. The abbreviations SHKA through SHKH are notations proposed for the genes encoding shikimate pathway enzymes in plants.

this multistep catalysis in a single active site without forming byproducts. A plant gene encoding 3-dehydroquinate synthase has been isolated from tomato (*Solanum lycopersicum*) by complementation of an *E. coli* *aroB* mutation that causes 3-dehydroquinate synthase deficiency. This single-copy gene is highly expressed in tomato roots, and its expression is induced by elicitor treatment in suspension culture cells. Plant and *E. coli* (*AroB*) 3-dehydroquinate synthases are monofunctional enzymes, while those from fungi are part of

a pentafunctional **AROM complex** that catalyzes five consecutive reactions of the shikimate pathway, that is, the conversion of DAHP to 5-enolpyruvylshikimate 3-phosphate.

The third and fourth reactions in the shikimate pathway include the dehydration of 3-dehydroquinate to introduce the first double bond in the ring and form **3-dehydroshikimate**, which is subsequently reduced to **shikimate** at the expense of NADPH. **3-Dehydroquinate dehydratase** (also known as **dehydroquinase**) and **shikimate dehydrogenase**

(also known as **shikimate:NADP⁺ oxidoreductase**) catalyze these respective reactions, and their activities are found on a bifunctional enzyme in plants. This combined activity has been purified to homogeneity from spinach (*Spinacia oleracea*) chloroplasts. The specific activity of the first enzyme, 3-dehydroquinate dehydratase, is 10% of that of shikimate dehydrogenase, which presumably helps to efficiently convert 3-dehydroshikimate to shikimic acid. This assumption is supported by the observation that, in the crystal structure of the *Arabidopsis* enzyme, the active sites of 3-dehydroquinate dehydratase and shikimate dehydrogenase are proximal and face each other, obviously to facilitate optimal local 3-dehydroshikimate concentration for effective shikimate dehydrogenase catalysis. Many plant species, including *Arabidopsis*, contain a single gene encoding 3-dehydroquinate dehydratase-shikimate dehydrogenase. The only known exception is tobacco (*Nicotiana tabacum*), whose genome possesses two genes encoding functional plastid and cytosolic enzymes. The function of the cytosolic protein remains to be determined.

The fifth step in the pathway is catalyzed by **shikimate kinase**, which phosphorylates shikimate at the 3-hydroxyl, using ATP as a co-substrate, to produce **shikimate 3-phosphate** (Fig. 7.17). Shikimate kinases belong to the family of nucleoside monophosphate (NMP) kinases and are composed of four domains: the core, lid, shikimate- and NMP-binding domains. Although plant shikimate kinases share at most 30% identity with their bacterial counterparts and are approximately 10 kDa larger, comparison of their crystal structures reveals high conservation in the architecture of the enzyme active site between plants and microbes. Similar to bacterial enzymes, plant shikimate kinases are controlled primarily by the cellular energy status (**energy charge**: the relative concentrations of ATP, ADP, and AMP in the cell).

Plant genomes contain variable numbers of genes encoding shikimate kinases: one in tomato (*Solanum lycopersicum*), two in *Arabidopsis*, and three in rice (*Oryza sativa*), among others. In *Arabidopsis*, the two shikimate kinase isoforms AtSK1 and AtSK2 exhibit differential expression profiles. AtSK1 is coexpressed with stress response-related genes, and its expression is induced more than tenfold in response to heat stress. In contrast, AtSK2 is coexpressed with genes involved in processes directly associated with the shikimate pathway, including amino acid and secondary metabolism. The AtSK1 and AtSK2 proteins have almost identical structures; however, their biophysical properties are distinct. AtSK1 forms a homodimer and remains stable at elevated temperatures (37°C), whereas AtSK2 exists as a monomer and is rapidly inactivated at high temperatures. Screening of plants with deficiencies in AtSK1 and AtSK2, respectively, for metabolic or growth phenotypes in response to heat stress should facilitate detailed investigation of the functions of these enzymes *in vivo*.

The penultimate enzyme of chorismate biosynthesis, **5-enolpyruvylshikimate-3-phosphate (EPSP) synthase**, catalyzes the reversible production of EPSP and phosphate from shikimate 3-phosphate and PEP. EPSP synthase is the

FIGURE 7.18 Glyphosate, herbicidal constituent of the commercial herbicide Roundup® is a competitive inhibitor of EPSP synthase.

best studied enzyme of the shikimate pathway, as it is the prime target of the commercially important herbicide **glyphosate** (Fig. 7.18). Cocrystallization of EPSP synthase with shikimate 3-phosphate alone and in combination with glyphosate revealed that binding of the first substrate, shikimate 3-phosphate, to the enzyme triggers a global conformational change from an “open” to a “closed” conformation, thereby forming the active site in the interdomain cleft of EPSP synthase. Glyphosate occupies the PEP-binding site of the enzyme–shikimate 3-phosphate complex, thereby competitively inhibiting the EPSP synthase with respect to the second substrate, PEP. Based on glyphosate sensitivity, EPSP synthases from different organisms have been divided into two classes. All plants and most bacteria, including *E. coli*, have glyphosate-sensitive **class I EPSP synthases**, whereas some bacteria, such as *Agrobacterium* sp. strain CP4, have **class II EPSP synthases** that are relatively resistant to glyphosate and, therefore, have been used to generate **glyphosate-resistant transgenic crops**.

EPSP synthase genes have been cloned from a number of plant species, and mutations and the structural basis of the glyphosate tolerance have been identified (see Box 7.1). The *Arabidopsis* genome contains two genes encoding one putative and one functional EPSP synthase, which is constitutively expressed at low levels.

The final enzyme of the pathway, **chorismate synthase**, catalyzes the elimination of phosphate and a hydrogen atom from EPSP to produce chorismate (see Fig. 7.17). The reaction (a 1,4-*trans*-elimination) is unusual and unique in nature. It requires a reduced flavin nucleotide cofactor (FMN₂; see Fig. 14.4) typically associated with redox reactions, even though the reaction does not involve an overall change in redox state. Despite the fact that chorismate synthases from different kingdoms are highly homologous and have similar structural folds, cofactor specificity, and kinetic properties, two classes have been distinguished based on their ability to reduce the oxidized FMN. Chorismate synthases from fungi are associated with a NADPH-dependent flavin reductase as part of a bifunctional enzyme, whereas plants and most bacteria have monofunctional enzymes that depend on an external source of FMN₂. Genes encoding chorismate synthases have been isolated from a number of plant species. The tomato (*Solanum lycopersicum*) genome contains two chorismate synthase genes that are differentially expressed.

7.1

Detoxification genes and resistant target enzymes can provide crop plants with herbicide tolerance

Several enzymes of amino acid biosynthesis are targets for commercially significant herbicides: GS is inhibited by L-PPT (**Basta**[®]) (see Section 7.2.1), **acetohydroxy acid synthase (AHAS)** is inhibited by five classes of herbicides (the major ones belonging to the **imidazolinones**, **sulfonylureas**, and **triazolopyrimidines** as will be discussed in Section 7.5.2), and EPSP synthase is inhibited by glyphosate (**Roundup**[®]), as discussed above.

Herbicide tolerance is considered a desirable agricultural trait because it allows farmers to control weeds without affecting crop plant growth. Both classical breeding and molecular genetic strategies have been used to introduce these traits into economically important plants. Among the successful approaches for genetically engineering herbicide tolerance is the expression of enzymes that detoxify or degrade the inhibitor, and the introduction of mutant target enzymes that are less sensitive to the inhibitor. For example, expression of the *Streptomyces hygroscopicus* **bar gene**, encoding **phosphinothricin acetyltransferase**, makes plants resistant to L-PPT, whereas a naturally occurring form of EPSP synthase from an *Agrobacterium* strain provides tolerance to high concentrations of glyphosate. Mutant EPSP synthase has also been characterized in *E. coli*. Here, a backbone plot of the *E. coli* enzyme highlights active site

residues (blue, numbered in red) and a conserved region (red). Conversion of the yellow Gly⁹⁶ residue to Ala makes the protein resistant to glyphosate.

7.3.2 Chorismate mutase is the committing enzyme in phenylalanine and tyrosine synthesis

The biosynthesis of **phenylalanine** and **tyrosine** may occur via two alternative pathways with either **arogenate** or **phenylpyruvate/p-hydroxyphenylpyruvate** as intermediates (Fig. 7.19). Recent genetic evidence suggests that the arogenate route is predominant in plants. This means that plants differ from enteric bacteria and fungi, which primarily use the phenylpyruvate route.

Chorismate mutase (CM) catalyzes the intramolecular rearrangement of the enolpyruvyl side chain of chorismate to produce prephenate, and it is the committing enzyme for phenylalanine and tyrosine biosynthesis. In many plants, this activity exists in two isoenzyme forms, **CM1** and **CM2**, which are regulated quite differently from one another. The plastid localization and regulatory behavior of CM1 are consistent with a role for this activity as a committing enzyme in an amino acid biosynthetic pathway.

CM1 is feedback-inhibited by each of the end products, phenylalanine and tyrosine, and is activated by tryptophan, the product of the other branch of the pathway. Tryptophan reverses

the inhibition by phenylalanine or tyrosine (Fig. 7.20). This mechanism regulates flux into the two competing pathways by increasing synthesis of phenylalanine and tyrosine when tryptophan is plentiful, and suppressing synthesis of phenylalanine and tyrosine when the supply of these amino acids is adequate.

The contrasting features of the CM2 isoform make this enzyme enigmatic. The activity of CM2 is not regulated by any of the aromatic amino acids, and unlike the other aromatic amino acid biosynthetic enzyme, CM2 lacks any obvious N-terminal plastid targeting sequence (transit peptide) and is cytosolic (Fig. 7.21). CM2 has roughly a 10-fold higher affinity toward chorismate than CM1. This is consistent with a presumably lower chorismate concentration in the cytosol, as chorismate is likely transported from plastids, in the absence of evidence for the existence of a cytosolic (partial or complete) shikimate pathway.

The *Arabidopsis* genome contains an additional gene encoding **CM3**. Like CM1, CM3 contains a putative plastid transit peptide and is subject to allosteric regulation, but its affinity toward chorismate is closer to that of CM2. All three *Arabidopsis* genes display differential expression, with *CM1* and, to a lesser extent, *CM3* being induced in response to elicitors and pathogen treatments. The different properties of CMs suggest their distinct physiological roles in plants.

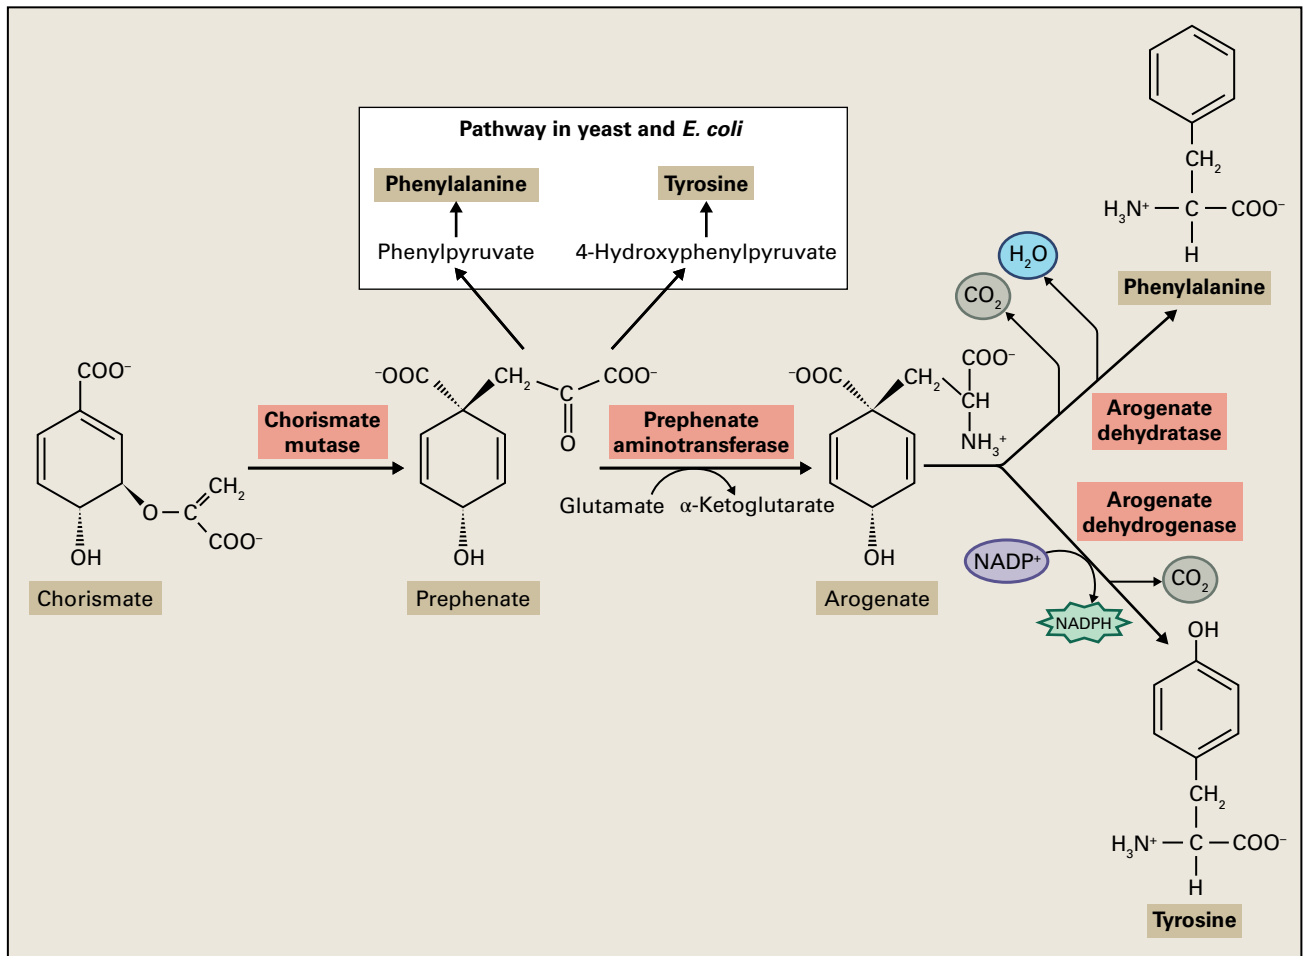

FIGURE 7.19 Phenylalanine and tyrosine are predominantly synthesized from aroenate in plants. This is in contrast to the major pathway in *Saccharomyces cerevisiae* and *E. coli*, where phenylpyruvate and 4-hydroxyphenylpyruvate are intermediates.

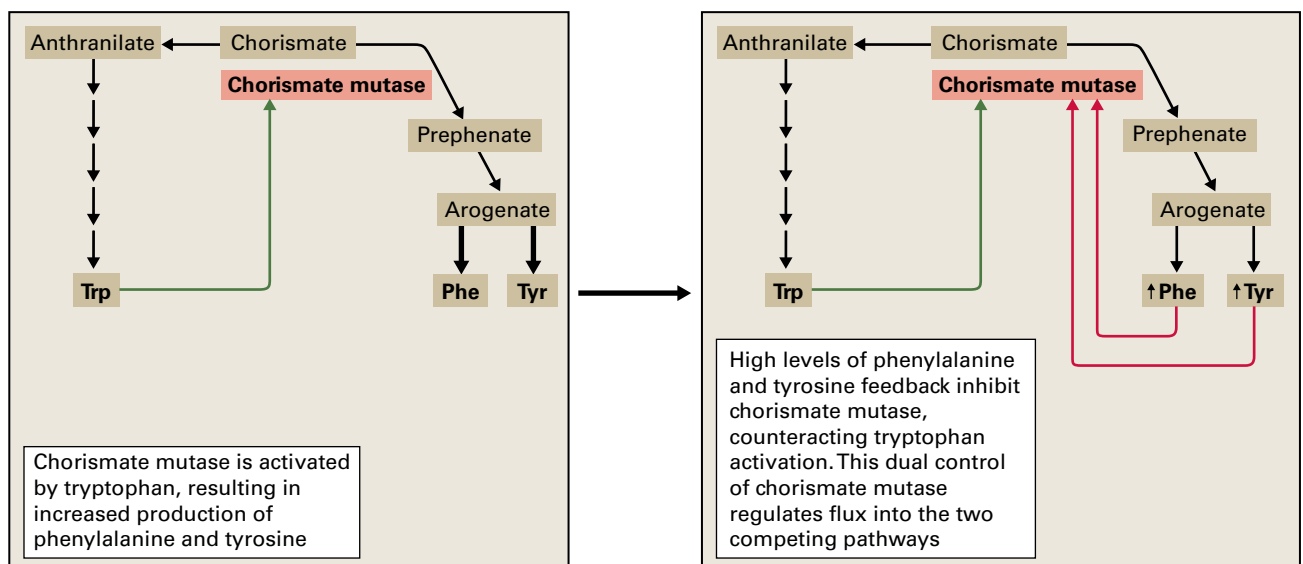

FIGURE 7.20 Allosteric regulation of chorismate mutase controls flux from chorismate into phenylalanine and tyrosine.

FIGURE 7.21 CM1 and CM2 isoforms have distinct subcellular localization and appear to have different physiological roles. CM1 is plastid-localized, whereas CM2 is cytosolic. Because the substrate for CM is produced in the plastid, the function of the cytosolic isoenzyme remains unknown. Export of chorismate from the plastid has not been investigated.

Interestingly, CM plays a critical role in interactions of phytoparasitic nematodes and phytopathogenic fungi (*Ustilago maydis*) with their host plants. Both nematodes and fungi inject their own CMs into the cytoplasm of plant cells. Probably in conjunction with plant CM2, these additional CM activities are assumed to increase the flow of chorismate from plastids to the cytosol and redirect the plant metabolome in favor of the parasite. This “**metabolic colonization**” is far from being understood.

The initial step of the **arogenate pathway**, the final step common to phenylalanine and tyrosine biosyntheses, is catalyzed by **prephenate aminotransferase**. This heat-stable PLP-dependent enzyme catalyzes a reversible transamination between prephenate and arogenate. A 10-fold higher affinity toward prephenate as compared to arogenate suggests that prephenate aminotransferase preferentially catalyzes the forward reaction under physiological conditions and directs the carbon flux from prephenate to arogenate. It utilizes either glutamate or aspartate as amino donor and is not inhibited by end products, consistent with it not acting at a branch point in the pathway. Prephenate aminotransferase genes have been cloned from a number of plant species, including *Arabidopsis*, petunia (*Petunia hybrida*), and tomato (*Solanum lycopersicum*), where they are coexpressed with other proteins involved in the shikimate pathway. *Arabidopsis* and tomato genomes appear to contain a single copy of prephenate aminotransferase, and a loss-of-function mutation in *Arabidopsis* is lethal at the one-cell stage of embryo development.

7.3.3 In plants, the pathway that synthesizes phenylalanine and tyrosine is regulated by its final reactions

The biosynthesis of **phenylalanine** and **tyrosine** in plants via the arogenate pathway represents an unusual case, wherein the committing reactions are also the last steps of the pathways.

The final enzyme of phenylalanine biosynthesis is **arogenate dehydratase**, which catalyzes the decarboxylation and dehydration of arogenate. Multiple genes encoding arogenate dehydratase have been isolated from a number of plant species. These plant genes encode monofunctional dehydratases that contain two domains: a catalytic domain and a C-terminal regulatory domain that is involved in the allosteric regulation by phenylalanine. Plant arogenate dehydratases display strict or preferred substrate specificities toward arogenate. However, some of them can also use prephenate as a substrate and convert it to phenylpyruvate, even though with V_{\max} always being 10- to 100-fold lower with prephenate than with arogenate. Tyrosine can activate arogenate dehydratases to redirect flux from tyrosine to phenylalanine biosynthesis.

Arogenate dehydrogenase (ADH) catalyzes the oxidative decarboxylation of arogenate to tyrosine. This NADP⁺-dependent enzyme lacks an additional tyrosine-binding domain, independent of the substrate binding site (unlike arogenate dehydratase), but it is feedback-inhibited by tyrosine competitively with respect to the arogenate substrate. ADH activities have been detected in a variety of plant species, however, genes encoding these enzymes have been isolated only from *Arabidopsis* and maize (two and four, respectively). *Arabidopsis* ADH1 exhibits strict substrate specificity toward arogenate, whereas ADH2 can also accept prephenate, but with a V_{\max} by three orders of magnitude lower than that with arogenate. The individual functions of ADH1 and ADH2 in *Arabidopsis* remain to be determined.

Biosynthesis of phenylalanine and tyrosine can also occur via the alternative phenylpyruvate and *p*-hydroxyphenylpyruvate routes, respectively, in which aromatization precedes the transamination reaction (see Fig. 7.19), which then is the final step. Arogenate dehydratases with activities toward prephenate, as well as ADH2, can catalyze the conversion of prephenate to the corresponding pathway intermediates, **phenylpyruvate** and ***p*-hydroxyphenylpyruvate**. However, **prephenate dehydratase** and **dehydrogenase** activities, respectively, have rarely been detected in plant tissues. This raises the question about the contribution of these pathways to phenylalanine and tyrosine biosynthesis under physiological conditions. The final steps in these pathways are catalyzed by phenylpyruvate and *p*-hydroxyphenylpyruvate aminotransferase, respectively. Genes encoding **aromatic amino acid aminotransferases** have been isolated from melon (*Cucumis melo*) and opium poppy (*Papaver somniferum*) (see Chapter 24). In *Arabidopsis*, seven genes were annotated as **tyrosine aminotransferases**, and two of the corresponding enzymes possess tyrosine aminotransferase activity. Owing to the reversibility of the aminotransferase reaction, tyrosine

aminotransferases can also be involved in the biosynthesis of **tocopherol** and **plastoquinone** by conversion of tyrosine to **homogentisate** via *p*-hydroxyphenylpyruvate.

In animals and some microbes, phenylalanine can be converted to tyrosine by **phenylalanine hydroxylase** (therefore, tyrosine is not an **essential amino acid** in our diet). Phenylalanine-specific aromatic amino acid hydroxylases (monooxygenases) have been identified in non-flowering plants including algae, mosses, and gymnosperms, but not in angiosperms. These plastid plant phenylalanine hydroxylases use 10-formyltetrahydrofolate, rather than a tetrahydropterin like the animal enzymes, as a cofactor and molecular oxygen to provide the oxygen of the phenolic hydroxyl group. They provide an alternative biosynthetic path to tyrosine.

7.3.4 The tryptophan biosynthesis pathway in plants has been dissected with molecular genetic techniques

Conversion of chorismate to **tryptophan** has significance beyond amino acid biosynthesis. Plants use this pathway to produce precursors for numerous secondary metabolites, including the hormone auxin, indole alkaloids, phytoalexins, cyclic hydroxamic acids, indole glucosinolates, and acridone alkaloids (Fig. 7.22). These metabolites serve as growth regulators,

defense agents, and signals for insect pollinators and herbivores. Some of these alkaloids, including the anticancer drugs vinblastine and vincristine, have great pharmacological value.

The biosynthetic pathway for tryptophan was the first proven to be amenable to detailed molecular genetic analysis (see Box 7.2); as a result of these studies, a generally accepted *in vivo* pathway has been constructed (Fig. 7.23). Genes for all of the enzymes have been characterized, and mutants have been identified for all but one of the seven proteins (indole-3-glycerol-phosphate synthase; IGPS; an antisense approach was chosen to downregulate this enzyme in *Arabidopsis*). The plant pathway comprises the same sequence of reactions seen in microorganisms.

7.3.5 Anthranilate synthase catalyzes the committing step in tryptophan biosynthesis

Anthranilate synthase (AnS) is an amino-accepting chorismate-pyruvate lyase that catalyzes the first step in tryptophan biosynthesis, the formation of anthranilate. It is a two-subunit enzyme in plants that functions as an $\alpha_2\beta_2$ complex. The α subunit catalyzes the amination of chorismate and removal of the *enol*pyruvyl side chain (yielding pyruvate), acting in concert with the **glutamine amidotransferase** activity of the

FIGURE 7.22 The indole ring (highlighted in yellow) derives from the amino acid tryptophan and is a common feature of many secondary metabolites in plants.

Various mutant screens have been used to elucidate the tryptophan biosynthesis pathway

In microorganisms, it is easy to identify mutants auxotrophic for amino acids by replica-plating colonies and comparing their growth on minimal and supplemented media. Auxotrophic colonies are identified by their inability to grow without the addition of amino acids. Because replica plating is not an option for plant geneticists, the search for mutants that require medium supplementation is much more difficult, and plant biosynthetic pathways were less amenable to genetic analysis before the advent of comparative genomics. This problem was overcome by devising rapid screens for mutants that accumulate an intermediate in the biosynthetic pathway, or that continue to grow in the presence of compounds that would be converted into toxic products if all the enzymes in the pathway were present and active. There are several such examples in the tryptophan pathway.

The strong blue fluorescence of **anthranilic acid**, the first intermediate in the tryptophan pathway, provides a phenotype for identifying *Arabidopsis* mutants with reduced activities for the first three pathway enzymes. Loss-of-function mutants of **phosphoribosyl anthranilate** (PR-anthranilate) **transferase** (*trp1*) or PR-anthranilate isomerase (*pai*; see Box 7.3) have strikingly blue fluorescent leaves under UV light. These leaves are filled with anthranilate compounds because they are unable to effectively convert

this intermediate to downstream products. This screen also provides a method for identifying *trp4* mutants with reduced **anthranilate synthase** (AnS) β subunit activity by screening *trp1* mutants for **second-site suppressor mutations** that decrease the ability to convert chorismate to anthranilate. Here, a diagram (A) of the phenotypic effects of mutations that abolish the activity in the first three enzymes of the pathway is accompanied by a photograph (B) taken under UV light, which reveals a single blue fluorescent *trp1* mutant plant growing among many wild-type *Arabidopsis* plants.

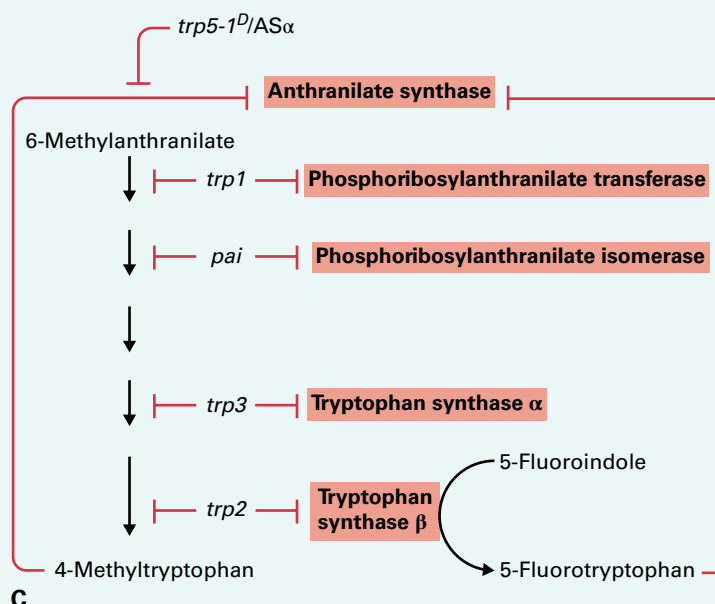

Toxic analogs of tryptophan and pathway intermediates have been used to identify both loss- and gain-of-function mutants. Analogs of pathway intermediates are toxic to plants because the enzymes of tryptophan biosynthesis convert them to tryptophan analogs (C). For example, 6-methylanthranilate is metabolized to 4-methyltryptophan, and 5-fluoroindole metabolizes to 5-fluorotryptophan because they inhibit AnS. Anthranilate analog-resistant plants fall into two categories: those with reduced activity of the enzymes that convert anthranilate to tryptophan (*trp1*, *pai*, *trp3*, and *trp2* mutants), and gain-of-function feedback-insensitive AnS *trp5D* mutants. These **relaxed allosteric regulation mutants** are also obtained by directly selecting

Genotype	Anthranilate synthase	PR-anthranilate transferase	PR-anthranilate isomerase	Phenotype in UV light
Wild type	Chorismate \longrightarrow Anthranilate	Anthranilate \longrightarrow PR-anthranilate	PR-anthranilate \longrightarrow CDRP	No fluorescence
<i>trp1</i>	Chorismate \longrightarrow Anthranilate	Anthranilate $\not\longrightarrow$ PR-anthranilate	PR-anthranilate \longrightarrow CDRP	Strong fluorescence
<i>trp1; trp4</i>	Chorismate $\not\longrightarrow$ Anthranilate	Anthranilate $\not\longrightarrow$ PR-anthranilate	PR-anthranilate \longrightarrow CDRP	No fluorescence
<i>pai</i>	Chorismate \longrightarrow Anthranilate	Anthranilate \longrightarrow PR-anthranilate	PR-anthranilate $\not\longrightarrow$ CDRP	Weak fluorescence

A

B

for resistance to tryptophan analogs (α -methyltryptophan, for example). Just as mutants of the first three steps of the pathway were targeted by use of anthranilate blue fluorescence screening, tryptophan synthase (TS)-deficient mutants have been identified by screening for

resistance to exogenous 5-fluoroindole, which is converted by the TS β subunit to toxic 5-fluorotryptophan.

FIGURE 7.23 Tryptophan biosynthetic pathway of *Arabidopsis*. The wild-type gene names (e.g., ASA1) and mutant designations (e.g., *trp5*) are indicated to the left of the arrows.

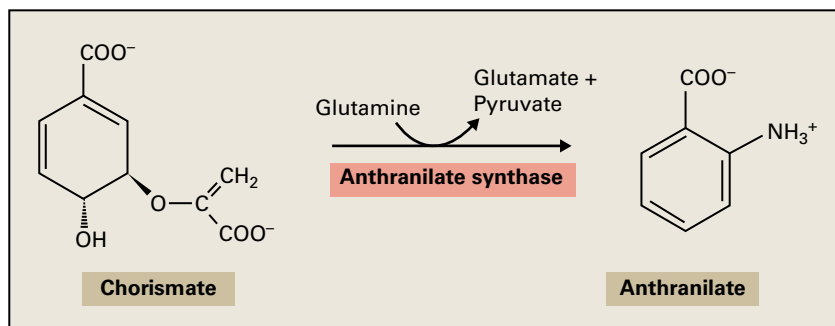

FIGURE 7.24 Anthranilate synthase catalyzes the first step of tryptophan biosynthesis. Note that the γ -amide group of glutamine becomes the aromatic amino group of anthranilate. This activity, often called a glutamine aminotransferase, is therefore correctly called a glutamine amidotransferase. Glutamine amidotransferases, which are PLP-independent, generally catalyze a reaction in which ammonia generated by hydrolysis of glutamine is channeled to a second active site where it acts as a nucleophile. The hydrophobic tunnel prevents protonation of NH_3 , and thus maintains its nucleophilicity.

β subunit (Fig. 7.24). Analysis of the crystal structure of the bacterial enzyme suggests that the binding of chorismate to the α subunit triggers a conformational change to an active state and creates an intermolecular **tunnel for ammonia transfer** from the β to α subunit. As is the case in microorganisms, the α subunit can function in the absence of β subunit amidotransferase activity, provided ammonium is present at sufficient concentration (Reaction 7.1). However, the glutamine amidotransferase activity is likely of primary importance for AnS function in plants. The *trp4* mutation in the *Arabidopsis* AnS β subunit gene 1 suppresses accumulation of anthranilate, which possesses a strong blue fluorescence under UV light (see Box 7.2).

Reaction 7.1: Anthranilate synthase

As expected for the committing enzyme in the tryptophan pathway, plant AnS activities are feedback-inhibited by micromolar concentrations of tryptophan in vitro. Tryptophan binds to the α subunit and restricts the AnS conformational change, suggesting the α subunit is responsible for the allosteric feedback inhibition by tryptophan. Most AnS α subunits in plants are feedback-sensitive to tryptophan, with the exceptions of feedback-insensitive tobacco and *Ruta graveolens* (common rue) α -subunit isoforms (see Box 7.3).

The use of toxic tryptophan analogs as false-feedback inhibitors allowed the identification of mutants with altered AnS regulation. Dominant *trp5-1D Arabidopsis* mutants that are resistant to **tryptophan analogs** have feedback-insensitive AnS activity. All four of these mutants resulted from the same aspartate to asparagine change in the AnS α -subunit gene *ASA1*, a mutation close to a region of microbial AnS enzymes important for feedback regulation. The *trp5-1* mutant has a threefold increase in free tryptophan, illustrating the importance of allosteric control in regulating tryptophan pools. Plants contain at least two genes encoding the α subunit and one gene encoding the β subunit. One of the

α -subunit genes is constitutively expressed, whereas the other is regulated developmentally and is induced in response to wounding and pathogens, suggesting its involvement in the production of tryptophan pathway-derived natural products as a part of plant defense.

7.3.6 Biochemical characterizations of PAT, PAI, and IGPS lag behind molecular and genetic analyses

The second enzyme in the tryptophan biosynthesis is phosphoribosylanthranilate transferase (PAT), which catalyzes the formation of 5-phosphoribosyl anthranilate by transferring the phosphoribosyl moiety from phosphoribosylpyrophosphate to anthranilate (Fig. 7.25). A single-copy gene encodes PAT in the *Arabidopsis* genome. *PAT* is constitutively expressed, and its mRNA level is post-transcriptionally enhanced by the first two introns in *Arabidopsis*.

While relatively little is known about the enzymology of plant PATs, the *Arabidopsis* enzyme has been the subject of detailed genetic and molecular analysis. *PAT* mutants fall into two general classes: auxotrophic plants, which have such low *PAT* enzyme activity that seedlings cannot grow on sterile medium without the addition of tryptophan, and prototrophs, which have enough residual activity to survive without amino acid supplementation. Unlike the **prototrophic mutants**, which grow with a normal morphology, adult *trp1* **auxotrophic mutants** are small, bushy, and have greatly reduced fertility, even when tryptophan is added to their growth medium (Fig. 7.26). Perhaps these developmental defects are caused by an inability to produce auxin (indole-3-acetic acid, IAA) or other metabolites derived from this pathway. Biochemical analysis of the prototrophic *trp1* mutants indicates the *PAT* enzyme activity is present in vast excess of that required for maintaining pathway flux. Five of the prototrophic mutants have 1% of wild-type enzyme activity or less, yet grow normally without tryptophan supplementation.

BOX
7.3

An alkaloid-producing plant has a feedback-insensitive AnS

While feedback regulation of AnS is a logical mechanism for controlling the accumulation of tryptophan, it could reduce the plant's ability to rapidly synthesize secondary metabolites in response to environmental stimuli.

The existence of naturally occurring **tryptophan-insensitive AnS** isoforms is one mechanism by which plants appear to avoid this potential difficulty. After treatment with fungal cell wall elicitor, *Ruta graveolens* cell cultures rapidly accumulate anthranilate-derived antimicrobial **acridone alkaloids** (e.g., **rutagravin**; A); during this period, AnS activity and AnS α -subunit mRNAs increase dramatically. Both control and elicitor-induced cultures have similar amounts of tryptophan-sensitive AnS activity, but elicited cultures accumulate a large amount of feedback-resistant AnS.

These biochemical data correlate well with results of gene expression studies. *R. graveolens* has two characterized AnS α genes: AS α 1 mRNA accumulation is stimulated after elicitation, whereas the amount of AS α 2 mRNA does not change (B). Further characterization of the two AnS α -isoforms expressed in *E. coli* showed that the inducible AnS α 1 activity is barely affected by the

presence of unusually high concentrations of tryptophan (up to 100 μ M). In contrast, the non-inducible AnS α 2 product has an apparent K_i of less than 3 μ M tryptophan, very similar to that observed for other characterized plant AnS activities. These results suggest that this alkaloid-producing plant makes an inducible AnS that is not subject to tryptophan inhibition and thus allows synthesis of anthranilate for secondary metabolism even under conditions where free tryptophan is plentiful.

Source: Last, Cereon Genomics LLC, Cambridge, MA; previously unpublished.

FIGURE 7.27 *Phosphoribosylanthranilate isomerase (PAI)* catalyzes the third step of tryptophan biosynthesis.

The third enzyme in the tryptophan biosynthetic pathway is **phosphoribosylanthranilate isomerase** (PAI; Fig. 7.27), which converts 5-phosphoribosylanthranilate to 1-(*o*-carboxyphenylamino)-1-deoxyribulose 5-phosphate (CDRP). Depending on ecotypes, *Arabidopsis* possesses three or four highly homologous *PAI* genes. In the Columbia ecotype, *PAI1* and *PAI2* are 99% identical, including their untranslated regions. This differs from the low degree of conservation observed for prokaryotic PAI proteins and suggests a recent **gene duplication** event or other mechanism that actively maintains the similarity of these genes. Each *PAI* gene exhibits a spatially and developmentally distinct expression pattern and a differential response to environmental stimuli. Owing to *PAI* gene redundancy, loss of any one gene does not reduce enzyme activity sufficiently to produce a distinct mutant phenotype. Even transgenic antisense-RNA plants with 10–15% of wild-type PAI enzyme activity do not show reduced growth rate, nor do they require tryptophan for growth. These observations suggest that PAI activity is present in excess of that required for normal growth. In the single PAI-deficient *Arabidopsis* mutant for which data have been published, deletion of one locus and DNA methylation-associated epigenetic silencing of the other gene were required to reduce the enzyme activity sufficiently to an undetectable level and to observe a visible phenotype (see Box 7.4; see also Chapter 9).

The penultimate enzyme of tryptophan biosynthesis, **indole-3-glycerol-phosphate synthase** (IGPS), catalyzes the decarboxylation and ring closure of CDRP (Fig. 7.28). It is the only enzyme known to catalyze the formation of the indole ring. One of two *Arabidopsis* genes encoding IGPS was isolated based on its ability to complement an *E. coli trpC*⁻ mutation despite low amino acid identity (22–28%) with microbial enzymes. Plant IGPSs exist as monofunctional enzymes, in contrast to fungal and bacterial IGPSs, which are synthesized as fusion proteins containing one or two other enzymes of the tryptophan biosynthetic pathway. Analysis of tryptophan and IAA levels in different *Arabidopsis* tryptophan biosynthesis mutants, as well as in transgenic plants with antisense

suppression of *IGPS*, suggested that indole-3-glycerol-phosphate might be the branch-point intermediate in tryptophan-independent auxin biosynthesis. It appears, however, that IAA in these mutants is a decomposition product of the chemically unstable IGPS that accumulates in tryptophan synthase mutants (see below). A **tryptophan-independent auxin biosynthesis** is, therefore, unlikely (see Chapter 17).

7.3.7 Tryptophan synthase catalyzes the final step in tryptophan synthesis

Tryptophan synthase (TS) is a bifunctional enzyme that catalyzes the last two-step reaction of tryptophan biosynthesis, the conversion of indole-3-glycerol phosphate (IGP) and serine to tryptophan (Fig. 7.29). The best characterized of the microbial tryptophan biosynthetic enzymes, TS exists as an $\alpha_2\beta_2$ heterotetramer, and the separate subunits are capable of catalyzing independently two partial reactions of the reaction sequence:

Reaction 7.2: TS α -subunit

Reaction 7.3: TS β -subunit

Biochemical and X-ray crystallographic studies of the *Salmonella typhimurium* TS enzyme have revealed that the indole intermediate generated at the active site of the α -subunit (TSA) is not ordinarily released from the enzyme, but rather travels through a 25-Å **intermolecular tunnel** to the β -subunit (TSB) active site (Fig. 7.30). This is comparable to the “**ammonia tunnel**” in glutamine amidotransferases (see Fig. 7.24). The two partial reactions are kept in phase by allosteric interactions between the two subunits, and each subunit can cause conformational changes that affect the catalytic

BOX
7.4Epigenetic regulation of *PAI2* results in partial tryptophan auxotrophy

Although blue fluorescence screening failed to reveal *pai* mutants in the *Arabidopsis* Columbia ecotype, an unusual blue fluorescent mutant with diminished PAI activity was identified in the Wassilewskija ecotype. Unlike the large number of *trp1* mutants and antisense-*PAI* lines that are uniformly fluorescent, the phenotype of this mutant is unstable, showing a high frequency of somatic reversion to wild type (see figure).

Unlike Columbia, which has three genes, wild-type Wassilewskija (A) has four *PAI* genes, with *PAI4* found in an inverted repeat with *PAI1* at the same genetic site as the Columbia *PAI1* locus. The blue fluorescent *pai* mutant contains a deletion that simultaneously inactivates the linked *PAI1* and *PAI4* genes, leaving only *PAI2* and *PAI3* intact and making the plant dependent on *PAI2* expression. The Wassilewskija *PAI2* gene is subject to epigenetic regulation and is normally hypermethylated (shown as Me-*PAI2** in B), which leads to low mRNA expression. The instability of the mutant phenotype can be accounted for by random reduction in methylation of Me-*PAI2** (C), which reactivates the gene and creates epi-revertant regions of the plant that are phenotypically wild type (not blue fluorescent). These revertant tissues have enough PAI enzyme activity to prevent accumulation of anthranilate and thus allow normal growth of the plant. Because the blue fluorescence is cell-autonomous, the phenotype of each part of the plant accurately reflects its epi-genotype.

This is an example of how genetic tools that became available from studies of biochemical genetics can open up new approaches to studying seemingly unrelated areas of biology. In fact, because of the powerful blue fluorescence phenotype and well-characterized *PAI* gene family, the epigenetically silenced *PAI2** gene led to new approaches for studying the interesting areas of gene silencing and epigenetics, which have since developed into a fascinating field (see Chapter 7).

activity of the other. For example, α -subunit binding stimulates β activity (Reaction 7.3) 30-fold compared with uncomplexed β subunit. Conversely, the rate of cleavage of IGP at the α -subunit active site (Reaction 7.2) is increased 20-fold by binding of serine to the pyridoxal phosphate cofactor at the β -subunit active site (Fig. 7.30). In contrast to mutual activation of the subunits in bacteria, only an activation of the

α -, but not the β -subunit, by the respective other subunit was observed upon formation of the $\alpha_2\beta_2$ TSA complex of maize.

Fungi possess a single gene encoding a bifunctional TSA-TSB enzyme, whereas *E. coli* and plants have separate genes encoding TSA and TSB. In the *Arabidopsis* genome, there are at least two and four putative genes encoding TSA and TSB, respectively. The functional relevance of TSA1 and TSB1 in

FIGURE 7.28 The indole-3-glycerol-phosphate synthase (IGPS) reaction produces the indole ring found in tryptophan and secondary metabolites.

FIGURE 7.29 Tryptophan synthase (TS) catalyzes the final step in tryptophan biosynthesis.

tryptophan biosynthesis has been demonstrated by the tryptophan auxotrophic phenotype of the *trp3* and *trp2* mutants, respectively. However, the function of the other isoforms is not fully understood. In contrast to *Arabidopsis*, maize (*Zea mays*) contains one TSA and two highly identical and redundant TSB genes. Only simultaneous loss of both TSB functions leads to tryptophan auxotrophy.

Plants possess additional enzymes besides TSA that produce indole from IGP. Indole is a common precursor not only of tryptophan, but also of other plant natural products. Thus, in maize, a separate **indole-3-glycerolphosphate lyase** (IGL) is responsible for the formation of **volatile indole** under herbivore attack, while BX1 (see Box 7.5) catalyzes the first step in the biosynthesis of natural **benzoxazinoid pesticides**. The *Arabidopsis* genome also contains an indole-producing TSA-like enzyme (IGL). While all three genes are TSA paralogs,

the corresponding proteins catalyze indole formation independent of a TSB-like subunit. As production of indole or benzoxazinoids sometimes exceeds that of tryptophan, the heterocomplex formation between TSA and TSB prevents the release of the indole intermediate and ensures a basal level of tryptophan for protein and auxin biosynthesis.

7.3.8 Aromatic amino acid biosynthesis occurs in the plastid

Aromatic amino acids are synthesized in the chloroplast, and several lines of evidence show that the total set of enzymes for the biosynthesis of phenylalanine, tryptophan, and tyrosine is found in plastids. Isolated chloroplasts incorporate $^{14}\text{CO}_2$ into

FIGURE 7.30 Tryptophan synthase (TS) consists of α - and β subunits that join to form two active sites with a hydrophobic tunnel between them that channels indole from the site where it is released from indole-3-glycerol phosphate to the site where it is condensed with serine. (A) The structure of TS from *Salmonella typhimurium* with α subunits in blue, β subunit N-terminal residues in yellow, and C-terminal residues in red. A molecule of indole-3-glycerol phosphate (red) is bound to the active site of the α subunit. (B) Schematic drawing of the tunnel that guides indole from the active site of the α subunit to that of the β subunit.

BOX 7.5

Plants have an alternative single-subunit TSA enzyme efficient in indole synthesis

Indole has been implicated as an intermediate in the synthesis of some secondary metabolites, for example, cyclic hydroxamic acids such as 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), the structure of which is shown. This would appear to create a dilemma, because in the well-characterized bacterial TS enzyme, indole moves through a tunnel from the TSA active site to TSB, and does not escape from the TS heteroenzyme. A novel variation on the TS mechanism is found in maize (*Zea mays*), where a mutant (*bx1*, for benzoxazin-less) that fails to accumulate the normally abundant DIMBOA has a defect in a TSA-like gene (*BX1*).

Unlike the *Arabidopsis* TSA1 protein, expression of the BX1 protein complements a *trpA* mutation even in the absence of a plant β subunit. This result argues that the BX1 protein can efficiently cleave IGP to form free indole without being activated by a TSB subunit. Kinetic analysis of the BX1 protein expressed in *E. coli* has confirmed

that the homomeric BX1 enzyme is 30-fold more efficient in catalyzing IGP cleavage than the *E. coli* $\alpha_2\beta_2$ heteroenzyme. This suggests that plants have modified an enzyme of tryptophan biosynthesis to serve as the committing enzyme of indole-derived secondary metabolism while retaining the $\alpha_2\beta_2$ heteroenzyme for tryptophan biosynthesis.

aromatic amino acids, and activities of almost all enzymes involved in chorismate and aromatic amino acid biosynthesis have been detected in chloroplast extracts. Consistent with this view, genes containing plastid targeting sequences have been cloned for at least one isoenzyme responsible for a given biochemical step in the plant aromatic amino acid pathway. Plastid localization for most pathway enzymes was confirmed using GFP (green fluorescent protein) fusion proteins. Import of precursor proteins of DAHP synthase, shikimate kinase, EPSP synthase, PAL, and TSA into isolated chloroplasts has been also demonstrated.

Subcellular fractionation and localization studies have uncovered a **cytosolic DAHP synthase** activity in some plants, and cytosolic isoforms both of CM (probably all plants) and **dehydroquinase dehydratase-shikimate dehydrogenase** (so far only found in tobacco; see Section 7.3.2) as well. The last two enzymes were confirmed at both biochemical and genetic levels. Genes encoding cytosolic tobacco (*Nicotiana tabacum*) dehydroquinase dehydratase/shikimate dehydrogenase 2 and *Arabidopsis* and petunia (*Petunia hybrida*) CM2 have been identified, and the cytosolic localization of the corresponding proteins was demonstrated. However, a gene encoding cytosolic DAHP synthase has not been identified, though several cytosolic enzymes catalyze the same reaction as DAHP synthase and are activated by Co^{2+} rather than Mn^{2+} . It seems unlikely that these are true enzymes of chorismate biosynthesis, because they can utilize a wide variety of aldehyde substrates in place of erythrose 4-phosphate, and their K_m values for erythrose 4-phosphate are tenfold higher than that of the Mn^{2+} -activated enzyme. Thus, these enzymes probably have metabolic roles in the cytosol unrelated to aromatic amino acid biosynthesis.

7.3.9 Aromatic amino acid biosynthesis is stress inducible

Unlike the aromatic amino acid biosynthetic enzymes in well-studied microbes such as *E. coli* and yeast, plant enzymes are regulated by environmental signals. This is logical, considering that, in contrast to the low abundance of the amino acids themselves, plants produce abundant, and in many cases highly inducible, secondary metabolites from intermediates or end products of these pathways. In fact, these enzymes of intermediary metabolism appear to be coordinately regulated with the pathways of aromatic secondary metabolism.

Evidence for this was first obtained in studies of the committing enzyme of aromatic amino acid biosynthesis. Mn^{2+} -dependent DAHP synthase activity and corresponding mRNA abundance increase in response to several treatments that induce secondary metabolite accumulation: wounding of plants, treatment of suspension cells with fungal elicitor, and bacterial pathogen treatment. The kinetics of wound-inducible DAHP synthase mRNA induction are similar to that of phenylalanine ammonia-lyase (PAL), the committing enzyme of aromatic secondary metabolism (Fig. 7.31A). This coinduction of gene expression in response to the environment is

not limited to the first enzyme of the shikimate pathway, because shikimate kinase, EPSP synthase, chorismate synthase, and PAL are all maximally induced within several hours after fungal elicitor treatment of tomato (*Solanum lycopersicum*) suspension cells. Similarly, CM1 activity is induced by wounding in potato (*Solanum tuberosum*) tubers, and CM1 and PAL mRNA are coordinately induced in elicited *Arabidopsis* suspension culture cells. In contrast, shikimate pathway genes exhibit different induction kinetics upon exposure of plants to ozone with DAHP synthase, 3-dehydroquinase dehydratase/shikimate dehydrogenase, and EPSP synthase showing the strongest induction. Only weak upregulation was observed for the other genes of the pathway.

There is also a strong correlation in *Arabidopsis* between upregulation of the genes of tryptophan biosynthesis and accumulation of the indolic secondary metabolite **camalexin** (see Fig. 7.22) in response to a variety of stressful environmental conditions. Both mRNAs and proteins for all of the enzymes of the tryptophan pathway are induced after treatment with bacterial pathogens, and the rates of induction are similar to that for camalexin accumulation. Not only is the timing of the responses coordinated, but the amount of camalexin that accumulates is tightly correlated with the degree of tryptophan pathway enzyme induction in response to various bacterial pathogens (Fig. 7.31B).

Recent progress in transcriptome analysis allowed use of bioinformatics to dissect and obtain a global view of the regulation of plant metabolic responses to a variety of abiotic and biotic stresses. This analysis revealed that genes encoding enzymes involved in catabolism of amino acids are generally much more sensitive and respond more quickly at the transcriptional level to environmental and stress-associated signals than genes encoding anabolic (allosteric and nonallosteric) enzymes. Thus, **amino acid catabolism** is subjected primarily to transcriptional regulation, whereas in the regulation of amino acid biosynthesis, post-translational allosteric feedback inhibition plays an important role. However, a strong transcriptional response of both anabolic and catabolic genes in the tryptophan pathway was observed in response of *Arabidopsis* shoots to UV-B treatment.

7.4 Aspartate-derived amino acids

Three pathways lead directly from aspartate to the amino acids **lysine**, **threonine**, and **methionine** (see Figs. 7.2 and 7.32). Threonine is then a precursor to **isoleucine**, and methionine is activated to **S-adenosylmethionine** (SAM), which is the most important donor of the methyl group in many methylation reactions and also serves as a precursor in the formation of ethylene, polyamines, and in the chain elongation pathway of glucosinolate formation.

Aspartate-derived amino acids are required in the diets of nonruminant animals, including humans. Some diets that rely on plant foods are deficient in one or more of these protein building blocks and can lead to health problems if the

FIGURE 7.31 Plants induce the enzymes of aromatic amino acid biosynthesis under conditions that cause increases in aromatic secondary metabolism. (A) Wounding of potato tubers causes increased DAHP synthase mRNA and enzyme activity. (B) Infection with a bacterial pathogen increases mRNAs for Arabidopsis tryptophan pathway enzymes and increases production of the antimicrobial indolic secondary metabolite camalexin, which fluoresces blue under UV light.

amino acid deficiencies of grains and legume seeds are not complemented by eating both in combination. Human vegetarians who do not eat any animal products must balance their diets with care to provide all essential amino acids in the proportions that are needed for protein synthesis.

Like humans, farm animals cannot subsist on a diet composed entirely of grain. For example, corn is commonly used in animal feed because it provides calories at low cost, but it has a poor amino acid content and composition, being especially deficient in lysine, but also tryptophan and methionine. On the other hand, soybean is lysine-rich but methionine- and threonine-poor. Supplementing the diets of soybean- or grain-fed animals with lysine, threonine, or methionine increases the growth rate of these animals but is expensive. Not surprisingly, researchers are interested in using conventional breeding and transgenic metabolic engineering approaches to increase the amounts of nutritionally important amino acids, in particular those derived from aspartate, in crop plants.

7.4.1 Threonine, lysine, and methionine are products of a branched pathway with complex biochemical regulation

Aspartate provides the entire carbon skeleton for **threonine**, making it useful to consider threonine biosynthesis as the main pathway (Fig. 7.33), with branches to lysine and methionine

(see Figs. 7.34 and 7.35). Aspartate is activated by phosphorylation by **aspartate kinase** (AK; also called aspartokinase), the committing enzyme for all aspartate-derived amino acid biosynthesis. **Aspartate 4-phosphate** (β -aspartyl phosphate) then goes through two NADPH-mediated reductions, which are catalyzed sequentially by **aspartate-semialdehyde dehydrogenase** and **homoserine dehydrogenase** (HSDH), to yield homoserine. Homoserine is then phosphorylated at the 4-position by **homoserine kinase**. **Homoserine 4-phosphate** is at the branching point of threonine and methionine biosynthesis. **Threonine synthase**, a pyridoxal phosphate-dependent enzyme that is allosterically activated by SAM (see Section 7.4.3), is a phospholyase that cleaves the carbon–oxygen bond of homoserine phosphate and then adds water to form the hydroxyl group of threonine.

Lysine biosynthesis presents a deviation from the general rule that the sequences of chemical reactions in complex amino acid biosynthetic pathways are uniform and evolutionarily conserved between all organisms possessing these pathways. It has been known for almost 50 years that the biosynthetic pathways leading to lysine are fundamentally different between bacteria and plants on the one hand, and fungi (asco- and basidiomycetes) on the other hand. In bacteria and plants, lysine is synthesized from aspartate via the **diaminopimelate (DAP) pathway** (Fig. 7.34). DAP is a component of the cell wall peptidoglycan in most bacteria, and the DAP pathway, therefore, fulfills two important functions in these organisms by supplying both DAP and lysine.

FIGURE 7.32 The aspartate-derived amino acids are produced in the plastid. Methionine activation to S-adenosylmethionine and methionine regeneration occur in the cytosol.

The fungal pathway proceeds through the intermediate α -aminoadipate, from which the name AAA pathway is derived. The starting point in AAA formation is the condensation of α -ketoglutarate and acetyl-CoA to give homocitrate (analogous to citrate formation in the TCA cycle), which is then converted in further TCA cycle-analogous reactions to α -ketoacidipate (corresponding to an α -ketoglutarate extended by a methylene group) that is transaminated to yield α -aminoadipate. A variant of the AAA pathway has been found in thermophilic bacteria and in archaea, and the evolutionary background of these convergent pathways of lysine biosynthesis is a challenging topic.

The committing enzyme in the DAP pathway of lysine biosynthesis is **dihydrodipicolinate synthase** (DHPS), which condenses aspartate 4-semialdehyde with pyruvate and cyclizes the product to 2,3-dihydrodipicolinate. For a long time, it was not clear by which reactions *meso*-2,6-diaminopimelate is

then formed in plants, because even within the bacteria several variants were found, none of which could be verified in plants. After an intensive search for orthologs of bacterial lysine biosynthesis genes in the *Arabidopsis* genome, followed by functional analysis of the gene products, it was uncovered that plants use yet another variant (Fig. 7.34): as in all bacterial variants, dihydrodipicolinate is reduced to **tetrahydrodipicolinate**. Then the pathways diverge; in plants, the acyclic form of tetrahydrodipicolinate is transaminated to give rise to L,L-DAP, which is then epimerized to *meso*-DAP.

(The term epimer is used when in a compound containing two or more chirality centers only one of these is converted to opposite chirality. The two compounds would then be diastereomers rather than enantiomers. A *meso*-form has a plane of symmetry, so the compound is overall achiral. The best known example is tartaric acid.)

At *meso*-DAP the variant pathways meet again, and lysine is formed by decarboxylation of *meso*-DAP. Within an amazingly short time, the crystal structure of the novel enzyme had been determined, giving testimony to the powerful support of biochemistry by genomics.

7.4.2 Methionine formation requires sulfur

In bacteria and plants, the continuous four carbon atoms in **methionine** are derived from the homoserine carbon skeleton. To replace the oxygen function by sulfur, the hydroxyl group must be activated. In bacteria and yeast, the activated form is *O*-succinylhomoserine and *O*-acetylhomoserine, respectively, while in plants it is *O*-phosphohomoserine (homoserine 4-phosphate), which is also the precursor of threonine (Fig. 7.35). In the **trans-sulfuration pathway**, the thiol group of cysteine is transferred to homoserine to produce homocysteine, through a cystathionine intermediate. **Cystathionine γ -synthase**, another pyridoxal phosphate-dependent enzyme, catalyzes the sulfur-linked joining of cysteine and homoserine 4-phosphate to form cystathionine (a thioether) and orthophosphate. Next, the C_3 skeleton of cysteine is cleaved by **cystathionine β -lyase** (again pyridoxal phosphate-dependent), now leaving the sulfur atom attached to the homoserine carbon skeleton; this produces **homocysteine**, pyruvate, and ammonium, making the reaction essentially irreversible. Direct sulfhydration of the activated homoserine with sulfide to give rise to homocysteine is the rule in bacteria and yeast, while in plants it seems to be of minor physiological significance. Homocysteine is then converted to methionine, with N^5 -methyltetrahydrofolate serving as the methyl donor, in a reaction catalyzed by **methionine synthase** (homocysteine methylase). This activity not only is involved in de novo methionine synthesis, but also functions in recycling the **S-adenosyl-L-homocysteine** produced when SAM donates its methyl group in a methylation reaction (Fig. 7.36). While all steps of aspartate-derived amino acids were known to occur in plastids, it seemed puzzling that the final step in methionine synthesis should be localized to the

FIGURE 7.33 The threonine biosynthetic pathway.

FIGURE 7.34 Lysine biosynthesis branches from the threonine pathway.

cytoplasm. This puzzle has been finally solved, however (see Section 7.4.4).

Methionine has two major fates: incorporation into proteins or conversion into SAM. SAM is a methyl donor used in DNA and RNA modification and in synthesis of abundant plant structural components, including lignin precursors,

choline and its derivatives, and **pectin** (methyl esters of polygalacturonic acid). The carbon skeleton of the methionine moiety of SAM is also used as a precursor to the plant hormone ethylene and to polyamines (see Chapter 17), and in the chain elongation pathway of glucosinolate biosynthesis (see Chapter 24). Radiotracer experiments with the aquatic

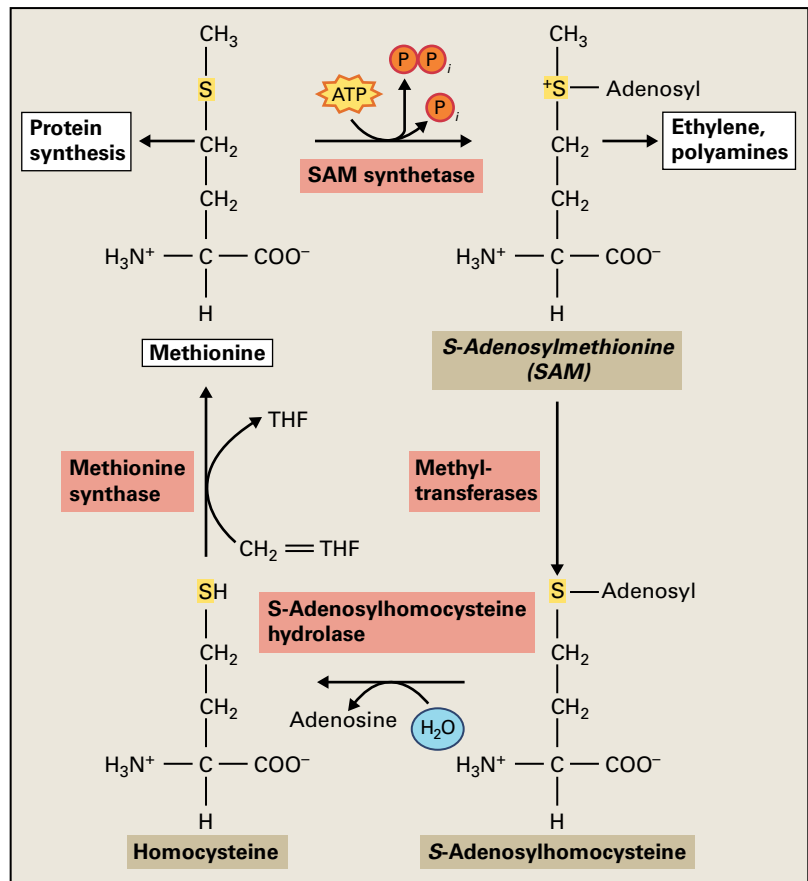

FIGURE 7.35 The methionine biosynthetic pathway. THF, tetrahydrofolate.

FIGURE 7.36 S-Adosylmethionine is produced from methionine and can be recycled to regenerate methionine. THF, tetrahydrofolate.

plant *Lemna paucicostata* (duckweed) indicate that more than 80% of the label from ^{14}C -methyl-labeled methionine was incorporated into lipids, pectins, chlorophyll, and nucleic acids, whereas less than 20% appeared in protein. Thus, apparently the majority of methionine is converted into SAM for transmethylation reactions in plants. Production of SAM is an energy-demanding process in the unusual course of which the entire triphosphate chain is displaced from ATP by SAM synthetase and pyro- and orthophosphate, respectively, are released (Fig. 7.36).

As is the case for most amino acids, their catabolism has been investigated to a much lesser extent than their biosynthesis. For methionine, it became only recently clear in *Arabidopsis* that in addition to its transamination, cleavage of methionine by **methionine γ -lyase** is the initial reaction in its degradation. This pyridoxal phosphate-dependent enzyme occurs in microorganisms, and based on amino acid sequence similarity an ortholog was identified in the *Arabidopsis* genome and the corresponding protein characterized. This cytosolic enzyme converts methionine to **methanethiol** ($\text{CH}_3\text{-SH}$), **α -ketobutyrate**, and ammonia. α -Ketobutyrate is the precursor of **isoleucine** (see Section 7.5.1) and is thus not exclusively formed by threonine deaminase as had been generally believed.

7.4.3 Regulation of threonine, lysine, and methionine synthesis is complex

Not surprisingly, the biochemical mechanisms regulating flux through the branches of the aspartate-derived amino acid pathway are complex. First, aspartate-derived metabolism

can follow three major routes, creating at least five branch point enzymes: **aspartate kinase (AK)**, **dihydrodipicolinate synthase (DHDPS)**, **homoserine dehydrogenase (HSDS)**, **threonine synthase (TS)**, and **cystathionine γ -synthase (C γ S)**. Of these, the first four are allosterically regulated in plants, and C γ S is regulated at the transcriptional and, in some plants, at the posttranscriptional level. Second, the products of these pathways are expected to be needed by the plant in different amounts at each stage of development. An overview of the types of regulatory mechanisms inferred by in vitro studies is shown in Figure 7.37. As described below, experiments with feedback-insensitive mutants and transgenic plants are clarifying the in vivo importance of these regulatory phenomena.

AK, the committing enzyme for the overall pathway, is a critical regulatory enzyme occurring in multiple classes of AK isoenzymes, which have divergent primary sequences and contrasting allosteric properties. Biochemical studies indicated the existence of at least two forms of AK activity that are separable by column chromatography. For example, barley AK-I is inhibited by lysine, an inhibition potentiated by SAM. AK-II and AK-III, however, are both sensitive to threonine inhibition. Molecular analysis has identified genes that express two classes of AK: monofunctional proteins that resemble the *E. coli* lysine-sensitive isoform, and bifunctional enzymes homologous to the *E. coli* threonine-sensitive isoform that contain an HSDH coding region at the C-terminus (AK-HSDH).

If feedback regulation of AK is primarily responsible for regulating flux to all three end products (threonine, lysine, and methionine/SAM), deregulating this enzyme should increase accumulation of all three amino acids, and this is indeed the case. Mutants with deregulated **lysine-sensitive AK** were

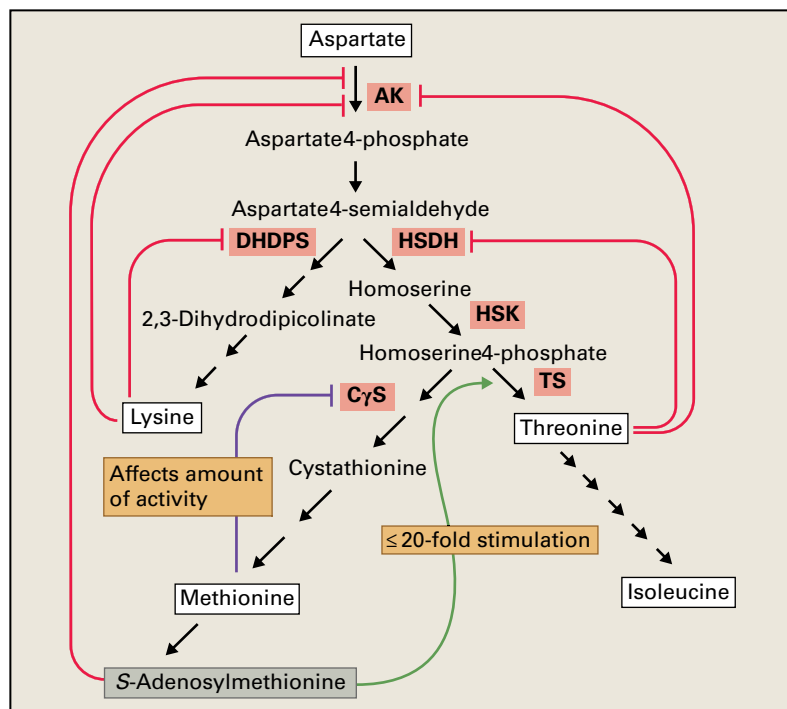

FIGURE 7.37 Biochemical regulatory mechanisms proposed to regulate the synthesis of amino acids derived from aspartate. Red lines indicate end-product inhibition, the purple line refers to a reduction in detectable enzyme, and the green lines indicate stimulation of activity.

FIGURE 7.38 Treatment of plants with lysine plus threonine allows selection for feedback-insensitive aspartate kinase mutants. AK_{Lys} and AK_{Thr} refer to AK isoforms that are inhibited by lysine or threonine, respectively. (A) Growth of wild-type plants or plant cell cultures on medium containing a mixture of lysine and threonine causes death by methionine starvation because of inhibition of AK activity. (B) Mutants arise that are insensitive to this normally toxic amino acid mixture. These plants (AK^*_{Lys}) contain amino acid changes in their lysine-sensitive aspartate kinase activities, which make them insensitive to feedback inhibition. This restores the plant's ability to synthesize methionine.

selected by taking advantage of the fact that administration of threonine and lysine causes starvation for methionine by reducing total AK activity through feedback inhibition. Mutants were selected with AK activities that were less sensitive to lysine inhibition (Fig. 7.38). In an analogous approach, transgenic tobacco (*Nicotiana tabacum*) or potato (*Solanum tuberosum*) plants were constructed to express a *lysC* gene encoding a feedback-desensitized AK protein from *E. coli*. That these mutants and transgenic plants overaccumulated threonine shows both that AK plays an important role in modulating threonine accumulation in plants and that lysine and methionine accumulation are influenced at later steps in the pathway.

In plants, DHDPS activity is very sensitive to lysine inhibition (the concentration to achieve 50% inhibition, or I_{50} , is 10–50 μ M), making it a likely candidate for a key regulator of lysine accumulation. Plant mutants with desensitized DHDPS were identified in several species by selection for resistance to the toxic lysine analog **S-aminoethyl-L-cysteine** (AEC). This molecule competes with lysine for incorporation into proteins and allows the identification of lysine-overproducer plants. AEC resistance in *Nicotiana sylvestris*, caused by production of a lysine-insensitive mutant DHDPS enzyme with a single amino acid change, led to these plants accumulating about 10-fold more lysine than did the wild type (Fig. 7.39). Similar results were obtained with transgenic plants that expressed bacterial DHDPS proteins, which are naturally about 20-fold less sensitive to lysine inhibition than plant enzymes are. In agreement with the mutant results, tobacco (*Nicotiana tabacum*) and oilseed rape (*Brassica napus*)

transformants accumulated greater amounts of lysine than did controls. These results demonstrate the importance of allosteric regulation of DHDPS in regulating lysine accumulation in plants.

Transgenic plants and mutants that simultaneously express both feedback-insensitive AK and DHDPS accumulate free lysine concentrations that exceed those in plants expressing the mutant DHDPS alone, and have less threonine than plants with the desensitized AK alone. These results provide two important lessons about regulation of flux through this pathway. First, the relative accumulation of threonine and lysine seems to be affected by the ability of DHDPS and HSDH to compete for limiting amounts of aspartate 4-semialdehyde. Second, the very high sensitivity of DHDPS to feedback inhibition ordinarily restricts flux into lysine biosynthesis, explaining why AK single-mutant plants preferentially accumulate threonine rather than lysine.

Homoserine 4-phosphate is the final intermediate common to synthesis of threonine/isoleucine and methionine/SAM. Thus, the relative ability of threonine synthase and cystathionine γ -synthase to compete for this intermediate is likely to be important for regulating metabolic flux through these pathways. Two mechanisms have been proposed to influence this partitioning (see Fig. 7.37): (a) stimulation of threonine synthase activity by the product of the competing pathway, SAM; and (b) modulation of cystathionine γ -synthase activity by methionine availability. Thus, flux from homoserine 4-phosphate into threonine or methionine biosynthesis may be primarily regulated by the amounts of methionine and SAM present.

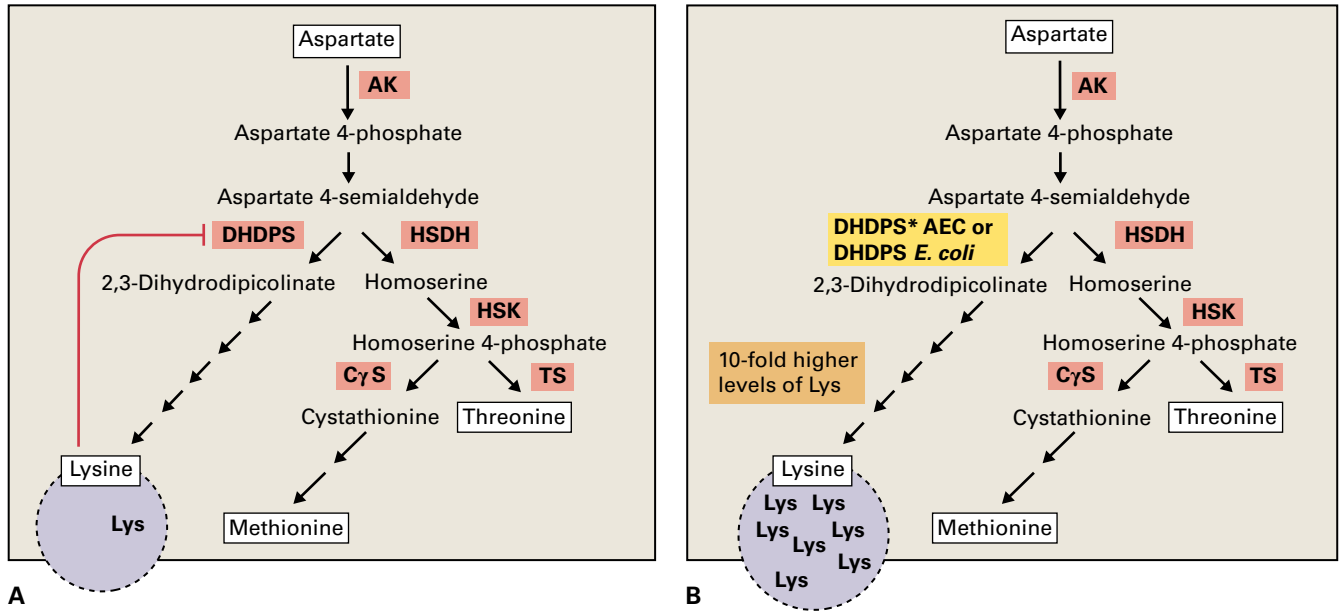

FIGURE 7.39 Dihydrodipicolinate synthase (DHDPS) regulates the accumulation of lysine in plants. (A) Feedback inhibition of DHDPS acts to control the flux from aspartate 4-semialdehyde into lysine. (B) Dominant feedback-insensitive DHDPS mutants can be selected by use of classical genetics (DHDPS* AEC) or by expression of feedback-insensitive *E. coli* enzyme in transgenic plants (DHDPS *E. coli*). These plants overproduce lysine in comparison with the plant that expresses the wild-type DHDPS activity.

FIGURE 7.40 Initial reactions in lysine catabolism.

7.4.4 Biosynthesis and degradation regulate lysine levels in a concerted manner that must be understood to produce high-lysine plants

High quantities of lysine accumulate in plants expressing feedback-insensitive mutant DHDPS, but this perturbation of metabolism, which also affects other amino acids, causes severe developmental defects. Increasing the nutritional value of crops requires engineering increased lysine content in seeds, but simply increasing lysine biosynthesis by expressing mutant DHPS in a seed-specific manner may not be enough to achieve this goal. Targeting high-level expression of deregulated enzyme activities to seeds actually causes an

enhancement of lysine breakdown. The first enzyme of **lysine catabolism** is **lysine-ketoglutarate reductase (LKR)**, which reduces the labile Schiff base that is formed between the ϵ -amino group of lysine and α -ketoglutarate, to a stable opine, **saccharopine** (Fig. 7.40). In the subsequent reaction, catalyzed by saccharopine dehydrogenase (SDH), the amine function is transferred to the α -ketoglutarate skeleton, giving rise to glutamate while the ϵ -C of the lysine C-skeleton now carries the carbonyl function (α -aminoadipic δ -semialdehyde, which is further degraded to yield acetyl-CoA). The bifunctional polypeptide LKR/SDH is induced by lysine through complex transcriptional and posttranslational controls and is also subject to regulation by stress-associated signals. In addition to encoding the bifunctional polypeptide, the complex *LKR/SDH* locus may encode monofunctional

LKR and monofunctional SDH (depending on the plant species). The independent function of these two monofunctional enzymes is not fully understood.

7.4.5 All aspartate-derived amino acids are synthesized in the plastid

Many of the enzymes of lysine, threonine, and methionine biosynthesis have been localized to the chloroplast by measuring their activities in chloroplast lysates. In addition, comparison of the DNA sequences of cloned plant genes for pathway enzymes with those of microbes has revealed N-terminal extensions that resemble characterized plastid-targeting sequences. The final steps of methionine biosynthesis were long thought to be the exception to this rule; however, there are three functional isoforms of **methionine synthase** (MS) in *Arabidopsis*, one localized to chloroplasts and the other two to the cytosol. The current understanding is, therefore, that chloroplasts are fully autonomous in the biosynthesis of all aspartate-derived amino acids, including methionine (see Fig. 7.32). The cytosolic forms of MS are thought to be involved in the regeneration of methionine from homocysteine that remains after SAM-dependent methylation reactions. SAM synthase is exclusively cytosolic, and carriers have been identified that mediate the transport of SAM into chloroplasts and mitochondria.

7.5 Branched-chain amino acids

Isoleucine, **leucine**, and **valine** form the small group of **branched-chain amino acids** classified as such based on their small branched hydrocarbon residues. The biosynthesis of the branched-chain amino acids by plants attracts considerable attention for several reasons: First, they represent three of the 10 **essential amino acids** that animals must obtain from their diet and are, therefore, nutritionally important. Second, this pathway is a significant target for a variety of commercially successful herbicides. Finally, the amino acid products serve as precursors for secondary metabolites (Fig. 7.41).

7.5.1 Threonine deaminase participates in the synthesis of isoleucine but not of valine

A unique feature of branched-chain amino acid biosynthesis is that isoleucine and valine are synthesized in chloroplasts from two parallel pathways utilizing the same set of four enzymes. Each of the four enzymes has dual substrate specificity, starting with either **pyruvate** (leading to valine) or **α -ketobutyrate**

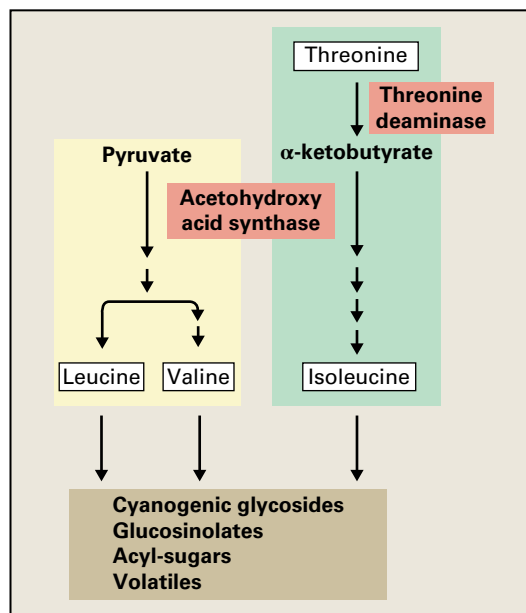

FIGURE 7.41 The branched-chain amino acids serve as precursors to plant secondary metabolites.

(leading to isoleucine). While pyruvate (C_3) is an intermediate of glycolysis, its C_4 counterpart, α -ketobutyrate, is produced by **threonine deaminase** (TD, also known as **threonine dehydratase**). TD is thus the committing enzyme of the isoleucine pathway and has no role in valine metabolism (Fig. 7.42). As described in Section 7.4.2, α -ketobutyrate can also be produced from methionine by **methionine γ -lyase**, but the normal activity of this enzyme is insufficient for rescuing the isoleucine deficiency in TD knockdown mutants. Thus, while TD and methionine γ -lyase appear to have overlapping functions in isoleucine biosynthesis, TD plays the dominant role in controlling the threonine flux toward isoleucine under normal growth conditions.

Similar to the bacterial enzyme, plant TD is a tetramer composed of identical subunits with a molecular mass of 59.6 kDa in *Arabidopsis*. In contrast to the *E. coli* enzyme, however, the plant TD dissociates into less active dimers at elevated isoleucine levels. Each subunit consists of an N-terminal PLP-binding catalytic domain and a C-terminal regulatory domain that is subject to feedback inhibition by isoleucine. Within the regulatory domain, there are two structurally different isoleucine allosteric binding sites. Binding of an isoleucine molecule to a high-affinity site promotes conformational changes that then allow the low-affinity site to bind a second isoleucine molecule, which leads to inhibition of the enzyme. The high-affinity binding site can also interact with valine. Such interactions induce conformational changes that trigger dissociation of isoleucine from the binding sites and thus the reversion of inhibition. An isoleucine-insensitive TD was identified in a screen for *Arabidopsis* mutants resistant to the isoleucine analog **L-O-methylthreonine**. Two amino acid substitutions, each in a different regulatory region, render the enzyme resistant to inhibition by isoleucine, and the mutant plants accumulate 20-fold more isoleucine than wild-type plants.

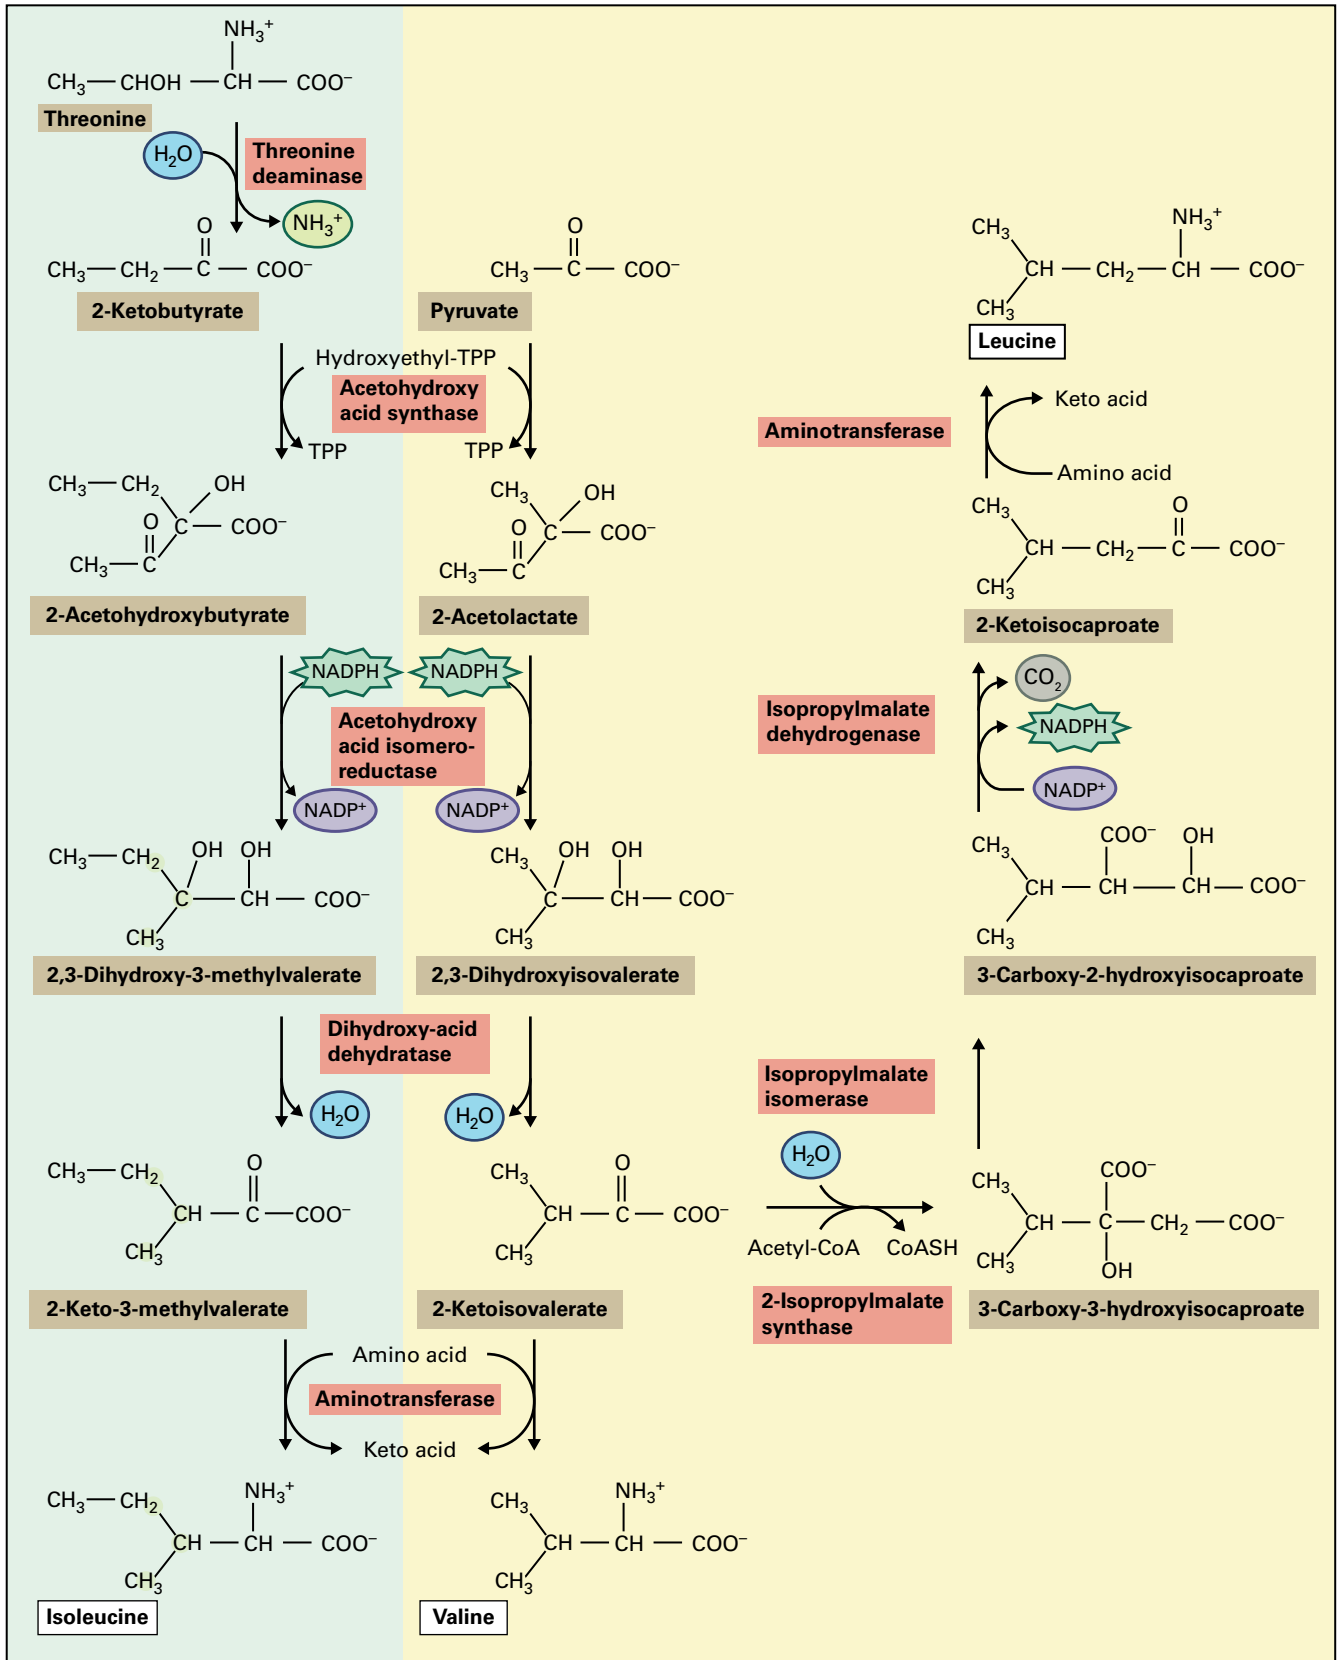

FIGURE 7.42 Biosynthesis of isoleucine, leucine, and valine.

BOX
7.6Threonine deaminase 2 is involved in plant defense against herbivores in *Solanum* species

Many plant species have a single *TD* gene, and defects in this gene result in isoleucine deficiency and impaired growth and development. However, cultivated tomato (*Solanum lycopersicon*) and related *Solanum* species contain a duplicated *TD* gene (*TD2*) that encodes a protein with 51% identity to *TD1*. In contrast to the constitutive expression of *TD1*, *TD2* transcripts accumulate to high levels in immature buds and unopened flowers. Moreover, *TD2* expression in leaves is activated by the jasmonate signaling pathway in response to herbivore attack. Analysis of *TD2*-deficient tomato plants revealed that *TD2* reduces herbivory by degrading threonine in the insect gut

and thereby functions as an antinutritive defense by limiting threonine supply needed for the growth of the lepidopteran larvae. In the gut, *TD2* undergoes proteolytic activation catalyzed by a chymotrypsin-like protease of the insect, which removes the C-terminal regulatory domain and generates an enzyme that degrades threonine without being inhibited by isoleucine. Truncated *TD2* can also use serine as a substrate (producing pyruvate and ammonia) and thus affect the availability of this amino acid as well. Interestingly, in *Nicotiana attenuata*, a single *TD* gene serves a dual role in both isoleucine biosynthesis and protection against lepidopteran herbivores.

7.5.2 The isoleucine and valine biosynthetic pathways share four enzymes

The first common enzyme in the biosynthesis of the branched-chain amino acids is **acetoxyacid synthase** (AHAS; also known as **acetolactate synthase**), which catalyzes the decarboxylation of pyruvate followed by its condensation with either pyruvate or 2-ketobutyrate to form 2-acetolactate or 2-acetoxybutyrate, respectively (Fig. 7.42). AHAS requires thiamine diphosphate as cofactor, which is anchored to the active site of the enzyme by a divalent metal ion such as Mg^{2+} . AHAS also requires flavin adenine dinucleotide (FAD), even though this cofactor does not participate in the principal reactions and may have instead a structural function.

Like the bacterial and yeast enzymes, plant AHAS comprises both a large catalytic subunit and a smaller regulatory subunit. The large subunit alone is insensitive to allosteric inhibition, but reconstitution *in vitro* with the small subunit stimulates enzymatic activity and confers sensitivity to inhibition by valine, leucine, and isoleucine. The inhibition of AHAS by all three branched-chain amino acids is an unusual feature of the plant enzyme, since most bacterial and fungal enzymes are sensitive to inhibition by valine only.

Moreover, valine and leucine act synergistically on the plant enzyme. Such synergistic inhibition is the result of the presence of a sequence repeat in the AHAS regulatory subunit. As confirmed by site-directed mutagenesis, one repeat binds leucine, while the other binds valine or isoleucine. Presumably as a result of this allosteric regulation, plant growth is inhibited when valine is added to the medium. Valine tolerance has been found in mutants of tobacco and *Arabidopsis* with feedback-insensitive AHAS activity. The tobacco *Val^R-1* mutant has a single amino acid change in the AHAS protein responsible for the altered allosteric regulation and *in vivo* amino acid resistance.

AHAS has been intensely studied because it is the target of five commercially important and structurally highly divergent classes of herbicides: **imidazolinones**, **sulfonylureas**, **triazolopyrimidines**, pyrimidyl-oxy-benzoates and sulfonylaminocarbonyltriazolinones (Fig. 7.43). Mutant plants that are resistant to inhibitors of some, or in certain cases even all, of these different herbicide classes express AHAS proteins with mutations in the large catalytic subunit that cause increased inhibitor resistance. In many cases, single nucleotide mutations confer resistance without affecting the catalytic efficiency of AHAS, and hence do not reduce the fitness of plants possessing these mutant enzymes. Thus, resistance to these herbicides can evolve rather readily in the field. The crystal structure of *Arabidopsis* AHAS with bound sulfonylurea or imidazolinone herbicides has revealed that these compounds do not bind to the active site itself, but rather block a protein channel through which the substrates have access to the active site.

The 2-acetoxybutyrate and 2-acetolactate intermediates are subjected to alkyl rearrangement and NADPH-mediated reduction by **acetoxyacid isomeroreductase** (also called reductoisomerase) to form the corresponding 2,3-dihydroxyvaleric acids (see Fig. 7.42). The crystal structure of the homodimeric enzyme from spinach (*Spinacia oleracea*) has been determined, and inhibitors of this enzyme also have herbicidal activity.

The next step is catalyzed by **dihydroxy-acid dehydratase**, a 2Fe-2S cluster protein, to produce the 2-ketovalerate products. The importance of this enzyme in branched-chain amino acid biosynthesis was confirmed through identification of isoleucine- and valine-requiring *Nicotiana plumbaginifolia* mutants that lack dihydroxy-acid dehydratase activity. Then the final step in isoleucine and valine biosynthesis is transamination of the keto acids to the respective amino acids. A single aminotransferase activity appears to be involved in both isoleucine and leucine (see below) biosynthesis, while a distinct 2-ketoisovalerate aminotransferase

FIGURE 7.43 Examples of the five classes of commercial herbicides that are AHAS inhibitors.

produces valine. The *Arabidopsis* genome contains a small gene family of **branched-chain aminotransferases** (BCAT). Three of these (BCAT2, BCAT3, and BCAT5) appear to be targeted to the plastid, where they likely participate in the

biosynthesis of the branched-chain amino acids, whereas BCAT1 is targeted to the mitochondrion and likely initiates the degradation of these amino acids. (BCAT4 actually transaminates methionine.)

7.5.3 Plant leucine biosynthesis follows the bacterial pathway

Leucine biosynthesis branches from 2-ketoisovalerate, the last intermediate of the valine biosynthetic pathway, and evidence indicates that plants use the pathway found in microbes (see Fig. 7.42). The committing enzyme for the pathway, **2-isopropylmalate synthase** (IPMS), catalyzes the transfer of an acetyl group from acetyl-CoA to 2-ketoisovalerate to produce 3-carboxy-3-hydroxyisocaproate (2-isopropylmalate or α -isopropylmalate). This enzyme is subject to feedback inhibition by micromolar concentrations of leucine. Biochemical characterization of recombinant proteins in conjunction with analysis of knockout mutants revealed that the *Arabidopsis* genome contains two IPMS genes encoding active IPMS proteins involved in leucine biosynthesis. The two genes are expressed in all organs at all developmental stages and can fully compensate for the absence of each other.

The second step in leucine biosynthesis is catalyzed by **isopropylmalate isomerase** (IPMI, also known as isopropylmalate dehydratase), which reversibly converts 3-carboxy-3-hydroxyisocaproate to 3-carboxy-2-hydroxyisocaproate (3-isopropylmalate or β -isopropylmalate). Similar to the bacterial enzyme, plant isopropylmalate isomerase has a heterodimeric structure with a large and a small subunit. In the *Arabidopsis* genome, a single gene encodes the large subunit, and three genes encode the small subunit. Detailed metabolic profiling of several mutants revealed the involvement of the large subunit in the biosynthesis of both leucine and chain-elongated methionine derivatives (see Section 7.4.2). In contrast, the small subunit determines the substrate specificity of the respective heterodimeric IPMI. One of the three *Arabidopsis* IPMI small subunits is responsible for leucine formation, while the other two mediate **methionine chain elongation**. As a result of differential tissue-specific expression of the small subunits, various IPMI heterodimers can be formed.

The penultimate reaction in leucine biosynthesis is the NAD^+ -dependent oxidative decarboxylation of 3-isopropylmalate to 2-ketoisocaproate (4-methyl-2-oxovalerate) catalyzed by **isopropylmalate dehydrogenase** (IPMDH). The partially purified enzyme is a target of the herbicidal compound *O*-isobutenyl oxalylhydroxamate. IPMDH genes have been cloned from several plant species, and they can complement yeast with a mutation in the *Leu2* gene, which encodes a functional IPMDH. The *Arabidopsis* genome contains three IPMDH genes, of which *IPMDH1* encodes a major enzyme with dual function in leucine biosynthesis and in methionine chain elongation in the course of aliphatic glucosinolate biosynthesis. Interestingly, IPMDH1 activity is regulated by thiol-based redox modification. Leucine biosynthesis is

completed by a transamination step catalyzed by the same BCATs that are involved in the formation of valine and isoleucine (see Section 7.5.2).

7.6 Glutamate-derived amino acids

Proline, arginine, and the (nonproteinogenic) amino acid **ornithine** are biosynthetically derived from **glutamate**. Proline has received major attention in plant biology because of its accumulation in responses to salt, drought, and metal stress. Although biochemical studies have rather neglected the synthesis of arginine in plants in the past, genomic annotations have provided missing information.

7.6.1 Proline metabolism is a target for metabolic engineering of stress tolerance

Understanding and manipulating proline biosynthesis in plants is largely motivated by observations that this cyclic secondary amino acid is one of several organic compounds that can function as **compatible solutes**. Compatible solutes are molecules that can accumulate to high concentrations in the cytoplasm without disrupting cellular activity and allow plants to lower their water potential and maintain turgor during dry or saline conditions (see Chapter 22). Proline also scavenges **reactive oxygen species** (ROS), which are formed under stressful conditions (see Chapters 21 and 22), and its function in stress situations is thus multifaceted. Water stresses cause considerable loss of agricultural productivity, making it desirable to develop **drought-tolerant plants** by conventional or transgenic strategies. Studies of genetically engineered plants that accumulate high levels of proline have provided clear evidence for the ability of proline to confer increased osmotic tolerance.

7.6.2 In plants, proline may be produced by two distinct pathways

Proline can be synthesized by two different pathways in plants. One originates from glutamate, the other from ornithine, although the details of the ornithine pathway are less clear (Fig. 7.44). The committing enzyme of the glutamate pathway, **pyrroline-5-carboxylate synthetase** (P5CS), is a bifunctional enzyme in plants. Its first activity, **γ -glutamyl kinase**, catalyzes the ATP-dependent phosphorylation of L-glutamate, and the γ -glutamyl phosphate produced is then reduced to **glutamic γ -semialdehyde** (GSA) by the NADPH-dependent GSA reductase. This intermediate spontaneously cyclizes to form Δ^1 -pyrroline-5-carboxylate (P5C, a Schiff base). The *Arabidopsis* genome harbors two closely related P5CS genes with nonredundant functions (see Section 7.6.3). P5C is then converted to proline by the NADPH-dependent enzyme P5C reductase.

Two routes proposed for the synthesis of proline from ornithine (Fig. 7.44) differ as to whether Δ^1 -pyrroline-5-carboxylate or Δ^1 -pyrroline-2-carboxylate (an imino acid) is the final intermediate in the pathway. In the first instance, transamination of ornithine occurs at the δ -C, while in the second instance it occurs at the α -C. Ornithine δ -aminotransferase (δ OAT) has been characterized at both the biochemical and molecular levels in plants.

7.6.3 Proline synthesis and breakdown are environmentally regulated in plants

Regulation of proline accumulation in plants occurs both at the enzyme level and through changes in gene expression. The committing enzyme P5CS appears to be rate limiting in plants, and its transcript as well as free proline increase rapidly in response to desiccation, salt stress, and treatment with abscisic acid, and they return to normal level when dehydrated plants are watered. In several plant species, PC5S overexpression (but not that of P5C reductase) leads to plants with increased soluble proline content and reduced sensitivity to osmotic stress. As the γ -glutamyl kinase activity of PC5S is feedback-inhibited by proline, this feedback loop paradoxically appears to counteract the effect of increased expression of the enzyme. Loss of feedback inhibition by a conformational change of the P5CS protein under stress conditions has been proposed. Expression of a wild-type feedback-sensitive, and a mutagenized feedback-insensitive, *Vigna aconitifolia* PC5S in tobacco (*Nicotiana tabacum*) revealed a higher accumulation of proline in control conditions. Proline accumulated to even higher levels under salt stress in those plants expressing the feedback-insensitive PC5S, indicating that feedback inhibition is not (fully) abolished under normal conditions.

Of the two PC5S genes of *Arabidopsis*, PC5S1 responds to osmotic stress, and the loss-of-function mutant displays increased ROS levels and hypersensitivity to stress. Mutant *pc5s2* plants, on the other hand, have developmental defects, in particular embryo abortion during late seed development (desiccation stage). Tissue-specific expression patterns of the two genes differ considerably, and the two genes, therefore, do not complement each other.

The contribution of the ornithine pathway to proline synthesis was investigated both in δ OAT loss-of-function mutants and in transgenic plants overproducing δ OAT. In *Arabidopsis* loss-of-function mutants, proline accumulates normally under stress conditions, whereas arginine and ornithine can no longer be catabolized. This indicates a purely catabolic function of δ OAT in arginine degradation, which occurs in mitochondria where δ OAT is localized. On the other hand, transgenic *Nicotiana plumbaginifolia* and rice (*Oryza sativa*) expressing *Arabidopsis* δ OAT accumulate more proline and are less sensitive to osmotic stress than wild-type plants. This discrepancy has not yet been resolved, but expression studies have shown that δ OAT transcript levels actually decreased slightly under salt stress, whereas those of P5CS

FIGURE 7.44 Multiple pathways are proposed for proline biosynthesis in plants. A glutamate-derived pathway is well established (black arrows), and increasing evidence suggests the importance of ornithine as a precursor (red arrows). The relative importance of the pathways through ornithine- δ -aminotransferase (dotted red arrow) or ornithine- α -aminotransferase (pathway with all red arrows) remains to be determined. In plants, the γ -glutamyl kinase (*proB* in *E. coli*) and GSA dehydrogenase (*proA* in *E. coli*) are synthesized in a protein fusion. This activity is referred to as Δ^1 -pyrroline-5-carboxylate synthetase.

increased. This would again point to the predominance of the glutamate-dependent pathway of proline biosynthesis.

As discussed in Section 7.4.4, catabolism can play an important role in determining the concentration of a free amino acid. We can expect this particularly for proline, because its levels fluctuate considerably with environmental conditions. **Proline dehydrogenase** catalyzes conversion of proline back to Δ^1 -pyrroline-5-carboxylate (P5C). The enzyme is a flavoprotein and is localized to the inner mitochondrial membrane. As P5C is in equilibrium with glutamic γ -semialdehyde (GSA), an NAD⁺-dependent P5C dehydrogenase will form glutamate, which can move into the cytosol. The resulting **proline-glutamate exchange** between the cytosol and the mitochondria feeds electrons into the mitochondrial electron transport chain. Proline dehydrogenase mRNA is regulated in a manner reciprocal to that of the biosynthetic enzyme P5CS during both dehydration/rehydration of a plant and salt stress and recovery. This suggests that proline degradation is suppressed during periods of rapid de

novo synthesis to prevent a futile cycle, and is then activated to bring proline concentrations back to prestress conditions.

When expression of an *E. coli* proline-insensitive γ -glutamyl kinase and a γ -glutamylphosphate reductase in tobacco or *Arabidopsis* is combined with simultaneous suppression of proline catabolism by expression of a *ProDH* antisense construct, the level of free proline increases up to 50-fold when the anabolic enzymes are targeted to plastids, and less when they are targeted to the cytosol. Apparently, proline can be synthesized both in the cytosol and in plastids.

7.6.4 Arginine is an amino acid rich in nitrogen

Arginine has a high N:C ratio (4:6) and serves as **nitrogen storage compound** in seeds, either in free form (e.g., in pea seeds) or in protein-bound form. In addition, it serves as a

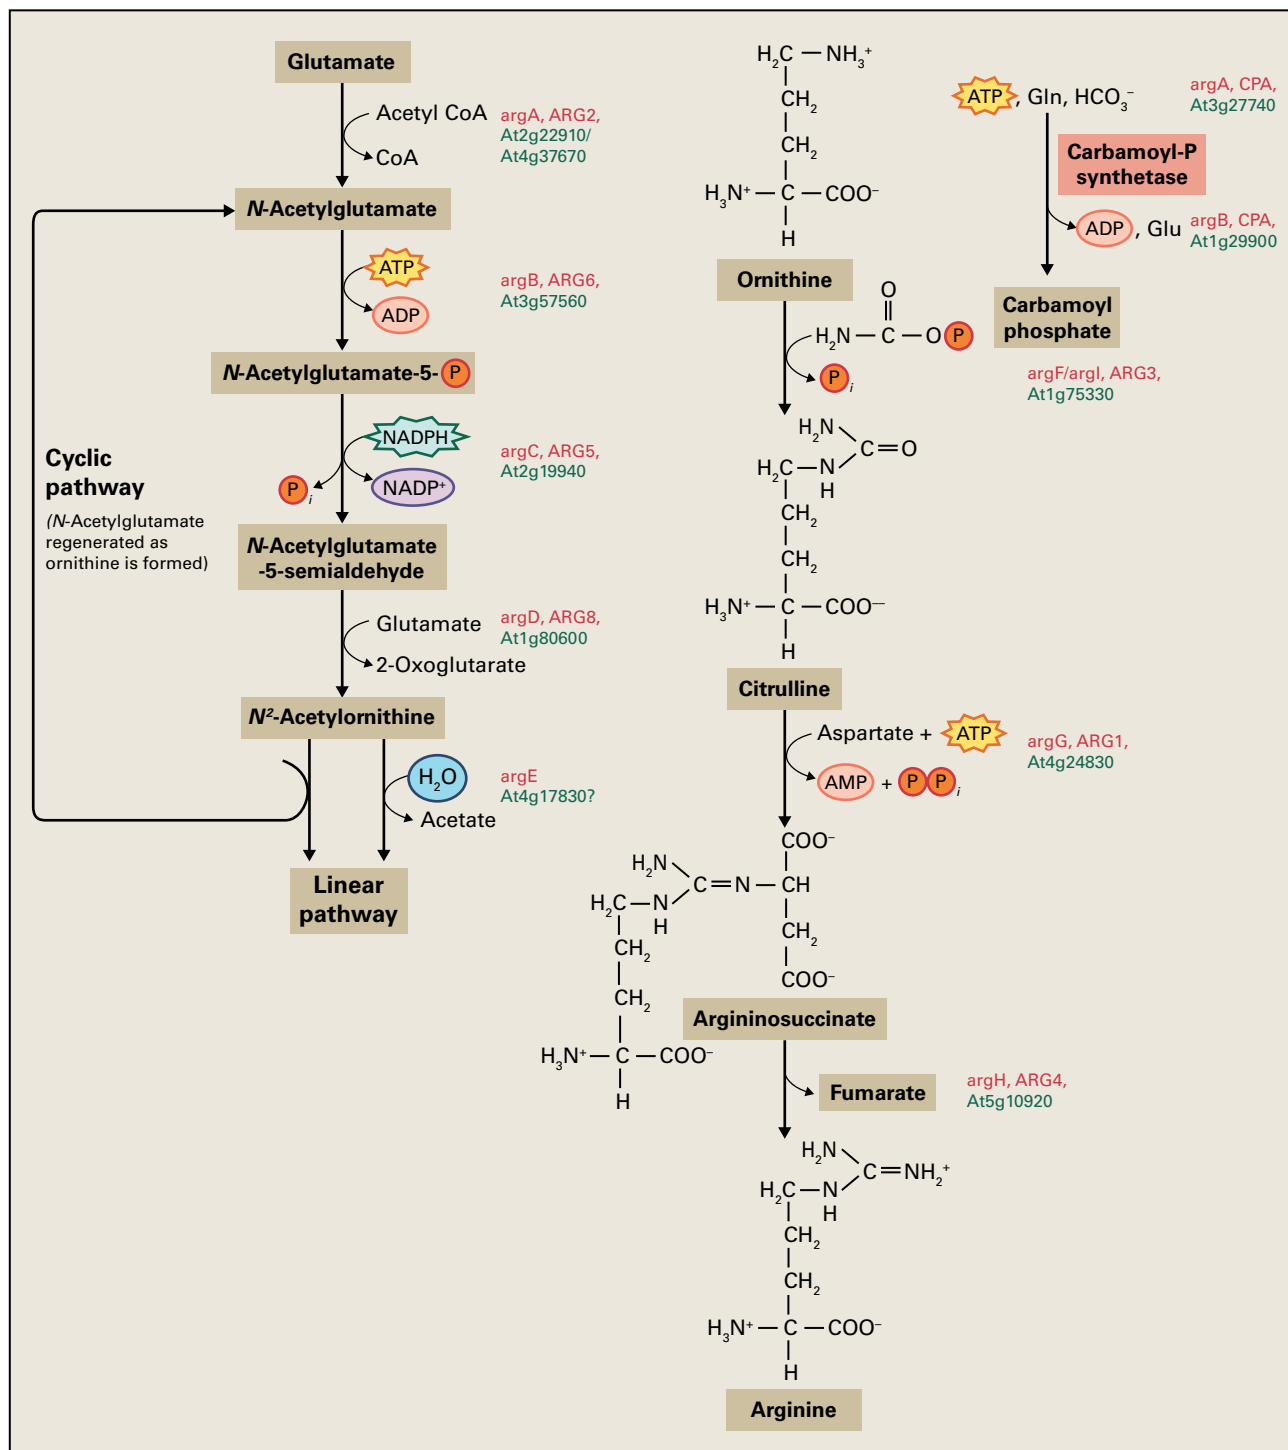

FIGURE 7.45 Biosynthesis of arginine. Structures are only shown for the pathway from ornithine to arginine. Structures in the ornithine pathway correspond to those also seen in Figure 7.42, with the notable difference that they are N-acetylated.

precursor in the biosynthesis of **polyamines**, certain alkaloids, and the signal molecule **nitric oxide (NO)**. In terrestrial (*ureotelic*) vertebrates, it is the immediate precursor of **urea**, the nitrogen excretion product in urine. The urea cycle and arginine biosynthesis pathway, therefore, figure prominently in textbooks of general biochemistry. A limited number of biochemical and in silico genome mining studies have

allowed elucidation of the pathway of arginine biosynthesis in plants, and these reactions are more or less identical to those in other organisms (Fig. 7.45). The pathway can be divided into two parts: from glutamate to ornithine, and from ornithine to arginine.

The ornithine pathway begins with the N-acetylation of glutamate by **N-acetylglutamate synthase (NAGS)**. The

following γ -phosphorylation and subsequent reduction to the semialdehyde are analogous to the reactions of free glutamate in proline biosynthesis (see Fig. 7.44). Because acetylation of the amino group prevents spontaneous cyclization to the pyrroline carboxylate, *N*-acetylglutamic semialdehyde can be transaminated to give rise to *N*-acetylornithine, from which ornithine is released either by hydrolysis or by transfer of the acetyl moiety to glutamate (transacetylation) within the cyclic pathway shown in Fig. 7.45.

Arginine synthesis is initiated by the carbamoylation of the δ -amino group of ornithine with **carbamoyl phosphate** as the activated intermediate in a reaction catalyzed by **ornithine carbamoyl transferase** (OCT) that produces **citrulline** (Fig. 7.45). Carbamoyl phosphate is also required in pyrimidine synthesis, and the enzyme catalyzing its synthesis, carbamoyl phosphate synthetase (CPS), is feedback-inhibited by UMP and activated by IMP. Ornithine thus serves the needs of both pathways. The N atom required to convert citrulline to arginine is transferred from aspartate via **argininosuccinate**, which is cleaved to yield arginine and fumarate. Direct measurement of enzyme activities, chloroplast proteome data, and prediction of putative target sequences that direct the respective proteins to plastids, have demonstrated that the pathway is likely localized entirely in chloroplasts.

Only a limited number of reports detail either the overexpression or downregulation/knockout of any enzyme of the ornithine and arginine pathway, respectively. Overexpression of tomato (*Solanum lycopersicon*) NAGS in *Arabidopsis* increases ornithine content and enhances salt tolerance. A metabolomic analysis of the *ven3* and *ven6* mutants of *Arabidopsis* (which have a defect in mesophyll development and, therefore, exhibit a reticulate leaf phenotype) revealed that the mutants have an increased ornithine and a decreased citrulline content and can be rescued by citrulline complementation. The two *VEN* genes encode subunits of CPS, and the functionality of the respective polypeptides in CPS has been confirmed. How the arginine biosynthetic pathway functions in leaf development remains to be shown.

As pointed out above, arginine serves as a nitrogen storage pool. The branch point enzyme in the formation of ornithine and arginine, NAGS, is subject to control by a protein named **PII**, which was first discovered in *E. coli* as a coordinator of C:N interactions and then found to be highly conserved in bacteria, archaea, and plants. The plant homolog is targeted to the plastid and binds α -ketoglutarate and ATP. High N conditions reduce α -ketoglutarate concentrations because of its function in N assimilation (see Section 7.2), and this favors the interaction of PII and NAGS, which leads to activation of arginine synthesis and eventually to increased N storage.

7.7 Histidine

The elucidation of the **histidine** biosynthetic pathway in *Salmonella typhimurium* more than 50 years ago was a milestone in the biological sciences, not only because of the

novel and complex reactions it involved, but because of the insight provided into the regulation of the pathway, which was instrumental in the development of the operon concept. Comparatively little work had been done on the plant pathway until the 1990s, when histidine biosynthesis was considered a potential target for the development of novel herbicides.

The plant research was instigated by the findings that a number of herbicidal compounds interfere with the biosynthesis of aromatic and branched-chain amino acids (see Sections 7.3.1 and 7.5.2). To date, plant genes encoding all of the eight enzymes required for histidine synthesis shown in Figure 7.46 have been identified. Although several textbooks list histidine as a member of the glutamate family, this is incorrect, because glutamate and glutamine contribute only N atoms to histidine synthesis rather than the C skeleton, as we saw for glutamate in the case of proline and arginine.

Histidine synthesis begins with the attachment of **5-phosphoribose** from 5-phosphoribosyl-1-pyrophosphate to ATP in an N-glycosidic linkage. Note the similarity of this reaction with the phosphoribosylation of anthranilate in tryptophan biosynthesis (see Fig. 7.25). Release of pyrophosphate by hydrolysis produces 5'-phosphoribosyl AMP. The six-membered ring of AMP opens by hydrolysis, and then isomerization to the ketone occurs, again as in the corresponding step in tryptophan biosynthesis (see Fig. 7.27). Ammonia provided by hydrolysis of glutamine in a **glutamine amidotransferase** reaction and being guided through a tunnel (see Fig. 7.24) affects the production of **imidazole glycerol phosphate** (IGP) and 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR). AICAR is used in a salvage pathway to regenerate ATP, while IGP is converted by consecutive dehydration, transamination, hydrolysis of the phosphate group, and two dehydrogenation steps to histidine (Fig. 7.46). This is a significant difference to tryptophan biosynthesis, where tryptophan synthase replaces the glycerol phosphate side chain of **indole glycerol phosphate** with serine to produce tryptophan directly (see Fig. 7.29).

All proteins involved in the histidine pathway carry an N-terminal extension either proven or assumed to direct the proteins to the plastids. It is generally accepted that the complete pathway operates in the plastid.

Of all the genes of the histidine biosynthetic pathway, only overexpression of either of the two genes encoding **ATP-phosphoribosyltransferase** (ATP-PRT), the first committed enzyme of the pathway, significantly increased the levels of free histidine in transgenic *Arabidopsis* (up to 40-fold). This indicates that ATP-PRT controls substrate flux through the pathway, which conforms with its feedback inhibition by histidine. ATP-PRT overproducing plants had a specifically increased Ni tolerance (the imidazole ring of histidine is an efficient Ni chelator; this is why His-tagged proteins bind to Ni columns and can be specifically eluted with imidazole), and in wild-type plants, Ni tolerance correlates with ATP-PRT transcript levels. Plants overexpressing ATP-PRT are less

FIGURE 7.46 Biosynthesis of histidine.

tolerant to Co and Zn, and tolerance to Cd and Cu is unaffected. His overproduction has a negative effect on biomass production, which is apparently related to the high energy (ATP) costs of its production.

The *Arabidopsis hpa1* mutant, which is deficient in one of the two histidinol aminotransferases (Fig. 7.46), is defective in root meristem maintenance, and this results in a short root system related to the moderately reduced histidine content. The *apg10* mutant of *Arabidopsis*, which has pale green cotyledons and leaves in the juvenile stage, has a

defect in the fourth enzyme of the histidine biosynthetic pathway that catalyzes the isomerization step after the ribose ring opening (Fig. 7.46). A similar phenotype had been seen in the *cue1* mutant, which has a defect in the plastid inner membrane phosphoenolpyruvate (PEP)/phosphate translocator that provides PEP for aromatic amino acid biosynthesis. In both mutants, levels of the other amino acids are affected as well, which is taken as evidence for a crosspathway regulation of amino acid metabolism (see Box 7.7 and Box 7.8).

BOX
7.7

Does crosspathway regulation of gene expression exist in plants?

Prokaryotes and fungi use different mechanisms to coordinate the regulation of amino acid biosynthetic enzymes. In Gram-negative bacteria, the structural genes for a pathway are cotranscribed from operons. Starvation for a single amino acid causes derepression of the transcription of that biosynthetic operon by a mechanism involving a repressor protein and transcriptional attenuation. However, many fungal amino acid biosynthetic enzymes are under complex global control. In yeast, starvation for a single amino acid leads to transcriptional derepression of three dozen biosynthetic enzymes in at least 12 pathways. This general control response in yeast is mediated by the **transcription factor GCN4p**, a leucine-zipper protein whose synthesis is translationally regulated in response to amino acid starvation. Thus, the transcription of amino acid biosynthetic enzyme genes is sensitive to the translational state of the yeast cell, even though these two processes are separated by the nuclear envelope. This strategy is similar to, yet mechanistically different from, bacterial transcriptional attenuation: both allow the translational state of the cell to influence transcription of amino acid biosynthetic enzymes.

Transcriptional profiling has more recently revealed that GCN4p is actually a master regulator of stress-induced gene expression, since out of several hundred yeast genes whose expression is affected by GCN4p, only about one quarter encode enzymes of amino acid metabolism.

Is there evidence for crosspathway regulation of amino acid biosynthesis in plants? Evidence is increasing for such a regulation, but no coherent picture has emerged yet. Starvation for aromatic amino acids, branched-chain amino acids, or methionine induces expression of the tryptophan pathway enzymes, but this response is not seen for a variety of other pathway enzymes. Starvation for histidine, however, by treatment of *Arabidopsis* seedlings with IRL 1803, an inhibitor of the histidine pathway enzyme imidazoleglycerol-phosphate dehydratase (see Fig. 7.46), increases accumulation of mRNAs for eight genes that encode enzymes involved in the biosynthesis of aromatic amino acids, lysine, histidine, and purines. It remains to be seen why starvation for histidine has unique consequences.

BOX
7.8

Plant amino acid biosynthetic pathways exhibit numerous gene duplications but few protein fusions

Notwithstanding the evolutionarily conserved reaction sequences of amino acid biosynthetic pathways between microorganisms and plants, the genetic organization of their enzymes in plants is in some ways quite different from what is found in microorganisms. In prokaryotes and fungi it is relatively unusual to discover **enzymes** with multiple **isoforms** encoded by separate genes. In contrast, many plant biosynthetic enzymes are encoded by multiple genes. In cases such as aspartate kinase, Δ^1 -pyrroline-5-carboxylate synthetase, threonine deaminase, or the anthranilate α subunit from *Ruta graveolens*, these isoforms have different biochemical properties. In other instances, the genes are regulated differently or encode proteins with distinct subcellular locations (e.g., GS). However, for the majority of proteins encoded by multigene

families, we still do not know what, if any, functional significance can be ascribed to the existence of multiple isoforms.

Another clear difference between plants and microbes is that **multifunctional proteins** are unusual in plants, and most enzymes of amino acid metabolism catalyze a single pathway step. Exceptions to this rule include the bifunctional Δ^1 -pyrroline-5-carboxylate synthetase, 3-dehydroquinate dehydratase-shikimate dehydrogenase, and the lysine catabolic enzyme lysine-ketoglutarate reductase-saccharopine dehydrogenase. In prokaryotes and fungi, fusion proteins are common and can include three or more different activities. For example, the **ARO1 protein** of yeast is a pentafunctional protein that catalyzes all but the first and final steps of chorismate biosynthesis.

Summary

Amino acids, the building blocks of proteins in all organisms, play additional roles in plants. In plants, amino acids serve as precursors to a plethora of natural products that provide defense against pathogens and herbivores and tolerance to abiotic stress. They also store or transport nitrogen from sources to sinks. The control of amino acid synthesis in plants, therefore, affects many aspects of growth, development, and survival.

The synthesis of essential amino acids in plants and the amino acid composition of seeds relate indirectly to animal and human nutrition. Thus, understanding the pathways that allow and control amino acid synthesis in plants has significance with regard to basic research on the control of metabolic pathways as well as practical implications. Although amino acid biosynthetic pathways have been well defined in microbes, the situation in plants is still less defined, in part because of additional unique complexities. For example, in many instances, plants have multiple isoenzymes that catalyze the same biosynthetic reactions. These isoenzymes may be localized in distinct organelles or distinct cell types, or may be present at different developmental stages. Defining each step in an

amino acid biosynthetic pathway and determining how each step is regulated, not only within the context of the respective pathway but rather in the context of the general metabolic network, are some of the key aspects of current research in amino acid biosynthesis in plants.

This chapter selectively highlights examples in which molecular, genetic, and biochemical approaches have been combined to elucidate the steps of these pathways in plants and to understand the regulation of these pathways at the level of gene regulation and beyond. Plant mutants in amino acid biosynthetic enzymes, which can now readily be identified in T-DNA insertion lines, have shown that the synthesis of amino acids *in vivo* affects numerous diverse processes, including photorespiration, hormone biosynthesis, and plant development. Use of transgenic approaches has revealed the feasibility of manipulating amino acid biosynthesis pathways in plants, with applications to engineering herbicide resistance and altering amino acid composition in seeds. Thus, while being products of primary metabolism, amino acids also control many diverse aspects of plant growth and development.

Lipids

*John Ohlrogge, John Browse,
Jan Jaworski, and Chris Somerville*

Introduction

The term **lipid** refers to a structurally diverse group of molecules that are preferentially soluble in a nonaqueous solvent such as chloroform. Lipids include a wide variety of fatty acid-derived compounds, as well as many pigments and secondary compounds that are metabolically unrelated to fatty acid metabolism. Although we limit our discussion of lipids to those compounds with origins in fatty acid synthesis, this limitation still provides a broad group of compounds to explore, many of which are vital to the normal functioning of a cell. Each plant cell contains a diverse range of lipids, often located in specific structures. Furthermore, different plant tissues contain different lipids.

Although the metabolism of fatty acids and lipids in plants has many features in common with other organisms, the lipid pathways in plants are complex and some are not yet well understood. The complexity arises primarily from cellular compartmentalization of the pathways and the extensive intermixing of lipid pools between these compartments (Fig. 8.1). In addition, plants collectively accumulate more than 200 different fatty acids, so there are many open questions about the nature of the enzymes involved in the synthesis of these compounds. Among the many challenges facing plant biochemists today is the complete elucidation of these pathways and the mechanisms that regulate them.

8.1 Structure and function of lipids

8.1.1 Lipids have diverse roles in plants

Lipids serve many functions in plants (Table 8.1). As the major components of biological membranes, they form a hydrophobic barrier that is critical to life (see Chapter 1). Membranes not only separate cells from their surroundings; they also separate the contents of organelles, such as chloroplasts and mitochondria, from the cytoplasm. Cellular compartmentalization depends on polar lipids forming a bilayer that prevents free diffusion of hydrophilic molecules between the cellular organelles and prevents diffusion in and out of the cells. The membranes of chloroplasts, in which the light reactions of photosynthesis take place, primarily contain **galactolipids**. Membranes external to plastids are composed mainly of mixtures of **phospholipids**. Although a single gram of leaf tissue may contain as much as 1 m² of membrane, lipids make up a relatively small proportion of the total mass of plant tissue (Fig. 8.2).

Lipids also represent a substantial chemical reserve of free energy. Because fatty acids are substantially more reduced organic molecules than carbohydrates, fatty acid oxidation has a higher potential for producing energy. Furthermore,

FIGURE 8.1 Lipid synthesis and metabolism take place in various organelles, and in many cases involve movement of lipids from one cellular compartment to another.

triacylglycerols are largely hydrophobic and exist in an essentially anhydrous environment. Carbohydrates, however, are hydrophilic, and the water of hydration adds substantially to their mass. Thus, on a mass basis, the ATP yield from catabolism to CO_2 and H_2O is approximately twice as high for triacylglycerols as for carbohydrates (Fig. 8.3). In cases where a compact seed mass is advantageous for facilitating dispersal or other processes, the carbon and energy required for seed germination are often stored in the form of triacylglycerols rather than as starch.

Fatty acids are also the precursors for other significant components of plant metabolism. The **waxes** that coat and protect plants from the environment are complex mixtures of long-chain hydrocarbons, aldehydes, alcohols, acids, and esters derived almost entirely from fatty acids. The **cutin** layer of epidermal cells also is composed of oxygenated fatty acids esterified with one another to produce a tough, polyester skin. Thus, in epidermal cells of aerial organs, the bulk of fatty acid synthesis is devoted to production of wax and cutin for protection (Fig. 8.4).

Some fatty acids play major roles in certain signal transduction pathways. The synthesis of the growth regulator **jasmonic acid** from linolenic acid and the activities of jasmonates as plant hormones and second messengers are widely studied (see Section 8.8.5 and Chapters 17 and 21). Similarly, phosphatidylinositol and its derivatives are messengers with regulatory roles, similar to messenger compounds found in other

eukaryotes, which play important roles in signal transduction pathways (see Chapter 18). Fatty acids may also be involved in regulating various cellular processes via protein acylation.

8.1.2 Most, but not all, lipids contain fatty acids esterified to glycerol

Fatty acids are carboxylic acids of highly reduced hydrocarbon chains. The typical fatty acids found in the membranes of plants contain 16 or 18 carbons and are listed in Table 8.2, along with some unusual fatty acids that typically accumulate only in the storage triacylglycerols of seeds. Some of the nomenclature used in abbreviations for fatty acids and lipids is described in Box 8.1.

A major fraction of the fatty acids in plants are the polyunsaturated fatty acids linoleic acid ($18:2^{\Delta 9,12}$) and α -linolenic acid ($18:3^{\Delta 9,12,15}$). Only a few plants accumulate fatty acids with double bonds closer to the carboxyl group than the $\Delta 9$ position. In addition to the C_{16} and C_{18} common fatty acids, some plants also produce fatty acids of 8–32 carbons in length that usually accumulate in storage lipids or epicuticular wax. The fatty acid composition of lipids can be determined using gas chromatography to separate the methylated derivatives of the fatty acids.

TABLE 8.1 Functions of lipid molecules in plants.

Function	Lipid types involved ^a
Membrane structural components	Glycerolipids Sphingolipids Sterols
Storage compounds	Triacylglycerols Waxes
Compounds active in electron transfer reactions	Chlorophyll and other pigments Ubiquinone, plastoquinone
Photoprotection	Carotenoids (xanthophyll cycle)
Protection of membranes against damage from free radicals	Tocopherols
Waterproofing and surface protection	Long-chain and very-long-chain fatty acids and their derivatives (cutin, suberin, surface waxes) Triterpenes
Protein modification	
Addition of membrane anchors	
Acylation	Mainly 14:0 and 16:0 fatty acids
Prenylation	Farnesyl and geranylgeranyl pyrophosphate
Other membrane anchor components	Phosphatidylinositol, ceramide
Glycosylation	Dolichol
Signaling	
Internal	Abscisic acid, gibberellins, brassinosteroids 18:3 Fatty acid precursors of jasmonate Inositol phosphates Diacylglycerols
External	Jasmonate Volatile insect attractants
Defense and antifeeding compounds	Essential oils Latex components (rubber, etc.) Resin components (terpenes)

^aThe isoprenoids and related lipids are described in Chapter 24.

Glycerolipids consist of fatty acids esterified to derivatives of glycerol. Four principal types are found in plants: triacylglycerols, phospholipids, galactolipids, and a sulfolipid. In addition, plants contain sphingolipids, which can be major components of the plasma membrane. In most cases, purification of a particular type of lipid from a plant extract yields a complex mixture. For example, seven different classes of phospholipids (Table 8.3) are defined by the structure of the head group, and each class is composed of distinct molecular species defined by the fatty acids attached to the *sn*-1 and *sn*-2 positions of the glycerol backbone. Thus, the phosphatidylcholine molecule depicted in Figure 8.5A has a saturated fatty

acid esterified to the *sn*-1 position and a di-unsaturated fatty acid esterified to the *sn*-2 position. Some of the factors that control the fatty acid composition of lipids are discussed in Sections 8.5.3, 8.7.1, and 8.7.4.

Lipids are usually stored as triacylglycerols, three fatty acids esterified to glycerol (Fig. 8.5B). Triacylglycerols are frequently referred to as neutral lipids because of their nonpolar nature. Found primarily in seeds and pollen, triacylglycerols serve as energy and carbon stores. Because neutral lipids are not soluble in the aqueous phase of cells, they do not contribute to the osmotic potential of the cell. This is important to their role as storage materials because they accumulate in

FIGURE 8.2 Approximate distributions of cellular constituents (as a percentage of total dry weight) and lipid types (as a percentage of total lipids by weight) in Arabidopsis leaf tissues. Some values were extrapolated from results obtained with other species.

ATP/g from sugar

ATP/g from fatty acid

FIGURE 8.3 Comparison of energy yield in animals from metabolism of fatty acids and carbohydrates to CO_2 and H_2O . Metabolism of fatty acids produces 0.41 mol of ATP per gram of fatty acid, whereas metabolism of carbohydrate yields 0.17 to 0.18 mol/g. Oxidation of one NADH by the mitochondrial electron transport chain is assumed to yield 2.5 ATP, whereas oxidation of one FADH_2 is assumed to yield 1.5 ATP. The number of ATPs derived from one NADH oxidized in the cytosol or peroxisome varies according to the mechanism by which the reducing equivalents (electrons) are transferred into the mitochondrion (see Chapter 14).

FIGURE 8.4 Scanning electron micrographs of wild-type and mutant Arabidopsis stems (A–C) and siliques (D–F). Wild-type surfaces (A, D) are covered with various tubes and lobed plates of wax. Surfaces of the cer7 mutant (B, E) have both fewer wax crystals and altered crystalline structures. Surfaces of cer17 mutants (C, F) have fewer tubes than the wild-type plants.

^a See Box 8.1 for an explanation of abbreviation nomenclature.

^b These five fatty acids are commonly found as the principal constituents of membrane lipids. The others are found principally in storage lipids.

BOX
8.1

Abbreviations make lipid nomenclature more manageable

A simple shorthand notation based on molecule length and the number and position of double bonds has been developed to designate fatty acids. For example, the saturated C16 fatty acid, palmitic acid (hexadecanoic acid), is designated 16:0. The first value, 16, represents the number of carbon atoms. The second value, 0, indicates the number of double bonds. The monounsaturated 18-carbon fatty acid, oleic acid (*cis*-9-octadecenoic acid), is designated 18:1^{Δ9}. The Δ9 superscript designates the position of the single double bond, counting the carboxyl group as carbon atom number 1. Because the double bonds in fatty acids are almost exclusively *cis* isomers, usually no designation for the configuration of double bond is used unless it is a *trans* isomer, as in 16:1^{trans Δ3}. As shown in the illustration of palmitic and linolenic acids, major saturated and unsaturated fatty acids in photosynthetic tissues, introduction of *cis* unsaturations creates bends in the acyl chain.

Double bonds are usually separated by one carbon in the fatty acid chain (e.g., in the polyunsaturated α-linolenic acid, 18:3^{Δ9,12,15}). It is sometimes useful to designate the position of the double bonds relative to the terminal methyl group (the omega carbon). Thus, an omega-3, or *n*-3, fatty acid contains a double bond three carbons from the methyl end of the fatty acid (e.g., 18:3^{Δ9,12,15} is an omega-3 fatty acid).

Abbreviations are also used to designate the position at which a fatty acid is esterified to the glycerol backbone of glycerolipids. *sn*-3 (stereospecific nomenclature-3) denotes the terminal hydroxyl that is phosphorylated in glycerol 3-phosphate, *sn*-2 refers to the central hydroxyl, and *sn*-1 is the terminal hydroxyl that is not phosphorylated.

Palmitic acid, 16:0

α-Linolenic acid, 18:3

amounts that would otherwise disrupt the maintenance of normal cellular osmolality.

Phospholipids are synthesized by esterification of fatty acids to the two hydroxyl groups of *sn*-glycerol 3-phosphate to produce phosphatidic acid. All other phospholipids are derived from phosphatidic acid by esterification of a polar “head group” to the phosphoryl group (Table 8.3). Phospholipids are **amphipathic**, containing both hydrophobic (noncharged, nonpolar) fatty acids and a hydrophilic (charged, polar) head group. This property allows phospholipids—and other amphipathic glycerolipids—to form a bilayer in which the hydrophilic heads are in contact with an aqueous environment such as the cytosol, while the hydrophobic tails remain in contact with other hydrophobic tails (Fig. 8.6; see also Chapter 1).

Galactolipids, another major class of glycerolipids, are localized in the plastid membranes. In these lipids, a galactosyl or sulfoquinovosyl group replaces the phosphoryl head group of the phospholipids (Table 8.3). The three major lipids belonging to this class of lipids are the two galactolipids monogalactosyldiacylglycerol and digalactosyldiacylglycerol and the plant sulfolipid sulfoquinovosyldiacylglycerol. These **glycolipids** contain high concentrations of polyunsaturated

fatty acids. In the photosynthetic tissue of some plants, α-linolenic acid (18:3^{Δ9,12,15}) can constitute as much as 90% of the fatty acids in glycolipids. Plants such as peas (*Pisum sativum*), in which glycolipids contain exclusively C₁₈ polyunsaturated fatty acids, are sometimes referred to as “18:3 plants.” Others, such as spinach (*Spinacia oleracea*), contain glycolipids having appreciable amounts of a C₁₆ polyunsaturated fatty acid, 16:3^{Δ7,10,13}, localized exclusively in the *sn*-2 position, and are called “16:3 plants.” The underlying difference between 18:3 plants and 16:3 plants is now understood: 18:3 plants synthesize most or all of their lipids in the endoplasmic reticulum (ER), whereas 16:3 plants utilize biosynthetic pathways in the plastid as well (see Sections 8.7.2 and 8.7.3).

Sphingolipids (Fig. 8.7), which represent approximately 5% of the total membrane lipids, are concentrated in the plasma membrane, where they make up as much as 26% of the mass of plasma membrane lipids. The sphingoid bases are generally toxic and are present in very low concentrations so that only the ceramides and glycosylceramides accumulate to any extent. Sphingolipids are unusual in that they are not esters of glycerol, but rather consist of a long-chain amino alcohol that forms an amide linkage to a fatty acid; the

TABLE 8.3 Major classes of membrane lipids.

Substituent			Name of lipid
Formula of Y	Name of X—OH	Formula of X	
<p>Glycerophospholipid (general structure)</p> <p>Saturated fatty acid (e.g., palmitic) Unsaturated fatty acid (e.g., oleic)</p>			
	Water	—H	Phosphatidic acid (PA)
	Choline	—CH ₂ CH ₂ N ⁺ (CH ₃) ₃	Phosphatidylcholine (PC)
	Ethanolamine	—CH ₂ CH ₂ NH ₃ ⁺	Phosphatidylethanolamine (PE)
	Serine		Phosphatidylserine (PS)
	Glycerol	—CH ₂ CH(OH)CH ₂ OH	Phosphatidylglycerol (PG)
	Phosphatidylglycerol		Diphosphatidylglycerol (cardiolipin)
	<i>myo</i> -Inositol		Phosphatidylinositol (PI)
None	Sulfoquinovose		Sulfoquinovosyldiacylglycerol (SQD), also called sulfolipid (SL)
	Galactose		Monogalactosyldiacylglycerol (MGD)
	Digalactose		Digalactosyldiacylglycerol (DGD)

The basic structure of a glycerolipid is shown at the top. The C3 backbone (highlighted in dark yellow) is usually esterified to two fatty acids at the carbons labeled *sn*-1 and *sn*-2. The modifications of the *sn*-3 carbon can be described by the substituents *X* and *Y*, which correspond to the compounds shown in the lower part of the table. *sn* numbers refer to the stereochemical nomenclature system, which is, by convention, based on the structures of *D*- and *L*-glyceraldehyde. The convention with respect to glycerol is that, in a Fischer projection of *L*-glycerol (not shown), the central hydroxyl is shown to the left. By definition, the carbon above the *sn*-2 carbon is the *sn*-1 position and the position below is the *sn*-3 position.

FIGURE 8.5 Space-filling and conformational models of (A) the phospholipid phosphatidylcholine and (B) triacylglycerol. The ester linkages are highlighted in yellow, and the glycerol backbone is in orange.

FIGURE 8.6 Computer simulation of a cross-section of a membrane. The coloring is as follows: phosphorus, dark green; nitrogen, dark blue; lipid oxygens, red; terminal chain methyl groups, magenta; other carbons, gray; water oxygens, yellow; water hydrogens, white. For clarity, the radii of heavy atoms are reduced slightly from their van der Waals values, the radii of water hydrogens are increased, and carbon-bound hydrogens are omitted.

acyl group is often longer than C_{18} . Complex sphingolipids, such as glucosylceramide, form from a simple sphingolipid (e.g., ceramide) by the addition of phosphocholine or one or more sugars. The synthesis of these lipids is discussed in Section 8.7.10.

8.2 Fatty acid biosynthesis

8.2.1 Fatty acid biosynthesis in plants is similar to that in bacteria

Fatty acid biosynthesis in plants takes place within plastids, organelles widely thought to have originated from a photosynthetic bacterial symbiont. Thus it is perhaps not surprising that fatty acid metabolism in plants closely resembles that of bacteria.

Acetyl-CoA is the initial substrate for synthesis of the carbon backbone of all fatty acids. A central intermediate in many aspects of cellular metabolism, it is produced and consumed by dozens of reactions in the cell (Fig. 8.8). Within plastids, pyruvate dehydrogenase directly produces acetyl-CoA from pyruvate generated during glycolysis (see Chapter 13).

During fatty acid biosynthesis, a repeated series of reactions incorporates acetyl moieties of acetyl-CoA into an acyl

FIGURE 8.7 Structures of selected plant sphingolipids. Sphinganine, 4,8-sphingadienine, and 4-hydroxy-8-sphingenine are called “sphingoid bases.” The carbons are numbered from the primary hydroxyl. The numbers in the names refer to the position of double bonds or of other functional groups as indicated. The fatty acids (R) are usually saturated or monounsaturated C_{16} – C_{26} hydroxy fatty acids.

FIGURE 8.8 Acetyl-CoA may be the most central intermediate in cellular metabolism, providing a link between many pathways. The major pathways involved in its production include glycolysis (via pyruvate dehydrogenase) and fatty acid oxidation. Acetyl-CoA is the starting material for biosynthesis of fatty acids, several amino acids, flavonoids (via chalcone synthase), sterols, and many isoprenoid derivatives synthesized in the cytosol. During respiration, acetyl-CoA is the source of carbon input into the citric acid cycle in the mitochondria. Despite this central role, acetyl-CoA is not believed to cross membranes and must be produced in the compartment in which it is utilized.

group of 16 or 18 carbons. The enzymes involved in this synthesis are acetyl-CoA carboxylase (ACCase) and fatty acid synthase (FAS) (Fig. 8.9). The name fatty acid synthase refers to a complex of several individual enzymes that catalyze the conversion of acetyl-CoA and malonyl-CoA to 16:0 and 18:0 fatty acids (see Section 8.4). **Acyl-carrier protein** (ACP), an essential protein cofactor, is generally considered a component of FAS.

Fatty acid biosynthesis is initiated by the ATP-dependent carboxylation of acetyl-CoA to form malonyl-CoA. Next, the malonyl group is transferred to ACP. Assembly of the fatty acid begins when a carbon-carbon bond forms between C-1 of an acetate “primer” and C-2 of the malonyl group on ACP, which releases CO_2 . This two-carbon chain length extension results initially in the formation of acetoacetyl-ACP.

Subsequently, a sequence of three reactions—reduction, dehydration, and reduction again—leads to the formation of the fully reduced acyl-ACP. This sequence, progressing in three steps from a 3-ketoacyl group to a saturated acyl group, is a common reaction series found in biochemical pathways. For example, both β -oxidation and the citric acid cycle use the same series of reactions, but in reverse order.

Fatty acyl chains and their derivatives are among the most reduced molecules found in cells. Producing these molecules from their more-oxidized precursors requires a large investment of reducing power. As indicated above, each cycle of two-carbon addition involves two reduction steps. Thus, for a typical C_{18} fatty acid, 16 molecules of NAD(P)H are consumed. In illuminated chloroplasts, abundant reducing power is available from Photosystem I. In the dark and in tissues

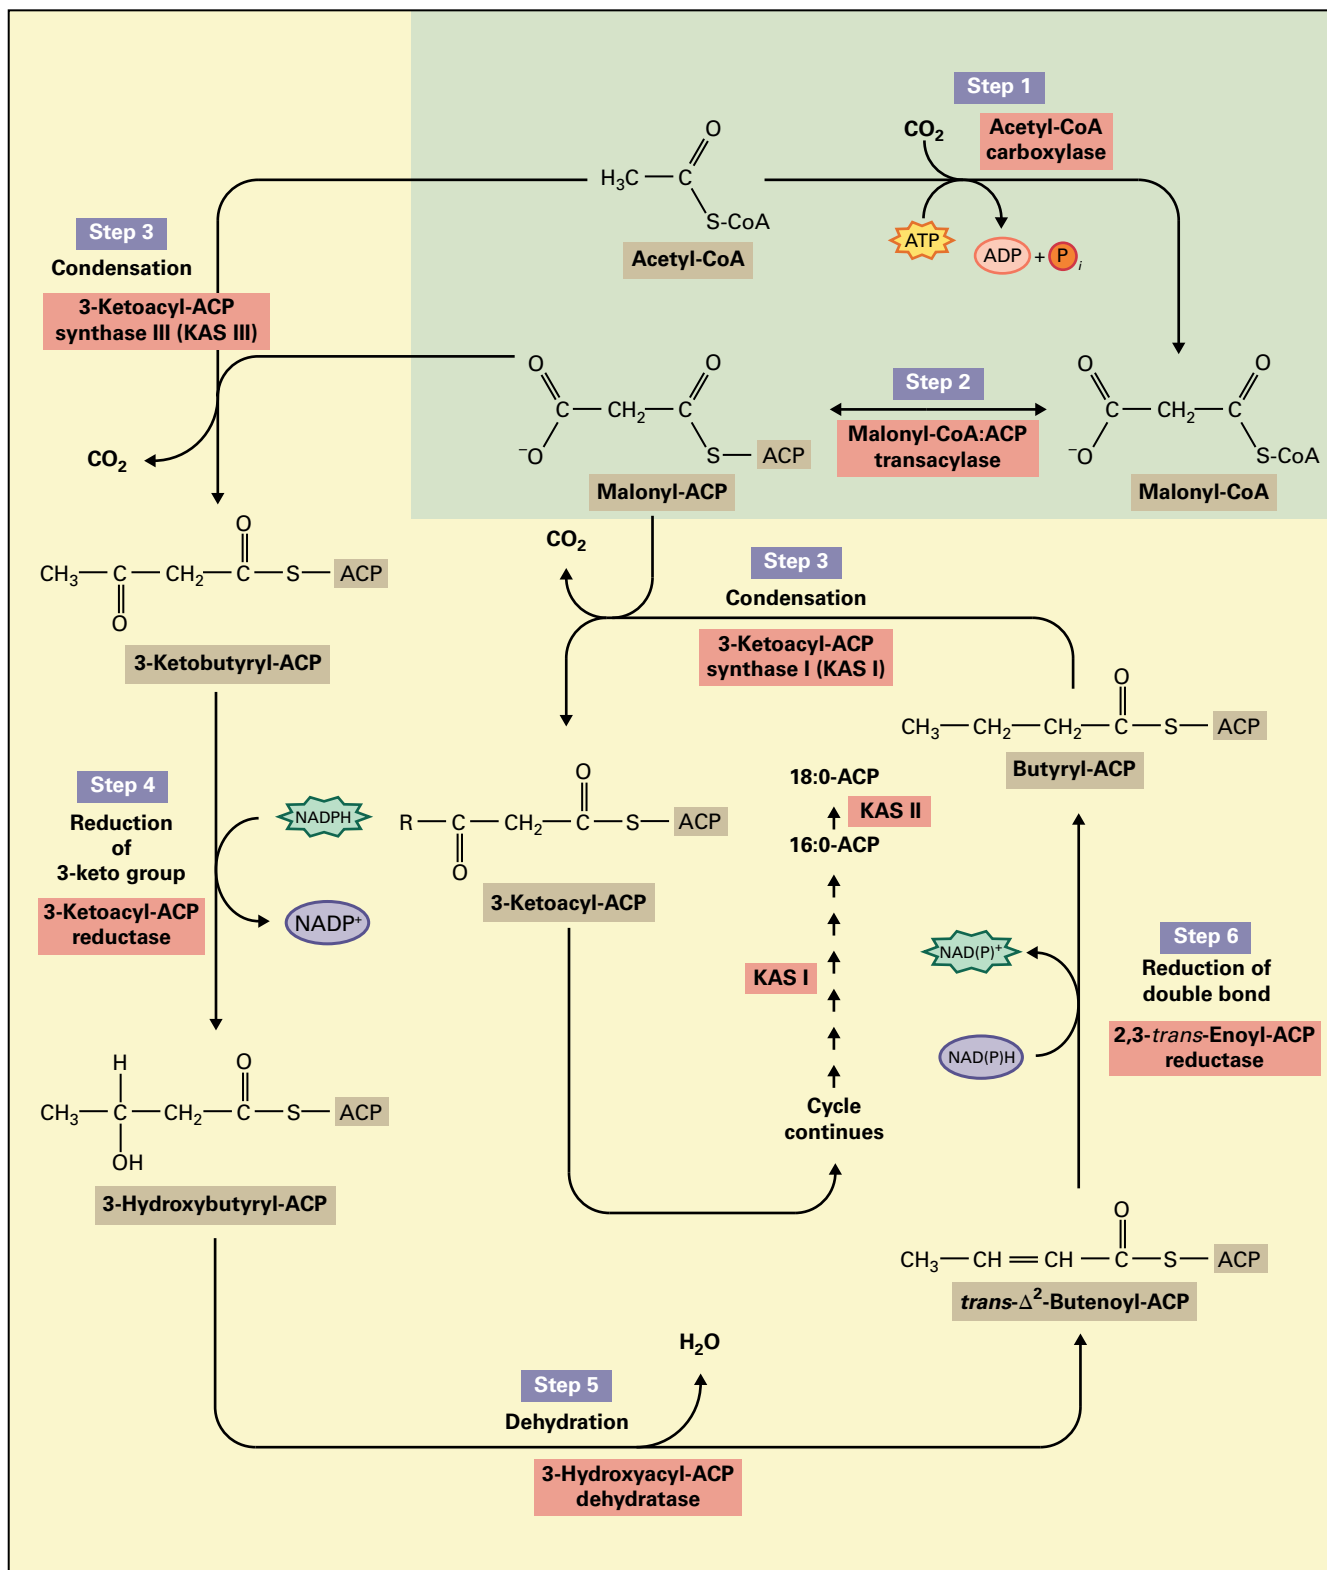

FIGURE 8.9 Overview of fatty acid synthesis. Fatty acids grow by addition of two-carbon (C_2) units. The reactions highlighted in yellow show how malonyl-CoA enters the cycle; those highlighted in orange represent the cyclic reactions. Synthesis of a C_{16} fatty acid requires that the cycle be repeated seven times. During the first turn of the cycle, the condensation reaction (step 3) is catalyzed by ketoacyl-ACP synthase (KAS III). For the next six turns of the cycle, the condensation reaction is catalyzed by isoform I of KAS. Finally, KAS II is used during the conversion of 16:0 to 18:0.

lacking chloroplasts, the oxidative pentose phosphate pathway is the most likely origin of reduced NADPH (see Chapter 13).

8.3 Acetyl-CoA carboxylase

8.3.1 Malonyl-CoA formation is catalyzed in a two-step reaction by acetyl-CoA carboxylase

Long-chain fatty acids are assembled two carbons at a time from acetyl-CoA; however, formation of the carbon-carbon bond between successive acetate units is an energy-consuming process. To provide an energetically favorable leaving group for the subsequent condensation reaction, cells first carboxylate acetyl-CoA. This ACCase reaction occurs in two steps: first, a biotin prosthetic group is carboxylated in an ATP-dependent process, and then acetyl-CoA reacts with carboxybiotin to produce malonyl-CoA (Reaction 8.1; see also Fig. 8.10). ACCase activity is highly regulated and a major biochemical control point that determines the overall rate of fatty acid synthesis in plant cells.

Reaction 8.1: Acetyl-CoA carboxylase

FIGURE 8.10 The acetyl-CoA carboxylase (ACCase) reaction. ACCase catalyzes step 1 in the reaction sequence shown in Figure 8.9. ACCase has three functional components that form malonyl-CoA from acetyl-CoA. (1) In an ATP-dependent reaction, biotin carboxylase activates CO_2 (as HCO_3^-) by attaching it to a nitrogen in the biotin ring of biotin carboxyl carrier protein (BCCP). (2) The flexible biotin arm of BCCP carries the activated CO_2 from the biotin carboxylase active site to the carboxyltransferase site (α -CT and β -CT). (3) The transcarboxylase transfers activated CO_2 from biotin to acetyl-CoA, producing malonyl-CoA.

8.3.2 Plants contain both homomeric and heteromeric forms of ACCase

ACCase catalyzes the initial step in fatty acid synthesis; indeed, in most plant cells, the major pathway consuming malonyl-CoA is plastid-localized fatty acid synthesis. However, plants also require malonyl-CoA outside the plastid, where it serves as a substrate for the flavonoid biosynthetic pathway, for fatty acid elongation reactions at the ER, for malonylation of some amino acids, and for the ethylene precursor, aminocyclopropanecarboxylic acid (Fig. 8.11).

In most plants, the plastid form of ACCase has four subunits: biotin carboxyl carrier protein (BCCP), biotin carboxylase (BC), and the α - and β subunits of carboxyltransferase (CT). These four subunits form a membrane-associated heteromeric complex of more than 650 kDa (Fig. 8.12). Three of the subunits are encoded by nuclear genes, whereas the fourth (β -CT) is encoded in the chloroplast genome.

The cytosolic form of ACCase is a single, large (greater than 500 kDa) homodimeric protein. The four subunits described above are integrated into domains of a single polypeptide, two of which associate to make up the homodimer (Fig. 8.12). This structure is similar to the ACCase found in animals and fungi. Indeed, there is as much as 50% amino

FIGURE 8.11 Multiple fates of malonyl-CoA. Malonyl-CoA produced by the ACCase reaction enters several pathways in plants. Within the plastid, malonyl-CoA is used exclusively for the production of fatty acids. In the cytosol, malonyl-CoA is the carbon donor for fatty acid elongation, producing the precursors for surface waxes and certain seed lipids. Condensation of three molecules of malonyl-CoA produces a diverse range of flavonoids and their derivatives (see Chapter 24). In many plant tissues, the major form of the ethylene precursor 1-aminocyclopropane-1-carboxylic acid is the inactive malonylated derivative, produced by reaction with malonyl-CoA. Finally, many D-amino acids and other secondary metabolites react with malonyl-CoA to form malonylated derivatives. CoASH, coenzyme A.

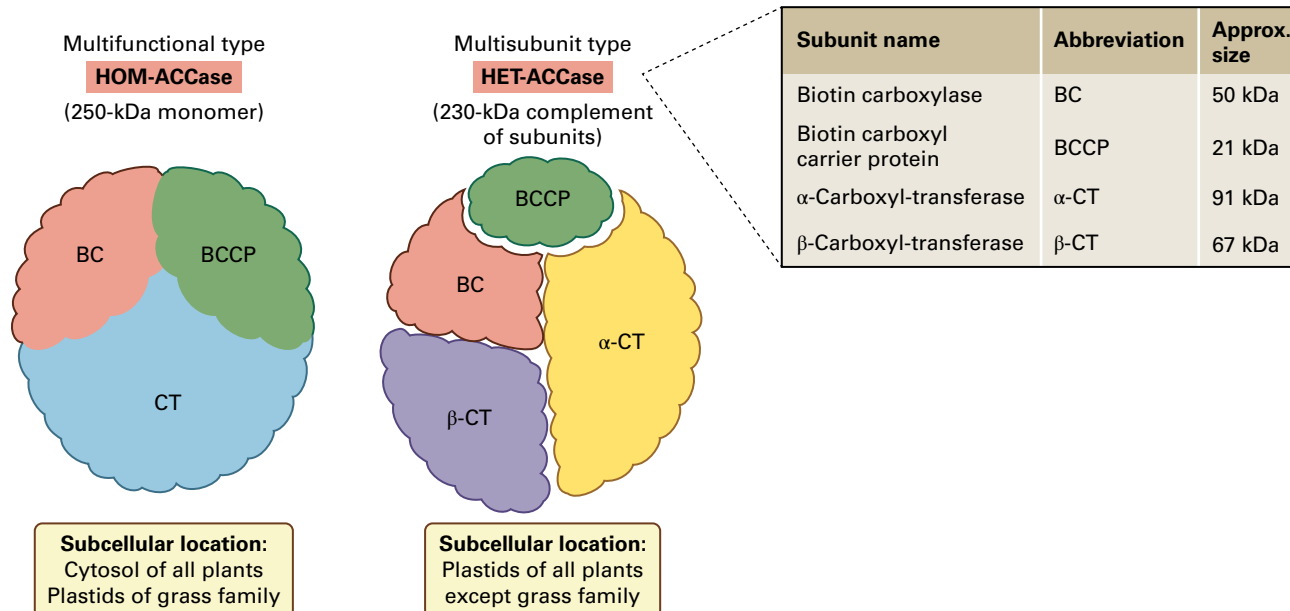

FIGURE 8.12 Two different forms of ACCase occur in plants: a homodimeric form (HOM-ACCase) with three functional domains encoded in a single polypeptide of about 250 kDa, and a heteromeric form (HET-ACCase) consisting of four subunits that together form a plastid-localized complex of 650–700 kDa.

acid identity between the sequences of the enzymes from organisms in these kingdoms.

Almost all monocot and eudicot plants so far examined have the two types of ACCase described above—with the

heteromeric, multisubunit form in the plastid and the homodimeric form in the cytosol. The grass family (Poaceae) is an exception, with similar homodimeric forms being found in both plastids and cytosol. Furthermore, the β -CT

gene is partially or completely missing from the chloroplast genome, and none of the subunits of the heteromeric ACCase can be found in sequenced grass genomes. Although the reason for the different ACCase organization in grasses remains unknown, it has substantial practical significance in agriculture. Several widely used grass-specific herbicides kill grasses by specifically inhibiting the homodimeric form of ACCase in the plastid, thereby blocking plastid fatty acid biosynthesis.

8.3.3 Malonyl-CoA formation is the first committed step in fatty acid synthesis and is highly regulated

In many primary metabolic pathways, biochemical regulation occurs at the first committed step. Although malonyl-CoA is used in several pathways in the cell, fatty acid biosynthesis is the only known fate for malonyl-CoA within the plastid. Therefore, the ACCase reaction in plastids is the first committed step for fatty acid synthesis. Several lines of evidence indicate plastid ACCase activity is tightly regulated and this regulation determines, in large part, the overall rate of fatty acid synthesis. First, the concentration of malonyl-CoA in chloroplasts changes quickly during light–dark transitions and remains proportional to the rate of fatty acid synthesis. Second, for herbicides that specifically target the plastid ACCase, the same concentrations inhibit foliar fatty acid synthesis both *in vivo* and *in vitro*. Finally, addition of exogenous lipids to suspension cultures slows production of new fatty acids. Analysis of the substrates and products of plastid fatty acid metabolism indicates this regulation occurs at the ACCase reaction. Thus, plastid-localized ACCase appears to be a highly regulated enzyme subject to feedback and other biochemical

controls. Post-translational activation of ACCase occurs by multiple mechanisms including feedback by acyl-ACP, phosphorylation, and redox regulation mediated by thioredoxin.

8.4 Fatty acid synthase

8.4.1 Different types of FAS exist in different kingdoms

FAS refers to all enzyme activities in fatty acid biosynthesis except ACCase. Although the reactions catalyzed by FAS are essentially the same for all organisms, two different types of FAS are found in nature. Animals and yeast use a Type I FAS, a single multifunctional enzyme complex characterized by large subunits (250 kDa). Each subunit can catalyze several different reactions. By contrast, plants and most bacteria have a Type II FAS, in which each enzyme activity resides on an individual protein that can be readily separated from the other activities participating in fatty acid synthesis. Type II FAS also includes ACP. The Type II FAS functions much like a metabolic pathway, whereas Type I FAS functions like a large protein complex (e.g., pyruvate dehydrogenase).

The assembly of a C_{18} fatty acid from acetyl-CoA in Type II fatty acid synthesis requires 48 reactions involving at least 12 different proteins. How is this complex pathway organized? Although no direct evidence has been established to date, supramolecular organization seems very likely. The estimated concentrations of many acyl-ACP intermediates of the pathway are in the nanomolar range, far below the K_m values predicted by kinetic analyses of the enzymes involved. Calculations suggest the enzyme activities available at these low substrate concentrations are not sufficient to support observed *in vivo* rates of fatty acid synthesis. Accordingly, some form of

FIGURE 8.13 Acyl-carrier protein (ACP), a small protein of 80–90 amino acids, participates as an acyl carrier in all reactions of fatty acid synthesis, as well as in desaturation and acyltransferase reactions. The prosthetic group is 4'-phosphopantetheine, which is covalently attached to the hydroxyl group of a serine residue in ACP. Shown is the structure of acyl-ACP.

substrate channeling seems essential. Furthermore, in osmotically lysed chloroplasts, neither acetyl-CoA nor malonyl-CoA competes with radiolabeled free acetate for incorporation into fatty acids, suggesting acetate is channeled directly into fatty acid synthesis. Thus, Type II fatty acid synthesis is catalyzed by separate enzymes that appear to be complexed in a tightly coupled synthesis pathway.

8.4.2 ACP transports intermediates of fatty acid synthesis through the pathway

After formation of malonyl-CoA in the ACCase reaction (step 1, Fig. 8.9), the assembly of fatty acids involves a central cofactor, ACP (Fig. 8.13). This small protein is about 80 amino acids long and contains a phosphopantetheine prosthetic group covalently linked to a serine (Ser) residue near the middle of the polypeptide chain. The phosphopantetheine group, also found in coenzyme A (CoASH), contains a terminal sulfhydryl. The thioester linkage that forms between a fatty acid and this sulfur is a high-energy bond with a free energy of hydrolysis similar to that for ATP.

8.4.3 Malonyl-CoA:ACP transacylase transfers a malonyl moiety from CoASH to ACP

ACP first becomes involved in the fatty acid synthesis pathway when the malonyl group produced by ACCase is transferred from CoASH to the sulfhydryl of ACP by the reactions catalyzed by malonyl-CoA:ACP transacylase (Reaction 8.2; see also step 2, Fig. 8.9).

The reaction mechanism involves a covalent malonyl-enzyme intermediate (Fig. 8.14). Analysis of the malonyl transacylase (note: the terms transacylase and acyltransferase are equivalent) from *E. coli* has demonstrated this intermediate

is a serine ester. After the malonyl-transacylation, all subsequent reactions of fatty acid synthesis involve ACP.

8.4.4 The three plant isoforms of 3-ketoacyl-ACP synthase demonstrate different substrate specificities

The defining reaction of fatty acid synthesis is the elongation of a “primer” acyl chain by two carbons donated from malonyl-ACP (step 3, Fig. 8.9). The condensation reaction to form a new carbon-carbon bond is catalyzed by 3-ketoacyl-ACP synthase (KAS), commonly called condensing enzyme (Fig. 8.15). All plants examined to date contain three KAS isoenzymes (I, II, and III), each distinguished by its substrate specificity. The general reaction for KAS occurs in two steps (Reaction 8.3; see also step 4, Fig. 8.9). The *in vitro* substrate specificity of each of the KAS isoenzymes suggests the role each plays in fatty acid biosynthesis. KAS I is most active with C_4 – C_{14} acyl-ACPs. KAS II accepts only longer-chain (C_{10} – C_{16}) acyl-ACPs as substrates. KAS III has a strong preference for acetyl-CoA rather than acyl-ACP. These *in vitro* activities suggest KAS isoenzymes act in sequence. KAS III initiates fatty acid biosynthesis, using acetyl-CoA as a primer. KAS I then extends the acyl chain to C_{12} – C_{16} . Finally, KAS II completes the synthesis to C_{18} .

8.4.5 The last three steps of the fatty acid synthesis cycle reduce a 3-ketoacyl substrate to form a fully saturated acyl chain

The initial reductive step of fatty acid biosynthesis is the conversion of a 3-ketoacyl-ACP to a 3-hydroxyacyl-ACP (Reaction 8.4; step 4, Fig. 8.9). Native 3-ketoacyl-ACP reductase has a molecular mass of 130 kDa and a subunit mass of 28 kDa, suggesting it is a tetramer. The predominant form

Reaction 8.2: Malonyl-CoA:ACP transacylase

FIGURE 8.14 Mechanism of the malonyl-CoA:ACP transacylase reaction. In the first step of the reaction, the malonyl group is transferred to a serine residue on the enzyme and CoASH is released. In the second step, the acyl group is transferred to the phosphopantetheine sulfhydryl group of ACP to form the malonyl-ACP thioester.

is NADPH-dependent and can account for all the required 3-ketoacyl-ACP reductase activity for fatty acid synthesis.

The removal of water from 3-hydroxyacyl-ACP to form 2,3-*trans*-enoyl-ACP is catalyzed by 3-hydroxyacyl-ACP dehydrase (Reaction 8.5; step 5, Fig. 8.9). The purified dehydrase from spinach (*Spinacia oleracea*) has a molecular mass of 85 kDa and a subunit size of 19 kDa. Thus, it appears to be a homotetramer. Its substrate specificity is very broad, with high activity demonstrated for acyl groups ranging from C₄ to C₁₆.

In the final reduction step, enoyl-ACP reductase converts the 2,3-*trans*-enoyl-ACP to the corresponding saturated acyl-ACP (Reaction 8.6; step 6, Fig. 8.9). Enoyl-ACP reductase exists in two isoforms. The major form is specific for NADH and a homotetramer with a native molecular mass of 115–140 kDa and a subunit molecular mass of 32.5–34.8 kDa. A second isoform uses either NADPH or NADH and is specific for longer-chain (C₁₀) enoyl-ACPs.

8.4.6 Thioesterase reactions terminate the fatty acid biosynthesis cycle

Each cycle of fatty acid synthesis adds two carbons to the acyl chain. Typically, fatty acid synthesis ends at 16:0 or 18:0, when one of several reactions stops the process. The most common reactions are hydrolysis of the acyl moiety from ACP by a thioesterase, transfer of the acyl moiety from ACP directly onto a glycerolipid by an acyl transferase, or double-bond formation on the acyl moiety by an acyl-ACP desaturase. The thioesterase reaction yields a sulfhydryl ACP (Reaction 8.7).

Two principal types of acyl-ACP thioesterases occur in plants (Fig. 8.16). The major class, designated FatA, is most active with 18:1^{Δ9}-ACP. A second class (FatB), typified by 16:0-ACP thioesterase, is most active with shorter-chain, saturated acyl-ACPs. In both cases, however, the metabolic consequence of these reactions is the same. Cleavage of the acyl moiety from ACP prevents extension and targets the acyl group for export out of the plastid by an unknown mechanism. Thioesterases play an important role in plants that have unusually short fatty acids, such as coconut (*Cocos nucifera*), many species of *Cuphea*, and California bay (*Umbellularia californica*). These plants have thioesterases that are especially active with C₁₀–C₁₂ acyl-ACPs; by prematurely terminating fatty acid biosynthesis, thioesterase activity results in the accumulation of 10:0 and 12:0 fatty acids in the seed triacylglycerols.

8.5 Desaturation and elongation of C₁₆ and C₁₈ fatty acids

If membranes contained only saturated or *trans*-unsaturated fatty acids, the hydrophobic lipid tails would form a semicrystalline gel, impairing the permeability barrier and interfering with the mobility of membrane components. By contrast, *cis*-double bonds, which introduce “kinks” into a fatty acid chain, can enhance membrane fluidity by dramatically lowering the temperature at which these ordered matrices melt.

FIGURE 8.15 3-Ketoacyl-ACP synthases catalyze Claisen condensations. This sequential reaction involves, first, the acyl transfer from an ACP or CoA thioester to an active site cysteine, followed by the entry of malonyl-ACP and decarboxylation of the malonate. The resulting carbanion then condenses with the acyl group to form a new C-C bond before release of the acyl group from the cysteine.

For example, the desaturation step that converts stearic acid (18:0) to oleic acid (18:1^{Δ9}) lowers the melting point of the fatty acid from 69°C to 13.4°C. Double bonds at other positions in the chain also exert large effects on the melting temperature of fatty acids and of the lipids that contain them (Fig. 8.17; see also Chapter 1, Table 1.2). Formation of such double bonds is catalyzed by various desaturase enzymes, which generate a diverse array of unsaturated lipids found in membranes, storage reserves, and extracellular waxes.

8.5.1 Plants contain a soluble, plastid-localized stearyl-ACP desaturase

Unsaturated C₁₈ acyl chains found in membrane lipids throughout the plant cell are products of a soluble chloroplast enzyme, stearyl-ACP Δ⁹-desaturase (Fig. 8.18). All eukaryotes and some prokaryotes have desaturases that catalyze similar reactions, but in all cases these enzymes are integral

Reaction 8.3: 3-Ketoacyl-ACP synthase (KAS)

Reaction 8.4: 3-Ketoacyl-ACP reductase

Reaction 8.5: 3-Ketoacyl-ACP dehydratase

membrane proteins. Recently, stearoyl-ACP Δ^9 -desaturase has come to be recognized as the prototype of a distinct family of structurally similar enzymes that introduce double bonds at various locations along the acyl chain. Species-specific genes for two isoforms, which catalyze desaturations

of palmitic acid at the Δ^4 or Δ^6 position, have recently been isolated from coriander (*Coriandrum sativum*) and black-eyed susan (*Thunbergia alata*), respectively.

Unlike the stearoyl-CoA desaturases of fungi and animals, which are located in the ER membranes, the members of the

Reaction 8.6: Enoyl-ACP reductase

Reaction 8.7: Thioesterase

FIGURE 8.16 Principal types of acyl-ACP thioesterases in plants. The FatA class is most active with 18:1^{Δ9} and the FatB class is most active with saturated acyl-ACPs. The FatA 18:1^{Δ9} thioesterase and the FatB 16:0-ACP thioesterase are found in all plant tissues. Some FatB thioesterases, especially those most active on acyl-ACP acyl groups shorter than C₁₆, are species specific.

stearoyl-ACP desaturase enzyme family are soluble, a fact that has greatly facilitated structural and mechanistic studies. The tertiary structure of castor bean (*Ricinus communis*) stearoyl-ACP Δ⁹-desaturase has been solved by X-ray crystallography (Fig. 8.19A). As the crystal structure shows, the protein contains a cavity that can bind the 18:0 substrate in the correct orientation with respect to the active site (Fig. 8.19B). The amino acid sequences of known soluble desaturases from

several plants are sufficiently homologous that we can deduce their active sites by mapping the sequences of the Δ⁴- and Δ⁶-desaturases onto the structure of the Δ⁹-desaturase. When the gene encoding the castor bean enzyme was expressed in *E. coli*, it produced a functional enzyme that could be purified in large amounts. Mössbauer spectrometry of the recombinant castor bean enzyme from cultures of *E. coli* grown in ⁵⁷Fe revealed the presence of a nonheme iron

center in the desaturases—a structure now known to be a Fe-O-Fe (diiron) center of the type found in bacterial methane monoxygenase (Fig. 8.19C). This provides an explanation for many properties of the desaturases, such as the

FIGURE 8.17 The transition temperature, or melting temperature, of a lipid is strongly influenced by the presence and position of double bonds in the acyl groups. In this example, the transition temperature has been determined for several molecular species of phosphatidylcholine in which the two acyl groups are C₁₈ fatty acids that contain double bonds at various positions along the chains. Thus, for instance, when the two acyl groups have double bonds between C-2 and C-3, the transition temperature is approximately 40°C, whereas for molecules with double bonds near the center of the acyl groups, the melting temperature is decreased by about 60°C. Thus, by controlling the position of the fatty acyl unsaturations, organisms can exert control over the physical properties of lipids.

observation that the overall desaturation reaction requires transfer of two electrons from a donor such as ferredoxin or cytochrome *b₅* (Fig. 8.20).

8.5.2 Most fatty acyl desaturases are membrane-localized proteins

Except for the soluble acyl-ACP desaturase family, all other fatty acid desaturases from animals, yeast, cyanobacteria, and plants are integral membrane proteins. The plant and cyanobacterial enzymes desaturate fatty acids of glycerolipids, whereas some yeast and animal desaturases act on acyl-CoAs.

FIGURE 8.18 Desaturation of stearic acid is catalyzed by stearyl-ACP Δ 9-desaturase.

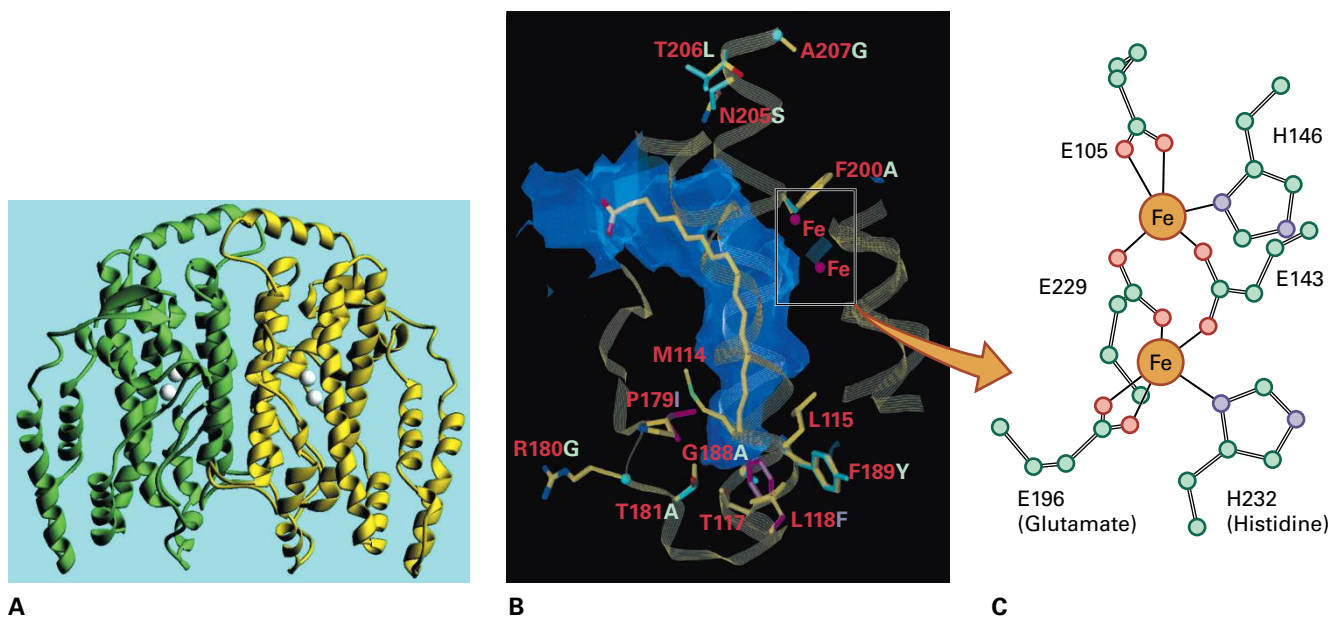

FIGURE 8.19 (A) Tertiary structure of stearyl-ACP Δ 9-desaturase dimer from *Ricinus communis*. The four white spheres near the center of the enzyme are two pairs of iron ions that catalyze the desaturation reaction. (B) Schematic view of the substrate channel of a stearyl-ACP Δ 9-desaturase monomer. A model of the stearyl substrate moiety is fitted in the binding pocket of the desaturase. (C) Details of the residues that coordinate the diiron-oxo group at the active site.

FIGURE 8.20 Proposed catalytic mechanism for fatty acid desaturation. In the resting state, the diiron center is in the oxidized (diferric, or Fe^{III}-Fe^{III}) form with a μ-oxo bridge. Reduction of both iron ions by electron transfer from two ferredoxins (Fdx) results in the reduced (diferrous, or Fe^{II}-Fe^{II}) form. The reduced enzyme binds molecular oxygen, resulting in the formation of a peroxo intermediate, “P.” Scission of the O-O bond results in the formation of an activated form of the diiron center, “Q” (diferryl, or Fe^{III}-Fe^{III}). By analogy with the methane monooxygenase reaction, Q has been proposed to perform an energy-demanding hydrogen abstraction from the methylene group of the unactivated fatty acid to yield a radical intermediate. Loss of the second hydrogen results in formation of the double bond along with the loss of H₂O and regeneration of the oxidized active site and the μ-oxo bridge.

Solubilizing and purifying the plant enzymes have proven very difficult, limiting investigation by traditional biochemical techniques. Genetic analysis in *Arabidopsis* has provided an alternative approach to biochemical methods for assessing the function of the enzymes.

The number and properties of different desaturases in plants are known from the isolation of a comprehensive collection of *Arabidopsis* mutants with defects in each of eight desaturase genes. The enzymes encoded by these genes differ in substrate specificity, subcellular location, mode of regulation, or some combination of these (Table 8.4). The mutants were identified by analyzing lipid samples from leaves or seeds of individual plants from heavily mutagenized populations. The biochemical defect of each class of mutants is shown by breaks in the pathway in Figure 8.21. The mutations that disrupt the activity of specific fatty acid desaturases are designated *fab2* and *fad2* through *fad8*. Two of the desaturases are ER-localized enzymes, oleate desaturase (FAD2) and linoleate desaturase (FAD3). Three structurally related enzymes are located in the plastids: one oleate desaturase (FAD6) and two functionally similar linoleate desaturases (FAD7 and FAD8). The identities of these enzymes have been confirmed by cloning the corresponding genes and using the cloned genes to complement the mutations in transgenic *Arabidopsis* plants, thereby restoring enzyme activity.

The ER-localized enzymes act on fatty acids esterified to phosphatidylcholine and possibly other phospholipids, and they utilize cytochrome b_5 as an intermediate electron donor. Cytochrome b_5 is reduced by another membrane protein, cytochrome b_5 reductase. Thus, three proteins are required for the overall desaturation reaction catalyzed by the ER-localized desaturases. In contrast, the membrane-localized chloroplast enzymes use soluble ferredoxin as an electron donor and act

on fatty acids esterified to galactolipids, sulfolipids, and phosphatidylglycerol (PG). Analysis of the mutants suggests the FAD4 enzyme is completely specific for PG, and the FAD5 enzyme appears to be specific for monogalactosyldiacylglycerol (Fig. 8.21). Despite differences in the glycerolipid substrates and electron donors used, and the position in which they insert the double bond, the majority of membrane-localized plant desaturases are structurally related to each other and to the membrane-localized desaturases from animals and yeast. They contain three histidine-rich sequences (typically HXXHH) that have been proposed to bind the two iron ions required for catalysis. Although the tertiary structure of the membrane-bound desaturases is not known, the iron-binding site may resemble that found in the diiron protein hemerythrin (Fig. 8.22).

From analysis of the effects of the mutations on glycerolipid fatty acid composition, a loss-of-function mutant appears to be available for every desaturase in *Arabidopsis* except stearoyl-ACP $\Delta 9$ -desaturase, which is encoded by a family of genes. Thus, the *fab2* mutation, which is one of the genes encoding stearoyl-ACP desaturase, causes a significant increase in stearate concentrations but does not completely eliminate unsaturated fatty acids.

8.5.3 What factors determine glycerolipid desaturation?

Of central importance to the mechanisms that control desaturation are the factors that determine the extent of desaturation of a specific glycerolipid in a particular membrane. In cyanobacteria, the steady-state concentration of an oleate $\Delta 12$ -desaturase mRNA is inversely correlated with temperature

TABLE 8.4 Fatty acid desaturases of *Arabidopsis*.

Name	Subcellular location	Fatty acid substrates	Site of double-bond insertion	Notes
FAD2	ER	18:1 Δ^9	$\Delta 12$	Preferred substrate is phosphatidylcholine
FAD3	ER	18:2 $\Delta^{9,12}$	$\omega 3$	Preferred substrate is phosphatidylcholine
FAD4	Chloroplast	16:0	$\Delta 3$	Produces 16:1- <i>trans</i> at <i>sn</i> -2 of phosphatidylglycerol
FAD5	Chloroplast	16:0	$\Delta 7$	Desaturates 16:0 at <i>sn</i> -2 of monogalactosyldiacylglycerol
FAD6	Chloroplast	16:1 Δ^7 18:1 Δ^9	$\omega 6$	Acts on all chloroplast glycerolipids
FAD7	Chloroplast	16:2 $\Delta^{7,11}$ 18:2 $\Delta^{9,12}$	$\omega 3$	Acts on all chloroplast glycerolipids
FAD8	Chloroplast	16:2 $\Delta^{7,11}$ 18:2 $\Delta^{9,12}$	$\omega 3$	Isoenzyme of FAD7 induced by low temperature
FAB2	Chloroplast	18:0	$\Delta 9$	Stromal stearoyl-ACP desaturase

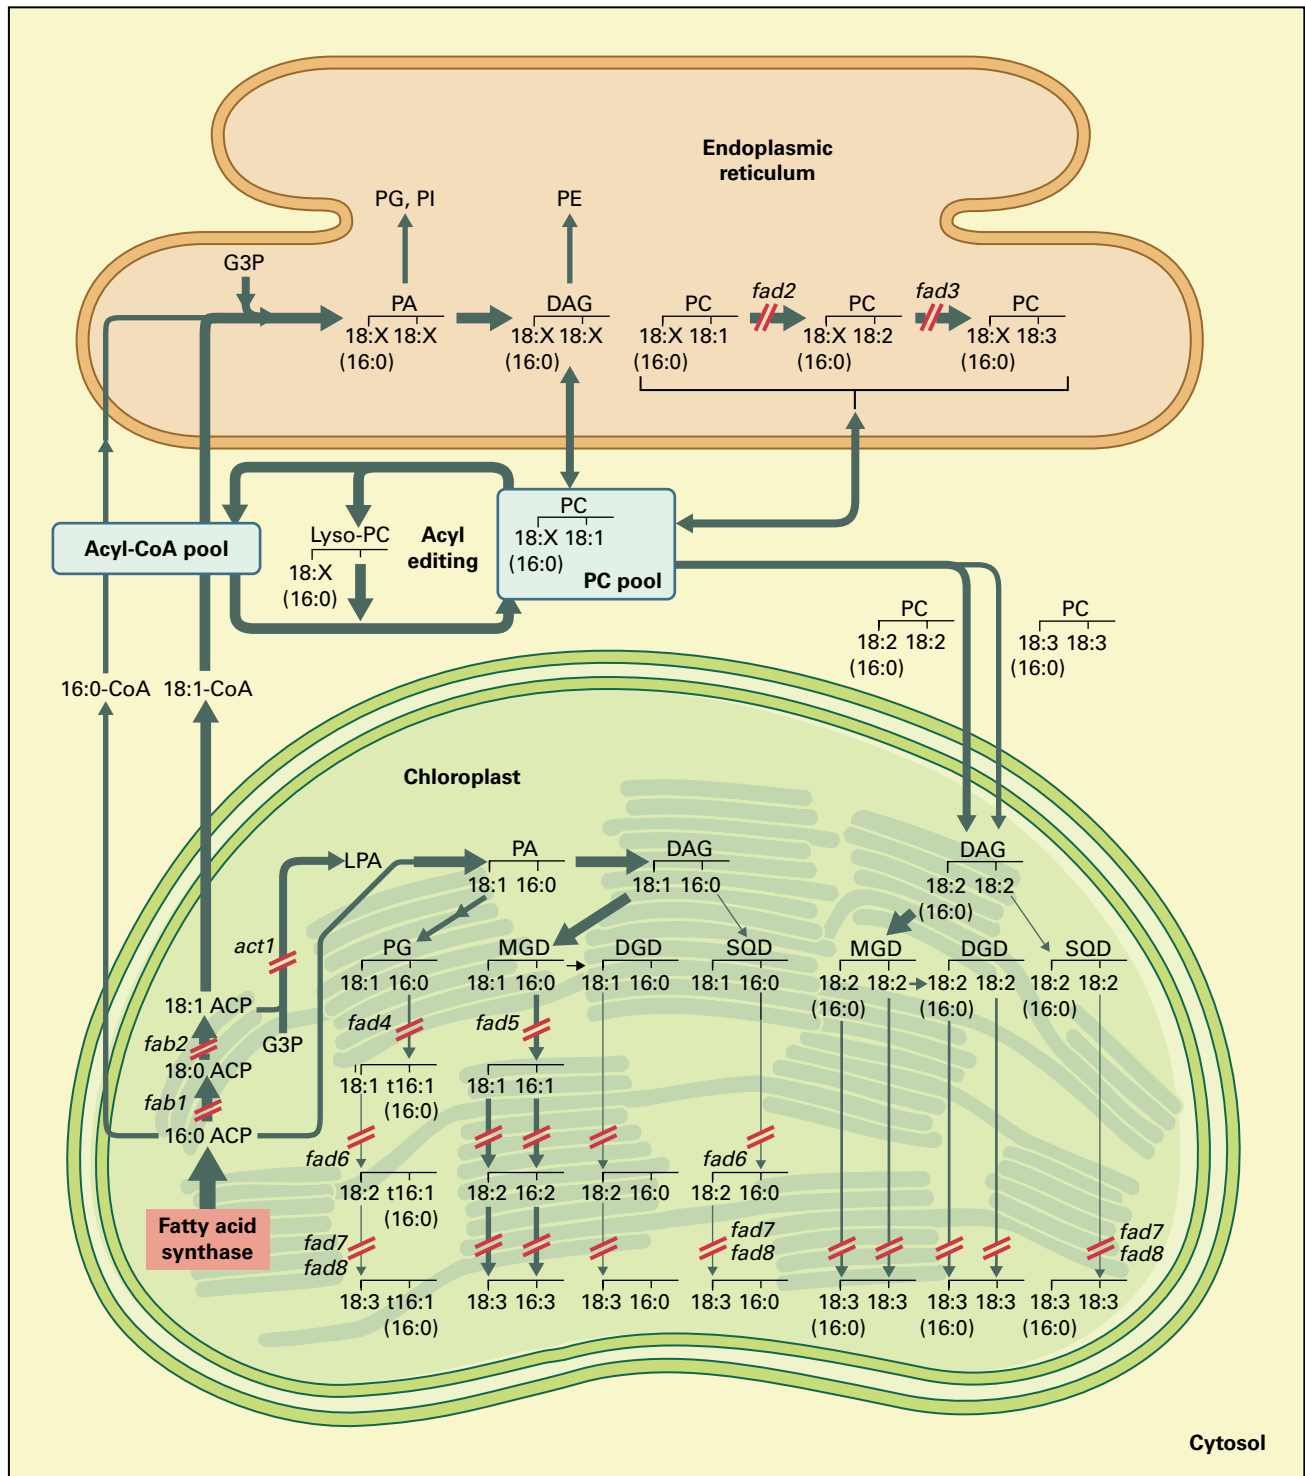

FIGURE 8.21 Abbreviated scheme for lipid synthesis in leaves of Arabidopsis. The set of reactions occurring solely within the chloroplast are termed the prokaryotic pathway; those that involve glycerolipid synthesis in the ER and subsequent transfer to the chloroplast constitute the eukaryotic pathway. After fatty acids leave the chloroplast, the largest flux measured in pea leaf labeling experiments is the exchange of acyl groups between the acyl-CoA pool and PC. Therefore, most fatty acids that exit the plastid are first esterified to PC rather than glycerol-3-phosphate. It is possible this reaction occurs at the chloroplast envelope or the plastid associated membrane. The breaks in the pathway (red) represent some of the enzymes for which mutations have been obtained in their genes in Arabidopsis (see Table 8.4). DAG, diacylglycerol; DGD, digalactosyldiacylglycerol; G3P, glycerol 3-phosphate; LPA, lysophosphatidic acid; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; MGD, monogalactosyldiacylglycerol; SQD, sulfoquinovosyldiacylglycerol.

FIGURE 8.22 Proposed ligation sphere of the integral membrane desaturases and related enzymes possessing two HXXHH motifs, in which all of the histidine residues have been shown to be essential for catalysis. The model is based on the structure of hemerythrin and shows a hydroxo bridge and a single carboxylate ligand that has yet to be defined. Question marks indicate the presence of two undefined ligands.

FIGURE 8.23 In cyanobacteria, the amount of desaturase mRNA is regulated by growth temperature.

(Fig. 8.23). Molecular and mutational analysis in *Synechocystis* PCC6803 demonstrated two-component regulators act as temperature sensors and induce the expression of desaturases and other genes in response to decreased temperature. These histidine kinase sensor components likely respond to changes in fluidity of the plasma membrane.

Most plants also increase the extent of membrane glycerolipid desaturation when grown at low temperature. The amount of mRNA for the desaturases genes in *Arabidopsis*, however, does not appear to change significantly in response to changes in growth temperature, with one exception: the *FAD8* gene, which exhibits a strong increase in mRNA abundance at low temperature. If a regulatory mechanism controlled desaturase gene expression in response to changes in the physical properties of membranes, we would expect this mechanism to detect large changes in membrane composition and to signal an increase in desaturase gene expression. However, expression of the cold-inducible *FAD8* gene is not altered in *fad7 fad8* double mutants, which are highly deficient in 16:3^{Δ7,10,13} and 18:3^{Δ9,12,15} fatty acids. Indeed, none of the loss-of-function *fad* mutations alters *FAD* gene expression. There is evidence the *FAD8* desaturase is regulated by increased turnover of the protein at high temperatures. Presumably, the complexities associated with regulating the composition of many intracellular membranes in plants may require posttranscriptional mechanisms that can adjust the composition of each membrane independently.

8.5.4 Specialized elongase systems produce long-chain fatty acids

Fatty acid synthesis generally results in C_{16} and C_{18} fatty acids, yet plants have numerous requirements for longer fatty acids. All plants produce waxes, usually derived from C_{26} to C_{32} fatty acids. Often, sphingolipids contain C_{22} and C_{24} fatty acids. And, in some plants, triacylglycerols contain large amounts of C_{20} and C_{22} fatty acids. Where and how are these very-long-chain fatty acids synthesized?

Plants and most other eukaryotic organisms have a specialized elongase system for extension of fatty acids beyond C_{18} . These elongase reactions have several important features in common with FAS reactions (see Fig. 8.9). Each uses a reaction series that condenses two carbons at a time from malonyl-CoA to an acyl primer, followed by reduction, dehydration, and a final reduction. The result is the same acyl intermediates are used for the two processes. Although the enzymology of the elongase is not well understood, several important differences between the two systems are known (Fig. 8.24):

- Fatty acid elongases are localized in the cytosol and are membrane-bound.
- ACP is not involved in this process.
- The elongase 3-ketoacyl-CoA synthase (elongase KCS) catalyzes the condensation of malonyl-CoA with an acyl primer.

Recent cloning of elongase KCS genes from *Arabidopsis* and jojoba (*Simmondsia chinensis*) has revealed these 60-kDa enzymes bear little sequence similarity to any other condensing enzymes. Identification of additional clones suggests the elongase KCSs in *Arabidopsis* belong to a complex gene family with 21 members. The requirement for multiple genes may be related to the relatively narrow acyl substrate specificity of elongase KCSs, so several different elongase KCSs would be required to synthesize a C_{30} fatty acid. Elongase KCSs may also be specific for a particular physiological function, such as wax biosynthesis or sphingolipid biosynthesis.

The additional components of the elongase system have only recently been identified in yeast, and *Arabidopsis* homologs have also been identified. The reductases and dehydrase are also membrane-localized, and the reductases prefer NADPH.

8.6 Synthesis of unusual fatty acids

8.6.1 More than 200 fatty acids occur in plants

Extensive surveys of the fatty acid composition of seed oils from different plants species have identified more than 200 naturally occurring fatty acids that can be broadly classified into 18 structural classes. The classes are defined by the number and arrangement of double or triple bonds and various

FIGURE 8.24 Sequence of events during a single cycle of fatty acid elongation by the membrane-bound fatty acid elongase system, which

functional groups, such as hydroxyls, epoxys, cyclopentenyl or cyclopropyl groups, or furans (Fig. 8.25).

The most common fatty acids, which often occur in both membrane and storage lipids, belong to a small family of C_{16} and C_{18} fatty acids that may contain as few as zero or as many

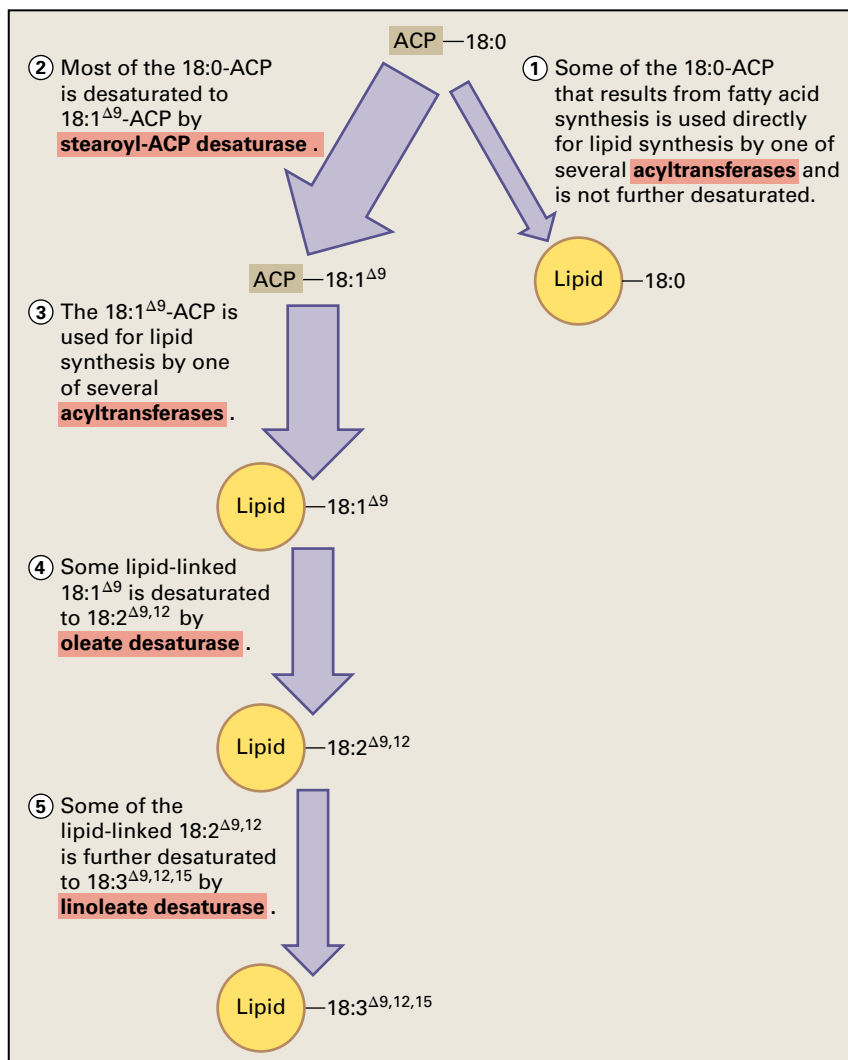

FIGURE 8.25 Some of the functional groups found in unusual plant fatty acids.

FIGURE 8.24 (Continued) consists of at least four components: 3-ketoacyl-CoA synthase (KCS), 3-ketoacyl-CoA reductase (KR), 3-hydroxyacyl-CoA dehydrase (DH), and enoyl-CoA reductase (ER). The initial cycle of elongation starts with a C_{18} acyl-CoA, either stearoyl-CoA or oleoyl-CoA. Steps 1–3 are catalyzed by KCS. First, the acyl-CoA acylates an active-site cysteine. Next, the malonyl-CoA binds to the active site. Finally, a concerted reaction occurs in which the malonyl moiety is decarboxylated and a Claisen condensation with the acyl group results. Then steps 4–6, a reduction, a dehydration, and a second reduction, occur sequentially on the remaining components of the elongase system and result in the release of an acyl-CoA that is two carbons longer than the starting acyl-CoA. This acyl-CoA may then undergo additional cycles of elongation or be used in other pathways of lipid metabolism.

FIGURE 8.26 Double bonds are introduced into fatty acids by a series of desaturases. The amount of a particular fatty acid that accumulates in a membrane varies from one membrane to another and is thought to be controlled partially by the activity of the various desaturases.

as three *cis*-double bonds. All unsaturated members of the family descend from the fully saturated species as the result of a series of sequential desaturations that begin at C-9 and progress in the direction of the methyl carbon (Fig. 8.26). Fatty acids that cannot be described by this simple model are generally considered “unusual” because each is found in only a few plant species and almost exclusively in the seed oil. Several of these unusual fatty acids, such as lauric (12:0), erucic (20:1^{Δ14}), and ricinoleic (12-OH, 18:1^{Δ9}) acids, are of substantial commercial importance (see Section 8.11.4).

8.6.2 Some enzymes that synthesize unusual fatty acids resemble enzymes involved in the biosynthesis of common fatty acids

Much of the research concerning unusual plant fatty acids has focused on identifying new structures or cataloging the composition of fatty acids found in various plant species. Less is known about the mechanisms responsible for the synthesis and accumulation of unusual fatty acids, or of their significance

to the fitness of the plants that accumulate them. However, the gene for the oleate $\Delta 12$ -hydroxylase that catalyzes the synthesis of ricinoleic and other hydroxylated fatty acids of castor bean (*Ricinus communis*) and *Lesquerella fenderli* exhibits about 70% amino acid sequence similarity to the microsomal oleate $\Delta 12$ -desaturase from the same species. To identify the amino acid differences responsible for causing the enzyme to be a hydroxylase instead of a desaturase, investigators have used site-directed mutagenesis to test the importance of the amino acids conserved in one class of enzymes but not in the other. On the basis of these studies, it appears the hydroxylase can be converted to a desaturase by as few as seven amino acid substitutions that alter the geometry of the active site.

The fact that such a small number of amino acid substitutions can alter the outcome of the enzymatic reaction indicates the diiron center used by these enzymes can catalyze different reactions, depending on the precise geometry of the active site. Indeed, evidence also indicates the enzymes that introduce epoxy groups and triple bonds are also structurally similar to the desaturases and hydroxylases. In contrast to the desaturases and hydroxylases, which act on saturated bonds, the epoxidases and acetylene forming enzymes are thought to act on double bonds, such that desaturation of a double bond

FIGURE 8.27 A small number of reactions can account for much of the chemical diversity observed in plant fatty acids. Desaturation and hydroxylation reactions can be catalyzed by enzymes that differ by as few as four amino acids. Epoxidases and acetylenases are also closely related to desaturases. Additional chemical diversity may arise through the action of enzymes that methylate double bonds to produce cyclopropanes and cyclopropenes.

gives rise to a triple bond, and oxidation of a double bond gives rise to an epoxy group. The formation of conjugated double bonds also requires a modified desaturase (a “conjugase”) acting on an unsaturated fatty-acyl substrate. Thus, many of the modifications found in fatty acids can be accounted for by a family of structurally related enzymes that can evolve from one specificity to another with only a few amino acid substitutions (Fig. 8.27).

These structural relationships have facilitated identification of many enzymes responsible for unusual fatty acid synthesis by their homology to sequences of enzymes involved in synthesis of usual fatty acids. For example, all membrane-bound desaturases described from animals, microbes, and plants contain three highly conserved histidine-rich sequences. Therefore, new enzymes related to the desaturase gene family can be identified relatively easily, even when overall homology is low. High-throughput sequencing of randomly selected cDNAs (expressed sequence tags) has facilitated the identification of dozens of enzymes responsible for unusual fatty acid synthesis. For instance, production of gamma-linolenate (18:3^{Δ6,9,12}) in seeds of borage (*Borago officinalis*), involves a Δ6-desaturase active on 18:2^{Δ9,12} at the *sn*-2 position of phosphatidylcholine. To clone the glycerolipid Δ6-desaturase gene, cDNAs from developing borage seeds were sequenced. One class of cDNAs showed low overall homology to other desaturases (about 30% identity at the amino acid level), but contained characteristic histidine boxes with spacings similar to those in the Δ6-desaturase of *Synechocystis*. Expression of the borage cDNA in transgenic plants led to production of gamma-linolenate and 18:4^{Δ6,9,12,15}. Similarly, as was successful for identifying the castor hydroxylase, enzymes

responsible for acetylenic, epoxy, and conjugated fatty acid production have been identified by their similarity to the Δ-12 desaturase sequence.

8.6.3 Unusual fatty acids occur almost exclusively in seed oils and may serve a defense function

Given that the ability to synthesize various unusual fatty acids must have evolved independently, their confinement to seed triacylglycerols indicates some selective constraint or functional significance. One possible function of unusual fatty acids is that, by being toxic or indigestible, they protect the seed against herbivory. Some unusual fatty acids may be inherently toxic, such as the acetylenic fatty acids or some of their metabolites. Other unusual fatty acids are toxic upon catabolism by the herbivore, such as the 4-fluoro fatty acids of *Dichapetalum toxicarium*. Cyclopentenyl fatty acids were long used in the treatment of leprosy, and the activity of hydnocarpic acid against many *Mycobacterium* species has been demonstrated. Cyclopropenoid fatty acids also appear to have biological activities, possibly because of accumulation in animal tissues of partial catabolites containing the cyclopropene ring, which inhibits β-oxidation of fatty acids. Malvalic and sterculic acids, produced by cotton (*Gossypium hirsutum*) plants, inhibit the growth of seed-eating lepidopteran larvae and may be part of a defense mechanism against these insects. These fatty acids may also be effective antifungal agents, inhibiting the growth of some plant pathogenic fungi at concentrations that appear biologically relevant.

FIGURE 8.28 The prokaryotic and eukaryotic pathways of plant glycerolipid synthesis. The prokaryotic pathway (lower panel) takes place in plastids and esterifies mainly palmitate to the sn-2 position of lysophosphatidate (LPA). The eukaryotic pathway (top panel) occurs outside the plastid, primarily in the ER and results in 18-carbon fatty acids esterified to the sn-2 position of glycerolipids. In the prokaryotic pathway, acyl-ACP is condensed with glycerol-3-phosphate (G3P) by a soluble enzyme, G3P acyltransferase (reaction 1). The product, LPA, partitions into the membranes where LPA is converted to phosphatidic acid (PA) by a membrane localized LPA-acyltransferase (reaction 2). PA is then converted to the other lipids found in chloroplasts. It is thought that most of the reactions of lipid synthesis by the prokaryotic pathway take place in the inner envelope of the plastids. The initial reactions of the eukaryotic pathway are similar except that acyl-CoA substrates are used and the G3P acyltransferase is associated with the ER. After desaturation of 18:1 to 18:2, lipids move from the ER to the other organelles, including the outer envelope of plastids. Eukaryotic lipids in the outer envelope are transferred into the inner membranes and modified by the replacement of headgroups and by the action of additional desaturases. CDP-DAG, cytidine diphosphate-diacylglycerol; DAG, diacylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; DGD, digalactosyl diacylglycerol; MGD, monogalactosyl diacylglycerol; SQD, sulfoquinovosyl diacylglycerol.

8.7 Synthesis of membrane lipids

Two distinct pathways—the “prokaryotic” and the “eukaryotic” pathways—exist for membrane glycerolipid synthesis in plants (Fig. 8.28). The prokaryotic pathway refers to the synthesis of lipids within the plastid. The eukaryotic pathway refers to the sequence of reactions involved in synthesis of lipids in the ER, transfer of some lipids between the ER and the plastid, and further modification of the lipids within the plastid. Superimposed on the main pathways for glycerolipid synthesis are several additional pathways for the synthesis of other lipids, such as waxes, cutin, suberin, sphingolipids, and sterols. Less is known about the cellular localization of these pathways. Sphingolipid synthesis is likely to take place in the ER, as are elongation of fatty acids for wax synthesis and production of oxygenated fatty acids for cutin synthesis.

8.7.1 Phosphatidic acids formed in the plastids via the prokaryotic pathway and in the ER via the eukaryotic pathway differ in fatty acyl composition and position

Glycerolipid synthesis involves a complex and highly regulated interaction between the chloroplast, where fatty acids are synthesized, and other membrane systems of the cell. The 16:0-, 18:0-, and 18:1^{Δ9}-ACP products of plastid fatty acid synthesis may be either incorporated directly into chloroplast lipids by the plastid-localized prokaryotic pathway or exported to the cytoplasm as CoA esters, which are then incorporated into ER lipids by an independent set of eukaryotic pathway acyltransferases (Fig. 8.28).

The first steps of glycerolipid synthesis are two acylation reactions that transfer fatty acids from acyl-ACP or acyl-CoA to glycerol 3-phosphate, forming phosphatidic acid (Fig. 8.29). Because of the substrate specificities of the plastid acyltransferases, the phosphatidic acid made by the prokaryotic pathway has 16:0 at the *sn*-2 position and, in most cases, 18:1^{Δ9} at the *sn*-1 position (see Fig. 8.28). In contrast to the plastid iso-enzymes, the acyl-transferases of the ER produce phosphatidic acid that is highly enriched with C18 fatty acids at the *sn*-2 position; 16:0, when present, is confined to the *sn*-1 position (see Fig. 8.28).

8.7.2 Membrane lipid synthesis requires a complex collaboration between cell compartments

Both the prokaryotic and eukaryotic pathways were proposed initially on the basis of labeling studies and have subsequently been tested by genetic studies in *Arabidopsis*. Both

are initiated by the synthesis of phosphatidic acid. In the chloroplast pathway, phosphatidic acid is used for the synthesis of PG or is converted to diacylglycerol (DAG) by a phosphatidic acid–phosphatase located in the inner plastid envelope. The DAG pool can act as a precursor for the synthesis of the other major chloroplast lipids: monogalactosyldiacylglycerol (MGD), digalactosyldiacylglycerol (DGD), and sulfoquinovosyldiacylglycerol (SQD), also called sulfolipid (see Fig. 8.28). In contrast to most other eukaryotic membranes, phospholipids (mostly PG) constitute 16% or less of the glycerolipids in chloroplast membranes (Fig. 8.30); the remainder is primarily galactolipid.

In the eukaryotic pathway, phosphatidic acid is synthesized in the ER from the acyl-CoA pool. This pool likely derives both from acyl-exchange reactions that reversibly equilibrate acyl groups in phosphatidylcholine (and other lipids) with acyl-CoA and from acyl-CoA that forms when fatty acids are exported from the plastid. ER-derived phosphatidic acid gives rise to the phospholipids, such as phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine, which are characteristic of the various membranes external to the chloroplast. However, the DAG moiety of phosphatidylcholine is returned to the chloroplast envelope, where it enters the DAG pool and contributes to the synthesis of plastid lipids (see Fig. 8.21). This lipid exchange between the ER and the chloroplast is reversible to some extent (see Section 8.7.4). The eukaryotic pathway is the principal route of glycerolipid synthesis in all nonphotosynthetic tissues as well as in the photosynthetic tissues of many plants. Among the angiosperms, only so-called 16:3 plants, such as spinach and *Arabidopsis*, produce more than 10% of their glycerolipids by the prokaryotic pathway (see Section 8.1.2 and below).

8.7.3 The fatty acid composition of lipids can reveal their pathway of origin

The relative amount of glycerolipid synthesized in plastids and the ER may vary in different tissues or in different plant species. In species such as pea (*Pisum sativum*) and barley (*Hordeum vulgare*), PG is the only product of the prokaryotic pathway, and the remaining chloroplast lipids are synthesized entirely by the eukaryotic pathway. By contrast, in leaves of 16:3 plants as much as 40% of cellular glycerolipid in leaf cells is synthesized within the chloroplasts. Because 16:3^{Δ7,10,13} is a major product of the pathway of glycerolipid synthesis in the chloroplast (see Fig. 8.21), the relative flux through the chloroplast prokaryotic pathway can be determined readily by the presence of this fatty acid (hence the name 16:3 plants). Plants with little or no 16:3^{Δ7,10,13} are called 18:3 plants. The contribution of the eukaryotic pathway to MGD, DGD, and sulfolipid synthesis is diminished in nonvascular plants, and in many green algae the chloroplast is almost entirely autonomous with respect to membrane lipid synthesis.

FIGURE 8.29 The biosynthetic pathway to phosphatidate. Fatty acids activated by esterification to CoASH or ACP are transferred by acyltransferases to the hydroxyl groups of glycerol 3-phosphate. The plastid glycerol-3-phosphate acyltransferase is a soluble enzyme. Other known acyltransferases are membrane-associated.

8.7.4 Large quantities of lipid move between the ER and chloroplasts

Each plant cell is autonomous with respect to glycerolipid synthesis, and there is no extensive transport of fatty acids or glycerolipids between cells. However, membrane biogenesis in plants involves a massive movement of fatty acids or lipids from one organelle to another (see Fig. 8.21). Quantitatively, the most significant movements of lipids are the export of fatty acids from plastids and the return of further desaturated acyl groups from the ER to the chloroplasts. In epidermal cells, there is also substantial movement of wax and cutin monomers from the ER to the extracellular space.

In the last few years, considerable progress has been made in understanding the mechanism of lipid transfer between the ER and the chloroplast. In particular, a series of mutants in *Arabidopsis* has allowed the identification of protein components of the transfer pathway. The current model proposes phosphatidic acid is generated from phosphatidylcholine in the ER and transported to the chloroplast inner envelope. An ATP-binding cassette (ABC) transporter transfers the phosphatidic acid through the inner envelope and makes it available to the enzymes of galactolipid and sulfolipid synthesis (Fig. 8.31). In terms of lipid trafficking, it is likely the plastid envelope is the most dynamic organellar membrane in nature.

Several lines of evidence indicate the existence of regulatory mechanisms that coordinate the activity of the two pathways for glycerolipid synthesis in plants. The *act1* (*acyl-CoA transferase1*) mutants of *Arabidopsis* are deficient in activity of chloroplast acyl-ACP:*sn*-glycerol-3-phosphate acyltransferase, the first enzyme of the prokaryotic pathway (see Fig. 8.21). This deficiency severely diminishes the flux through the prokaryotic pathway but is compensated for by increased synthesis of chloroplast glycerolipids via the eukaryotic pathway (Fig. 8.32). These and related results indicate that, even in case of a major disruption of one of the pathways of glycerolipid synthesis, mechanisms exist to ensure the synthesis and transfer of enough glycerolipids to support normal rates of membrane biogenesis. This striking example raises many unanswered questions. In particular, how is the demand for increased glycerolipid synthesis communicated to the lipid biosynthetic pathways during membrane expansion?

8.7.5 During de novo glycerolipid synthesis, the change in free energy that drives attachment of the polar head group is provided by nucleotide activation of either diacylglycerol or the head group itself

A general reaction common to all phospholipid biosynthesis pathways involves attachment of the phospholipid head group. In one case, a hydroxyl located on the head group carries out a nucleophilic attack on the β-phosphate group of

FIGURE 8.30 Glycerolipid compositions differ in different cell types. In leaves, where the most abundant membranes are chloroplast lamellae, galactolipids are the most abundant class. In roots, by contrast, most of the membranes are present in extraplastidic systems such as the ER and Golgi apparatus. Seeds of oilseed species, such as *Arabidopsis*, contain mostly TAGs.

FIGURE 8.31 Possible routes for lipid trafficking between ER, chloroplasts, and other membranes via membrane contact sites in a plant cell. (A–D) denote proposed contact zones for lipid trafficking between membranes: (A), chloroplast–ER contact; (B), plasma membrane–ER contact; (C), ER in contact with both chloroplast and plasma membrane; and (D), contact between chloroplast and plasma membrane. Other possible membrane contact sites pictured are between the ER and mitochondria, trans-Golgi and tonoplast, respectively. Inset: steps in the movement of glycerolipid from the ER to the chloroplast and synthesis of chloroplast MGD and DGD by the prokaryotic and eukaryotic pathways. TGD1–3 and TGD4 are component proteins of an ATP binding cassette (ABC) transporter. FAS, fatty acid synthesis; iE, inner envelope; oE, outer envelope.

CDP-DAG. In the other, the *sn*-3 hydroxyl of DAG attacks the β -phosphate of a CDP-activated head group (Fig. 8.33). Thus, phospholipid biosynthesis can be divided into two general types of pathways: the CDP-DAG and DAG pathways.

Unlike prokaryotes, in which only the CDP-DAG pathway is present, plants, yeast, and animals synthesize phospholipids by using both the CDP-DAG and the DAG pathways, but the contributions of each pathway vary. For example, yeasts can synthesize all their phospholipids by

using the CDP-DAG pathways, but under some conditions, they can repress a CDP-DAG pathway and use DAG instead. Animals make their major phospholipids—phosphatidylcholine and phosphatidylethanolamine—by using DAG pathways. The details of the synthesis of phospholipids in plants are not well characterized, and much of what is known has been learned by analogy to other organisms. Many of the pathways present in animals and yeast, for example, also are present in plants, although the extent to which each pathway

FIGURE 8.32 Flux diagrams for wild-type *Arabidopsis* and *act1* mutant, showing how fatty acids synthesized in chloroplasts are directed to different lipids in the chloroplasts and extraplastidic membranes. The diagram shows the average fate of 1,000 molecules of fatty acid. In wild-type *Arabidopsis* approximately 39% of the fatty acids are used for lipid synthesis within the chloroplast. Of the remaining fatty acids, about 27% are used for synthesis of lipids for extrachloroplast membranes such as the ER, Golgi, and plasma membrane, and roughly 34% are transferred to the chloroplast for lipid synthesis. In a mutant of *Arabidopsis* deficient in plastid glycerol-3-phosphate acyltransferase activity, most of the fatty acids are exported to the cytoplasm and then approximately 61% are reimported into the chloroplast. This suggests a mechanism that adjusts the flow of lipid between the membranes when necessary. SL, sulfolipid; UL, unknown lipid; other abbreviations as in Figure 8.28.

contributes to the final phospholipid components of a cell may vary among organisms.

8.7.6 Phosphatidate is a substrate for both the CDP-DAG and DAG pathways

CDP-DAG is synthesized from phosphatidate and CTP by CDP:diacylglycerol cytidyltransferase (Fig. 8.33). In plants, this membrane-bound enzyme is associated with several different organelles, localized in the inner chloroplast envelope and the inner mitochondrial envelope. Two CDP:diacylglycerol cytidyltransferases occur in *Ricinus communis* endosperm: one localized in the mitochondria, the other in a microsomal

fraction. DAG is produced by the dephosphorylation of phosphatidate by phosphatidate phosphohydrolase, an enzyme located in the inner chloroplast envelope membrane, microsomes, and soluble fractions. Analogy to yeast phospholipid synthesis makes it likely a mitochondrial form of this enzyme also exists, although it has not yet been detected in plants.

8.7.7 CDP-DAG and DAG pathways generate distinct types of lipids

Phospholipids derived from CDP-DAG include PG, the only phospholipid found in chloroplast thylakoids, and diphosphatidylglycerol (cardiolipin), which occurs exclusively in

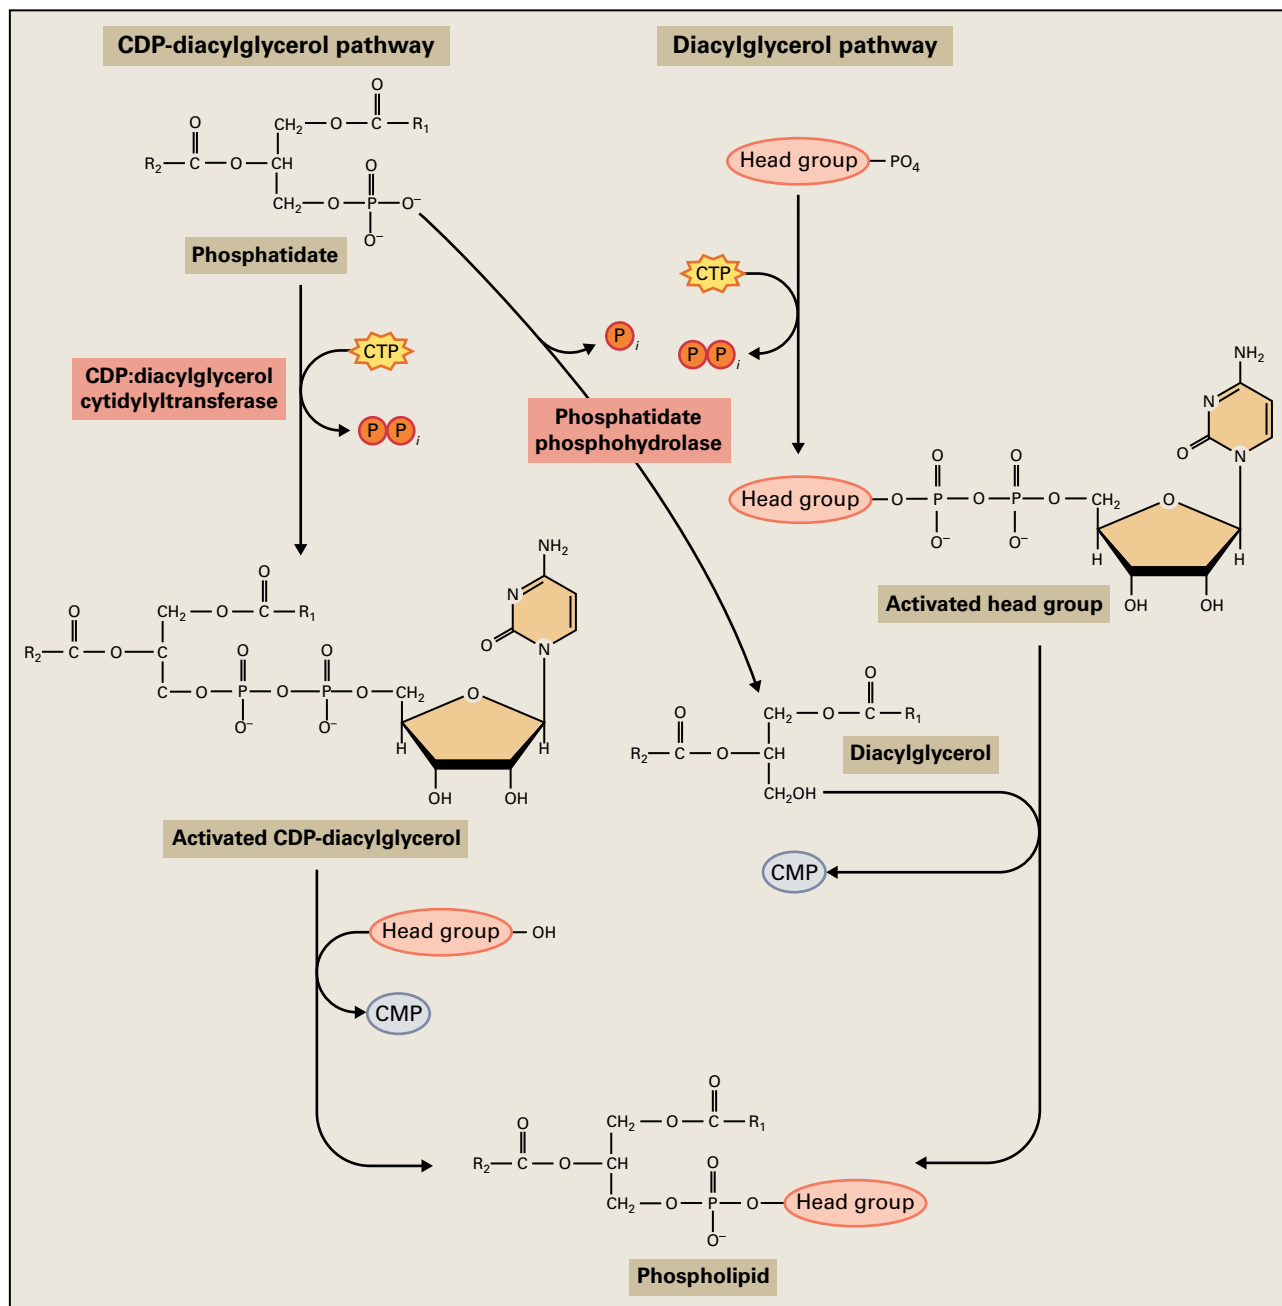

FIGURE 8.33 Two general strategies for forming the phosphodiester bond of phospholipids. In the CDP-diacylglycerol pathway, an activated DAG is used. In the diacylglycerol pathway, the head group is activated by CTP.

the inner mitochondrial membrane. As in *E. coli*, PG is synthesized in two steps in plants. Reaction of CDP-DAG with glycerol 3-phosphate produces phosphatidylglycerol phosphate, which is then dephosphorylated to yield PG (Fig. 8.34). This reaction also can take place in the ER. In mitochondria, diphosphatidylglycerol is synthesized by the reaction of PG with a second molecule of CDP-DAG.

Other phospholipids synthesized from CDP-DAG include phosphatidylinositol and phosphatidylserine (Fig. 8.34). Phosphatidylinositol is synthesized from free inositol in a reaction catalyzed by phosphatidylinositol synthase. Phosphatidylserine synthesis in most plant tissues uses Ser and

is catalyzed by phosphatidylserine synthase in a reaction similar to that found in *E. coli* and yeast. This contrasts with phosphatidylserine synthesis in animals, in which phosphatidylserine is a product of the DAG pathway, arising from phosphatidylethanolamine by exchanging ethanolamine with a Ser (see next section).

The DAG pathway is used primarily for the synthesis of phosphatidylethanolamine and phosphatidylcholine in both plants and animals. In each case, DAG displaces a CMP from CDP-ethanolamine or CDP-choline to produce phosphatidylethanolamine or phosphatidylcholine, respectively (Fig. 8.35). The synthesis of the two CDP-alcohols parallels the synthesis of

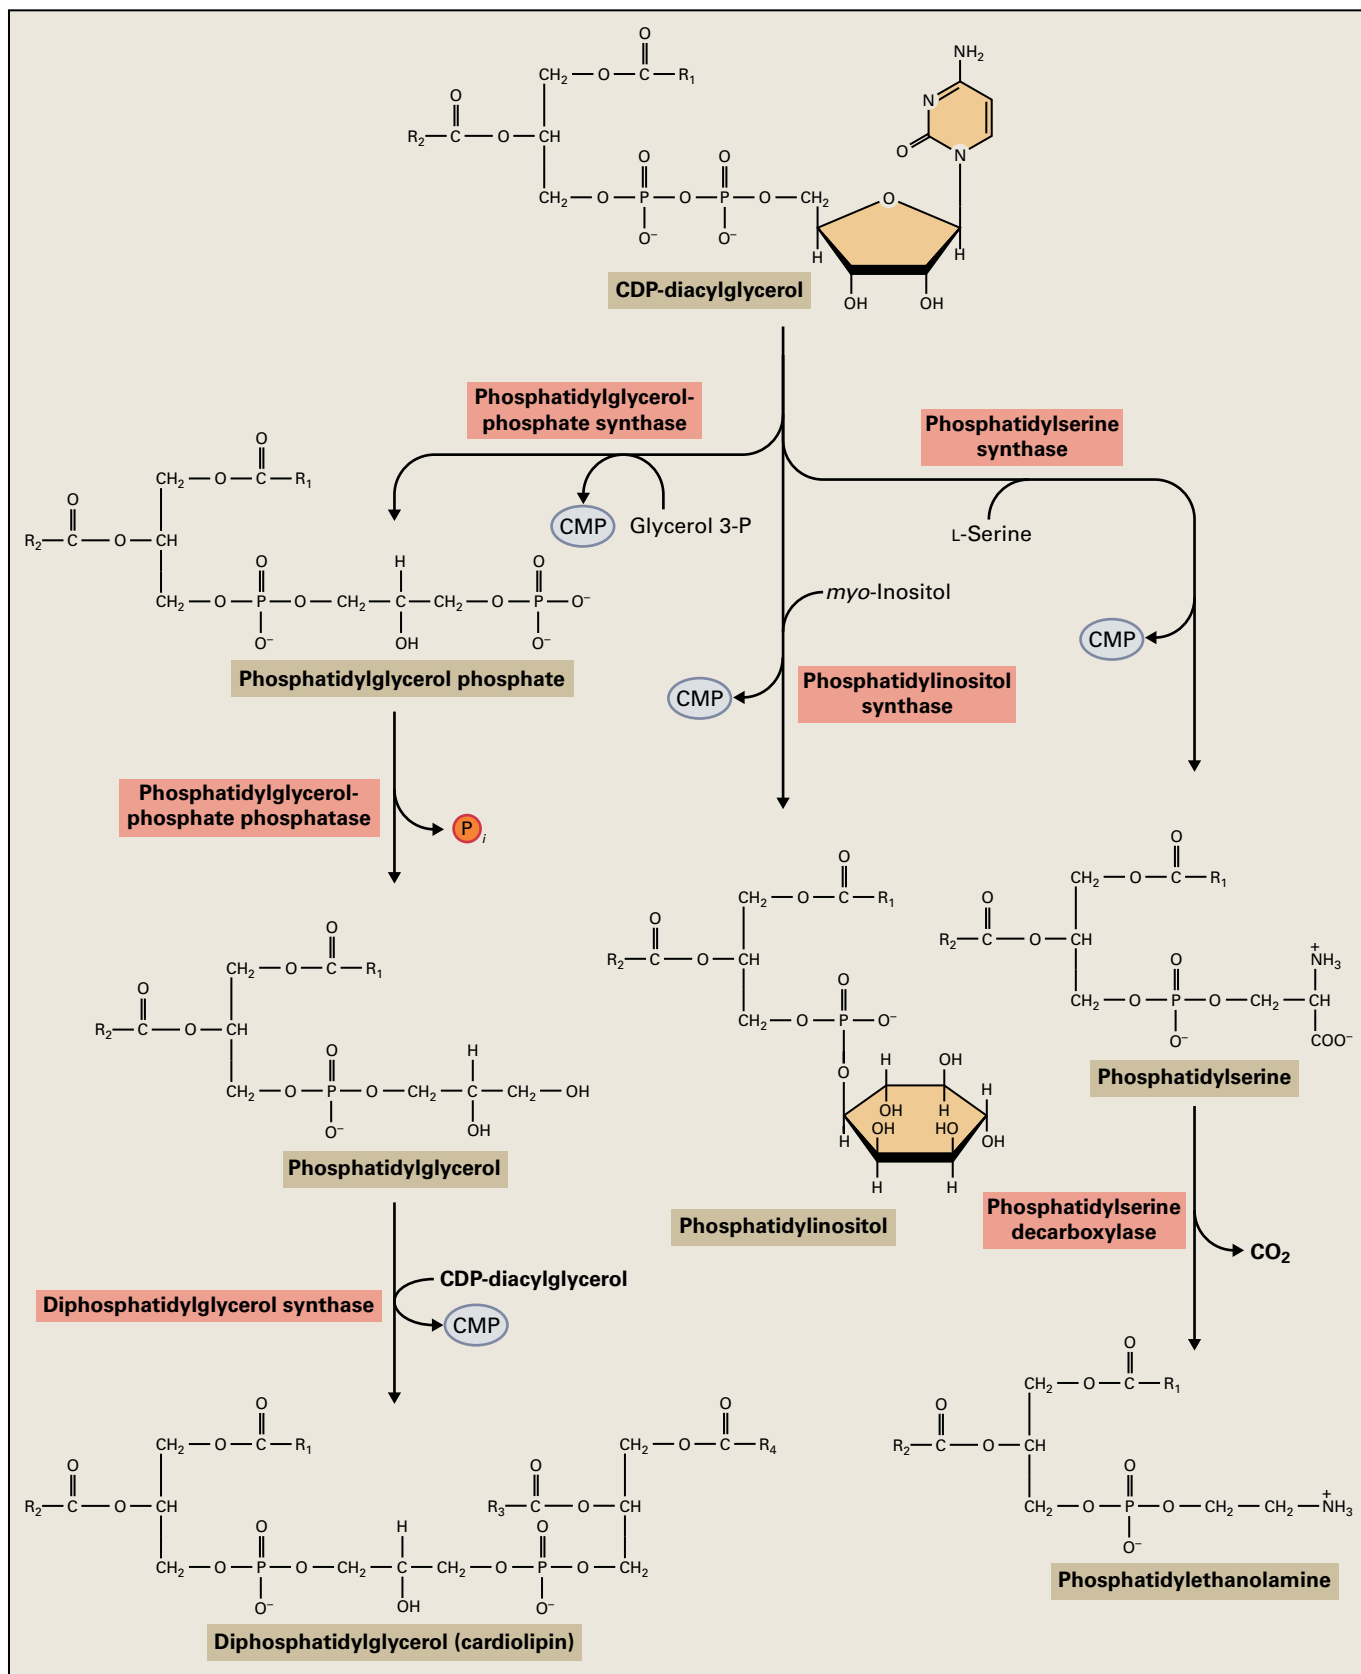

FIGURE 8.34 Synthesis of phospholipids by the CDP-diacylglycerol pathway. Phosphatidylserine, phosphatidylinositol, and phosphatidylglycerol phosphate are synthesized when the head group displaces CMP from CDP-diacylglycerol. Phosphatidylglycerol phosphate is dephosphorylated to phosphatidylglycerol. Diphosphatidylglycerol (cardiolipin) is formed by reaction of phosphatidylglycerol with a second molecule of CDP-DAG.

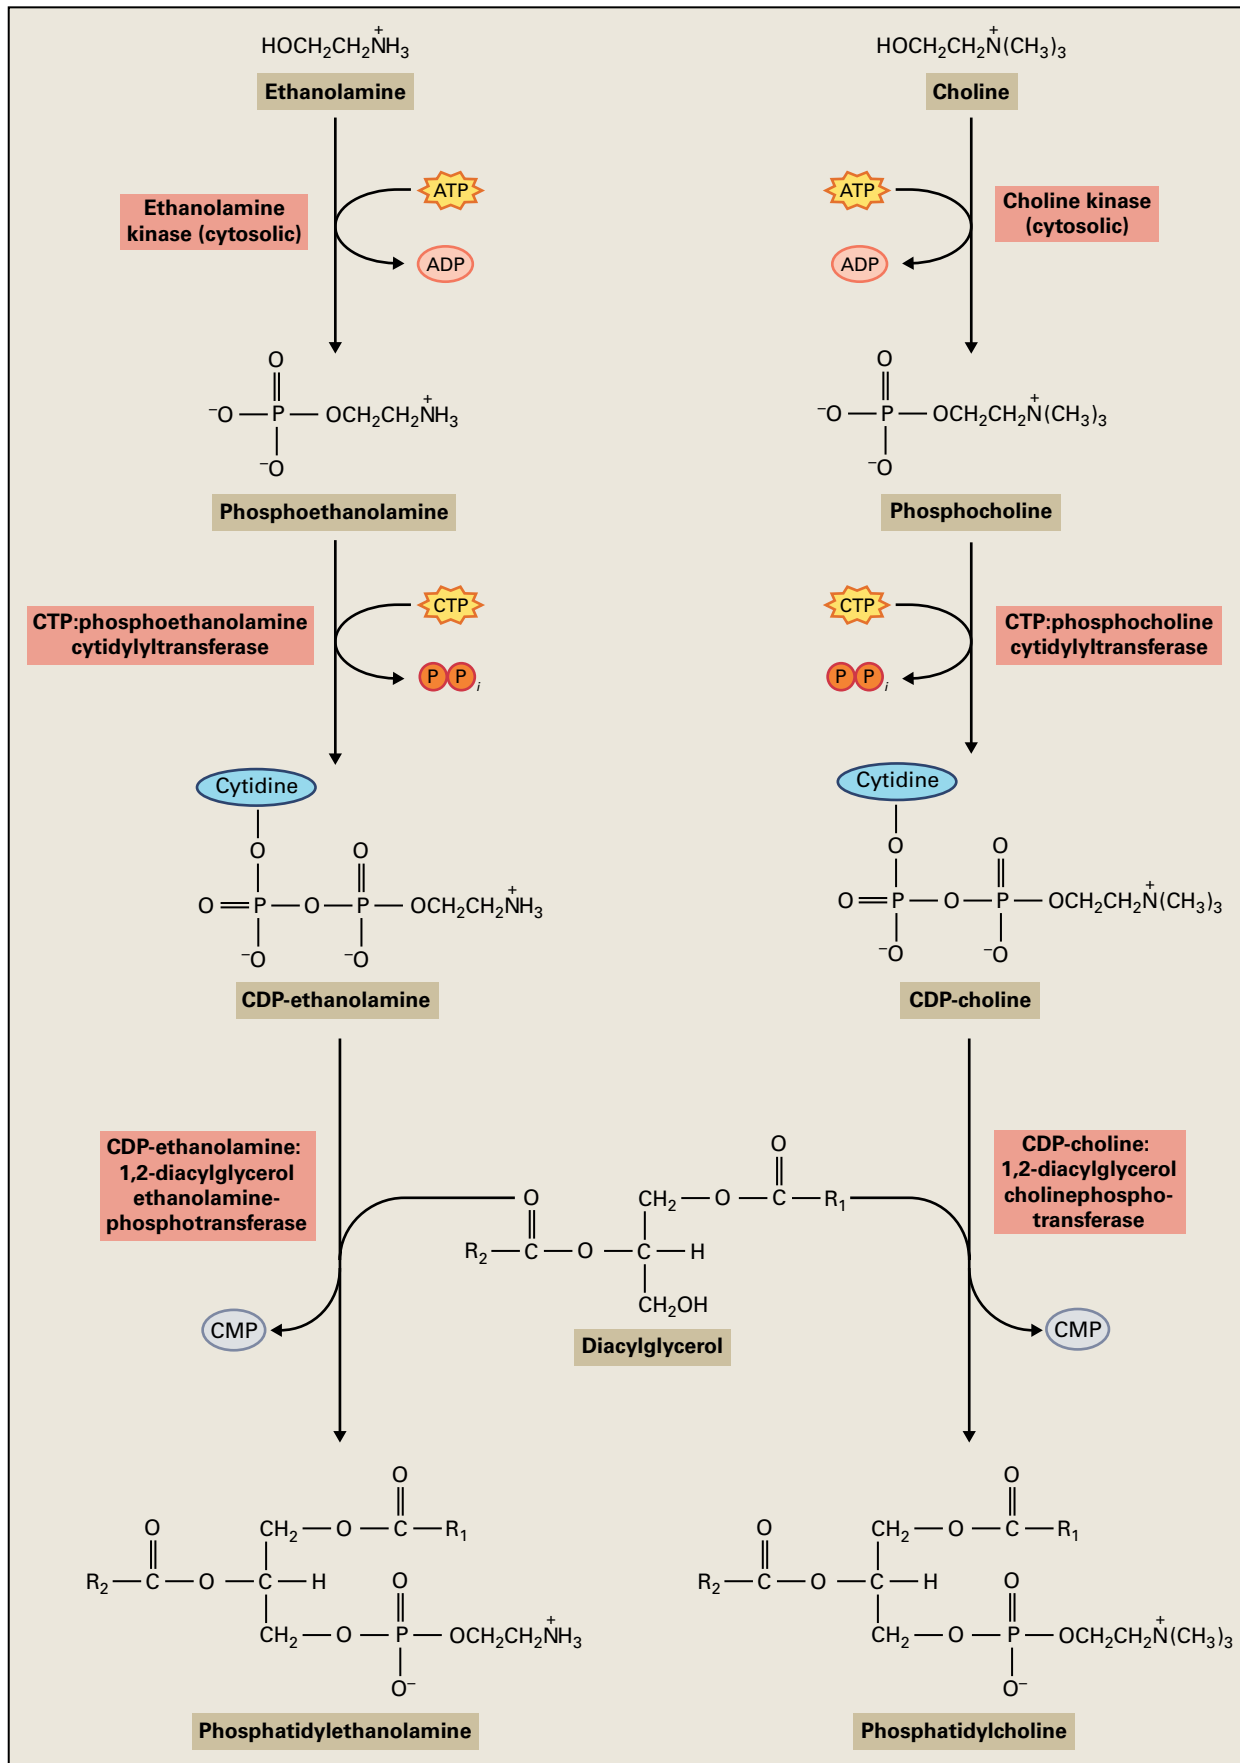

FIGURE 8.35 The diacylglycerol pathway is the principal route for synthesis of phosphatidylcholine and phosphatidylethanolamine in plants.

CDP-DAG. For example, choline is first phosphorylated to form phosphocholine before reacting with CTP to produce CDP-choline.

8.7.8 Pools of CDP-DAG-derived phospholipids and DAG-derived phospholipids interact in plants and in animals

Tracing the origin of specific lipids is often more difficult than the preceding section might suggest. For example, phosphatidylethanolamine, a phosphatidylserine precursor in animals, is a product of the DAG pathway in both animals and plants. In germinating *Ricinus communis* endosperm, phosphatidylserine appears to be made exclusively from DAG by the phosphatidylethanolamine exchange reaction (Fig. 8.36). Likewise, phosphatidylethanolamine can be generated from phosphatidylserine by decarboxylation. The net effect of this cycle is to produce ethanolamine from Ser. Indeed, this may be the primary metabolic source of ethanolamine. Direct conversion of phosphatidylethanolamine to phosphatidylcholine occurs in animals and yeast by sequential methylation of phosphatidylethanolamine by *S*-adenosylmethionine. In plants, however, this appears to be only a minor pathway, with phosphatidyl-

choline synthesized almost entirely from CDP-choline and DAG. Phosphocholine is synthesized by the methylation of phosphoethanolamine, with *S*-adenosylmethionine acting as the methyl donor. Thus in plants, choline originates mainly from ethanolamine, but phosphatidylcholine does not typically originate from phosphatidylethanolamine.

8.7.9 Galactolipids and sulfolipids are synthesized from DAG

DAG produced from phosphatidic acid by a specific phosphatase in the plastid is the substrate for galactolipid and sulfolipid synthesis. Cleavage of uridine diphosphate (UDP) esters provides energy for several of the reactions. UDP-galactose and UDP-sulfoquinovose are substrates for MGD and sulfolipid synthesis, respectively. The synthesis of DGD involves transfer of a second galactose from UDP-galactose to monoacylglyceroldiacylglycerol (Fig. 8.37). UDP-sulfoquinovose synthesis has been studied in *Arabidopsis* and the purple photosynthetic bacterium *Rhodobacter sphaeroides*. In *Arabidopsis*, the *SQD1* gene encodes the enzyme that catalyzes the synthesis of UDP-sulfoquinovose from UDP-glucose and sulfite (Fig. 8.38).

All organisms that carry out oxygenic photosynthesis contain sulfolipid as a major component of their photosynthetic

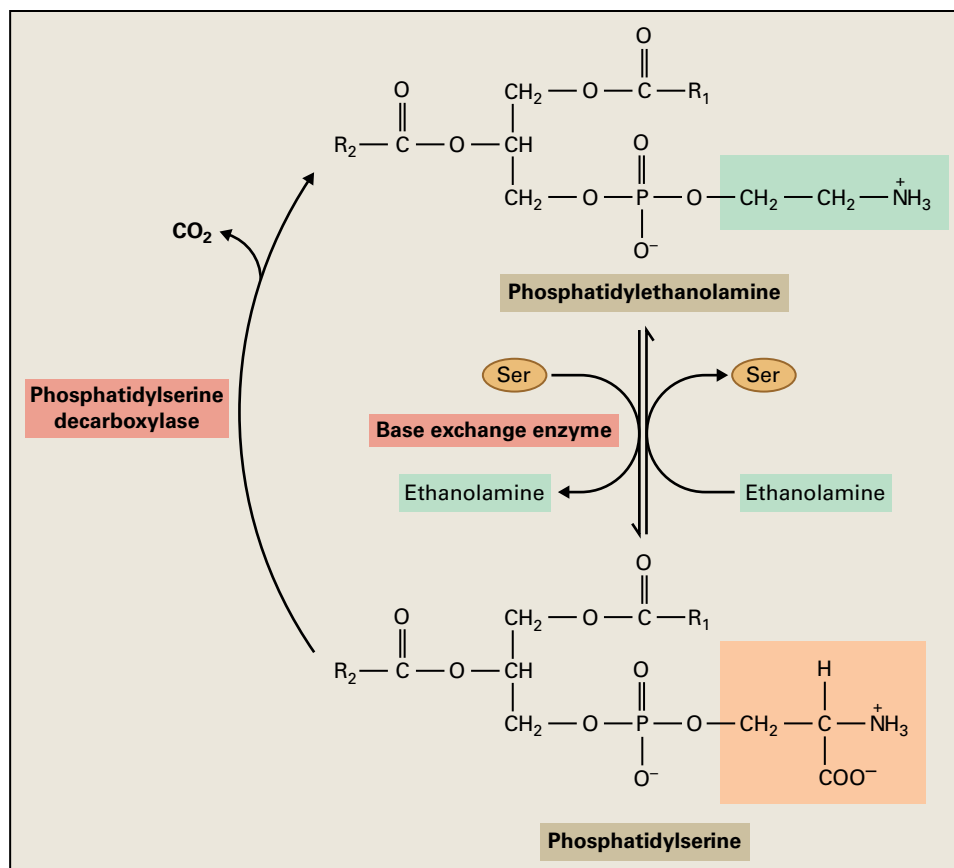

FIGURE 8.36 Synthesis of phosphatidylserine from phosphatidylethanolamine has been observed in some plant tissues.

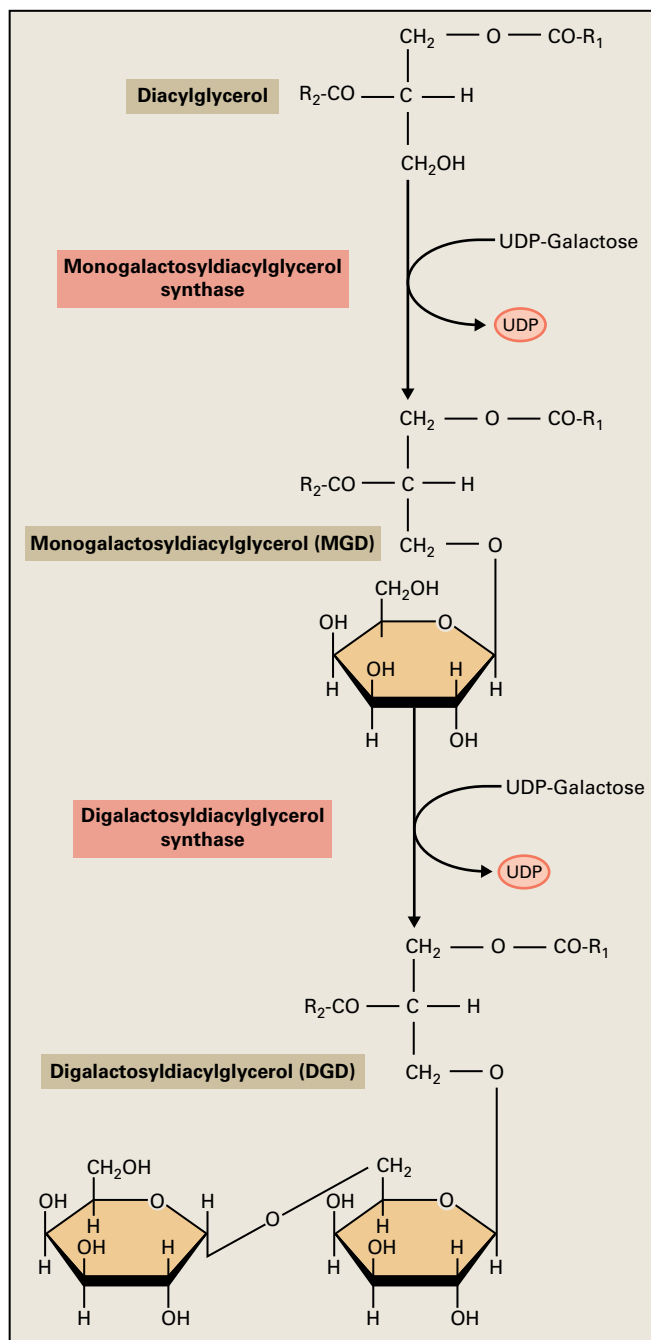

FIGURE 8.37 Pathway of synthesis of galactolipids. The synthesis of MGD is catalyzed by a typical glycosyltransferase that transfers galactose from the nucleotide sugar-activated UDP-galactose to DAG. Similarly, the synthesis of DGD involves a second transfer from UDP-galactose to MGD.

lamellae—a fact stimulating sustained interest in the possibility this lipid plays an essential role in supporting the light reactions of photosynthesis. Mutants of *R. sphaeroides* or cyanobacteria that are unable to synthesize sulfolipid, however, have normal rates of photosynthesis. Apparently, the main reason photosynthetic organisms have sulfolipid is to minimize the phosphate required for synthesizing the large amounts of membrane necessary to support high rates of light capture (Box 8.2).

8.7.10 Ceramide is the building block of plant sphingolipids

Just as DAG is the basic component of all glycerolipids, ceramide is the basic component of all sphingolipids. Complex sphingolipids, such as the glucosylsphingolipids and glucosylinositolphosphorylceramides (GIPC) that predominate in plants, are formed by modification of ceramide. The structures of the most commonly occurring long-chain bases, glucosylceramide and glucosylinositolphosphorylceramide are shown in Figure 8.7.

The initial phase of ceramide synthesis involves condensation of a palmitoyl-CoA with Ser, resulting in a 3-ketosphinganine (Fig. 8.39). This reaction is analogous to the condensation reactions catalyzed by FAS and elongases. Subsequently, the 3-keto group is reduced to the alcohol to produce sphinganine. Much of the sphinganine is then hydroxylated at the C-4, although in some plants there is a competing C-4 desaturase. The ceramide is then synthesized using sphinganine *N*-acyl transferase to transfer an acyl-CoA to the modified sphinganine. The acyl groups can range from C16 to C26, although C24 followed by C16 are the predominate fatty acids found in the ceramides. Also, the C16 fatty acids are predominately found in the glucosylceramides, whereas the very long chain fatty acids are found in glucosylinositolphosphorylceramides. Often, the fatty acid is hydroxylated at C-2 subsequent to formation of the ceramide.

In the second phase of synthesis, ceramide is converted to the complex sphingolipids. Glucosylceramide synthase is used to attach glucose to the ceramide from either UDP-glucose or steryl glucoside. Ceramides can also be converted to inositolphosphorylceramide using inositolphosphorylceramide synthase and the inositol phosphate donated from phosphatidyl inositol. Nothing is known about the subsequent reactions in plants that lead to glucosylinositolphosphorylceramide and its derivatives.

There is much interest in the function of sphingolipids in plants. They are enriched in detergent-resistant membranes, where they are presumed to play a structural role. In addition, mounting evidence suggests they function in signaling pathways involved with regulation of stomatal opening and programmed cell death. With mutants of sphingolipid metabolism becoming available, characterization of these roles should be forthcoming.

8.8 Function of membrane lipids

8.8.1 Membrane lipid composition affects plant form and function

Each membrane in a plant cell has a characteristic and distinct complement of lipid types (Fig. 8.40), and within a single membrane, each class of lipids has a distinct fatty acid

FIGURE 8.38 Sulfolipid biosynthesis. *SQD1* protein adds sulfite to UDP-glucose, and the resulting UDP-sulfoquinovose (UDP-SQ) is then used to transfer sulfoquinovose to DAG to form sulfoquinovosyldiacylglycerol (SQD).

BOX 8.2

Plants conserve phosphate by using sulfolipids and galactolipids for chloroplast membrane synthesis

Each gram of leaf material contains approximately 1 m² of chloroplast membrane. If this membrane were composed primarily of phospholipids, as the membranes from animals and fungi are, plants would require much more phosphate for growth than they currently do. Given that phosphate is a limiting nutrient in many natural ecosystems, it is advantageous to plants to minimize the need for phosphate in membrane synthesis. In what appears to be an evolutionary adaptation to the problem of phosphate limitation, plants and other photosynthetic organisms use monogalactosyldiacylglycerol (MGD), digalactosyldiacylglycerol (DGD), and sulfoquinovosyldiacylglycerol (SQD, or sulfolipid) as substitutes for phospholipids such as phosphatidylglycerol (PG). For example, in the chloroplast membranes of spinach (a 16:3 plant), less than 15% of the bilayer lipids are phospholipids (see graph).

Evidence in support of this concept was obtained by the isolation of sulfolipid-lacking mutants of the photosynthetic purple bacterium *Rhodospirillum rubrum* and the cyanobacterium *Synechococcus* PCC7942. When the mutants were grown in the presence of high concentrations of phosphate, their growth rate and photosynthetic characteristics were indistinguishable

from those of the wild type. Under conditions of limiting phosphate, however, the growth of the mutants was inhibited. In addition, as the amount of phosphate available for membrane synthesis became limiting, several novel glycolipids accumulated to high concentrations.

16:1t, 16:1^{trans} Δ 3

composition. Until recently, we knew almost nothing about the reasons for this remarkable diversity. Our knowledge remains limited, but the examples discussed in this section demonstrate some of the important developmental processes

and responses to environmental factors that are affected by membrane lipid composition.

One of the most visually dramatic phenotypes produced by a change in lipid composition is that of the *fab2* mutant of

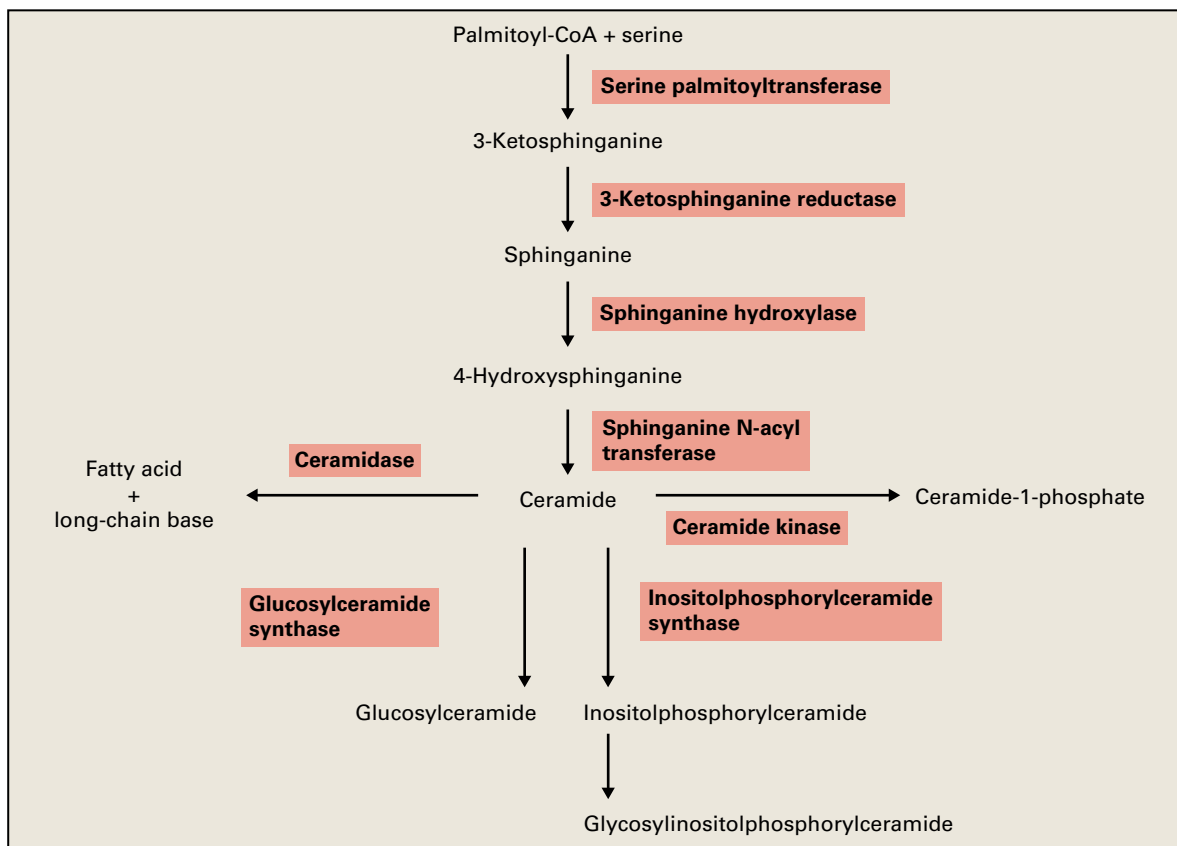

FIGURE 8.39 Spingolipid biosynthetic pathway in plants. All enzymatic reactions have been demonstrated *in vitro*. Reactions involved in long-chain base desaturation and acyl chain hydroxylation apparently occur following ceramide formation.

FIGURE 8.40 Comparison of the lipid compositions of chloroplasts and mitochondria.

Arabidopsis. The *fab2* plants are miniatures, a result of the accumulation of 18:0 in membrane lipids (Fig. 8.41A). The decrease in leaf size results from decreased size of several specific cell types. The failure of mesophyll and epidermal cells to enlarge produces a dramatic “brick-wall” appearance to the cross-section of a mutant leaf, contrasting with the characteristic, less compact leaf anatomy evident in the wild type (Fig. 8.41B,C). We do not know the mechanism by which increased 18:0 produces the miniature phenotype, but biophysical principles lead to the expectation that increased temperature would ameliorate the effects of increased saturation on the bilayer. Accordingly, the morphology of *fab2* more closely resembles that of the wild type when plants are grown at 35°C (Fig. 8.41D,E). Furthermore, at this temperature, *fab2* leaves develop typical palisade and spongy mesophyll layers.

8.8.2 Photosynthesis is impaired in plants that lack polyunsaturated membrane lipids

Highly unsaturated 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13} fatty acids account for approximately 70% of all the thylakoid membrane fatty acids in plants and more than 90% of the fatty acids in MGD, the most abundant chloroplast lipid (see Fig. 8.40). These high amounts are noteworthy because free radical

FIGURE 8.41 Morphology of the *fab2* mutant of *Arabidopsis*. (A) The growth of the mutant (at right) at 22°C is strongly reduced. The mutant plant is small because its cells (B) compared to wild type (C) do not enlarge to the same extent. Growth at higher temperature partially suppresses the deleterious effects of the *fab2* mutation (D) on growth and development. The mutant grown at 36°C more closely resembles the wild-type control (E). Source: (A–E) Lightner et al. (1994). *Plant J.* 6:401–412.

byproducts of the photosynthetic light reactions stimulate oxidation of polyunsaturated fatty acids. If plants maintain high levels of unsaturation in thylakoids despite the risk of oxidation, one might reason photosynthesis is critically dependent on membrane unsaturation. Surprisingly, an *Arabidopsis* triple mutant (*fad3 fad7 fad8*) completely lacking 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13} exhibits normal rates of growth and photosynthesis at 22°C (Fig. 8.42), demonstrating that 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13} are not essential for photosynthesis in plants. These two fatty acids are not irrelevant, but their role is more subtle than expected. In fact, the loss of 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13} has noticeable effects on photosynthesis only at low (below 10°C) and high (above 30°C) temperatures.

Although eliminating triunsaturated 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13} has only minor consequences for photosynthesis, the process is greatly affected in an *Arabidopsis fad2 fad6* mutant lacking the diunsaturated fatty acids 18:2^{Δ9,12} and 16:2^{Δ7,10} and their downstream triunsaturated derivatives 18:3^{Δ9,12,15} and 16:3^{Δ7,10,13}. These mutants lose nearly all

photosynthetic capacity and cannot grow autotrophically. Nevertheless, *fad2 fad6* plants grow on sucrose media, where growth and organ development are remarkably normal (Fig. 8.42). These observations indicate the vast majority of receptor-mediated and transport-related membrane functions required to sustain the organism and induce proper development are well supported in this double mutant, which contains almost no polyunsaturated lipids. Apparently, therefore, photosynthesis is the only vegetative cell function that requires high levels of membrane polyunsaturation.

The work with *Arabidopsis* mutants indicates plants require polyunsaturated lipids to maintain the photosynthetic machinery, but this is not true of cyanobacteria. Mutants of *Synechocystis* PCC6803 that lack polyunsaturated fatty acids can photosynthesize normally, except at low temperature.

8.8.3 Does lipid composition affect chilling sensitivity?

One of the most extensively studied issues in membrane biology is the relationship between lipid composition and the ability of organisms to adjust to temperature changes. Chilling-sensitive plants undergo sharp reductions in growth rate and development at temperatures between 0°C and 12°C (Fig. 8.43). **Chilling injury** includes physical and physiological changes induced by low temperatures as well as subsequent symptoms of stress. Many economically important crops are sensitive to cold, including cotton, soybean (*Glycine max*), maize (*Zea mays*), rice (*Oryza sativa*), and many tropical and subtropical fruits. In contrast, most plants of temperate origin that continue to grow and develop at low temperatures are classified as chilling-resistant plants, including *Arabidopsis*.

In attempts to link the biochemical and physiological changes that characterize chilling injury with a single “trigger” or site of damage, investigators have suggested the primary event of chilling injury is a phase transition from the liquid crystalline state to the gel state in cellular membranes (Fig. 8.44). According to this proposal, the phase transition from liquid crystalline to gel alters the metabolism of chilled cells and leads to injury and death of the chilling-sensitive plants. Because desaturation of membrane lipids favors membrane fluidity (see Section 8.5), researchers have sought to define the relationship between membrane composition and chilling sensitivity. A related hypothesis specific to chloroplast membranes has been proposed, in which molecular species of chloroplast PG containing a combination of saturated fatty acid (16:0 and 18:0) at the *sn*-1 position of the glycerol backbone and either a saturated fatty acid or 16:1^{Δ3}-*trans* fatty acid at the *sn*-2 position are suggested to confer chilling sensitivity on plants. Because the *trans*-double bond leaves the 16:1^{Δ3}-*trans* fatty acid with a structure similar to 16:0 (see illustration in Box 8.1), these molecules are termed disaturated PG. The presence of significant quantities of disaturated PG in the chloroplast membranes would presumably promote the change from liquid crystalline to gel phase at chilling temperature, and the phase separation within the membranes would cause chilling sensitivity.

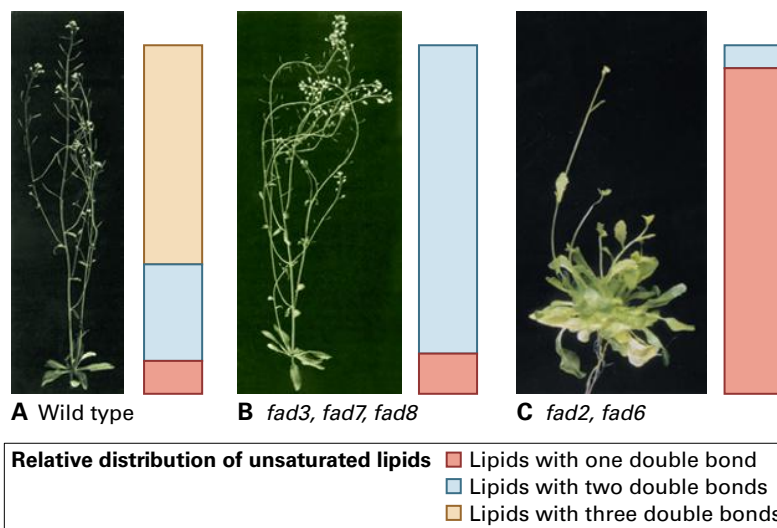

FIGURE 8.42 *Arabidopsis* mutants reveal the roles of polyunsaturated fatty acids. Compared with a wild-type plant shown in (A), a mutant lacking 18:3^{A9,12,15} and 16:3^{A7,10,13} fatty acids (B) grows normally at 22°C. However, this mutant is male-sterile because jasmonate derived from 18:3^{A9,12,15} is required for pollen maturation and release. A mutant deficient in all polyunsaturated fatty acids cannot grow autotrophically. When grown in sucrose-enriched medium (C), this mutant is robust, indicating that photosynthesis is the only process that absolutely requires a polyunsaturated membrane. Source: (A, B) McCann & Browse (1996). *Plant Cell* 8:403–416. (C) McCann & Browse (1998). *Plant J.* 15:521–530.

FIGURE 8.43 Exposure of chilling-sensitive plants such as cucumber (*Cucumis sativus*) to 2°C for 1 day causes severe injury. The plant on the right was kept at 25°C.

Source: Somerville, Carnegie Institute of Washington, Stanford, CA; unpublished results.

As shown in studies with five different *Arabidopsis* mutants, diminished unsaturation resulted in plants that grew well at 22°C but were less robust than wild type when grown at 2–5°C. These results were observed even though the lipid changes in most of the mutants were insufficient to cause a lipid-phase transition. In addition, the low-temperature symptoms that developed in these lines appeared to be quite distinct from classic chilling sensitivity (Fig. 8.45A,B). Increased concentrations of disaturated PG (to as much as 60% of total PG) were obtained in transgenic *Arabidopsis*, and in these plants the damaging effects of low temperature became evident more quickly.

A complementary series of experiments was carried out in tobacco (*Nicotiana tabacum*), a chilling-sensitive plant. Transgenic expression of exogenous genes was used to specifically decrease the concentrations of disaturated PG or to bring about a general increase in membrane unsaturation, and the damage caused by chilling was alleviated to some

extent. These findings indicate the extent of membrane unsaturation or the presence of particular lipids such as disaturated PG can affect the low-temperature responses of plants. However, some research indicates the relationship between membrane unsaturation and plant temperature responses is subtle and complex. In the *Arabidopsis fab1* mutant, disaturated molecular species of PG accounted for 43% of the total leaf PG—a higher percentage than is found in many chilling-sensitive plants. Nevertheless, the mutant was completely unaffected (when compared with wild-type controls) by a range of low-temperature treatments that quickly led to the death of cucumber (*Cucumis sativus*) and other chilling-sensitive plants. Growth of *fab1* plants slowed, relative to the wild type, only after more than two weeks' exposure to 2°C (Fig. 8.45C,D). These results indicate membrane unsaturation does contribute to chilling damage but that other processes are also important.

FIGURE 8.44 Thermal transition from the gel phase (L_{β}) to liquid crystalline phase (L_{α}) in a pure phosphatidylcholine bilayer (lower panel). At low temperatures, motion of the fatty acid chains is limited by Van der Waals forces. As the temperature is raised through the phase transition, heat is absorbed (upper panel) and Van der Waals forces are disrupted to form a bilayer with melted fatty acid chains (L_{α}).

FIGURE 8.45 Three different chilling responses in lipid mutants of *Arabidopsis*. (A) Compared with wild-type plants (left), the *Arabidopsis fad6* mutant (right) becomes chlorotic after three weeks at 5°C. (B) *fad2* *Arabidopsis* plants die after seven weeks at 6°C. (C) Compared with wild-type plants (left), the *fab1* mutant (right) is unaffected by up to one week of exposure to chilling at 2°C. (D) After four weeks at 2°C, however, *fab1* plants (right) show clear symptoms of chlorosis and reduced growth.

FIGURE 8.46 Cold acclimation allows plants to survive freezing. The *Arabidopsis* plants on the right were incubated at 4°C for 4 days to acclimate the plants, after which both pots were kept at –5°C for 4 days, and then transferred to growth conditions at 23°C for 10 days.

Source: M. Thomashow, Michigan State University, East Lansing; previously unpublished.

8.8.4 Membrane lipid composition can influence plant cell responses to freezing

Freezing stress in plants differs from chilling stress, and tolerance of freezing requires a specialized set of biological mechanisms. During initial freezing of plant tissue (down to –5°C), ice forms outside the plasma membrane. Because solutes are excluded from the ice, the solute concentration in the remaining extracellular aqueous phase increases, forcing water out through the plasma membrane by osmosis, and plasmolyzing the cell. When the temperature increases again and the ice melts, cellular damage may result.

If plants are allowed to acclimate to cold by growth at low, but not freezing, temperatures for a few days before exposure to freezing, many can withstand freezing to temperatures that would otherwise cause extensive damage or death (Fig. 8.46). Protoplasts from rye (*Secale cereale*) leaves have been used as a model system to investigate the molecular basis for this acclimation response (Fig. 8.47).

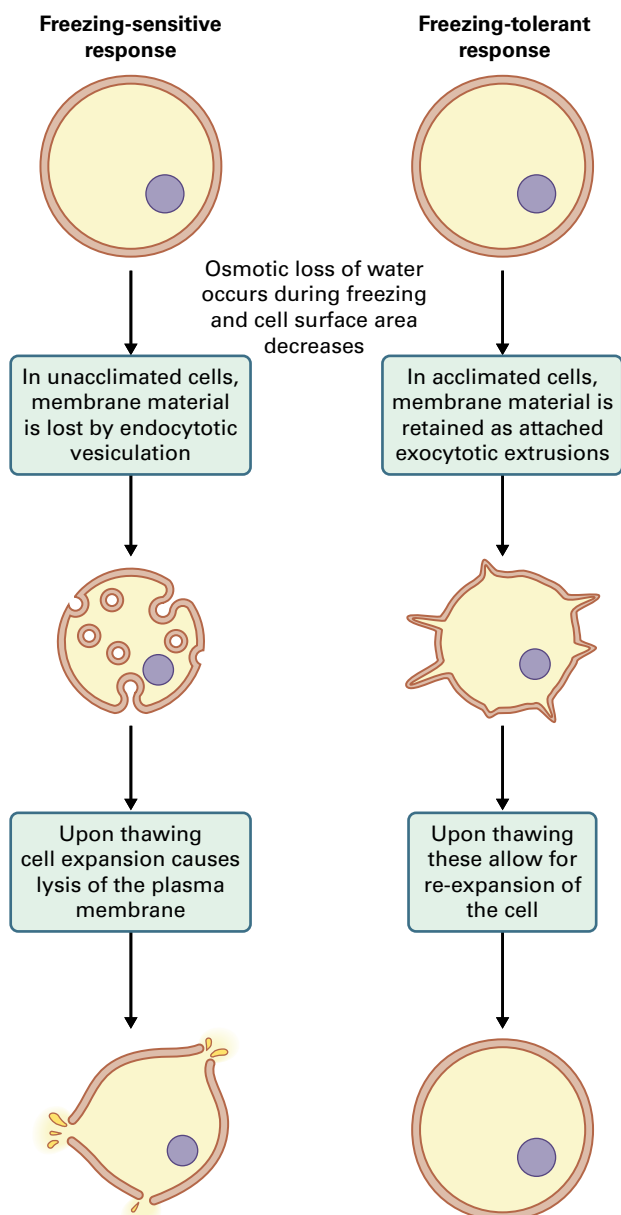

FIGURE 8.47 During freezing stress, changes in plasma membrane morphology determine death or survival of the cell.

When nonacclimated protoplasts are placed in a hyperosmotic medium, the plasma membrane buds off endocytotic vesicles, as shown in Figure 8.47. However, if the protoplasts are first preincubated with monounsaturated or diunsaturated species of phosphatidylcholine, so that the phospholipid is incorporated into the plasma membrane, hyperosmotic treatment results in the formation of exocytotic extrusions. Disaturated species of phosphatidylcholine do not induce this change. These differences in plasma membrane behavior correlate with protoplast survival during freezing: Preincubation of nonacclimated protoplasts with monounsaturated or diunsaturated phosphatidylcholine is as effective as cold acclimation in promoting protoplast survival, whereas preincubation with disaturated phosphatidylcholine has no beneficial effect. These observations suggest cold acclimation increases unsaturated phospholipids in the plasma membrane. Physicochemical considerations

indicate such changes could mediate the shift from formation of endocytotic vesicles to formation of exocytotic extrusions.

8.8.5 Membrane lipids function in signaling and in defensive processes

Plants, animals, and microbes all use membrane lipids as precursors for the synthesis of compounds that have intracellular or long-range signaling activities. Intriguingly, many of the lipid derivatives characterized as signaling molecules in animals may also have roles in plant signaling. These include phosphatidic acid, DAG, ceramide, lyso-phosphatidylcholine, and *N*-acylethanolamine.

Phosphatidylinositols, frequently referred to as phosphoinositides, have important functions in signal transduction pathways. Their role in regulation of metabolic pathways has been most extensively studied in animal systems, but recent studies suggest they may serve a similar function in plants (see Chapter 18). In the principal active molecule, the phosphatidylinositol 4, 5-bisphosphate (PIP_2), the inositol moiety is phosphorylated at C-4 and C-5. In animals, phosphoinositides serve as second messengers to extracellular signals. The signal activates a phosphatidylinositol-specific phospholipase C, which cleaves PIP_2 to produce inositol 1,4,5-triphosphate (IP_3) and DAG, each of which acts as a second messenger (Fig. 8.48).

Jasmonate is another lipid-derived plant growth regulator (see Chapter 17). The structure and biosynthesis of jasmonate have intrigued plant biologists because of the parallels to some eicosanoids, which are central to inflammatory responses and other physiological processes in mammals. In plants, jasmonate derives from $18:3\Delta^{9,12,15}$ that is released from membrane lipids by specific lipases. The linolenic acid is oxidized by lipoxygenase, and the resulting product, 9-hydroperoxylinolenic acid or 13-hydroperoxylinolenic acid, may be further metabolized by one of three routes to produce a wide variety of derivatives, collectively referred to as oxylipins (Fig. 8.49).

The pathways by which 13-hydroperoxylinolenic acid may be metabolized are shown in Figure 8.50. The enzyme hydroperoxide lyase catalyzes α -scission of the *trans*-11,12-double bond to produce a C_6 aldehyde, *cis*-3-hexenal, and a C_{12} compound, 12-oxo-*cis*-9-dodecenoic acid. The acid is subsequently metabolized to 12-oxo-*trans*-8-dodecenoic acid, also known as the wound hormone traumatin. The enzyme allene-oxide synthase catalyzes the dehydration of 13-hydroperoxylinolenic acid to an unstable allene oxide, which readily decompose to form 9,12-ketols or 12,13-ketols. However, allene-oxide cyclase catalyzes the synthesis of the 9*S*,13*S* isomer of 12-oxo-phytodienoic acid, which can be further metabolized to (3*R*,7*S*) jasmonic acid.

The actions of jasmonate are dramatic and wide-ranging. Jasmonate is a key component of a wound-signaling pathway that allows plants to protect themselves against insect attack. When applied to plants at low concentrations, jasmonate induces expression of genes that lead to the production of proteinase inhibitors and other defense compounds. Furthermore, mutants of tomato (*Solanum lycopersicum*) and *Arabidopsis* that are deficient in jasmonate synthesis are much more susceptible to insect damage (Fig. 8.51).

FIGURE 8.48 *Phospholipase C* hydrolyzes phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-triphosphate and DAG.

FIGURE 8.49 The lipoxygenase pathway. In the dioxygenase reaction catalyzed by lipoxygenase, there is no net oxidation or reduction. A cis-trans conjugated diene, 13-hydroperoxylinolenic acid, forms in the reaction. The hydroperoxy acid can be metabolized by three separate pathways to a wide variety of products, including jasmonate. The pathway starts with the action of lipoxygenase on 18:3^{A9,12,15} to produce 9-hydroperoxylinolenic acid or 13-hydroperoxylinolenic acid, depending on the source of the enzyme.

Jasmonic acid itself is not an active hormone—it must be converted to an amino acid conjugate such as jasmonoyl-isoleucine, a ligand for the jasmonate receptor (see Chapter 17). A different role for jasmonate was revealed by the *fad3 fad7 fad8* triple mutant of *Arabidopsis*, which cannot synthesize jasmonate

because it lacks the precursor 18:3^{A9,12,15}. The plants are male-sterile because pollen does not mature properly and is not released from the anthers. Application of jasmonate or linolenic acid to the anthers restores fertility, demonstrating jasmonate is a key signal in pollen development. The same mutant has been

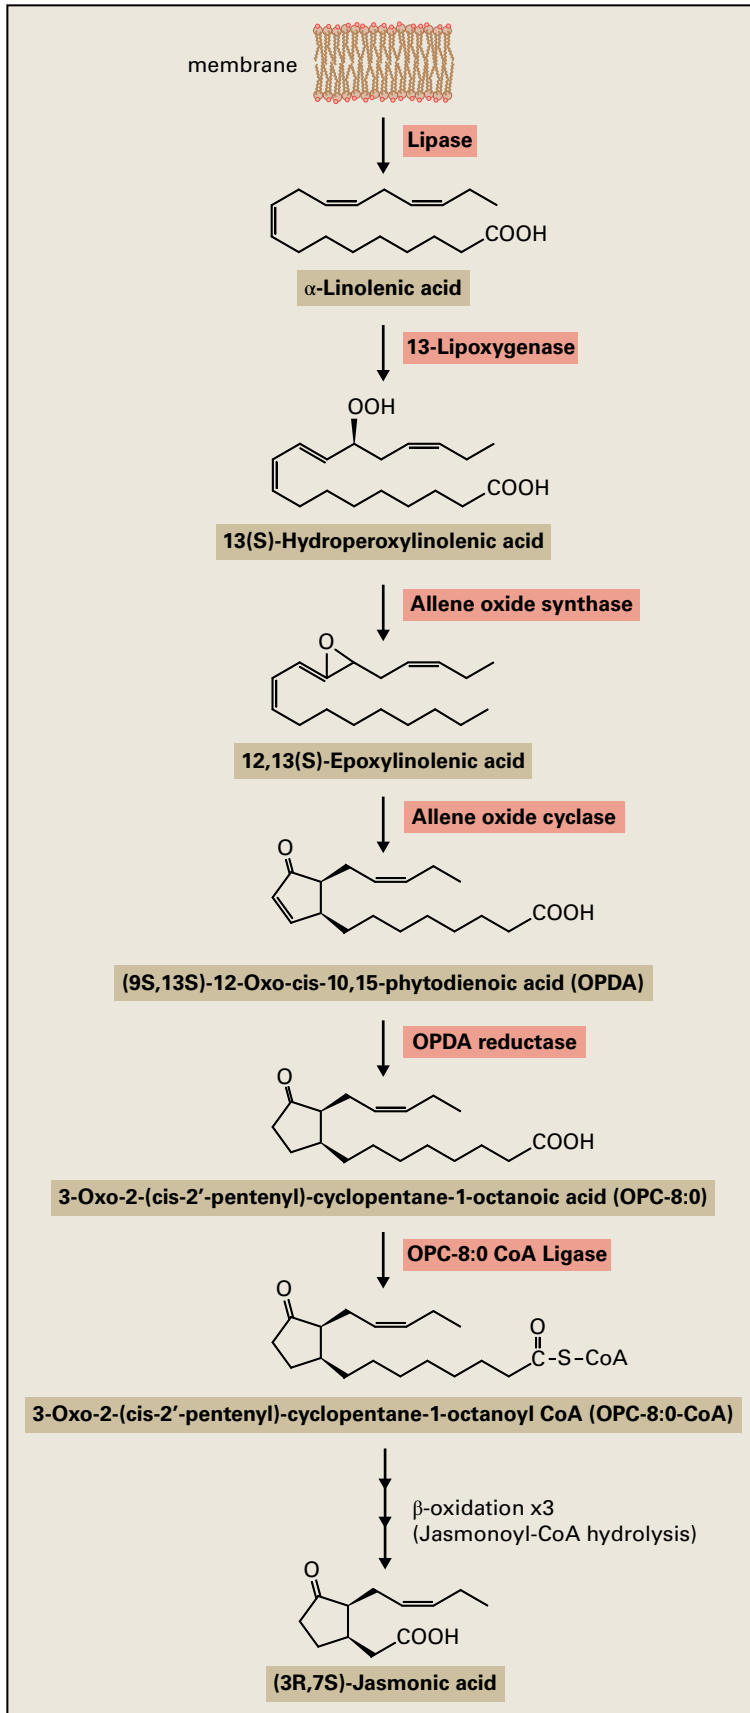

FIGURE 8.50 Metabolism of 13-hydroperoxylinolenic acid. Additional reactions not shown include conversion of 11,12-epoxylinolenic acid to 13-hydroxylinolenic acid by peroxygenase and rearrangement of the 13-hydroxylinolenic acid to form 15,16-epoxy-13-hydroxyoctadecenoic acid. Also cis-3-hexenal and its corresponding alcohol are thought to give rise to several isomers.

FIGURE 8.51 *Jasmonic acid signaling protects plants from insect predation. Wild-type Arabidopsis and a *fad3 fad7 fad8* mutant were enclosed with adult flies of the fungal gnat *Bradysia impatiens*. The larvae of the flies feed on roots and stems, leading to plant death. The mutant plants, which were unable to synthesize jasmonic acid because of the *fad* mutations, were sprayed with either water or low concentrations of jasmonic acid.*

FIGURE 8.52 (A) Schematic of cutin deposition in a leaf. Cutin covers the outer wall of epidermal cells. Thickness, structure and composition of the various layers of the cuticle can vary significantly depending on species, organs or developmental stage. Wax crystals are not always present on the surface. Epicuticular waxes cover the cuticle proper, which is cutin embedded with intracuticular waxes. The cuticular layer is thought to contain cutin and polysaccharides of the cell wall but might also contain intracuticular waxes. Included for illustration are a trichome on the adaxial surface and a stomate on the abaxial surface. (B) Cutin is deposited on the outer surface of epidermal cells. In the upper panel, a section of a leaf has been stained with Sudan III, which stains lipophilic materials. The lower panel is an autoradiograph of a leaf after incubation with radioactive fatty acids for 24 h. Subsequent extraction with methanol and methanol:chloroform (1:1 by vol.) removed the soluble fatty acids, leaving only cutin in place.

used to demonstrate jasmonate (with ethylene) is an important chemical signal in nonhost resistance against fungal pathogens. Transcriptional profiling of the jasmonate response in *Arabidopsis* stamens led to the identification of jasmonate ZIM-domain (JAZ) proteins that are repressors of jasmonate signaling. The active form of jasmonate hormone, jasmonoyl-isoleucine, relieves repression by promoting binding of JAZ proteins to the F-box protein, coronatine-insensitive 1 (COI1), and their subsequent degradation by the ubiquitination/26S-proteasome pathway (see Chapters 10 and 17).

In addition to jasmonate, several other oxylipins have been reported to function as signal molecules. In particular, the oxylipin traumatin has been suggested to trigger cell division at the site of wounds, leading to the development of a protective callus. The lipoxygenase product 13-hydroxylinolenic acid triggers phytoalexin production. Similarly, C6–C8 alkenals act as volatile elicitors of a defense response in cotton.

8.9 Synthesis and function of extracellular lipids

8.9.1 Cutin, suberin, and their associated waxes provide lipophilic barriers to water loss and pathogen infection

Plants synthesize two types of lipid polymer that provide a crucial interface for interaction with and protection from the environment. The aerial parts of terrestrial plants are covered by a film of soluble and polymerized lipids, collectively called the cuticle (Fig. 8.52). This cuticle is synthesized by and deposited on the surface of epidermal cells that surround all aerial organs. The development of cuticles gave early land plants the ability to survive in dry environments. Indeed, one primary

role of this layer is to provide a permeability barrier against water loss; it also provides important resistance to pathogens, insects, and UV penetration.

The cuticle is composed of two types of lipids: an insoluble lipid polyester called cutin, which is a structure unique to plants, and the surface waxes, which cover the cutin matrix and are soluble in organic solvents (Fig. 8.52; see also Section 8.9.2). Cutin is a polymeric network of oxygenated C_{16} and C_{18} fatty acids and glycerol linked primarily by ester bonds. The monomers that give rise to cutin have largely been deduced by analyzing the composition of chemically depolymerized cutin. The principal constituents are monohydroxy-, polyhydroxy-, and epoxy fatty acids (Fig. 8.53, Table 8.5). In addition, at least *Arabidopsis* and *Brassica napus* contain dicarboxylic acids as major monomers.

The interesterified acyl chains of cutin form a relatively inelastic meshwork with a strongly hydrophobic character. However, because of the relatively large “pore size” of the cutin network, cutin does not provide the major barrier to plant water loss. Rather, it may act as a relatively inelastic

outer skin that contributes to rigidity in turgid plant tissues. Because of its physical strength, cutin also provides defense against penetration of pathogens. To penetrate the cutin layer, some pathogens probably need to secrete cutinases, enzymes that hydrolyze the ester linkages. Furthermore, some mutants in cutin biosynthesis are more susceptible to bacterial and fungal pathogens. Plants with certain alterations in cutin biosynthesis also have fusions of organs such as petals and sepals, indicating cutin also plays a role in maintaining organ identity and plant morphology.

Many aspects of cutin structure and assembly are poorly understood. For example, although esters formed between the carboxyl group of one fatty acid to glycerol or to a primary or secondary hydroxyl group of another fatty acid are considered the major linkages, the three-dimensional architecture of the monomers is a major unknown (Fig. 8.53). Possible arrangements of the acyl chains and glycerol include dendrimeric (tree-like) or cross-linked structures. In addition, the number of monomers that determine the overall size of the polymer

FIGURE 8.53 Structures of common cutin monomers, and hypothetical monomer connectivity patterns. (A) Representative structures within each monomer group. Mid-chain oxygen-functionalized monomers, which include epoxy, hydroxy, vicinal dihydroxy and oxo groups, can be found in addition to normal fatty acids, ω -hydroxy fatty acids and α,ω -dicarboxylic acids (DCAs). (B) A small segment of ω -hydroxy fatty acid-rich polyester is illustrated to show the dominant primary ester linkages that form chains, along with a secondary ester linkage to enable a branch point. (C–E) Two-dimensional ball-and-stick representations of possible monomer connectivity patterns to give hypothetical local polyester domain structures. Only mid-chain OH groups are depicted; other mid-chain functional groups are not shown, as are possible nonester connectivities and esterification to a cell wall substrate. (C) Organization of fatty acid and ω -hydroxy fatty acid monomers to produce a dendrimer. (D) Organization of DCA and glycerol monomers to produce a cross-linked domain. (E) Organization of DCA and glycerol monomers to produce a dendrimer structure, achieved by allowing free OH groups on some of the glycerol monomers.

TABLE 8.5 Monomer composition of cutin and suberin.

Monomer	Cutin	Suberin
Glycerol	10–50% of monomers	20–60% of monomers
Unmodified fatty acids	Minor (C ₁₆ –C ₁₈)	Minor (C ₁₆ –C ₂₆)
α,ω -Dicarboxylic fatty acids	Minor ^a	Common and substantial (C ₁₆ –vC ₂₆)
ω -Hydroxy fatty acids	Major (C ₁₆ –C ₁₈)	Common and substantial (C ₁₆ –C ₂₆)
Mid-chain modified ω -hydroxy fatty acids (C ₁₆ –C ₁₈)	Major	Minor ^b
Fatty alcohols	Rare and minor (C ₁₆ –C ₁₈)	Common and substantial (C ₁₈ –C ₂₂)
Ferulate	Low	High

^aC₁₆–C₁₈ dicarboxylates are major monomers in *Arabidopsis* and *Brassica napus* cutin (>50%).

^bIn some cases is substantial. Substituted dicarboxylic acids are also frequently found in suberins.

has not been defined. Cross-linking of cutin to the cell wall is believed to occur, but the extent and nature of such linkages has not been determined.

The cutin monomers that are produced in epidermal cells are synthesized from fatty acid precursors by CYP450 oxidases that introduce hydroxyl groups. Apparently, cutin components are transported to the plasma membrane and secreted into the cell wall space (Fig. 8.54). How the cutin monomers are polymerized and transported to the site of cutin deposition is not well understood. At least some acyl monomers are attached to glycerol-3-phosphate inside the cell, by an acyltransferase reaction similar to the first reaction of membrane glycerolipid assembly. Unlike the reaction producing intracellular glycerolipids, however, the acyl precursors of cutin are esterified to the *sn*-2 position of glycerol, rather than the *sn*-1 position. Furthermore, some of these acyltransferases are plant-specific bifunctional enzymes that remove the phosphate to produce monoacylglycerol (MAG) products. Whether MAG is exported from cells, or if larger oligomers are assembled before export, is unknown. Additional assembly steps presumably occur outside the plasma membrane or, indeed, outside the cell wall. Movement of monomers or oligomers through the cell wall might be facilitated by lipid transfer proteins, after which “polyester synthase” may catalyze further growth of the cutin polymer. Specific GDSL-motif lipases can catalyze the transacylation of hydroxy fatty acid-monoacylglycerols to form oligomers at the cell wall-cuticle interface and are postulated to be “polyester synthases”.

All plants also produce suberin, another extracellular lipid polymer associated with cell walls. The two polymers have similarities in their chemical composition and in the enzymes involved in their synthesis. However, there are a number of key differences. First, cutin accumulates outside the epidermal cell wall, whereas suberin is deposited on the inner side of the primary cell wall facing the plasma membrane. Second, cutin deposition is polar; it accumulates on only the outermost surface of epidermal cells and at the interface between the plant and its environment. In contrast, suberin can surround the

entire plasma membrane of cells. Third, whereas cutin synthesis is restricted to epidermal cells, a much wider range of cell types and organs produces suberin. In roots, suberin is deposited as the Casparian bands/strip of endodermal cells, and suberin lamellae also surround these cells (Fig. 8.55; see also Chapter 24). The Casparian band/strips of very young portions of roots is thought to be comprised primarily of lignin or lignin-like substances whereas the canonical suberin lamellae are found in the zone of maturation. Suberin is also present in the periderm of mature roots and on the surface of tubers of roots and stems, and in seed coats. Suberin is a major component of the phellem of stems (e.g., cork) of woody plant species. Cork oak trees produce a commercially important phellem layer that is several centimeters thick and 50% suberin by weight. Suberin also surrounds the plasma membrane of bundle sheath cells of C4 species, where it may prevent CO₂ diffusion from bundle sheath cells. In many other tissues suberin is deposited in response to wounding and abiotic stresses, even in those tissues that normally synthesize cutin.

To accomplish the uptake of water and minerals from the soil, roots maintain hydrophilic contact with soil moisture through an extensive network of root hairs. The suberized Casparian bands/strip in the endodermal cells of plant roots is one system of control employed by plants to regulate what enters and exits the vasculature, and what is distributed to the aerial portions of the plant. The hydrophobic nature of the Casparian strip restricts movement of water and nutrients through the apoplast. This ensures solutions only enter endodermal cells by crossing the plasma membrane (embedded with selective transport proteins), where they then move symplastically to the vasculature. The suberized endodermal cells are also thought to prevent water and mineral movement out of the vasculature, thereby contributing to “root pressure,” which aids in the initial movement of water and nutrients up the xylem to the aerial portions of the plant.

The main compositional differences between cutin and suberin are in their fatty acids. In suberin, they usually do not

FIGURE 8.54 Mechanisms and cellular locations of cutin and suberin assembly and deposition. The enzymes of monomer synthesis, including acylglycerol synthesis, are thought to be localized to the ER. Polyester synthases (PS) are broadly defined as enzymes catalyzing the formation of ester bonds between monomers, and also between putative polyester oligomers or domains. Additional enzymes may also anchor the polymers to the cell wall (CW). Four possible mechanisms and associated routes leading from the ER to the external face of the plasma membrane are shown (A–D). In addition, two possible mechanisms of passage of lipophilic precursors from the plasma membrane (PM) through the apoplast to the final site of assembly and deposition are depicted for the case of cutin synthesis (i and ii). Similar mechanisms may be operating for suberin assembly and deposition, but are not shown. The mechanisms are not necessarily mutually exclusive, and not every possibility is shown. (A) PM-anchoring ER domain. This could involve a spatial coupling of monomer synthesis and transport across PM. Transport may be accomplished via an ABC transporter (ABC). (B) Cytoplasmic carrier protein. (C) Oleophilic droplets. Osmophilic particles have been observed in the outer CW of rapidly expanding epidermis and could constitute oleophilic droplets on their way to the cuticle. These droplets could originate from ER, in a way similar to the budding process proposed for the ontogeny of seed oil-bodies. (D) Golgi-mediated secretion vesicle mechanism. This would be a likely possibility if polyester domains or polymers were formed in the ER or if polyesters were attached to polysaccharides inside the cell. It is also possible that a polyester attachment site is added intracellularly to CW polysaccharides. Mechanisms (A) and (B) would most likely accommodate transport of monomers or oligomers. By contrast, mechanisms (C) and (D) could also accommodate polymer domains. (1) Unchaperoned movement of lipidic precursors or oleophilic droplets across the apoplast. (2) Movement of monomers, oligomers of polymers bound to a protein carrier (e.g., lipid transfer proteins) or after attachment to a carrier such as a CW polysaccharide.

have secondary alcohols or epoxy groups and are often longer than 18 carbons (Table 8.5). In addition, suberin has a relatively high content of dicarboxylic acids and a polyaromatic domain (Fig. 8.55). Despite differences in the deposition sites and composition of suberin and cutin monomers, their biosynthesis involves similar reactions catalyzed by isoforms of the same enzyme families (see Fig. 8.53 and Fig. 8.54).

Similar to cutin, solvent-soluble waxes are embedded in or associated with suberin. However, suberin has some associated waxes that are not typically found in the cuticle. Similar to the cuticle, suberin-associated waxes consist of alkanes, primary alcohols, and fatty acids. Unique to suberin waxes are alkyl hydroxycinnamates and monoacylglycerols, which are metabolically related to suberin.

8.9.2 Epicuticular wax reduces water loss

Cutin alone is not sufficient for determining the barrier/water-retarding properties of the cuticle. The aerial surfaces of plants are covered with a layer of chloroform-soluble, nonvolatile lipids, collectively called wax (see Fig. 8.52). Waxes are embedded into the polymeric cutin matrix, and in many plants waxes also extend beyond the cutin to the plant surface. The wax layer reduces water loss by orders of magnitude, making terrestrial plant life possible.

The amounts and composition of wax deposited are controlled by the plant in response to environmental factors such as relative humidity, soil moisture, and light intensity (Fig. 8.56). Wax composition varies from one plant species to

FIGURE 8.55 Suberin deposition in the root endodermis. (A) Cross-section of a dicotyledonous root in its primary developmental state showing the suberized endodermis and hypodermis (exodermis), both with characteristic Casparian strips (red dots) in the radial cell walls and suberin lamellae (yellow) deposited onto the inner surfaces of the primary cell walls (gray). (B) Representation of the barrier function of the Casparian strip which restricts water flow through the apoplast into the root vasculature. Most water and solute uptake by roots occurs via the symplast.

FIGURE 8.56 Wax composition of *Brassica oleracea* plant grown in high-humidity conditions in tissue culture or in low-humidity conditions in a glasshouse.

another, but wax generally contains a mixture of long-chain hydrocarbons, acids, alcohols, ketones, aldehydes, and esters. In addition, triterpenoids are frequently extracted in the wax fraction. The functional significance of interspecies differences in wax composition is not known. However, the study of mutants with altered wax composition indicates wax composition affects wax crystal structure. Some plants produce filaments, others produce plates or tubes or spiral-shaped forms (Fig. 8.57). The chemical composition of epicuticular waxes correlates with wax crystal structure: tubules are formed when secondary alcohols are abundant, whereas

triterpenoids or primary alcohols form platelets in certain species. Different crystal structures may vary in their ability to reflect light—a property that may be useful for adaptation to growth in different light intensities. More importantly, perhaps, some pathogens and herbivorous insects are attracted to or repelled by specific wax compositions. Thus, wax composition may reflect the balance of selective biotic and abiotic pressures exerted on a particular plant species.

Wax monomers are synthesized from C_{16} and C_{18} fatty acids by an elongase complex located in the ER (Fig. 8.58). Although most enzymes involved in elongation, reduction, and oxidation

FIGURE 8.57 Scanning electron micrograph of the surface of a *Sorghum bicolor* leaf sheath. In this species, the wax crystallizes as filaments that appear to emerge from defined regions of the cuticle. Scale bar (lower left) = 10 μm . Source: Jenks et al. (1994). *Int. J. Plant Sci.* 155:506–518.

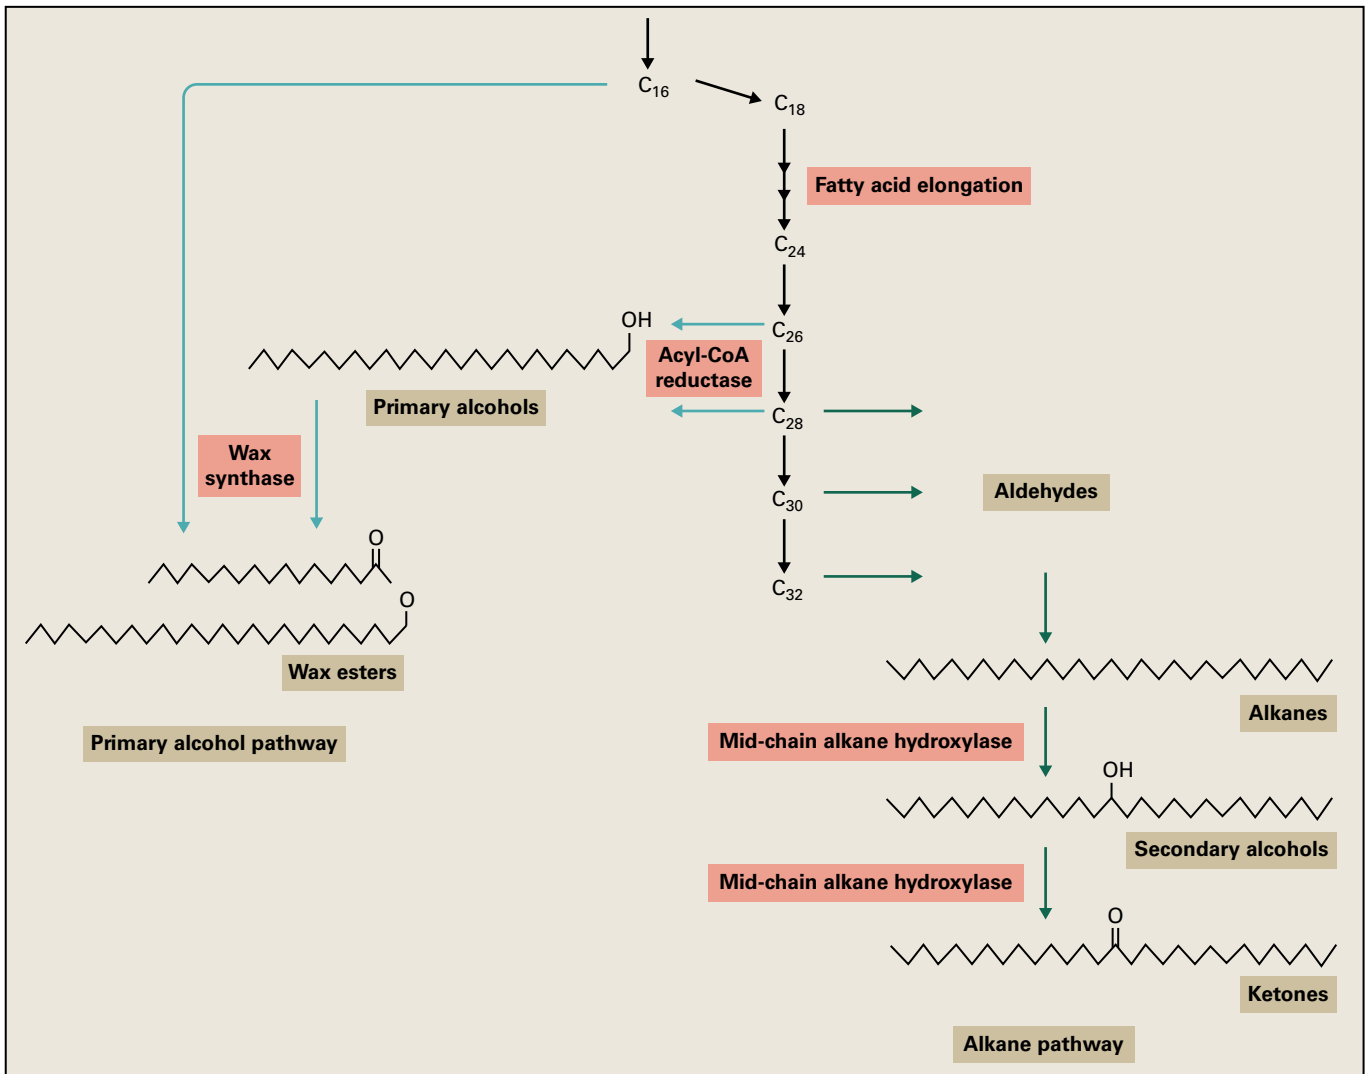

FIGURE 8.58 Simplified pathways for surface wax biosynthesis.

have been identified, the decarbonylation step, which produces the major alkane components of waxes, is still uncertain. Transport of wax across the plasma membrane involves ABC transporters, which results in wax accumulation inside the

epidermal cells when mutated (Fig. 8.59). As with cutin biosynthesis, it is not well understood how wax monomers move from the plasma membrane through the cell wall to reach the outermost surface of epidermal cells. Because the principal

FIGURE 8.59 Current models of wax export to the cuticle. The mechanisms for transport of wax molecules from epidermal cells to the surface of plants are currently unknown. Two hypothetical routes for movement of wax from the ER to the PM are shown: direct molecular transfer at ER-plasma membrane contact sites, or Golgi-mediated vesicular traffic through the secretory pathway. In either case, wax molecules cross the plasma membrane via ABC transporters (ATP-binding cassette transporter); movement through the cell wall to the cuticle may involve lipid transfer proteins, (LTP). Lipids may accumulate at the air interface based on their insolubility in the aqueous apoplast. FAE, fatty acid elongase.

components are completely insoluble in aqueous solutions, the monomers are possibly transported by lipid-transfer proteins (Fig. 8.59). Lipid-transfer proteins are the most abundant proteins secreted at the surface of plant cells, and their small size may allow them to permeate the pores of the cell wall-carbohydrate matrix.

8.9.3 Surface lipids are required for male fertility and productive pollen-pistil interactions

Pollen grains are covered with a waxy layer called the exine, which is composed of a complex polymer called sporopollenin. This polymer is related to cutin, and mutations in its synthesis result in male sterility. Embedded in the exine is a layer of lipophilic material called tryphine or pollenkitt (Fig. 8.60; see also Chapter 19). In *Arabidopsis*, the tryphine layer includes small lipid bodies that appear to contain primarily C_{28} and C_{30} wax monomers. Probably an important function of the tryphine layer is to reduce water loss from the

FIGURE 8.60 Transmission electron micrograph through an *Arabidopsis* pollen grain.
Source: D. Preuss, University of Chicago; previously unpublished.

pollen grain. However, experiments using *Arabidopsis*, rice, and other mutants with altered exine composition hint at a more complex role for these lipids. Some mutants are male-sterile; however, the fertility of their pollen can be rescued by mixing irradiation-killed wild-type pollen with mutant pollen. Accordingly, some factor in the wild-type pollen appears to complement the defective pollen. These experiments suggest the normal exine coat may play a signaling role in pollen–pistil interactions (see Chapter 19).

8.10 Synthesis and catabolism of storage lipids

Lipids in the form of triacylglycerols are widely found as a major carbon and chemical energy reserve in seeds, fruits, and pollen grains (Fig. 8.61). One of the few plants that stores lipids in a form other than triacylglycerols is jojoba (*Simmondsia chinensis*), a perennial shrub that stores fatty acids as wax esters in seeds. Plant storage lipids are also an important source of dietary fats for humans and other animals. Approximately 40% of the daily energy requirement of humans in industrialized countries is supplied by dietary triacylglycerols, of which more than half is from plant sources. Furthermore, triacylglycerols find use in manufacturing industries, particularly in the production of detergents, coatings, plastics, and specialty lubricants. For both food and industrial applications, the fatty acid composition of the oil determines its usefulness and, therefore, its commercial value.

8.10.1 Triacylglycerol synthesis involves acyltransferase and acyl-exchange reactions that move fatty acids between pools of membrane and storage lipids

Many of the biochemical reactions and some aspects of sub-cellular compartmentalization of triacylglycerol synthesis in developing oilseeds are the same as for membrane lipids. Because of interest in the factors that control the precise fatty acid composition of triacylglycerols, however, it is useful to consider seed lipid biosynthesis in terms of a pathway that emphasizes the acyltransferase and acyl-exchange reactions (Fig. 8.62). This pathway was proposed based on results from many oilseed species but is shown to describe the metabolism of developing *Arabidopsis* seeds. *Arabidopsis* seed lipids contain substantial proportions of both unsaturated C18 fatty acids (30% 18:2 ^{Δ 9,12}, 20% 18:3 ^{Δ 9,12,15}) and long-chain fatty acids (22% 20:1 ^{Δ 11}) derived from 18:1 ^{Δ 9}. As a result, *Arabidopsis* is a good model for the biochemistry of oilseeds rich in 18:2 ^{Δ 9,12}/18:3 ^{Δ 9,12,15} fatty acids and oilseeds from other species containing longer fatty acids.

As they are in other tissues, 16:0-ACP and 18:1 ^{Δ 9}-ACP are usually the major products of plastid fatty acid synthesis and 18:0-ACP desaturase activity in oilseeds. In seed tissues, these products are hydrolyzed to free fatty acids by thioesterases in the plastid stroma and transferred through the plastid envelope by an unknown mechanism. The free fatty acids are converted to acyl-CoAs in the outer plastid envelope, forming the substrates for subsequent acyltransferase reactions. Newly produced 18:1 ^{Δ 9}-CoA, 18:0-CoA, and 16:0-CoA can be used for the synthesis of phosphatidylcholine and phosphatidic acid, as shown in Figure 8.62. Phosphatidylcholine is the main substrate for the sequential desaturation of 18:1 ^{Δ 9} to 18:2 ^{Δ 9,12} and 18:3 ^{Δ 9,12,15}. CDP-choline:diacylglycerol cholinephosphotransferase is responsible for net synthesis of phosphatidylcholine. In addition, phosphatidylcholine to DAG interconversions are catalyzed by phosphatidylcholine:diacylglycerol cholinephosphotransferase (PDCT) through the phosphocholine headgroup exchange between PC and DAG (Fig. 8.62), providing an alternate route for entry of 18:1 ^{Δ 9} into phosphatidylcholine for desaturation and transfer of 18:2 ^{Δ 9,12} and 18:3 ^{Δ 9,12,15} to the DAG pool for triacylglycerol synthesis.

The acyl-CoA pool does not contain only 16:0 and 18:1 ^{Δ 9}; exchange of 18:1 ^{Δ 9} from 18:1 ^{Δ 9}-CoA with the fatty acid at position *sn*-2 of phosphatidylcholine releases 18:2 ^{Δ 9,12} and 18:3 ^{Δ 9,12,15} back into the cellular acyl-CoA pool. In some oilseeds, including *Arabidopsis* and rapeseed (*Brassica napus*), 18:1 ^{Δ 9}-CoA can be modified by elongation to 20:1 ^{Δ 11}-CoA and 22:1 ^{Δ 13}-CoA. Synthesis of DAG may also involve these components of the acyl-CoA pool, as does the final acylation of DAG to form triacylglycerol by the enzyme acyl-CoA:1,2-diacylglycerol O-acyltransferase. At least two rather different forms of this enzyme occur in plants: one with at least six membrane-spanning domains and a smaller enzyme with three predicted membrane

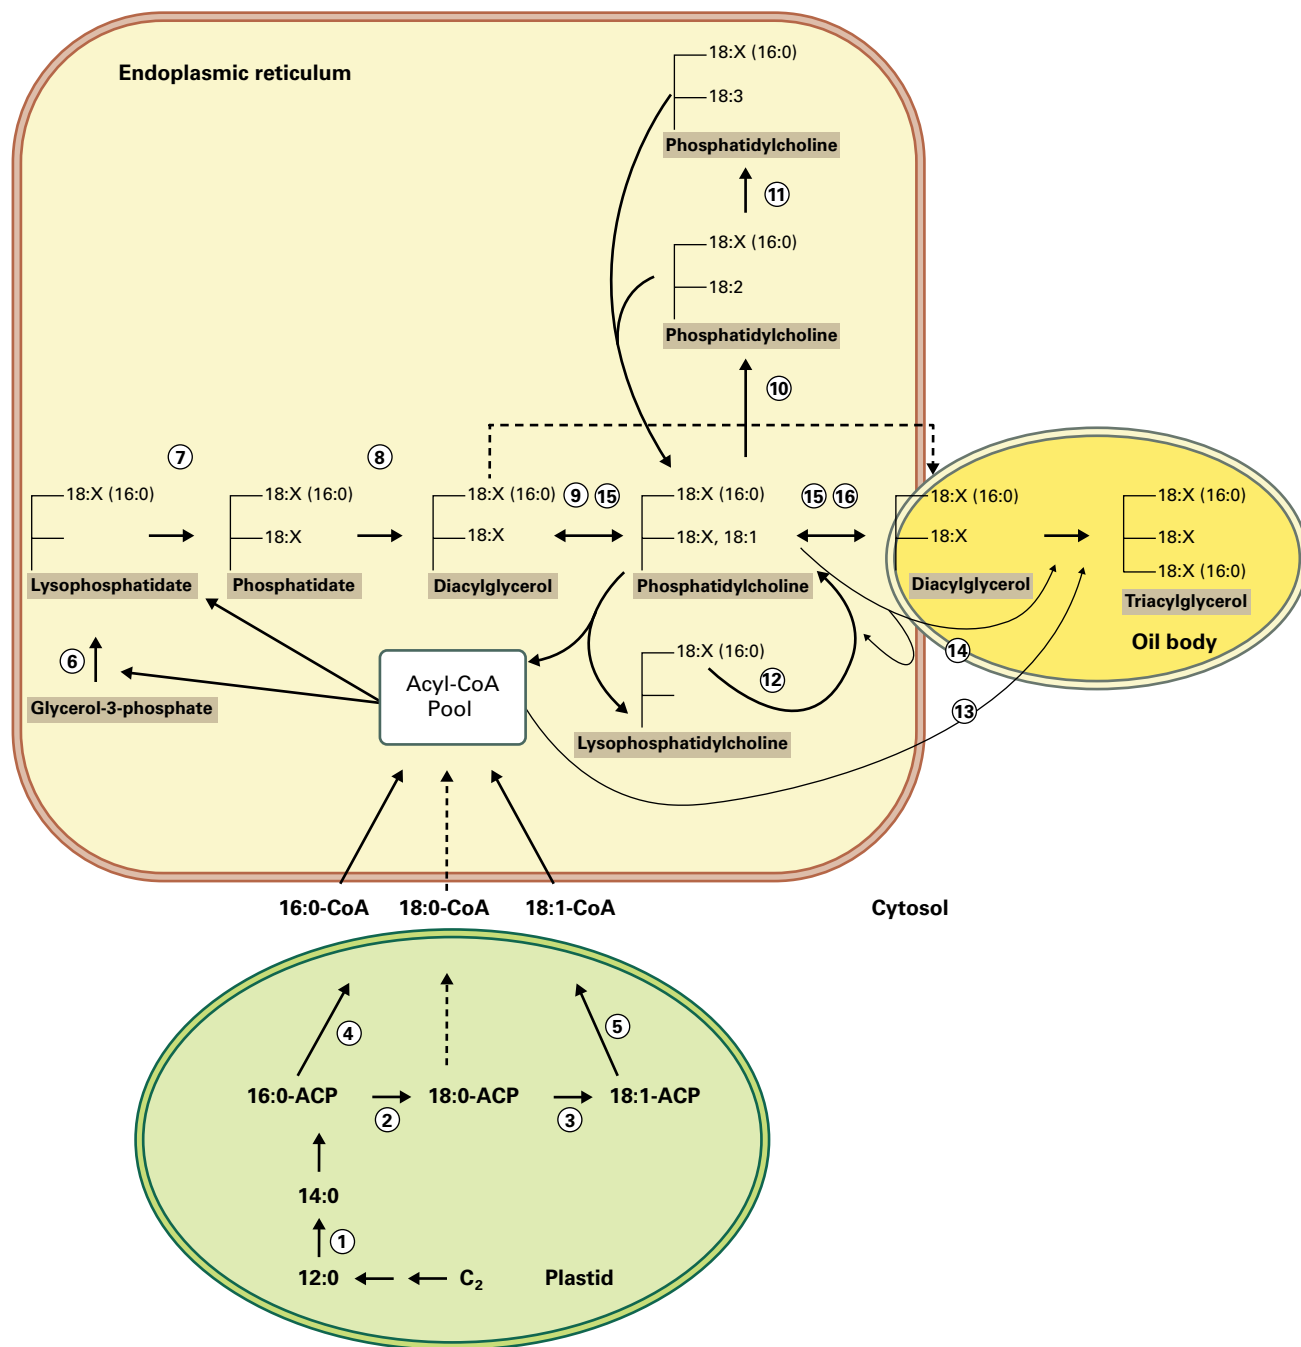

FIGURE 8.62 Pathway of triacylglycerol synthesis as deduced from *in vivo* labeling of developing soybean embryos and *Arabidopsis* seeds. The largest flux measured during labeling experiments is reaction 12, the exchange of acyl groups between the acyl-CoA pool and PC. Therefore, most fatty acids that exit the plastid are first esterified to PC rather than glycerol 3-phosphate. The dotted line represents that a small flux of de novo synthesized DAG can be used to make TAG however most DAG fluxes through PC prior to TAG synthesis. 1, KAS I- and KAS III-dependent FAS; 2, KAS II-dependent FAS; 3, stearoyl-ACP desaturase; 4, palmitoyl-ACP thioesterase; 5, oleoyl-ACP thioesterase; 6, acyl-CoA:glycerol-3-phosphate acyltransferase (GPAT); 7, acyl-CoA:lysophosphatidate acyltransferase (LPAT); 8, phosphatidate phosphatase (PAP); 9, CDP-choline:diacylglycerol cholinephosphotransferase (CPT); 10, oleate desaturase (FAD2); 11, linoleate desaturase (FAD3); 12, acyl-CoA:lysophosphatidylcholine acyltransferase (LPCAT); 13, acyl-CoA:diacylglycerol acyltransferase (DGAT); 14, phospholipid:diacylglycerol acyltransferase (PDAT); 15, phosphatidylcholine:diacylglycerol cholinephosphotransferase (PDCT); 16, other possible reactions for conversion of PC to DAG include phospholipase C, phospholipase D together with reaction 8, and the reverse of reaction 9.

spanning domains. Evidence suggests, for both plants and animals, these two isozymes occur in different subcellular locations. Triacylglycerol can also be formed by transfer of an acyl group from phosphatidylcholine to DAG by the

enzyme phosphatidylcholine:diacylglycerol acyltransferase. The relative contribution of these alternative enzymes to the *in vivo* flux of triacylglycerol synthesis in oilseeds varies in different species.

8.10.2 Triacylglycerols accumulate in discrete subcellular organelles called oil bodies

In oilseeds, oil bodies are droplets of triacylglycerols surrounded by a monolayer of phospholipids, with the hydrophobic acyl moieties of the phospholipids interacting with the triacylglycerols and the hydrophilic head groups facing the cytosol. Oil bodies also contain major protein components called oleosins, which are not found in significant amounts in any other cellular location (Fig. 8.63). Oleosins are low-molecular-mass proteins (15–25 kDa) that contain a sequence of 70–80 hydrophobic amino acids toward the middle of the protein. The sequence of this hydrophobic domain is conserved in oleosins from different plant species, but these proteins are not found in animals, bacteria, or fungi. Although some question of the protein secondary structure in the hydrophobic domain (β -strand or β -sheet) remains, there is general agreement that it protrudes into the triacylglycerol core of the oil body. Possibly, the more hydrophilic N- and C-terminal domains form amphipathic helices at the oil body surface.

Oleosins are found only in oil bodies of seeds and pollen, both of which undergo dehydration during maturation.

In contrast, lipid droplets in fruit mesocarp (such as those of avocado and olive (*Olea europaea*)) do not contain oleosin homologs. Thus, oleosins may stabilize oil bodies at low water potential in mature seeds and pollen when hydration of the surface phospholipids is not sufficient to prevent the oil bodies from coalescing and fusing. Oleosins also may regulate the size of oil bodies by imparting a defined curvature to the surface, which could be important for regulating the surface-to-volume ratio to facilitate rapid breakdown of oil bodies during germination. In this respect, the mesocarp lipids in avocado and olive are not thought to contribute to the germination or growth of the seedling, but are probably made by the plant to facilitate seed dispersal by animals.

The ontogeny of oil bodies is not absolutely clear, but one model suggests they arise by deposition of triacylglycerols between the two leaflets of the ER and then develop into discrete organelles that may or may not remain attached to the ER membranes (Fig. 8.64). This model accounts for the monolayer membrane of oil bodies and is consistent with biochemical results demonstrating triacylglycerol synthesis by microsomal membrane preparations. However, enzymes of oil synthesis are also reported to be associated with isolated oil bodies. The exact nature of the relationship between the oil bodies and ER takes on extra significance because DAGs are precursors for the synthesis of both triacylglycerols and the major membrane

FIGURE 8.63 (A) Transmission electron micrograph close-up of oil body. (B) Scale-model of an oil body. The oleosin molecule is depicted in the shape of an 11-nm-long hydrophobic stalk attached to an amphipathic and hydrophilic globular structure that forms the outer surface of the oil body. FIGURE 8.64 Model of the synthesis and degradation of an oil body in an embryo during seed maturation and post germination. For clarity this model is not drawn to scale. The oil body diameter of 1–2 μm is actually 50–100 fold larger than an ER cross-section.

phospholipids. Because many oilseeds contain high amounts of unusual fatty acids that are largely excluded from the membrane phospholipids, it follows DAGs must occupy a critical branch point in oilseed lipid metabolism.

8.10.3 Membrane and storage lipids often have distinct compositions

Unusual fatty acids (see Table 8.2 and Fig. 8.25) often constitute 90% or more of all fatty acids produced in the seed, but in almost all cases these fatty acids are present almost exclusively in triacylglycerols and are excluded from membrane lipids. This probably occurs because fatty acids with unusual structures could create undesirable physical or chemical properties in the membrane or perturb membrane fluidity. Therefore, plants that produce such unusual fatty acids must also have mechanisms to prevent accumulation of these compounds in membranes. Furthermore, hydroxy-fatty acids, epoxy-fatty acids, and some other unusual fatty acids are first synthesized on phosphatidylcholine, a major membrane lipid. What mechanisms ensure first the removal of these modified fatty

acids from phospholipids and then their targeting to storage oils? At present, no clear or complete answer is available. However, developing seeds from species that produce unusual fatty acids might rely on phospholipases that can remove the fatty acids from polar lipids. Furthermore, these seeds usually have a suite of specialized acyltransferases and other enzymes specific for metabolizing unusual fatty acids.

Another possible method for keeping membrane and storage fatty acids distinct is subcellular compartmentation. Although membrane and storage lipid synthesis proceed by similar pathways and share common chemical intermediates (phosphatidate, DAG, and phosphatidylcholine; see Fig. 8.62), the specialized enzymes involved in storage oil biosynthesis may reside in domains of the ER distinct from enzymes that process the “common” fatty acids for incorporation into membranes.

8.10.4 Regulation of seed oil biosynthesis

Most plant vegetative tissues have a lipid content of 5% or less by dry weight, and, of this, less than 1% is in the form of triacylglycerol. In contrast, the total lipid content of many oilseeds

is over 50% of the dry weight, and more than 95% of this lipid is in the form of triacylglycerol. The conversion of sugars into triacylglycerol in developing oilseeds is thus a classic example for the developmental and tissue-specific regulation of metabolism.

Regulation of oil synthesis in seeds occurs by multiple mechanisms. One level of control involves allosteric enzyme regulation, for example at the enzyme acetyl-CoA carboxylase. In addition, analysis of mRNAs expressed in developing seeds indicates enzymes of fatty acid biosynthesis and oil body assembly are, for the most part, coordinately regulated at the level of mRNA expression. In addition, a number of enzymes of lipid metabolism belong to gene families and sometimes there is a specific member of the family that is only expressed in seeds. The transcription factor WRINKLED 1 (*WRI1*) plays a major role in controlling expression of genes involved in seed oil biosynthesis. Oil content in the *wri1* mutant of *Arabidopsis* is 80% reduced, whereas overexpression of the *WRI1* gene increases seed oil content. Some direct targets of this transcription factor are genes encoding enzymes of fatty acid biosynthesis and genes of glycolysis that provide precursors for fatty acid synthesis. Other transcription factors including LEAFY COTYLEDON1 (*LEC1*) act upstream of *WRI1* and are involved in the complex network of transcriptional regulation of embryo development in seeds. Metabolite (sugar)-sensing mechanisms also provide input for integration of primary metabolism in seeds, but are not yet understood at the mechanistic level. Identifying the factors and understanding the mechanisms that control oil biosynthesis in plants is providing one basis for successful engineering of oil content in seeds and perhaps in other plant tissues.

8.10.5 In some seeds, Rubisco acts without the Calvin–Benson cycle to provide a higher efficiency of carbohydrate to oil conversion

During seed development, photosynthate from the mother plant is imported in the form of sugars, and the seed converts these into precursors of fatty acid biosynthesis. In many seeds, the traditional glycolysis pathway plays a central role in this conversion (see Chapter 13). Pyruvate produced by glycolysis is then converted to acetyl-CoA by the plastid pyruvate dehydrogenase complex. In this reaction, the three carbons of pyruvate are converted to two carbons of acetyl-CoA with the loss of one carbon as CO_2 . Thus, the conversion of carbohydrate to oil results in the loss of one third of the carbon.

Many seeds, however, are green and express substantial levels of Rubisco. It has been discovered that Rubisco and enzymes of the pentose phosphate pathway can act together to increase the efficiency of carbohydrate to oil biosynthesis. In this alternative pathway, the glyceraldehyde-3-phosphate dehydrogenase (GAP-DH) and phosphoglycerate kinase (PGK) reactions that normally produce phosphoglycerate

(PGA) during glycolysis are bypassed, and PGA is instead produced by Rubisco. The net result is 20% more acetyl-CoA available for oil synthesis and 40% less loss of carbon as CO_2 . However, the GAP-DH and PGK reactions normally provide reductant and ATP cofactors. To make up for the loss of these cofactors, in the Rubisco bypass pathway the seeds are green and produce cofactors through the light reactions of the photosystems.

8.10.6 Mobilization of storage lipids provides carbon and chemical energy for germination and pollination

Triacylglycerols function as an efficient source of carbon and energy for germination of seeds and pollen because lipids are a far more compact form of storage than is carbohydrate or protein (see Fig. 8.3). Relatively few species accumulate significant quantities of storage lipids in roots, tubers, or other storage organs where compact size is not important. Because of their hydrophobicity and insolubility in water, triacylglycerols are segregated into lipid droplets, which do not raise the osmolarity of the cytosol. Furthermore, unlike polysaccharides, triacylglycerols do not contain extra weight as water of solvation. The relative chemical inertness of triacylglycerols allows their intracellular storage in large quantity without risking undesired chemical reactions with other cellular constituents.

The same properties that make triacylglycerols good storage compounds present problems in their utilization. Because of their insolubility in water, triacylglycerols must be hydrolyzed to fatty acids before they are available for metabolism. The relative stability of the C–C bonds in the alkyl moiety of a fatty acid is overcome by activation of the fatty acid carboxyl group at C-1 by attachment to CoASH, followed by oxidative attack at the C-3 position. This latter carbon atom is also called the β -carbon in common nomenclature, from which the oxidation of fatty acids gets its common name: β -oxidation. The oxidation of long-chain fatty acids to acetyl-CoA by a four-step cycle is a central energy- and carbon precursor-yielding pathway during the germination of seeds and during the germination and growth of pollen tubes during fertilization. The acetyl-CoA formed during β -oxidation may be converted, via the glyoxylate cycle and gluconeogenesis, to carbohydrate (Fig. 8.65; see also Chapter 14). Mutants that are blocked in triacylglycerol hydrolysis, β -oxidation, or some steps of the glyoxylate cycle require an additional supply of carbohydrate to successfully establish seedlings after germination.

In addition to its special role in triacylglycerol mobilization after seed and pollen germination, the β -oxidation pathway also occurs in essentially all other plant cells. In most cells there is a continual slow turnover of membrane lipids and carbon from their fatty acids is recycled via β -oxidation. In addition, the synthesis of the hormone jasmonic acid requires three cycles of β -oxidation (see Fig. 8.50). Although the biological role of fatty acid oxidation differs in different

FIGURE 8.65 Mobilization of storage lipids after seed germination and their conversion to carbohydrate involves multiple pathways and subcellular compartments (see also Fig. 14.41). The triacylglycerol (TAG) lipase TAGL hydrolyzes TAG stored in oil bodies to produce fatty acids (FAs) and glycerol. Glycerol kinase (GK) produces glycerol 3-phosphate (G-3-P), which can enter gluconeogenesis (blue shading). FAs are imported into the glyoxysome via the COMATOSE (CTS) ATP-binding cassette (ABC) transporter. FAs are activated by a long-chain acyl-CoA synthetase (LACS) and enter the core reactions of β -oxidation (light green background): acyl-CoA oxidase (ACX), multifunctional protein hydratase (MFP/Hydratase), multifunctional protein dehydrogenase (MFP/DH), and 3-ketoacyl-CoA thiolase (KAT). Hydrogen peroxide (H_2O_2) is broken down in the glyoxysome matrix by catalase (CAT) or is broken down as it passes through the membrane by an ascorbate peroxidase (APX)/monodehydroascorbate reductase (MDAR) electron transfer system. Glyoxysomal malate dehydrogenase (MDH) operates in the reverse direction to convert oxaloacetate (OAA) to malate and is dedicated to regenerating NAD^+ from $NADH$ for the continued operation of β -oxidation. Citrate synthase (CSY) is also essential for β -oxidation and plays a role in the glyoxylate cycle. Malate synthase (MLS) and isocitrate lyase (ICL) are unique to the glyoxylate cycle and localize to the glyoxysome. The aconitase (ACO) and MDH reactions of the glyoxylate cycle are cytosolic; MDH operates in the forward direction to produce OAA and $NADH$. Phosphoenolpyruvate (PEP) carboxykinase (PCK) is the major controlling step of gluconeogenesis (blue background), producing PEP from OAA. The contribution of the mitochondrial tricarboxylic acid (TCA) cycle to the production of OAA is not included. MDA, monodehydroascorbate; ASC, ascorbate.

tissues and from organism to organism, the central enzyme reactions are essentially the same. Details of the enzymatic mechanisms can be found in biochemistry textbooks that focus primarily on animal metabolism. Therefore, the discussion below highlights those features of the pathway that differ between plants and animals.

8.10.7 β -Oxidation takes place in peroxisomes

The major site of fatty acid oxidation in animal cells is the mitochondrial matrix. In contrast, fatty acid oxidation in plants occurs primarily in the peroxisomes. In germinating seeds peroxisomes are often referred to as glyoxysomes, because they are also the site of several reactions of the glyoxylate cycle (Fig. 8.65).

In animals the glyoxylate cycle does not exist and most acetyl-CoA produced by the β -oxidation pathway enters the TCA cycle and is completely oxidized to CO_2 with production of additional metabolic energy. However, in plants the biological role of β -oxidation in peroxisomes is also to provide biosynthetic precursors from stored lipids. During germination, a large proportion of the triacylglycerols stored in seeds is converted into glucose, sucrose and a variety of essential metabolites. In many plants, sucrose produced from fatty acids is translocated from the seed tissues to the emerging shoots and roots of the seedlings. This process begins when fatty acids released from triacylglycerols are activated to form their CoA derivatives and are oxidized in peroxisomes. The acetyl-CoA produced is converted by way of the glyoxylate cycle to C_4 precursors for gluconeogenesis (Fig. 8.65; see also Chapter 14, Fig. 14.41). Peroxisomes contain high concentrations of catalase, which converts the H_2O_2 produced by β -oxidation to H_2O and O_2 .

The β -oxidation enzymes of peroxisomes form a protein complex. As in the oxidation of fatty acids in mitochondria, the intermediates are CoA derivatives, and the process consists of four steps (Fig. 8.66):

- dehydrogenation to a Δ^2 -*trans* unsaturated molecule
- addition of water to the resulting double bond
- oxidation of the β -hydroxyacyl-CoA to a ketone
- thiolitic cleavage by CoASH.

The difference between the peroxisomal and mitochondrial pathways lies in the first step. In peroxisomes, the flavo-protein dehydrogenase that introduces the double bond passes electrons directly to O_2 , producing H_2O_2 . This strong and potentially damaging oxidant is immediately cleaved by catalase to H_2O and $\frac{1}{2}\text{O}_2$ (Fig. 8.66). In contrast, in mitochondria, the electrons removed in the first oxidation step pass through the respiratory chain to O_2 , leaving H_2O as the product, a process accompanied by ATP synthesis. In peroxisomes, the energy released in the first oxidative step of fatty acid breakdown is dissipated as heat.

8.11 Genetic engineering of lipids

8.11.1 Improvement of oil quality is a major objective of plant breeders

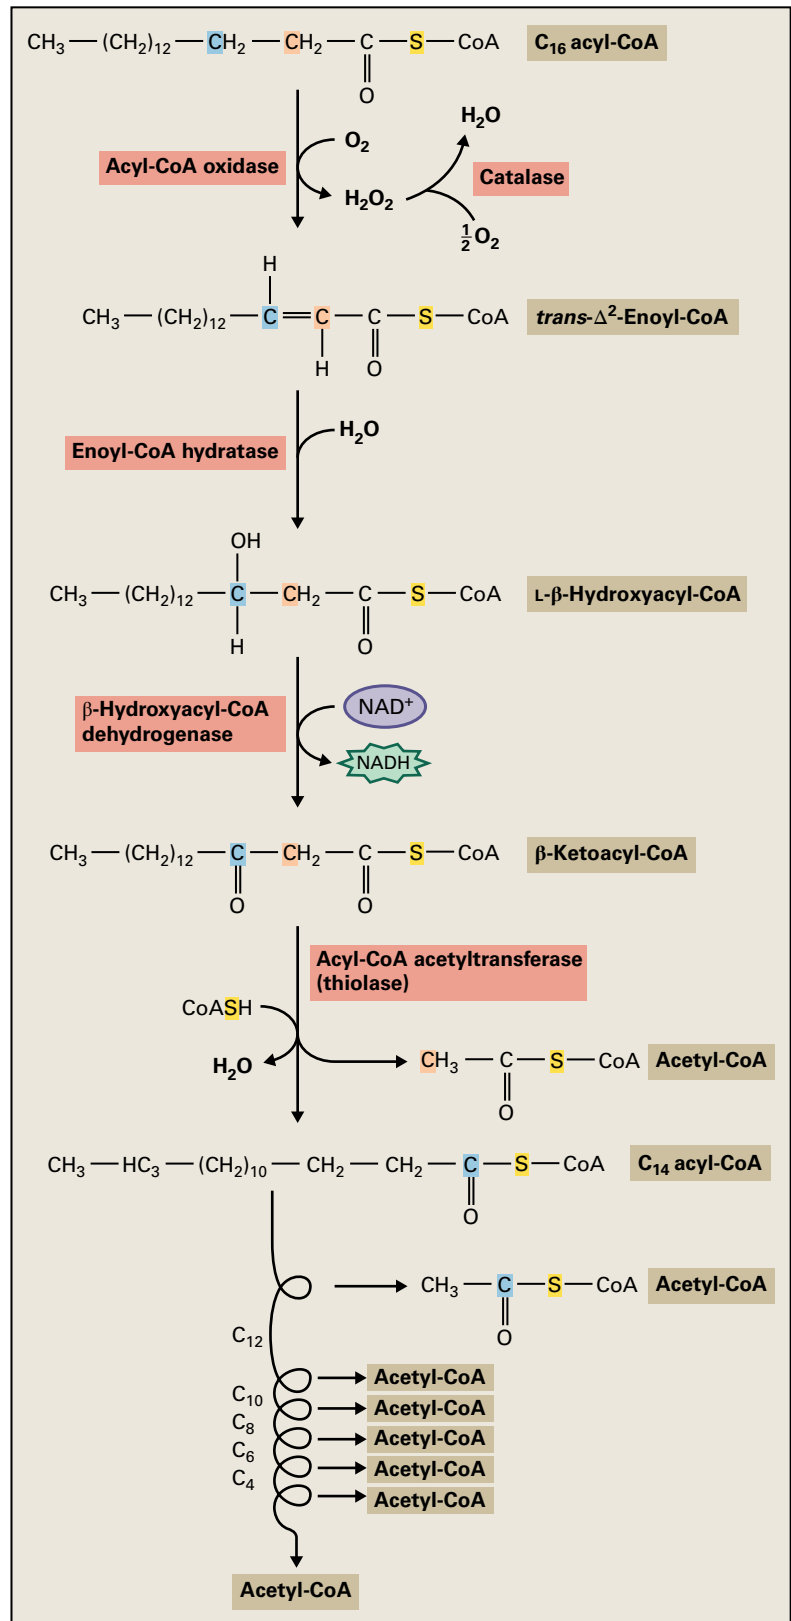

Rapeseed and many other members of the Brassicaceae, as well as some other species, contain large proportions of very-long-chain (20- to 24-carbon) monounsaturated fatty acids. These are synthesized by chain elongation of 18:1 ^{Δ^9} , as discussed earlier. Erucic acid (22:1 ^{Δ^{13}}), which accounts for about 50% of the fatty acids in rapeseed oil, can cause heart disease when included in the diet of laboratory animals. Although high erucic acid content made rapeseed oil useful for certain industrial applications, it prevented the widespread use of rapeseed as an edible oil crop. In the 1950s, an extensive search was made for varieties of *B. napus* with low erucic acid and glucosinolate content, another antinutritional component of oil from *Brassica* species (Fig. 8.67; see also Chapter 16). During a period of about 20 years, several natural isolates containing reduced amounts of erucic acid were identified, and the two loci responsible for the phenotype were introgressed into cultivars of *B. napus* by many rounds of back-crossing. To distinguish the cultivars that produced oil with low erucic acid (LEAR) from those with high erucic acid (HEAR) content, the LEAR cultivars are now called canola (Fig. 8.67). Expression of a 3-ketoacyl-CoA synthase in transgenic canola plants restored the high erucic acid trait. Thus, the two genes introgressed into *B. napus* to produce canola are now known to encode naturally occurring mutations in two genes for 3-ketoacyl-CoA synthase.

8.11.2 Edible oils can be improved by metabolic engineering

Approximately 20% of the calories consumed by humans in developed countries are derived from plant oils. The fatty acid composition of dietary oils, particularly the saturated fatty acid content, is believed to influence the etiology of major diseases such as atherosclerosis and cancer. Many attempts have been made to alter the fatty acid compositions of food oils and reduce the proportions of 16:0, 18:0, 18:2 ^{$\Delta^{9,12}$} , and 18:3 ^{$\Delta^{9,12,15}$} in favor of 18:1 ^{Δ^9} . The move to develop monounsaturated oils is based on epidemiological data and laboratory experiments that suggest these oils reduce atherosclerosis (and associated heart attacks and strokes) by increasing the ratio of high-density lipoproteins to low-density lipoproteins in the blood. Furthermore, oils low in 18:2 ^{$\Delta^{9,12}$} and 18:3 ^{$\Delta^{9,12,15}$} are much more stable, particular in high-temperature food frying.

The targets for reducing polyunsaturates are the 18:1 ^{Δ^9} - and 18:2 ^{$\Delta^{9,12}$} desaturases of the ER, which, in *Arabidopsis*, are encoded by the *FAD2* and *FAD3* genes. Isolation of these genes by **gene-tagging** (*FAD2*) and **map-based**

FIGURE 8.66 β -Oxidation pathway in peroxisomes. In each pass through the sequence, one acetyl residue is removed in the form of acetyl-CoA from the carboxyl end of an acyl-CoA. Seven passes through the cycle are required to oxidize a C_{16} fatty acid to eight molecules of acetyl-CoA.

cloning (*FAD3*) in *Arabidopsis* led quickly to identification of analogous genes in soybean, canola, and other crops, enabling genetic engineering of edible oils with improved nutritional properties. One success involves cosuppression

of the oleoyl desaturase in soybean, which increased oleic acid levels from less than 10% to more than 85% of the total fatty acids; at the same time, saturated fatty acids were reduced from more than 15% to less than 5%. Oil from

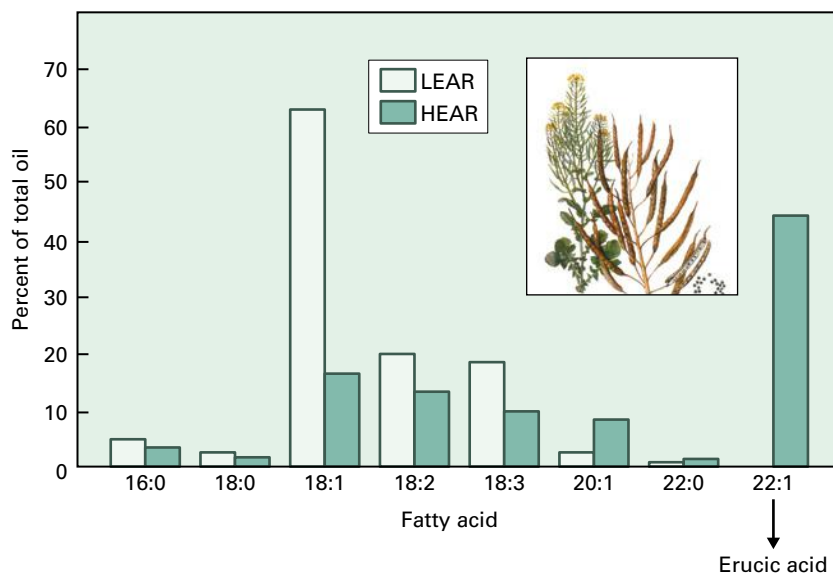

FIGURE 8.67 Fatty acid composition of seed oil from high and low-erucic acid rapeseed (HEAR and LEAR, respectively) varieties. Additional improvements by plant breeding have reduced the 18:3 content of the most recent cultivars to a small percentage of the total fatty acids, with corresponding increases in the 18:1 content. Rapeseed is the major oilseed crop of Europe, Canada, and many countries with short growing seasons. After soybean and oil palm, it is the world's third largest source of vegetable oils. Varieties that have been bred to contain low amounts of erucic acid are referred to as canola. Because of its high oil content (45% of seed weight) and relative ease of transformation, canola has become the first crop genetically engineered to produce new oils.

these soybean varieties is similar in composition to olive oil and has both improved health benefits due to the reduction in omega-6 fatty acids and improved oxidative stability. Mutation breeding programs have also led to the production of high-oleate lines of canola, sunflower (*Helianthus annuus*) and other oilseed crops.

The 20- and 22-carbon ω -3 fatty acids in fish oils, particularly eicosapentaenoic acid and docosahexaenoic acid, have health benefits that include likely reductions in heart disease, stroke, and other metabolic syndromes. Producing these fatty acids in seed oils is an attractive goal in oilseed engineering and has been achieved by the transgenic expression of a condensing enzyme (3-ketoacyl-CoA synthetase) to catalyze fatty acid elongation and up to three fatty acid desaturases (Δ 6-, Δ 4-, and ω -3 desaturase). This type of multienzyme pathway engineering is complex, but the availability of suitable genes from many animals and microbes allowed the testing of several different enzyme combinations. Some transgenic lines produce >20% of the target ω -3 polyunsaturated fatty acids and represent examples where plant genetic engineering may contribute substantially to improving health benefits of some foods.

8.11.3 Molecular genetic approaches have been used to increase oil yields

In addition to efforts to modify the types of fatty acids produced in plant seeds, there is considerable interest in increasing the yield of oil obtainable from oilseed crops. But a major

unanswered question in plant lipid metabolism remains: What determines the quantity of oil stored in a seed? In addition to its interest to basic researchers, this question is of considerable practical importance if chemicals or fuels derived from oilseeds are to compete economically with petrochemical alternatives.

More than 30 reactions are required to convert acetyl-CoA to triacylglycerol, so many genes could control the yield of the end-product storage oil. Several approaches have resulted in increased oil content in seeds. For example, expression of diacylglycerol acyltransferase in soybean or rapeseed increased seed oil content and overexpression of the *WRINKLED1* (*WRI1*) transcription factors also led to a higher level of oil in seeds.

In addition to their major use as food, plant oils are also considered as a source of fuel such as "biodiesel." Methyl esters of plant fatty acids have similar performance characteristics as petroleum-derived diesel fuel but produce less greenhouse gas and lack some pollutants produced by burning diesel fuel. In Europe approximately 12 billion liters of biodiesel were produced in 2014. Nevertheless, due to the large quantities of transportation fuel needed, this biodiesel accounted for less than 5% of the total fuel market. Greater production might be possible from perennial tropical species such as oil palm (*Elaeis* sp.) that produce as much as 4,000 liters of oil per hectare per year with low inputs of agrochemicals. If it becomes possible to genetically engineer oil palm, or expand its range, it may be viable to produce fuels and chemicals from a renewable source at a cost that is competitive with petroleum.

8.11.4 Fatty acids have numerous industrial applications

Soybean, palm, rapeseed, and sunflower oils account for approximately 80% of the world production of vegetable oil, with approximately 140 million metric tons of oil consumed in 2011. Most plant-derived oil is currently used for food, and over 90% of the fatty acids found in food oils are restricted to four structures: 16:0, 18:1, 18:2, and 18:3. However, nonfood industrial uses of plant lipids include the manufacture of soaps and detergents, paints, varnishes, lubricants, adhesives, and plastics (Table 8.6). These nonfood uses often depend on the special physical and chemical properties of “unusual” fatty acid structures that are not found in oils consumed for food. The largest nonfood use, by volume, is lauric acid (C₁₂) from coconut and palm kernel for the production of detergents and soaps. The castor plant produces ricinoleic acid (12-hydroxyoctadecenoic acid), which is used for the production of a wide variety of compounds. For example, ricinoleic acid can be pyrolyzed to sebacic acid, which is used to produce certain types of nylon. The lithium salts of sebacic acid are also used as high-temperature greases for jet engines. Erucic acid from rapeseed is used to make erucamide, a slip agent in the plastics industry that makes plastic films and other products easier to handle.

At present, genetic engineering of oilseeds is concerned with altering the quality of oil produced in temperate crops. An immediate goal is to expand the range of fatty acids available from crop species so that the uses of plant fatty acids can be expanded.

8.11.5 High-lauric-content rapeseed: a case study in successful oilseed engineering

Many of the unusual fatty acids found in nature have important industrial uses; however, the plants producing them are often poorly suited for high-production agriculture. As an

alternative, the isolation of key genes directing the synthesis of a particular fatty acid can provide the means to genetically engineer agronomically suitable oilseed crops to produce the desired oil more easily and cheaply. The acyl-ACP thioesterases were the first enzymes of lipid biosynthesis for which genes were engineered and introduced into transgenic plants to produce a commercial product. A major ingredient of soaps, shampoos, detergents, and related products are the surfactants derived from lauric (12:0) and other medium-chain fatty acids that are obtained from coconut or palm kernel oils grown in the tropics. Worldwide, several billion dollars worth of such oils are used for production of surfactants. In part because of periodic price instability in these raw material supplies, a long-term goal of the surfactant industry has been to establish a temperate crop that could produce medium-chain fatty acids. Such a crop could provide alternative supplies and thereby lower or stabilize prices.

The advent of plant gene transfer techniques raised the question of whether temperate oilseed crops could be engineered to produce medium-chain fatty acids and other novel fatty acid compositions with the use of foreign genes. For example, it was unclear whether addition of new, unusual fatty acids might disrupt lipid metabolism, or some other process, in oilseed cells. More specifically, would a new fatty acid such as lauric acid be correctly targeted to triacylglycerol and excluded from membranes?

Research led first to biochemical demonstration of the existence of medium-chain acyl-ACP thioesterases and then to the cloning of a 12:0-ACP specific thioesterase from the California bay tree (*U. californica*). Introduction of a single gene encoding the 12:0-ACP thioesterase into transgenic plants dramatically altered the chain length of fatty acids stored in the seed oils. In 1995, the first commercial production of a genetically engineered oil was obtained when about 1 million pounds of oil was extracted from rapeseed plants engineered to produce 40% to 50% lauric acid (Fig. 8.68).

TABLE 8.6 Some nonfood uses of plant fatty acids. In all cases the genes responsible for synthesis of the specialty fatty acid composition in these oils have been identified.

Lipid type	Example	Major sources	Major uses
Medium-chain	Lauric acid (12:0)	Coconut, palm kernel	Soaps, detergents, surfactants
Long-chain	Erucic acid (22:1)	Rapeseed	Lubricants, slip agents
Epoxy	Vernolic acid	Epoxidized soybean oil, <i>Vernonia</i>	Plasticizers, coatings, paints
Hydroxy	Ricinoleic acid	Castor bean	Coatings, lubricants, polymers
Trienoic	Linolenic acid (18:3)	Flax	Paints, varnishes, coatings
Wax esters	Joboba oil	Joboba	Lubricants, cosmetics

FIGURE 8.68 Expression of a cDNA from California bay that encodes a medium-chain acyl-ACP thioesterase (MCTE) under control of the seed-specific napin promoter (Napin-MCTE) diverts carbon into medium-chain fatty acids to produce an oil with high laurate content.

FIGURE 8.69 Reaction catalyzed by oleate hydroxylase. Analogously to the FAD2 oleate desaturase that produces linolenate, the oleate substrate is esterified to phosphatidylcholine during the reaction.

8.11.6 Expression of a glycerolipid hydroxylase from castor bean can drive synthesis of ricinoleic acid in transgenic plants

Ricinoleic acid (12-OH-18:1^{Δ9}) produced by castor bean is an extremely versatile natural product with industrial applications that include the synthesis of nylon-11, lubricants, hydraulic fluids, plastics, cosmetics, and other materials. However, castor bean contains ricin, an extremely toxic lectin (see Chapter 10, Box 10.1), as well as other poisons and allergens. In addition, agronomic problems result in poorer yields than other crops. As a result of these and other factors, castor bean is a minor crop grown mainly in nonindustrialized countries.

The successful cloning of a gene that encodes the hydroxylase responsible for 12-OH-18:1^{Δ9} synthesis from 18:1^{Δ9} relied on a detailed understanding of the biochemistry involved. For some time, the conversion of 18:1^{Δ9} to 12-OH-18:1^{Δ9} was thought to involve a single enzyme inserting a hydroxyl group

at the same position as the double bond introduced by FAD2 desaturase (Fig. 8.69). Consideration of the probable reaction cycle of the desaturases suggested that 12-OH-18:1^{Δ9} might be produced by a stalled desaturase. Partial sequencing of randomly chosen cDNAs from a library derived from developing castor bean endosperm identified a relatively abundant cDNA that encodes a protein with homology to the glycerolipid desaturases of other oilseeds. Expression of the castor bean cDNA in transgenic *Arabidopsis* and other plants led to the synthesis of 12-OH-18:1^{Δ9} in seed tissues.

Unfortunately, when a transgene encoding a fatty acid modification enzyme is expressed in a heterologous host, accumulation of derivatized fatty acids is far less than in the species from which the gene was cloned. While castor oil contains >90% ricinoleate, transgenic *Arabidopsis* expressing the castor hydroxylase contain a maximum of only 17% hydroxy fatty acids in the seed oil. Understanding and overcoming the factors limiting accumulation of novel fatty acids is currently the major challenge in oilseed engineering. It is likely that accumulation of ricinoleic acid in castor bean seeds required

not only the evolution of the hydroxylase enzyme from an ancestral FAD2 desaturase (Section 8.6.2), but also the coevolution of one or more of the enzymes of lipid synthesis to efficiently incorporate ricinoleic acid into triacylglycerol.

Summary

Lipids have diverse and essential roles in plants. As the hydrophobic barrier of membranes, they are essential for integrity of cells and organelles. Surface lipids protect plants from desiccation and from pathogen attack. In addition, they are a major form of chemical energy storage in seeds and are now recognized as a key component of some signal transduction pathways. Most lipids, but not all, contain fatty acids esterified to glycerol, and consideration of this area of metabolism involves, first, the synthesis of the fatty acid and, second, the assembly of a range of glycerolipid structures after esterification of two or three fatty acids to a glycerol backbone.

Fatty acid biosynthesis in plants is carried out in the plastid and begins with the carboxylation of acetyl-CoA by acetyl-CoA carboxylase to produce malonyl-CoA. This is the first committed step of the pathway and is a major site for biochemical regulation of fatty acid production. Acetyl-CoA and malonyl-CoA are subsequently converted into fatty acids by a series of reactions that add two carbons at a time to a growing chain. Acyl carrier protein is a 9-kDa cofactor protein that transports the intermediates of fatty acid synthesis through the pathway. Three condensing enzymes with different chain length specificity are required to assemble the 18 carbon fatty acids that are the major product of plastid fatty acid synthesis.

The first double bond is introduced by stearoyl-ACP desaturase, a soluble plastid enzyme unlike all subsequent fatty acyl desaturases that are membrane proteins localized in the ER or the plastid. Fatty acid biosynthesis can be terminated by hydrolysis of the thioester bond of acyl-ACP or by transfer of the acyl group to a glycerolipid. Free fatty acids released by the acyl-ACP thioesterases are exported from the plastid and converted to acyl-CoA at the plastid envelope.

There are two distinct pathways for the synthesis of membrane glycerolipids. The prokaryotic pathway, located primarily at the chloroplast inner envelope, uses 18:1-ACP and 16:0-ACP for the sequential acylation of glycerol 3-phosphate and synthesis of glycerolipid components of the chloroplast membranes. The eukaryotic pathway involves (a) export of 16:0 and 18:1 fatty acids from the chloroplast to the ER as acyl-CoAs and (b) their incorporation into phosphatidylcholine and other

In support of this hypothesis, it was shown that coexpression of a castor isozyme of acyl-CoA:diacylglycerol acyltransferase with the hydroxylase increased the hydroxy fatty acid content of *Arabidopsis* seed oil from 17% to nearly 30%.

phospholipids that are the principal structural lipids of all the membranes of the cell except the chloroplast. In addition, the DAG moiety of phosphatidylcholine can be returned to the chloroplast envelope and used as a second source of precursors for the synthesis of chloroplast lipids.

Membrane lipids serve as a hydrophobic barrier, delimiting the cell and dividing it into functional compartments. The membrane lipid composition also affects plant form as well as many cellular functions. For example, photosynthesis is impaired in plants lacking polyunsaturated membrane lipids, and lipid composition can affect chilling sensitivity and influence plant cell responses to freezing. In addition, membrane lipids function in signal transduction pathways and defensive processes.

Storage lipids play a distinctly different role from membrane lipids. Storage lipids are almost exclusively triacylglycerols and accumulate in discrete subcellular organelles called oil bodies. The mobilization and catabolism of triacylglycerols provides energy and carbon for seedling growth after germination. The catabolism of the fatty acids released from triacylglycerol occurs via β -oxidation in peroxisomes. Acetyl-CoA produced by β -oxidation is converted to sugars for seedling growth by the glyoxylate cycle.

Plants are capable of synthesizing unusual fatty acids, with more than 200 different fatty acids having been found in different species. Some of the enzymes that synthesize unusual fatty acids show close resemblance to common fatty acid enzymes, such as membrane-bound desaturases. These unusual fatty acids are found almost exclusively in seed oils, and it is thought that they may serve a defense function.

Although several key steps remain uncertain, plant biochemists have defined almost all the enzymatic reactions involved in the biosynthesis and degradation of the major lipid components of plant cells. Many of the remaining questions center on the regulation of lipid biosynthesis, the details of signaling, and the cellular organization and transport of lipids. Furthermore, of over 700 genes in *Arabidopsis* annotated as potentially involved in lipid metabolism, there remain at least 500 whose function has not been demonstrated experimentally.

Genome Structure and Organization

Christopher D. Town and Frank Wellmer

Introduction

The essence of every characteristic of a species, from its morphology to timing of senescence, resides in information stored in its DNA, its genome. Large-scale, relatively inexpensive DNA sequencing has yielded complete genome sequences for a large number of microorganisms and complete, or nearly complete, sequences for numerous higher eukaryotes, including many plant species. In this chapter, we present a DNA sequence-centric view of the plant genome, its organization, and the mechanisms by which the encoded genes are expressed and their expression regulated.

Most of an organism's genes reside on nuclear DNA; however, plastids and mitochondria also contain DNA, which encodes some of the gene products required for organelle function and reproduction (see Chapter 6). Several traits encoded by organellar genes are in commercial use in plant crops, such as cytoplasmic male sterility in sorghum (*Sorghum* sp.) and maize (*Zea mays*). Traits arising from organellar genes can be clearly recognized by their uniparental inheritance patterns, because in most species mitochondria and chloroplasts are inherited only through the maternal contribution to the seed.

In the 1950s, plant geneticists found that pieces of genetic material could move from place to place in the genome. These mobile genetic elements were subsequently found to be ubiquitous components of genomes. This raised the possibility that such mobile elements could be responsible for larger-scale genomic changes than the accumulation of single-point mutations, and that they could, in fact, facilitate evolutionary change. While genome sequencing has, in general, simply

added greater detail and specificity to what we have learned previously from genetics, cytogenetics, and molecular biology, there have also been major advances in the fields of epigenetics and the regulation of gene expression by families of small RNA molecules.

9.1 Genome structure: a 21st-century perspective

The first complete plant genome sequence, that of *Arabidopsis thaliana*, was published in 2000. Until then, our view of the structure and content of plant genomes was based on a number of techniques that had evolved over the entire 20th century. While informative, these techniques lacked the resolution provided by DNA sequencing. Some of these 20th-century methodologies and results are described here, followed by a description of the various approaches used for whole genome sequencing and the wealth of information and insights that these methods have generated.

9.1.1 Microscopy at progressively higher resolution reveals increasing detail of chromosome structure

Chromosomes were first visualized at the turn of the 20th century, and they were recognized as the bearers of a cell's hereditary material. As more became known about DNA,

chromosomes of higher eukaryotes were found to contain many centimeters, even meters, of double-stranded DNA molecules in compact chromosomal structures that, when visualized in cells at the metaphase of mitosis, are only microns in length. Increasing microscopic resolution allowed visualization of different features of chromosomes at a level that can now, to some extent, be described in terms of DNA sequence (Fig. 9.1).

Visualization of mitotic metaphase chromosomes using light microscopy reveals their basic features: the centromeres (responsible for orderly segregation of sister chromatids at mitosis), the chromosome arms, and the telomeres (tips of the chromosomes) (Fig. 9.1). Chromosomes can be visualized in a less condensed state during the pachytene stage of meiosis; in fact, chromosomes at this stage are frequently used as the

substrates for fluorescence in situ hybridization (FISH, Box 9.1) to determine the chromosomal localization of particular types of DNA sequence. At this level of resolution, the distinction between hetero- and euchromatin is more evident, as are structures known as heterochromatic knobs. At the limits of resolution of light microscopy, DNA fibers can be visualized and either subjected to FISH (fiber-FISH) or even digested by restriction enzymes to produce an optical map.

For the highest levels of resolution, whole chromosomes can be visualized by scanning electron microscopy, and they can be partially disassembled to reveal the nucleoprotein scaffold to which the DNA strands attach. Ultimately, chromosomes can be resolved to a “beads on a string” level, which reveals how histones are involved in the packing of DNA into chromatin (see Fig. 9.1). The most basic level

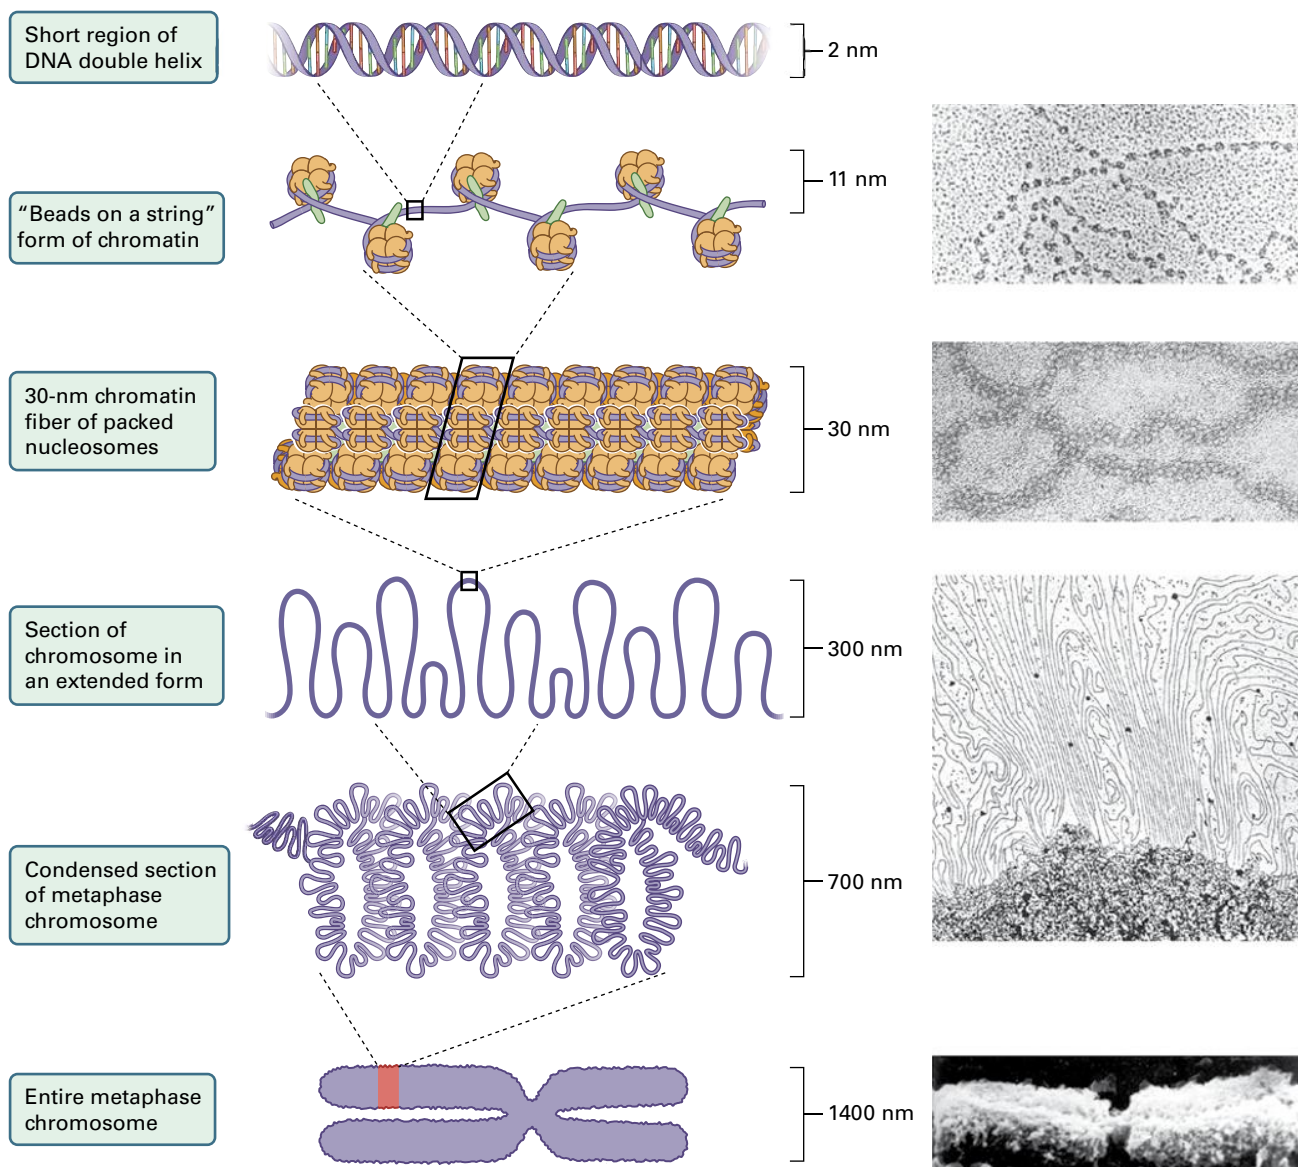

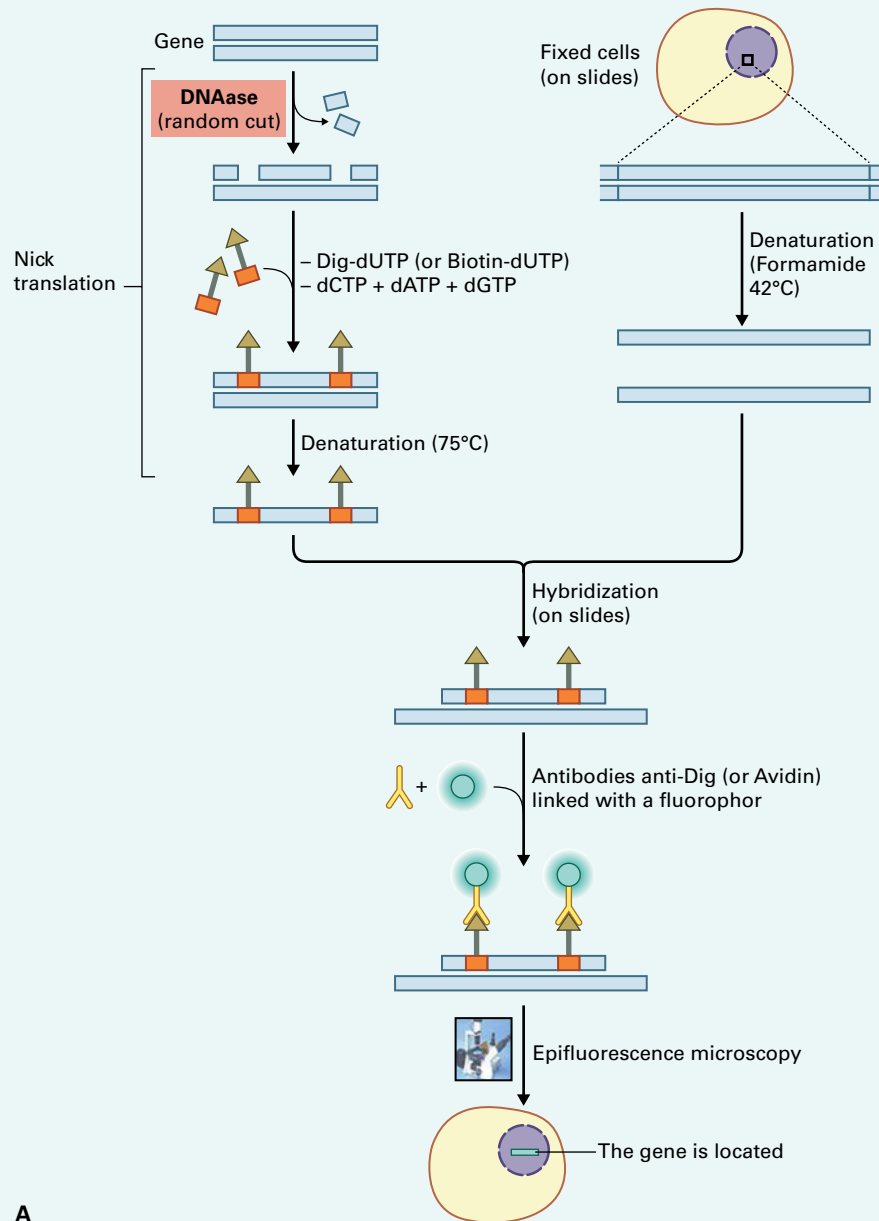

FIGURE 9.1 Organization of DNA and proteins into chromatin at different levels of condensation. The cartoons on the left show DNA, DNA wrapped around nucleosomes, packed nucleosomes, extended loops of packed nucleosomes, DNA as it might be condensed into metaphase chromosomes, and a complete metaphase chromosome. Images at right are scanning electron micrographs at different levels of resolution that can be inferred from the scales on the cartoons.

BOX
9.1

Fluorescence in situ hybridization is a technique used to localize DNA sequences on chromosomes

A

B

Fluorescence in situ hybridization (FISH) is a cytogenetic technique used to detect and localize specific DNA sequences on chromosomes. In FISH, DNA molecules representing a feature of a genome are labeled with a fluorescent dye, hybridized to chromosomes or DNA molecules immobilized on a glass slide, and then examined by fluorescence microscopy (A).

(A) Scheme of a FISH experiment designed to localize a gene to a particular chromosome. (B) Assignment of linkage group to chromosomes by FISH. For identification of chromosomes, pachytene preparations were probed with 5S rDNA (red) and *MtR1*, a repetitive element found near centromeres (green). Centromeres are indicated by arrowheads.

FIGURE 9.2 *C* values (haploid genome size in base pairs) from various organisms. Most eukaryotes have haploid genome sizes between 10^7 and 10^{11} bp of DNA.

of chromatin structure is the **nucleosome** array, called first-order condensation to distinguish it from subsequent higher-order condensation. A nucleosome consists of DNA wrapped two full turns (166 bp) around a globular octamer of histone proteins made up of two tetramers, each consisting of H2A, H2B, H3, and H4.

9.1.2 Genome size is highly variable among flowering plants

The size of the nuclear genome varies widely among organisms, with haploid DNA content (**C value**) ranging from 10^7 to 10^{11} base pairs (bp). The human genome is in the middle of this range, at 3×10^9 bp. Although it has been assumed that the apparent complexity of an organism correlates roughly with genome size—humans have larger genomes than most insects, and insects have larger genomes than fungi—this correlation is not universal. For example, some amphibians have genomes almost 50 times larger than that of humans, and cartilaginous fish generally have larger genomes than bony fish. Plant genomes are represented throughout the size range, with one of the smallest known plant genomes belonging to *Arabidopsis thaliana*, and one of the largest to a member of the lily family, *Fritillaria assyriaca* (Fig. 9.2).

In the mid-20th century, the term **C-value paradox** was coined to describe the lack of a direct relationship between

genome size and organismal complexity. With the sequence of many genomes in hand, the sequence features of different classes of DNA that contribute to the paradox are known, although their significance and contribution to organismal complexity are still not well understood. In plants, at least, some of the size variation can be attributed to one or more rounds of genome duplication, and often much more to the expansion of families of (retro)transposons, as well as to present-day polyploidy (see Section 9.3).

DNA sequencing has provided more accurate estimates for the sizes of plant genomes; however, for the many plant and animal genomes for which DNA sequence data are not available, estimation of DNA content in isolated nuclei stained with a fluorescent dye has become accepted as a reliable and quite precise measure of genome size.

9.2 Genome organization

9.2.1 Nuclear genomes contain unique, single-copy sequences as well as repetitive DNA

Before the advent of DNA sequencing, one method for studying a genome's sequence composition was Cot analysis (see Box 9.2). By this method, a genome could be divided into

BOX
9.2

Cot analysis can be used to quantify repetitive DNA in a sample

Cot analysis is a technique used to measure the amount of repetitive DNA in a sample. It is based on the principles of DNA reassociation kinetics and involves denaturing a DNA sample and then allowing it to reanneal and following the fraction of DNA remaining single stranded over time (which can be days for a complex DNA sample).

In a typical plot, the fraction of single-stranded DNA is plotted against the product of the DNA concentration at zero time (c_0) and the measurement time (t), hence the term "Cot." This is a second-order reaction in which single-stranded molecules must find their complement to renature. As genome size increases, the number of copies of each sequence per gram of DNA decreases, and hence renaturation takes longer.

(A) Reassociation kinetics of a series of homogeneous DNA samples of increasing complexity (length of unique sequence). For any single DNA species, reassociation is a second-order reaction as the separated single-stranded molecules seek out and reassociate with their complements. As the length of the molecular species increases, its molar concentration (for a fixed mass of DNA) decreases and hence reassociation takes longer. (B) Comparison of reassociation kinetics of *E. coli* and calf thymus DNA. (C) The complex reassociation curve for calf thymus DNA can be reconstructed as the sum of three simple second-order components, with different $Cot_{1/2}$ values present in different amounts as shown here.

three components: highly repetitive, intermediately repetitive, and single-copy DNA. Even with the large amounts of DNA sequence now available, these broad categories still provide a useful framework for thinking about plant genome structure, although the boundaries between each of these categories are fluid.

By definition, single-copy DNA is present in only one copy per haploid genome; in practice, this is now considered low-copy DNA. This class of DNA sequences contains almost all of the gene-coding sequences in a genome. However, in most plant genomes more than half of the genes belong to gene families of various sizes. Thus, depending upon the criterion of sequence similarity being considered (e.g., >80% nucleotide identity), closely related genes would hybridize in a reassociation experiment and align with high fidelity in an *in silico* analysis, and so would no longer be classified as single copy.

Highly repetitive DNA is easier to define, and a good example is the tandem repeats found in plant centromeres. Some highly repetitive sequences that have a base composition significantly different from the average for that genome were originally called satellite DNA, because they were found at a different buoyant density in cesium chloride density gradient separations; this name persists today. In most animals and yeast, satellite DNA is AT rich, but examples from plants tend to be GC rich. Satellite DNA is primarily associated with either the centromere, or the telomeres in plants, and it is usually heterochromatic; that is, it remains condensed and inactive in interphase.

Intermediate repeated DNA sequences generally occur in a few tens to tens of thousands of copies in the genome. There are many thousands of families of intermediate repeat DNA, with the members of any one family being very similar, but not identical. Considered in terms of classical Cot analysis, members of one family would cross-hybridize during reassociation experiments. These sequences would be 80% or more identical at the nucleotide level. Within this broad category of repetitive DNA, one can find transposons, retrotransposons, structural RNAs including ribosomal, transfer and other RNA species, and some large protein-coding gene families. A significant number of these families of repeated sequences occur as tandem repeats, as exemplified by the ribosomal RNAs in the nucleolar organizer region (NOR) and the 5S RNA clusters. Some examples of large protein-coding gene families that occur as tandem repeats are the histone genes and the disease resistance genes.

9.2.2 Genetic and physical maps provide complementary views of genome organization.

Genetic maps are essentially ordered lists of the distinctive features (markers) along each chromosome and the relative distance between them (determined by the frequency of recombination between them during meiosis). These markers may be based upon either DNA sequence or phenotypic traits (e.g., plant height, leaf shape, disease resistance, stress tolerance).

Where genetic maps have been aligned with sequenced genomes, there is excellent correspondence between the order of sequence-based markers in the genetic map and the occurrence of these marker sequences in the genome itself. In some genome sequencing projects, genetic maps can facilitate the ordering and orientation of DNA sequence assemblies. The alignment of a genetic map with the corresponding annotated genome sequence also allows identification of candidate genes that lie close to the position on the genetic map of a phenotype of interest (e.g., seed yield, oil composition, etc.). A variety of methods can then be used to determine which of the candidate genes may actually control the phenotype of interest.

While a genetic map defines a chromosome in terms of recombination among loci to give a relative genetic distance between them (genetic space), a **physical map** is an ordered representation of many large DNA fragments (typically ≈ 100 kb) into which the genome has been decomposed. Given the number and sizes of plant genomes of interest to researchers, a prelude to large-scale sequencing is often the creation of a physical map. High-resolution physical mapping uses cloned sections of DNA to create maps of contiguous, overlapping fragments of DNA that can span very long distances. The region defined by such a map is called a **contig**, since it is constructed from contiguous clones.

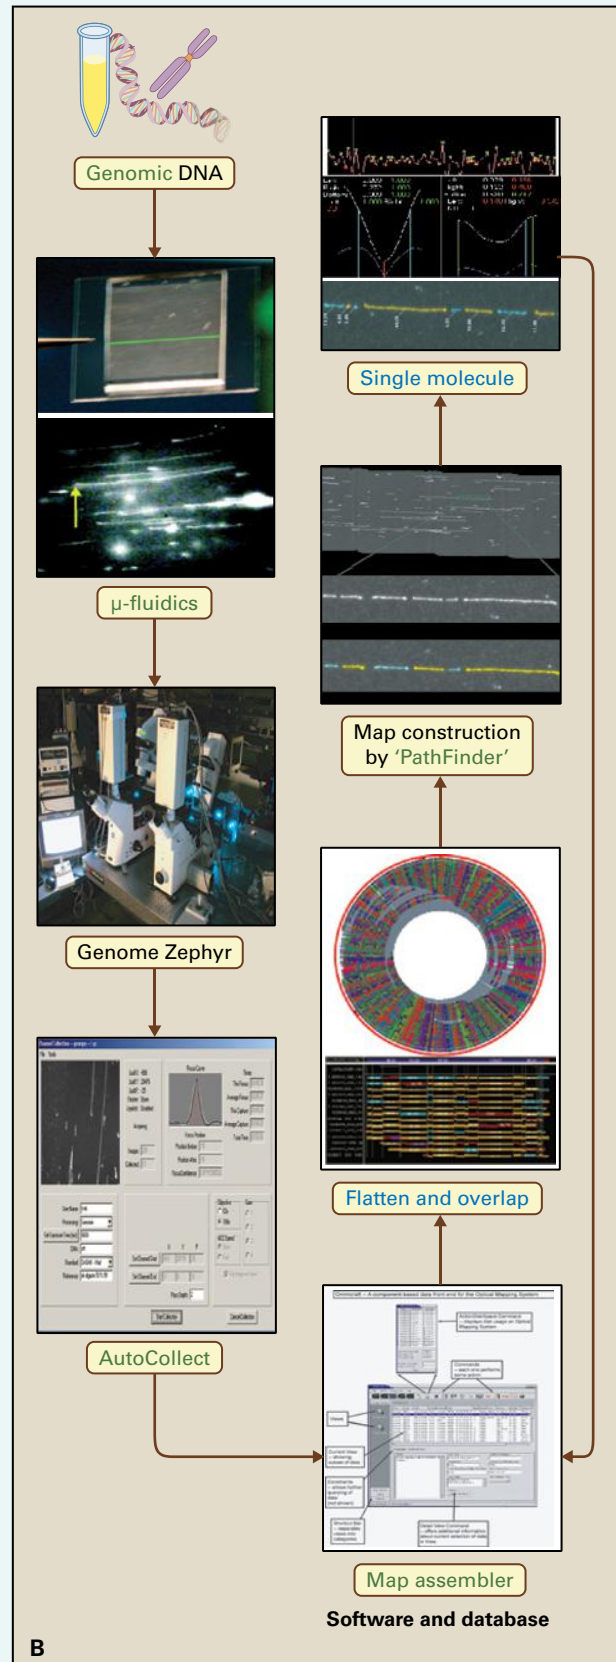

A common strategy for building a physical map involves the construction of a bacterial artificial chromosome (BAC) library. BACs are plasmid cloning vectors that use the replication origin of F-factors and so are propagated in *E. coli* as single (or very low copy) plasmids. The low copy number and use of recombination-deficient host cells contribute to the stability of the DNA molecules. Most BAC libraries have inserts of 100–150 kb genomic DNA, but larger insert sizes can also be generated. A technique called “fingerprinting” is then used to determine how these randomly cloned fragments overlap (see Box 9.3): The DNA of each BAC is digested with one or more restriction enzymes, and the sizes of the resultant fragments determined. Each BAC produces a characteristic set of fragments; two BACs overlap (their DNA inserts came from the same region of the genome) if they have a certain number of band sizes in common.

Originally, sizing was carried out on long agarose gels, but a newer technique, high information content fingerprinting, uses a combination of multiple restriction enzymes and four-color labeling, followed by resolution on a capillary DNA sequencing machine to produce a larger number of more accurately sized fragments and thus, a higher resolution map. This method of determining fragment overlap is being superseded by the generation of a set of sequence tags for each BAC using BAC pools and multiplexed sequencing (whole genome profiling, see Box 9.3).

Optical mapping (see Box 9.3) represents a further refinement of physical mapping. Here, isolated DNA molecules, typically a few hundred kilobase pairs in length, are immobilized on glass slides and digested with a restriction enzyme. Regardless of which method is used to tag each BAC or DNA fiber (band size or sequence), contigs of overlapping BACs or fibers are then assembled on the basis of shared tags.

BOX 9.3

The physical mapping of large genomes involves different methods

BAC fingerprinting. (A) (i) Bacterial artificial chromosome (BAC) library that represents 7–30 (or more) genome equivalents is constructed using a number of different restriction enzymes. (ii) Each clone is digested, and the resultant fragments are separated to produce a set of sized fragments, the DNA “fingerprint.” (iii) A full pairwise comparison of all clones is performed to detect the proportion of shared bands among each pair of clones, and contigs of overlapping clones are constructed. At high-stringency, some overlaps are not detected (blue bands indicate gaps in the assembly). (iv) End clones from each contig can be compared at a relaxed cutoff score to detect smaller overlaps. (v) The contigs are aligned to the genetic map using shared markers to verify the map and to further merge contigs. The pink boxes indicate BAC-end sequences that have been used as genetic markers to align contigs to the genetic map.

Optical Mapping. (B) High molecular weight DNA from isolated nuclei is gently spread and fixed on a slide

to produce long, isolated DNA fibers. The DNA is digested with an appropriate restriction enzyme, resulting in visible nicks in the DNA. The stained DNA is scanned with high-resolution automated microscopes, and the lengths of the succession of restriction fragments are profiled. Optical maps generally produce longer contigs (up to ≈ 50 Megabase pairs) than either the classical fingerprinting or whole genome profiling approach.

Whole genome profiling (C) (i) BAC clones are available in a 384-well plate format. (ii) BAC DNA is extracted after pooling each row (24 BACs) and each column (16 BACs). (iii) Pooled BAC DNA is digested (for example, with *EcoRI/MseI*) and amplified after barcoded adapters are ligated for pool identification after sequencing. (iv) Deconvolution: sequence tags (30–50 per BAC) are assigned to individual BACs based on presence in one row and one column pool. (v) Overlapping (sets of) sequence tags from individual BAC clones generate contigs. Together, these contigs represent a sequence-based physical map of the genome.

9.2.3 Plant genome sequencing has provided a high-resolution view of genome structure

The sequencing of plant nuclear genomes began in 1997, following the adoption of *Arabidopsis thaliana* as a model for plant genomics and the recognition of two features critical for success: a small genome (initially estimated to be ≈ 120 Mb) and relatively little repetitive DNA. Over the next decade, sequencing technologies, sequence assembly techniques, and genome-oriented bioinformatics improved significantly. As a result, larger and more complex genomes, such as that of wheat (*Triticum* sp., see Fig. 9.2) are being sequenced. The following discussion provides a basis for understanding the various methods used for generating sequences of a whole genome, as well as the advantages and limitations of the different methods. Embedded in this discussion are concepts of strategy and technology, with strategy changing as technology develops.

The first genome-sequencing projects used a BAC-based strategy (see Box 9.4), in which a physical map was constructed from BACs, and BACs were sequenced individually. Individual BAC sequences were assembled separately and then joined together based upon sequence overlaps, aided by physical and genetic maps, to form complete chromosomes (also known as pseudomolecules). Because this approach is labor intensive and requires sequencing of thousands of BACs, methods for whole genome shotgun (WGS) sequencing were developed (Box 9.4).

WGS, in which the whole genome is fragmented and DNA sequenced as a single preparation, became more feasible as

sequence assembly algorithms became increasingly sophisticated, and computers increasingly powerful. WGS has the disadvantage, however, that highly similar sequences arising from different parts of the genome co-assemble and, therefore, cannot be easily resolved. This problem remains with less expensive DNA sequencing technologies that have a higher output but also higher error rates and shorter read lengths.

In most genome projects, some effort is made to sequence the ends of various defined-size fragments to produce “mate pair” sequences that are often useful in resolving DNA repeats. It is, nevertheless, not uncommon to find that genomes with even modest amounts of repetitive DNA cannot be fully assembled, so a significant fraction of the genome remains uncharacterized as a collection of collapsed reads. Genetic and physical maps originally used to validate BAC-based sequenced genomes now play important roles in the ordering and orienting of genome assemblies that may contain hundreds to thousands of sequence scaffolds.

9.2.4 Genome annotation reveals the biological functions encoded in the DNA sequence

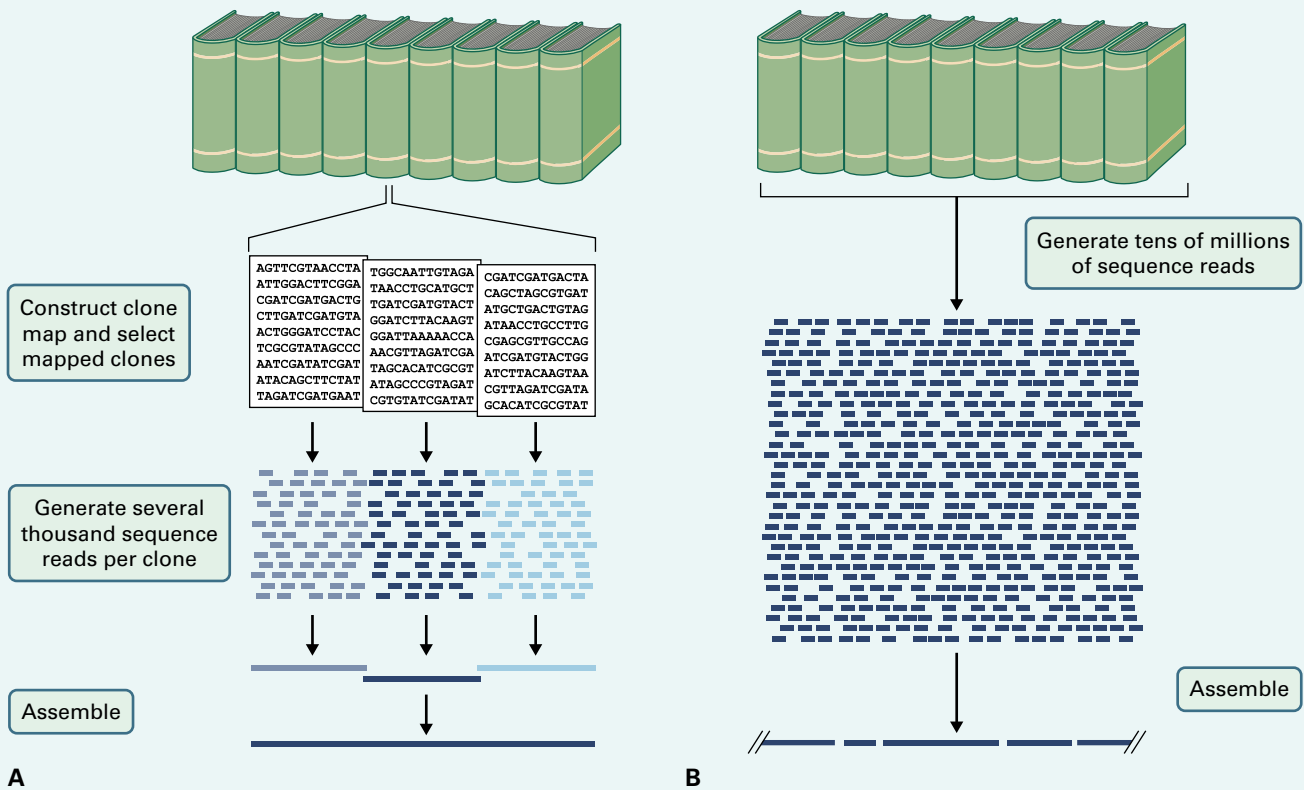

The DNA sequence alone is not particularly informative. **Genome annotation** is the process by which regions of the genome (DNA sequence) are recognized as encoding genes and the structure of the gene is defined (exons, introns, and other features) and its function inferred. Two general methods are used to define gene structures.

BOX
9.4

Genome sequencing involves different strategies

In a BAC-based sequencing project (A), genomic DNA is partially digested with restriction enzymes such that BAC clones each contain $\approx 100\text{--}150$ kb DNA. The clones are organized into a physical map (see Box 9.3), after which individual BAC clones representing a minimum tiling path through the genome are sequenced and used to reconstruct the genome. In a whole genome shotgun (WGS) approach (B), the entire genome is fragmented usually by sonication or hydrodynamic shearing followed

by size selection into pieces that vary according to the sequencing technology to be used. This collection of unordered fragments (numbering many millions) is then sequenced, and sophisticated assembly algorithms are used to reconstruct the entire genome. Although the assemblies produced by WGS approaches are generally slightly less accurate or complete, this approach is far less laborious or costly than the BAC-based approach, which has become essentially obsolete.

One method is based on available sequences of mRNAs (sequenced as cDNA) and proteins (generally inferred from nucleotide sequences, but sometimes also from direct protein sequencing). Various algorithms can be used to align pre-existing sequences to a new genome, and many of these algorithms can also recognize conserved splice sites (GT...AG; so-called spliced alignment) to define exon-intron boundaries. The most accurate gene structures are defined by full-length cDNAs that have captured the entire protein coding sequence of a particular gene. Alignments of nucleotide and protein sequences from other species are also informative, but become progressively less so as the evolutionary distance between the new genome and available sequence increases. Overall alignments between two related genomes can also be highly informative, as sequences that are conserved between

two genomes are thought to have functional significance and, thus, to encode either genes or regulatory sequences.

The second method for defining gene structures is strictly computational and relies on differences in base composition and adjacent nucleotide frequencies (di-, tri-, tetranucleotides, etc.) and their transition probabilities between exons, introns, and intergenic sequences. These sophisticated programs frequently involve hidden Markov models (HMMs; see Box 9.5) and are generally trained on a small, well-defined set of structures that have been identified in the new genome (or that of a close relative) using existing sequences.

Together, these two methods are used to identify gene structures throughout a new genome, both in regions where there is supporting evidence from nucleotide and protein sequences and in those where there is not. Gene structures

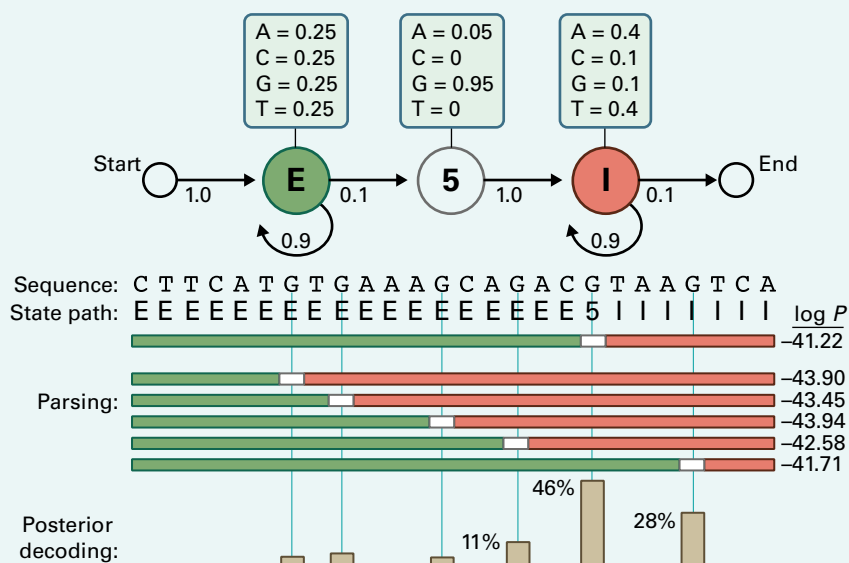

BOX
9.5

Hidden Markov models (HMMs) underlie many gene prediction programs

Hidden Markov models (HMMs) are statistical methods used to help define gene structures. In this example, the DNA sequence begins in an exon, contains one 5' splice site, and ends in an intron, as shown in the "state path." To infer where the switch from exon to intron occurs (i.e., the location of the 5' splice site), the sequences of exons, splice sites, and introns must have different statistical properties, including base composition and higher order oligonucleotide frequencies, etc.

Suppose exons have a uniform base composition (25% probability of each base), introns are A/T rich (for example, 40% each for A/T, 10% each for C/G), and the 5' splice site consensus nucleotide is almost always a G (for example, 95% G and 5% A). We can construct an

HMM that invokes three *states* we might assign to a nucleotide: E (exon), 5 (5' splice site), and I (intron). Each state has its own *emission probabilities* (shown above the states), which model the base composition of exons, introns, and the consensus G at the 5' splice site. Each state also has *transition probabilities* (arrows), the probabilities of moving from this state to a new state. The transition probabilities describe the linear order in which we expect the states to occur: one or more Es, one 5, one or more Is. In practice, HMMs are given training sets of genes with known structures (inferred from full-length cDNAs), from which transition probabilities can be calculated and gene structures predicted on new DNA sequence.

supported only by computational methods are considered unreliable predictions in some plant genomic communities.

Prediction of gene structures (Box 9.6) results in the definition of a protein coding sequence (CDS) for each gene. Assignment of function to these genes then relies upon their matches to other genes in databases such as GenBank or SwissProt. Here, the matching is done at the amino acid level, since protein sequences are generally more conserved across species than nucleotide sequence. The function of the database match is then transferred to the new protein. This method can result in potentially erroneous annotations because only a fraction of all the proteins in GenBank or similar databases have actually had their annotated function confirmed experimentally. This phenomenon of "transitive error propagation" is well recognized in the annotation community and will gradually decrease as the functions of more proteins are elucidated experimentally.

9.2.5 DNA sequencing has informed our understanding of genome organization at the DNA level

The organization of the *Arabidopsis* genome provides an excellent model and starting point from which to understand the overall structure of many plant genomes. The genome sequencing project produced approximately 105 Mb of DNA sequence, with the unsequenced portions around the centromeres estimated to be ≈ 15 Mb, for a total genome size of 120 Mb. Subsequent measures using flow cytometry have suggested that the amount of unsequenced DNA was larger, with a total genome size of ≈ 150 Mb, but this does not affect our description of the basic genome features, which are found in most of the other plant genomes. As with a number of plants and animals, the small genome size of *Arabidopsis*

BOX
9.6

Various kinds of evidence are used to support gene structure predictions

The support of gene structure predictions includes computational gene predictions, spliced alignments to the genome sequence of cDNAs, expressed sequence tags (ESTs) from the same species, and spliced alignments of proteins from the same or related species. The alignment algorithms are splice-site aware and, thus, identify and support the correct structure for the gene under study. The view shows an approximately 4.5-kb window along the minus strand of *Arabidopsis* chromosome 1 in the region encoding the 3-methylcrotonyl-CoA carboxylase 1 (At1g03090). The curated gene structures are shown in dark green on the white background towards the bottom of the window, with exons shown as solid

bars and introns and UTRs as open bars. The box with the black background above this curation shows the collective evidence (from bottom to top): splice site predictions, computational gene predictions, protein alignments shown in orange, EST alignments from searching the various plant Gene Indices in varied colors, and *Arabidopsis* transcript assembly alignments at the top shown in bright pink. The vertical marker line indicates the position of a skipped exon (supported by both cDNA and protein alignments) that results in two protein isoforms.

correlates with its short life cycle: Plants with larger genomes tend to reproduce more slowly.

The main features of the chromosome shown in Figure 9.1 can now be described at the DNA sequence level.

Most genes are found in the euchromatic chromosome arms

The chromosome arms stretching from the telomeres to the pericentromeric regions close to the centromeres comprise ≈ 100 Mb of sequence and are more or less uniformly gene rich. The *Arabidopsis* genome encodes approximately 30,000 protein-coding genes, as well as many transfer RNA (tRNA) genes and various classes of noncoding RNA genes with a

variety of regulatory functions. These numbers continue to increase as more small genes (both protein-coding and regulatory) are discovered. The average *Arabidopsis* protein-coding gene contains five exons and occupies approximately 2 kb of genomic sequence from start to stop codon. As described below, a gene's regulatory sequences may lie upstream, downstream, or within this region, although most promoter functions are typically found upstream of the transcription start site. Genes are separated by ≈ 2.5 kb of DNA (including regulatory regions), for a gene density of one gene every 4.5 kb. This is among the highest gene densities found in plants and is comparable to the genomes of *Brachypodium*, the moss *Physcomitrella*, and the unicellular *Chlamydomonas*. With few exceptions, only one strand of any particular region of the

FIGURE 9.3 Genes (protein-coding sequences) are found on either DNA strand, but rarely in the same region on both strands. Because transcription is always 5' → 3', genes on opposite strands are transcribed in opposite directions; transcription may be convergent or divergent. Note the orientation of the conserved splice site boundaries on the two strands. Green boxes represent the protein coding region of the transcripts (CDS), and blue depicts the 5' and 3' untranslated regions (UTRs). On rare occasions, two genes may occur in the same region of the DNA, but on opposite strands, with one gene lying within the intron of the other.

double helix actually encodes a protein. Thus, protein-coding genes may lie on either strand and be transcribed in either direction (Fig. 9.3).

Telomeres guard the ends of chromosomes

Chromosome arms end in telomeres, which are specialized structures that protect chromosome ends, ensure their faithful replication, and prevent the shortening of chromosomes during successive rounds of DNA synthesis (see Chapter 6). The canonical plant telomeric repeat (TTTAGGG) is found in almost all plant species for which this element has been sequenced. In *Arabidopsis*, telomeres are ≈2–3 kb in length.

In eukaryotes, a specialized enzyme called **telomerase** maintains the single-stranded overhang remaining after chromosome DNA replication to keep it from being shortened during each cell division (see Fig. 6.10). Telomerase is a reverse transcriptase with a segment of RNA integrated into its three-dimensional structure. The RNA functions as the template for the new telomere sequence. Telomeres also seem to function in maintaining “nonsticky” ends on the chromosomes. By contrast, according to cytogenetic analyses, the ends of broken chromosomes are very sticky, readily joining with any other available DNA fragment. Telomeres also appear to play a role in the organization of chromosomes in the nucleus, attaching the chromosome to the fibrous nuclear lamina on the inner surface of the nuclear envelope (see Chapter 5).

Centromeres are responsible for the precise segregation of chromosomes into daughter cells during division

Cytologically, chromosome centromeres (Fig. 9.4) are heterochromatic (highly condensed) chromatin constrictions to which the spindle fibers attach to facilitate the separation of replicated chromatids in mitosis and meiosis. Among the simplest of characterized centromeres are those of the budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*, which are only tens to hundreds of nucleotides in length. However, plant centromeres are almost invariably much larger and more complex. Analogous to the alpha satellite repeat that characterizes the centromeres

of human genomes, plant centromeres typically contain tandem arrays of one or more species-specific sequences, generally between 150 and 200 bp in length (approximately the length of DNA wrapped around a nucleosome). In addition, centromeres are rich in retrotransposon sequences. Despite information about their sequence content, the essential sequence components of plant centromeres are not well defined. Centromeres are better recognized by the proteins that bind to the DNA in this region, especially histone CENH3. Approximately 50 proteins are constitutively or transiently associated with yeast centromeres, and homologs of many of these are found in plants, including CENP-C, CENP-H-1 and CCAN, ASK, CBF5, and Bub-like proteins.

The size of the centromeres varies between species and even across chromosomes within an individual species, ranging from 50 kb to many megabases. Despite a limited understanding of the functional elements of plant centromeres, both DNA sequence and the associated proteins, it is becoming possible to construct artificial chromosomes capable of sustained autonomous replication and of moving parts or all of important metabolic or developmental modules into other varieties or species for crop improvement (Fig. 9.5).

The **pericentromeric regions** flanking the centromeres extend many megabases and have a low gene density, high content of transposons, and, predominantly, retrotransposons (see Section 9.3). Genetic recombination is also suppressed in these regions.

Genes encoding the RNA components of ribosomes are localized to a small number of genome regions

Nucleolar organizer regions (NORs) are cytologically identifiable regions of the chromosome around which ribosomal RNA transcription, biogenesis, and assembly occur. Ribosomal RNA (rRNA) is needed in such large quantities for ribosome structure and protein synthesis in active cells that it would be impossible for one or a few copies of rRNA genes to keep up with translational needs. At the DNA sequence level, these regions consist of many tandem repeats of an approximately 10-kb sequence that encodes the 28S, 18S, and 5.8S RNA components of the ribosome (Fig. 9.6). The coding

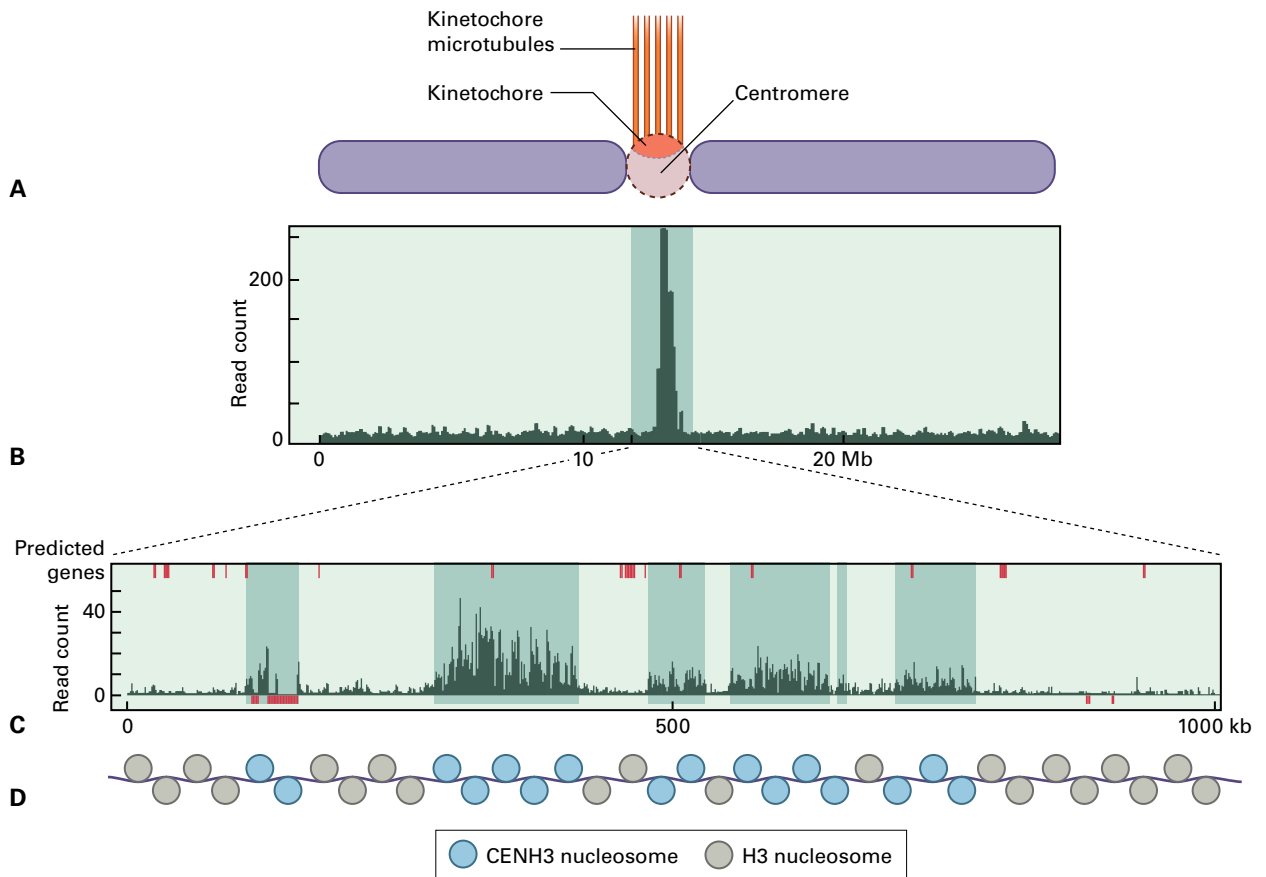

FIGURE 9.4 Structure of the centromere of chromosome 8 of rice (*Oryza sativa*). (A) General structure of a chromosome displaying chromosome arms (blue), centromere (red), kinetochore (yellow), and microtubules (purple). Only one sister chromatid is shown for simplicity. (B) Localization of CENH3 (a centromere-specific histone 3 variant) to the centromeric region deduced from ChIP-Seq (see Box 9.10) against CENH3 across the entire chromosome. The gray box indicates the crossing over-suppressed region of the chromosome. (C) Expanded view of the CENH3-binding domain. Predicted genes (red boxes) are located predominantly outside CENH3 binding domains (gray boxes), and the 155-bp centromeric repeat (CentO) arrays are shown as red boxes beneath the mapped reads. (D) Representation of nucleosome pattern across Cen8 in rice. Gray circles represent nucleosomes with canonical histone H3, and cyan circles represent CENH3-containing nucleosomes. Not drawn to scale.

FIGURE 9.5 Artificial mini-chromosomes carrying sets of genes can be constructed for plant genetic engineering.

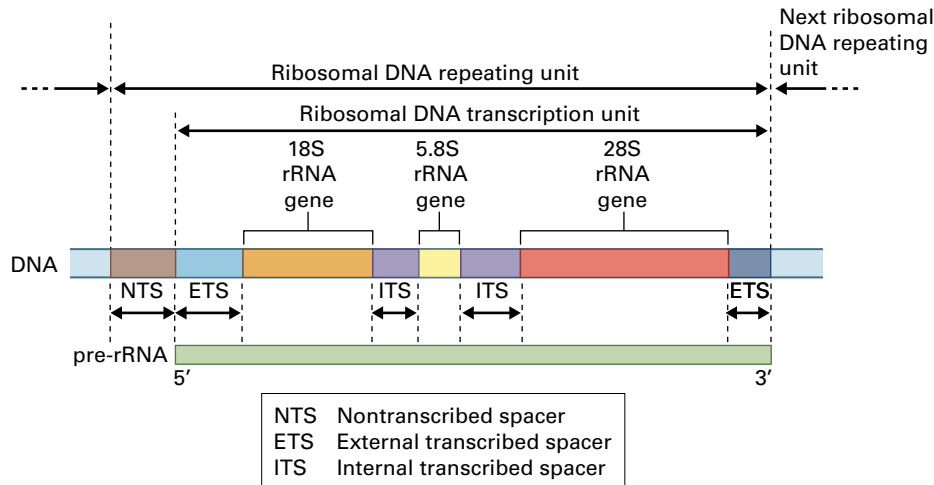

FIGURE 9.6 The eukaryotic ribosomal DNA repeating unit. Most plant ribosomal genes lie within a repeating unit ranging from 7,800 to 185,000 bp long. The repeating unit is composed of highly conserved rRNA genes separated by short stretches of spacer sequences that are not transcribed (NTS, ETS, and ITS). Ribosomes contain four distinct RNA molecules of sizes 18S, 5.8S, 28S, and 5S that contribute to their structure. Genes for the first three are contained on a rDNA repeating unit, whereas the 5S gene is found elsewhere in the genome.

FIGURE 9.7 Maize (*Zea mays*) chromosomes provide an example of heterochromatic knob(s). (A) A micrograph of a maize microsporocyte nucleus at the pachytene stage, showing the ten chromosomes and the nucleolus. (B) Schematic drawing identifying the chromosomes. In the pachytene stage, homologous chromosomes reside side-by-side and appear thick enough to enable the identification of individual chromosomes by their structural features (e.g., positions of centromere and knobs).

sequences of these three genes are highly conserved across species, but the intergenic transcribed spacer (ITS) is much more variable and has been used for exploring relationships between species. Each species typically contains only one or two NORs; their number and chromosomal location(s) being determined by FISH. The other RNA component of the ribosome (5S RNA) is also encoded in tandem arrays, but these are found at other chromosomal locations. In *Arabidopsis*, the principal 5S RNA gene clusters are found in the centromeric regions of chromosomes 3, 4, and 5.

Condensed chromatic can often be visualized as heterochromatic knobs

Heterochromatic knobs are recognized cytologically as regions of highly condensed chromatin separated from the centromeres. They are more common in plants with larger genomes, such as

maize (Fig. 9.7). The single heterochromatic knob in *Arabidopsis* lies on chromosome 4; it has been fully sequenced and found to consist in large part of retrotransposons.

9.2.6 Larger genomes are structurally more complex, with gene islands interspersed between large regions of repetitive sequence

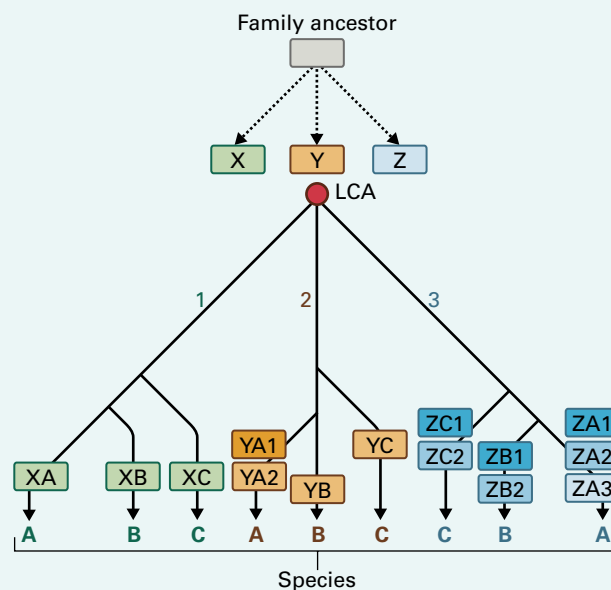

The structural features described above are common for many of the smaller plant genomes (<1 Gb); the maize genome, however, presents a somewhat different picture of genome organization that may also be characteristic of other large genomes of the Poaceae (grasses/cereals) and other families or genera. The maize (*Zea mays*) genome consists of approximately 80% repetitive DNA, much of which encodes

BOX
9.7

Homology, orthology, and paralogy are important concepts in plant evolution and speciation

Homologs are genes that share a common origin. From an evolutionary perspective, there are two types of homologous genes: orthologs are genes that originated from the same gene in the last common ancestor of the two species, and paralogs are genes that are related by duplication. Successive rounds of genome duplication can generate complex ortholog and paralog relationships.

In the figure, X, Y, and Z represent three paralogous genes that existed prior to the last common ancestor of the hypothetical tree. In branch 1, XA, XB, and XC in the three species A, B, C involves only vertical inheritance and the genes are orthologs. Branch 2 shows lineage-specific duplication in species A, such that YA1 and YA2 are paralogs (in-paralogs) within species A and co-orthologs to YB and YC. In branch 3, lineage-specific duplications or triplications in each species mean that ZA1–ZA3 are in-paralogs to each other and co-orthologs to ZB1–2 and ZC1–2. The situation can be further complicated by subsequent differential gene loss in individual lineages.

retrotransposons (see Section 9.3). In contrast to most plant genomes, which are organized into gene-rich euchromatic chromosome arms and gene-poor heterochromatic centromeres, the maize genome consists of gene islands within oceans of retrotransposons. The gene islands are small, containing from one to seven genes (an average of four) and covering ≈ 50 kb, with several times this distance between adjacent gene islands. While this model likely holds for other members of the Poaceae with large, highly repetitive genomes, such as wheat (*Triticum* sp.) and barley (*Hordeum vulgare*), it remains to be seen if it also applies to monocots outside the grasses or to large dicot genomes such as lettuce (*Lactuca sativa*), sunflower (*Helianthus annuus*), or onion (*Allium cepa*).

9.2.7 Ancestral genome duplications have played a major role in plant genome structure

Plant genome sequences provide striking and clear evidence of large-scale duplication events that may have occurred from a few to more than 100 million years ago (Box 9.7). Evidence for such events is frequently displayed in the form of a dot plot (Fig. 9.8), in which the coordinates of the two axes represent the position of a genome feature, and each dot represents a region of similarity between two parts of the genome. Dot plots are frequently performed in protein space, since these protein sequences are generally more conserved over greater evolutionary time than DNA sequences, thus permitting detection

and visualization of older duplication events. In a dot plot of a genome against itself, the central diagonal (if shown) simply represents the position of the same conserved feature on the two coordinates, while series of dots forming diagonals off this central line show evidence for segmental duplications.

The timing of genome duplication events can be inferred from the divergence of the two sequences. This is calculated as the synonymous substitution rate in protein-coding sequences (inferred from either genomic or EST sequences), which in turn is calibrated by cross-reference to fossil records. Synonymous substitutions refer to changes in the third base positions of codons that do not affect a protein's amino acid sequence and are thus not under selective pressure.

Basing plant evolutionary history on DNA sequence is becoming increasingly complex and sometimes controversial as data accumulate and more sophisticated methods of analysis are applied. Duplication events become progressively more difficult to detect as one looks further back in time. As more sequence divergence occurs, there may be successive changes at the same nucleotide position, making it increasingly difficult to recognize paralogous pairs.

Following genome duplication events, gene loss and changes in gene function are both possible. The terms subfunctionalization and neofunctionalization were first proposed many years ago in the context of the duplication of individual genes, rather than large-scale genome duplication. Subfunctionalization describes how the two progeny from an originally single copy gene may take on different roles that collectively amount to the same activity of the original gene,

FIGURE 9.8 Dot plot of the *Arabidopsis thaliana* genome against itself showing evidence of ancestral duplication events. Chromosomes are arranged in the order of descending size. Each dot represents a cluster of similar genes found at two different places in the genome. The lines circled represent a region at the bottom of chromosome 2 that is duplicated at the bottom of chromosome 3 (note the symmetry around the diagonal line that denotes self-identity). The figure was produced using the CoGe software suite.

FIGURE 9.9 Subfunctionalization and neofunctionalization. A single gene contains promoter elements that drive expression in both flowers and roots. After duplication and degeneration, there are three possible outcomes. Under the subfunctionalization scenario, each gene retains only one of the promoter elements and becomes specialized for expression in only one of the two organs. Under the neofunctionalization scenario, one of the promoter elements mutates (or the gene acquires a new element) that now drives expression in leaves. Under the third (nonfunctionalization) scenario, one copy of the gene is no longer expressed and is often referred to as a pseudogene.

both in terms of pattern of expression and biochemical activity. Neofunctionalization describes the situation where one of the duplicated genes takes on a function not previously associated with its parent gene (Fig. 9.9). These changes can occur in either the regulatory or structural (protein-coding) region of the gene. Once duplicated, at least one of the duplicate genes is free to diverge or evolve without maintaining its original function, which might be essential for survival of the organism.

9.2.8 Related plant species display evolutionarily conserved organization and arrangement of single-copy genes

Genetic mapping and genome sequencing projects have revealed that gene content and order along large segments of chromosomes are often conserved among related species in both the plant and animal kingdoms. This colinearity of genetic loci or genes is called **synteny**. The first striking example of synteny across multiple plant species was demonstrated for the grasses (Fig. 9.10A), but as more sequence-based genetic maps and sequenced genomes have been generated, it is clear that the same kinds of relationships can be found within other families, for example the Solanaceae (tomato, potato, pepper, eggplant, etc.) and the legumes (*Medicago*, *Lotus*, common bean, soybean, pea, etc.).

With more distant species, synteny is usually inferred from the order of presumed orthologous protein sequences, rather than directly from comparison of nucleotide sequences. An example of rice–maize synteny is shown in Figure 9.10B. The lengths of synteny blocks decrease as one compares progressively more distant species; however, even between species that lie in different families and diverged as much as 50 million years ago, or more, many short synteny blocks can still be found (known as microsynteny). Synteny is not only of academic interest, but can be used to exploit knowledge about a sequenced genome to infer positional and sequence information about a gene of interest in a related genome that may be considered too large for cost-effective sequencing (for example, leveraging information from the *Medicago truncatula* genome to identify a candidate symbiosis gene in *Pisum sativum*).

9.3 Transposable elements

Transposable elements are sections of DNA (sequence elements) that move, or **transpose**, from one site in the genome to another. These mobile DNA elements can make up a significant portion of the nuclear genome, and they carry genetic information with them as they transpose, making them important features of genome organization. Transposable elements from organisms as diverse as *Drosophila*, yeast (*Saccharomyces cerevisiae*), and maize (*Zea mays*) show a substantial conservation in organization, sequence, and mode of transposition and are classified according to their sequence organization and mode of transposition (Table 9.1).

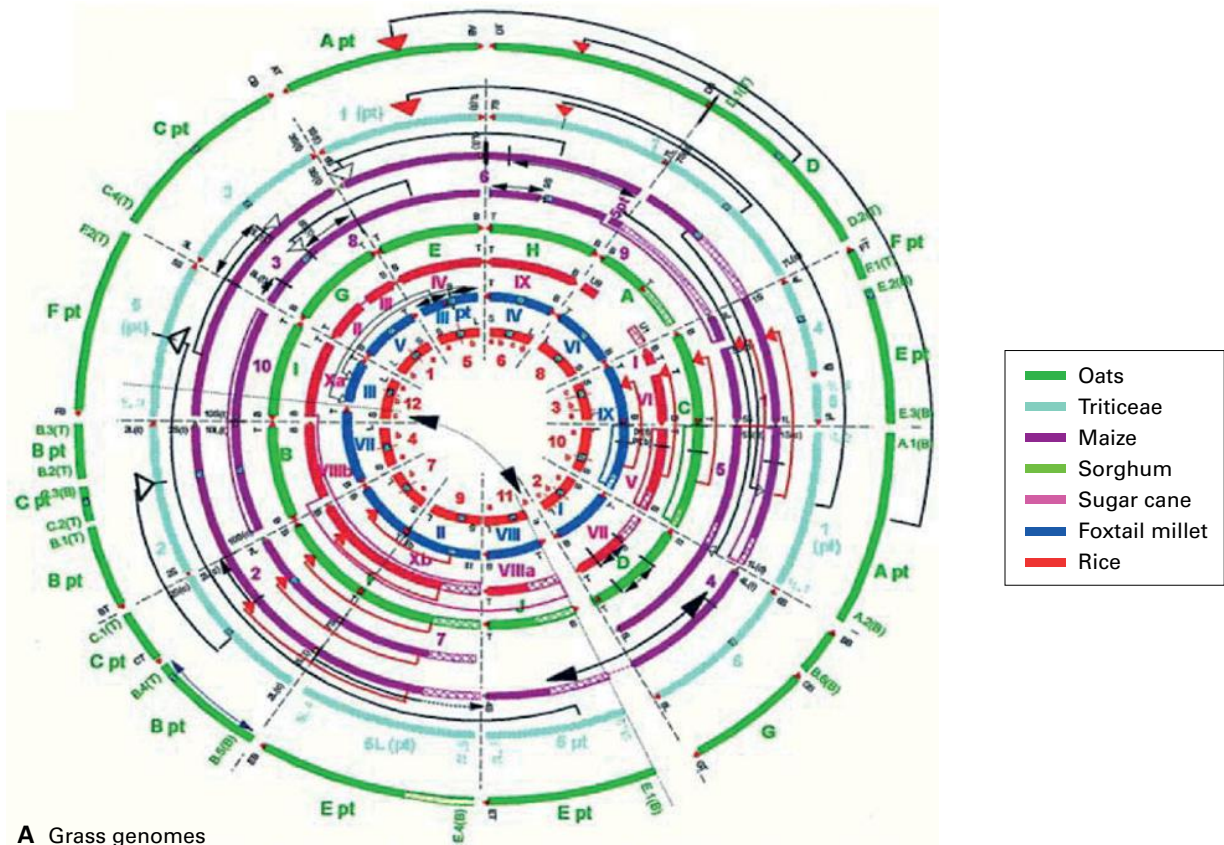

FIGURE 9.10 Synteny between different grass genomes. (A) Consensus grass comparative map. The data have been drawn from many sources: Oats–wheat–maize–rice; wheat–rice; maize–rice; maize–wheat; maize–sorghum–sugarcane; and foxtail millet–rice. Arrows indicate inversions and transpositions necessary to describe present-day chromosomes. Locations of telomeres (Δ) and centromeres (\square) are shown where known. Hatched areas indicate chromosome regions for which very little comparative data exist. Chromosome nomenclatures indicate arm (short/long or top/bottom). (B) A more detailed view of synteny between soybean and common bean is shown in the alignment of their genetic maps.

TABLE 9.1 Classification of plant transposons based upon structural features.

Order	Superfamilies	TSD
<i>Class I (retrotransposons)</i>		
LTR	Copia, Gypsy	 4-6
DIRS		 0
PLE	Penelope	 Variable
LINE	L1	 Variable
	I	 Variable
SINE	tRNA, 7SL	 Variable
<i>Class II (DNA transposons) – Subclass 1</i>		
TIR	Tc1-Mariner, hAT, Mutator, P	 2-11
PIF-Harbinger		
<i>Class II (DNA transposons) – Subclass 2</i>		
Helitron		 0
Structural features		
Long terminal repeats	Terminal inverted repeats	 Noncoding region
Diagnostic feature in noncoding region	Region that can contain additional ORF(s)	
Protein-coding domains		
AP: Aspartic proteinase	APE: Apurinic endonuclease	ENV: Envelope protein
GAG: Capsid protein	HEL: Helicase	INT: Integrase
RH: RNase H	RPA: Replication protein A	RT: Reverse transcriptase
YR: Tyrosine recombinase	Y2: YR with YY motif	Tase: Transposase (* with DDE motif)

TSD, target site duplications.

9.3.1 Retrotransposons are mobile elements that move via an RNA intermediate.

The two basic types of transposable elements are classified according to their mode of transposition: Class I elements transpose via an RNA intermediate and are known as **retrotransposons**, and LTR retrotransposons possess long terminal repeats and encode a GAG protein (involved in

the production of virus-like particles), a POL protein (reverse transcriptase) and sometimes also an ENV (envelope protein), frequently fused together as a polyprotein. Retrotransposons are likely viral in origin, as evidenced by their transposition mechanism, which proceeds through an intermediate in much the same way that a retrovirus replicates in a host genome (Fig. 9.11A), although there is scant evidence for actual viral particle intermediates in the case of

FIGURE 9.11 (A) Mechanism of retrotransposon transposition. The element to be transposed is copied (transcribed) into an RNA intermediate. This is reverse-transcribed into cDNA which is then inserted into a new location. (B) Structure and transposition of a class II transposable element. A common feature of transposable elements is the flanking of the element by short inverted repeat sequences. A model for transposition suggests that the enzyme transposase recognizes these sequences, creates a stem/loop structure, and then excises the loop from that region of the genome. A staggered cut is made at the new insertion site. After the transposon is inserted the single-stranded regions resulting from the staggered cut are filled in resulting in target site duplication.

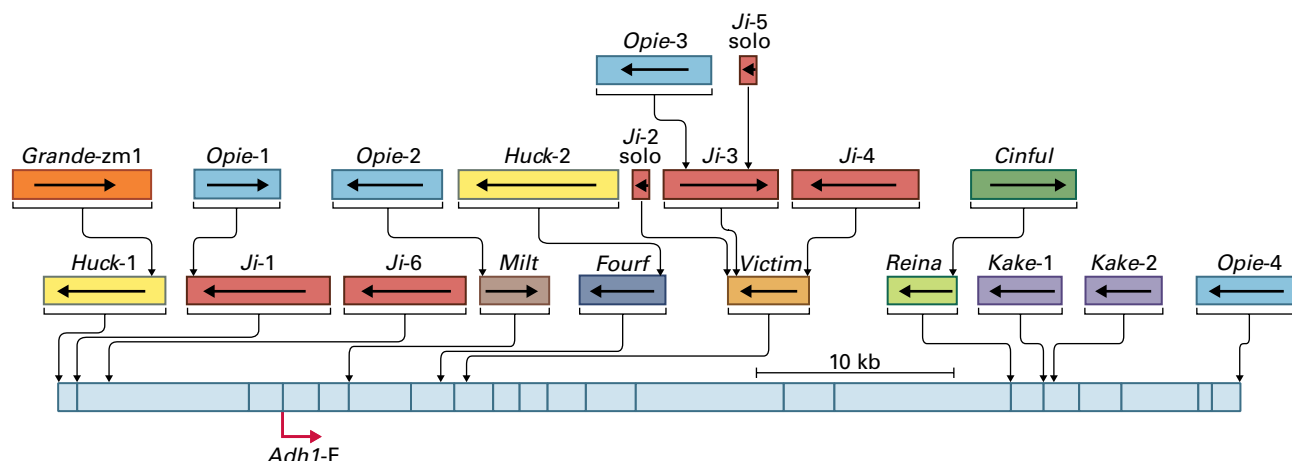

FIGURE 9.12 Multiple transposition events in the maize genome. Repetitive DNA sequences of the maize genome in the region around the *Adh1* gene. Retrotransposons make up much of the region of the maize genome around the *Adh1* gene. Classes of sequence motifs are named (e.g., Opie for blue) and have been placed on the map in the positions where the insertions occur.

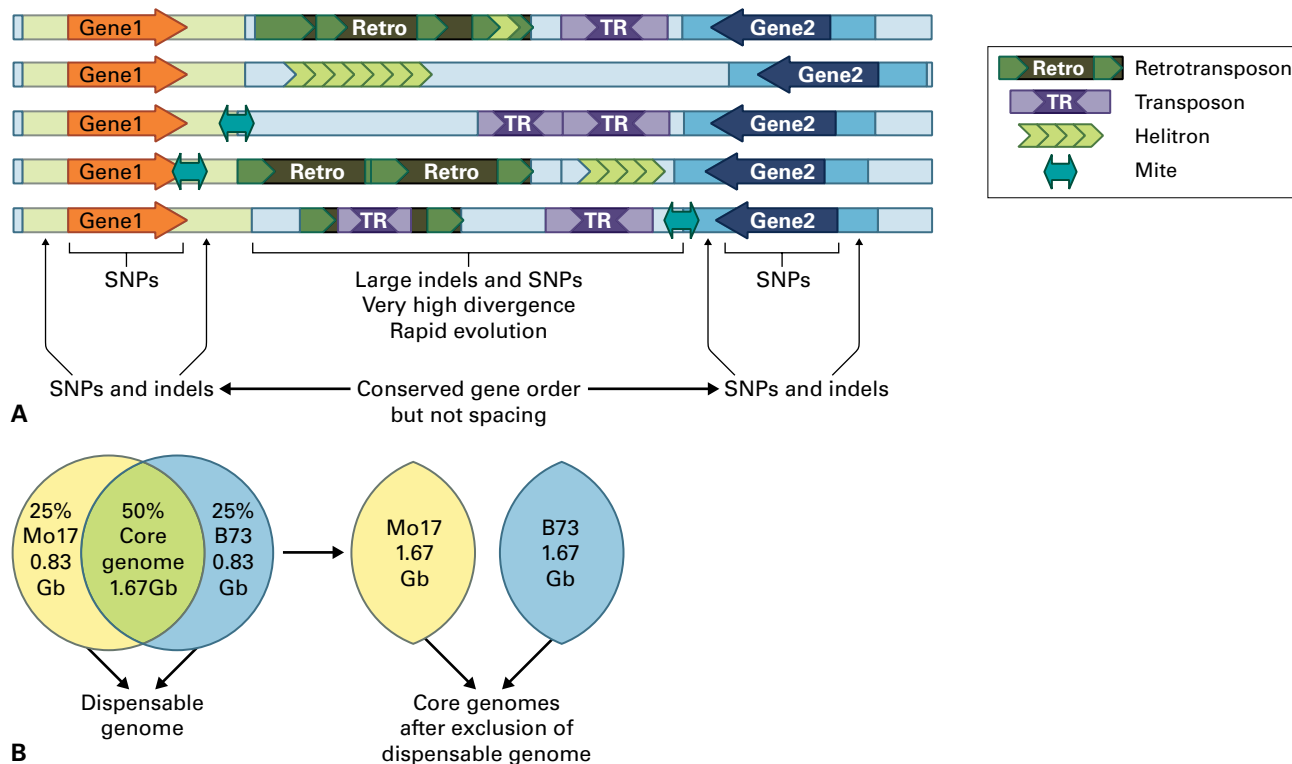

FIGURE 9.13 Diversity within different maize cultivars and the pan-genome concept. (A) Sequence variation in a short segment of the maize genome. Five different alleles of a short segment encompassing two genes are represented. (B) The pan-genome concept. About two-thirds of the maize genome is shared by the Mo17 and B73 cultivars, while the other one-third is unique to each cultivar.

plant retrotransposons. Class II elements are **DNA transposons** that transpose via a DNA intermediate and upon excision often leave an altered DNA sequence (footprint) behind at the original position (Fig. 9.11B).

In terms of quantity or copy number, retrotransposons (either active or degenerate versions thereof) greatly outnumber

DNA transposons in plant genomes. In large genomes such as those of cereals and other species, such as iris or lily, they can make up 50–90% of the genome. A now classic example of how transposons and transposon expansion can contribute to genome size can be seen in an analysis of a group of nested transposons found in the maize genome

(Fig. 9.12). By comparison of the sequence similarities between the LTR ends of the different members of this complex array of insertions, it was possible to determine the relative age of these events as this build-up occurred (the repeats at the ends of the most recent insertion event being most similar to each other while those at the ends of the oldest insertion event being most diverged).

Sequence analysis of multiple maize accessions has revealed surprising genome diversity. Although many accessions/varieties have the same genetic map (gene order), with only minor variations within genes, there is great sequence diversity between genes (Fig. 9.13A) as well as some variation in gene content, including copy number of multigene families. This kind of variation is likely to be found in other species in which there has been recent transposon activity (i.e., within the last few million years). As a result of this activity, not all members of a single species have the same genetic content. This has led to the concepts of a species' core genome and pan genome, originally proposed for bacterial species. The core genome refers to the set of genes shared by all members of the species, whereas the pan genome describes the total collection of genes in that species as a whole (essentially the intersection and union of each individual's genetic repertoire respectively; Fig. 9.13B).

Many regions of the genome classified as retrotransposon-related based upon their sequence are no longer functional retrotransposons due to sequence changes that disrupt their protein-coding ability. Some of these DNA sequences may still transpose under the influence of intact retrotransposons, and their promoters may also influence the expression of normal genes near their site of insertion into the genome.

Other class I transposons are LINES (long interspersed elements) and SINES (short interspersed elements). Full-length LINES range from 4 to 9 kb in length; their transposition requires element-encoded endonuclease, reverse transcriptase, and nucleic acid binding activities. SINES are small (80–500 bp) nonautonomous elements that use the LINE enzymatic machinery for transposition.

9.3.2 Maize DNA transposons were discovered as elements responsible for chromosome breakage and color variation

Class II elements (see Box 9.8) were the first to be discovered as the *Ac/Ds* transposable element system in maize (Fig. 9.14). The *Ac/Ds* system consists of two types of elements: the **autonomous element** (*Ac*; *activator*), and the **nonautonomous element** (*Ds*; *dissociator*). The *Ac* element is autonomous because it encodes all products required for its transposition in a 4.6-kb DNA sequence. The central region encodes a 3.5-kb transcript of the transposase that excises both *Ac* and all members of the *Ds* family. Inverted repeats of 11 bp on each end of the *Ac* DNA region function in

transposase recognition. In addition, when the element inserts into a new position in the genome, a pair of 8-bp direct repeats generated from the host genome is added to flank the element. These direct repeats, which remain fixed in the genome even after the element transposes out again, are referred to as a **footprint** of the transposition event (see Fig. 9.11B). Inverted repeats at the ends and footprints of insertion/excision events are characteristic of DNA transposable element families like *Ac/Ds*, but the size and sequences of these signatures are specific characteristics of each family.

Ds elements are a family of related DNA sequences recognized by the transposase encoded by *Ac*. They are nonautonomous because they do not encode their own transposase; rather, *Ds* transposition depends on the presence of *Ac* and its gene products. To date, seven different superfamilies of Class II transposons have been discovered in plants, and examples of at least some of these families are found in all plant genomes. MITEs (miniature inverted-repeat transposable elements) are short, nonautonomous DNA elements that are widespread and abundant in plant genomes and require transposases from other elements for their transposition. Most MITEs have been divided into two major groups on the basis of shared structural and sequence characteristics: *Tourist*-like and *Stowaway*-like.

9.3.3 Transposable elements can function in diverse species

Transposable elements from one species can also be active in other species, and this has given rise to the technology of **transposon tagging** to create gene disruptions and mutant phenotypes. For example, a tobacco transposon *TnT* has been introduced into *M. truncatula* by *Agrobacterium*-mediated transformation. Transposon-tagged lines can be screened for a phenotype of interest, after which the insertion site can be identified by target site rescue and sequencing. Alternatively, in the case of a sequenced genome, the location of random insertion sites can be identified by sequencing, leading to the identification of plant lines containing insertions in genes of interest.

9.3.4 Transposition events can cause mutations and changes in gene expression

Most plant genomes contain a small number of intact, potentially active transposons and a much larger number of defective elements. Transposition events can cause mutations. Unlike Class I elements, Class II elements generally produce unstable mutations. After excision, the impact of the residual target site duplication depends on its location in the regulatory or coding regions and on whether it allows restoration of a disrupted reading frame. Many of the variegated

patterns in flowers and in maize kernels are due to transposon excision events (Fig. 9.14). Transposons may affect the expression of neighboring genes, both by read-through transcription into the gene and by the spread of epigenetic silencing from the transposon into nearby regions of the genome (Fig. 9.15).

9.4 Gene expression

The development of plants and their ability to respond to changes in the environment depend largely on the readout of the information within their genome. This process of **gene expression** requires the transcription of genes into RNA and

in many cases the translation of these RNAs into the ultimate gene products—proteins. This section examines the molecular machinery that mediates gene expression and describes some of the most common regulatory mechanisms that control gene activities in plants.

9.4.1 RNA polymerases have distinct functions in the transcription of nuclear genes

RNA polymerases (RNAPs) are the enzymes that synthesize the different types of RNA found in plant cells. In plants, up to five different RNAPs mediate the transcription

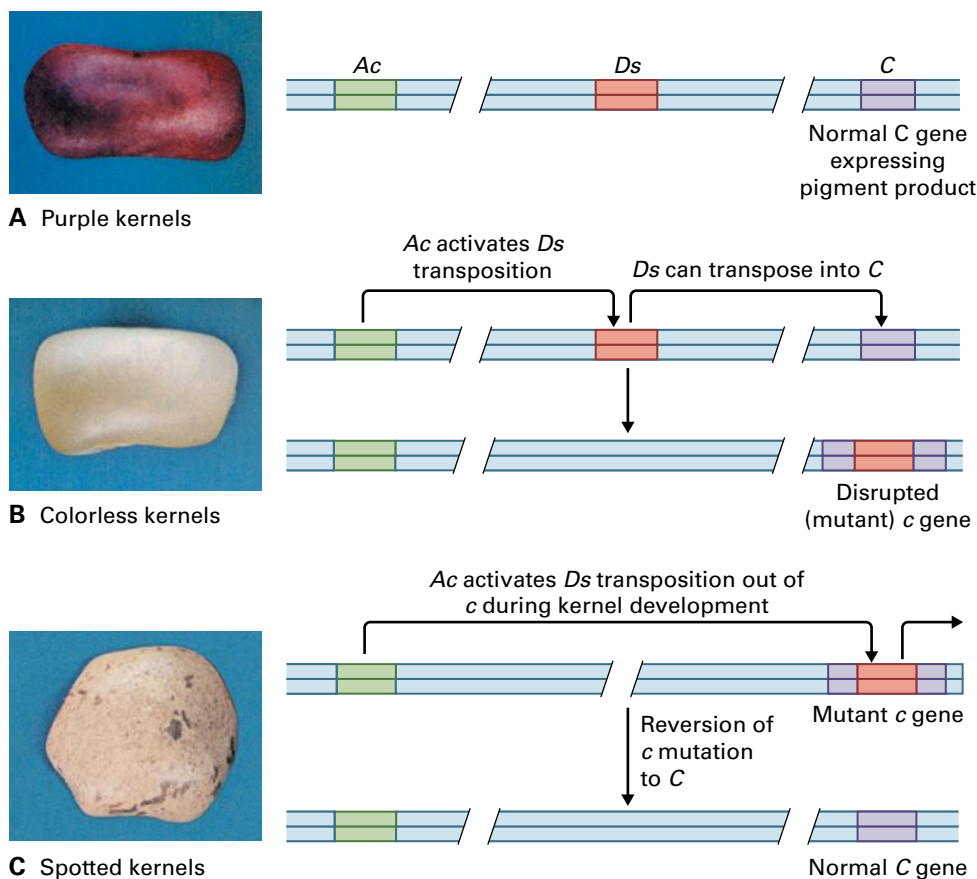

FIGURE 9.14 Variegated corn and effects of transposition of the color patterns in corn kernels. Barbara McClintock was the first scientist to recognize the existence of transposable DNA elements in the genome. She proposed that genes, or sections of genes, could “jump” from one position in the genome to another, based on her observations of the genetics of certain maize kernel phenotypes. The following example illustrates the progression of events: (A) The C gene encodes maize pigments that make the kernels purple, so when C is active, kernels are purple. (B) Ac encodes a transposase that mediates transposition of the Ds element. C is inactivated when the transposable element Ds is inserted into it, resulting in a colorless mutant phenotype (c). (C) If Ds is transposed (“jumps”) out of the mutant c gene during the course of development, C is restored to activity, and purple sectors are seen within a colorless background.

of genes in the nuclear genome, and additional RNAPs are responsible for transcription of organellar genomes (see Chapter 6). The nuclear RNAPs (designated RNAP I–V) have distinct functions and synthesize different types of RNAs (Table 9.2).

The role of **RNAPI** in gene expression is highly specific in that it only transcribes the 45S ribosomal RNA (rRNA) precursor, which is processed into 5.8S, 18S, and 28S rRNAs. Despite this limitation, RNAPI-mediated transcription accounts for up to 50% of RNA synthesis in growing cells.

RNAPII is responsible for the transcription of protein-coding genes and thus synthesizes messenger RNAs (mRNAs). In addition, it transcribes microRNA (miRNA) genes and synthesizes small nuclear RNAs (snRNAs), as well as *trans*-acting small interfering RNAs (ta-siRNA) (see Chapter 6). Because of its central importance for the expression of proteins, RNAPII has been studied extensively and its structure has been resolved in atomic detail (Fig. 9.16).

RNAPIII transcribes genes coding for transfer RNAs (tRNA), 5S rRNA, and a variety of other small RNAs.

RNAPIV and **RNAPV** have been discovered only relatively recently, and in contrast to RNAP I to III, which are present in all eukaryotes, appear to be plant-specific (RNAPV is only found in angiosperms, or flowering plants). Furthermore, these RNAPs are not essential for the viability of a plant, unlike RNAPs I, II, and III. The function of RNAPIV is to synthesize small interfering RNAs (siRNAs). RNAPV transcribes noncoding RNAs involved in siRNA-mediated gene silencing (see Chapter 6).

Because of structural differences, RNAPs differ in their sensitivity to inhibitors of transcription. For example, RNAPII is highly sensitive to α -amanitin, a cyclic octapeptide found in the *Amanita* genus of mushrooms and one of the main sources of mushroom poisoning. In contrast, RNAPI is insensitive to α -amanitin, and RNAPIII has intermediate sensitivity. RNAPIII can be further selectively inhibited by taigetoxin, a bacterial phytotoxin. Because of these differences in sensitivity, RNAP-specific inhibitors such as α -amanitin and taigetoxin are useful in distinguishing between transcripts generated by different RNAPs.

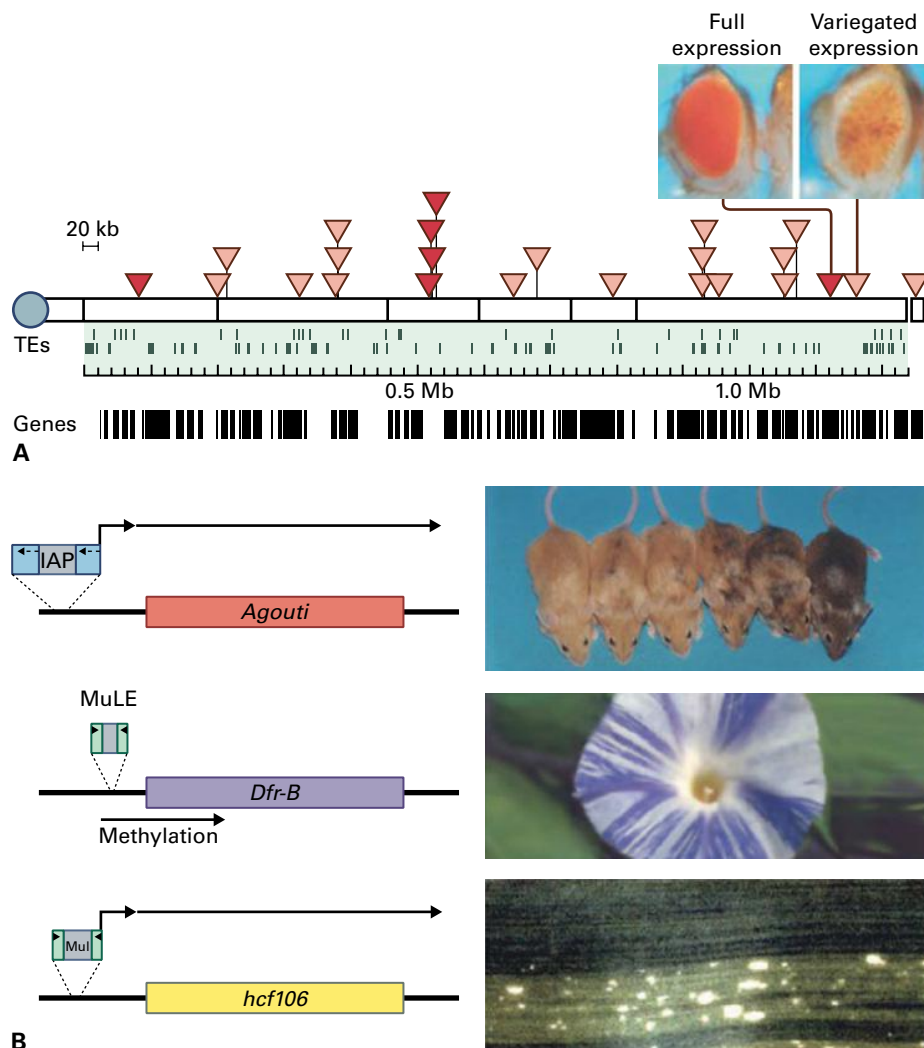

FIGURE 9.15 Transposable elements can have a variety of effects on nearby genes. (A) Position effect variegation in *Drosophila melanogaster*. The expression of a transgene conferring red eye color depends on its proximity to transposable elements. Solid red triangles indicate insertion sites that confer full red color in a white-eyed mutant, while transgenes inserted at sites shown by hatched triangles produce variegated eye color due to modulation of expression by nearby transposable elements. (B) Three examples of variegation induced by transposon insertion close to a protein-coding gene. In mice, the IAP retrotransposon produces an outward-reading transcript that extends into the *agouti* coat-color gene. The level of *agouti* transcript, and the color of the coat, is subject to the epigenetic status of the retrotransposon and is heritable. In morning glory (*Ipomoea* sp.) flowers, DNA methylation of a nonautonomous MuLE transposon can spread to the promoter of the dihydroflavonol reductase gene, creating petal-color streaks. In maize (*Zea mays*), the activity of one TE family regulates two epialleles. In sectors where the Mutator transposon family is active, the mutant phenotypes of both epialleles occur, generating single sectors of pale green (high chlorophyll fluorescence, *hcf106* mutant) and necrotic spotted (*les28* mutant) tissue on leaves⁹². *hcf106* transcripts are initiated by a nonautonomous (Mu1) transposon only when the autonomous transposon elsewhere in the genome is inactive.

TABLE 9.2 Plant nuclear RNA polymerases and their products.

RNAP	RNA synthesized
I	5.8S, 18S and 28S rRNAs
II	mRNAs, miRNAs, snRNAs, ta-siRNAs
III	5S rRNA, tRNAs, snRNAs
IV	siRNAs
V	noncoding RNAs

9.4.2 General transcription factors and RNA polymerases form the basal transcriptional machinery

The process of transcription can be divided into three consecutive phases: (i) initiation of transcription, (ii) an elongation step that leads to the formation of an RNA product through RNAP activity, and (iii) termination.

The initiation of transcription is an important control step that depends on the formation of a **transcription preinitiation complex** (Fig. 9.17). This multisubunit protein complex is composed of an RNAP and associated proteins (Table 9.3)

FIGURE 9.16 Crystal structure of the RNAPII elongation complex from yeast (*Saccharomyces cerevisiae*). The polymerase subunits are color-coded according to the key between the top and side views. Template DNA, nontemplate DNA, and product RNA are shown in blue, cyan, and red, respectively.

FIGURE 9.17 Schematic representation of the RNAPII preinitiation complex and its interactions with transcription factors and chromatin remodeling complexes on DNA. Light-brown beads symbolize nucleosomes.

that modulate RNAP activity and recruit the enzyme to the promoters of genes. For example, RNAPII cannot bind to DNA alone; rather, it requires the presence of several **general transcription factors** (TFIIA, B, D, E, F, and H). TFIID, itself a multiprotein complex, constitutes the key set of proteins in the transcription preinitiation complex.

One of the TFIID components, **TATA binding protein** (TBP) recognizes the **TATA box** (Fig. 9.17), a DNA sequence motif located in the promoters of many protein-coding genes around position -30 (i.e., 30 nucleotides upstream from the transcription initiation site, which corresponds to the first nucleotide of the RNA). TBP-mediated binding of the TFIID complex to a promoter leads to the sequential recruitment of additional general transcription factors and RNAPII into the preinitiation complex and subsequently to the initiation of transcription.

9.4.3 The expression of many plant genes changes during development or in response to environmental cues

Some plant genes are constitutively expressed, meaning that they are transcribed in all cells of a plant. These genes often function as **housekeeping genes**, because they encode

TABLE 9.3 Components of the RNAPII preinitiation complex in Arabidopsis.

Factor	Number of subunits	Function
TFIIA	3	Stabilizes TBP-TATA interaction

proteins that are involved in basic cellular functions such as carbohydrate metabolism or protein biosynthesis. However, not all genes in a nuclear genome are expressed at all times; many are transcribed only at certain stages of plant development or in specific tissues or cell types. The expression of even other genes depends on environmental signals or stresses to which the plant has to adapt. The term **differential gene expression** refers to such changes in transcriptional activities during development or in response to environmental

BOX
9.9

Gene expression in plants can be analyzed by different methods

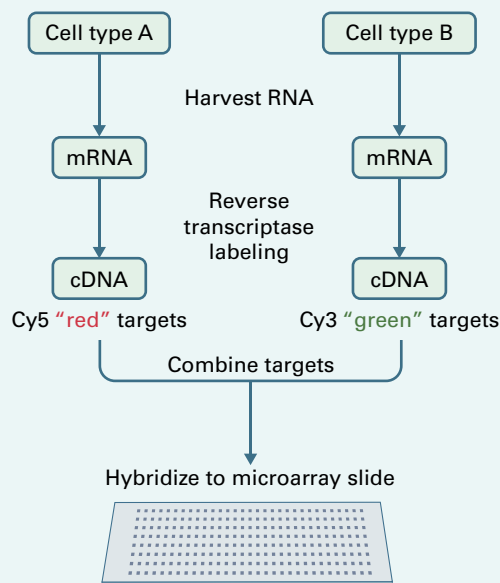

Methods for analyzing gene expression in plants can be divided into single-gene and genome-wide approaches. To determine the expression pattern of a single gene in a plant, a number of established experimental methods can be used, and the most common include **reverse transcriptase PCR (RT-PCR)**, **in situ hybridization**, and **reporter gene approaches**.

RT-PCR is based on the synthesis of complementary DNA (cDNA) from mRNA isolated from specific tissues or cell types. This reaction is catalyzed by the enzyme reverse transcriptase, which was first isolated from RNA viruses. A PCR reaction with gene-specific primers then leads to the detection of cDNAs from specific genes. Through the use of DNA-binding dyes, the amplification of cDNA fragments by PCR can be followed in real time, allowing the quantitation of transcripts in a sample. This approach, known as **quantitative real time RT-PCR (qRT-PCR)**, has become a standard in molecular biology.

In situ hybridization is based on direct detection of mRNA in a tissue sample. An RNA probe complementary to the mRNA of interest is synthesized and labeled with an epitope tag for detection. This probe is then incubated with entire plant organs (known as whole-mount *in situ* hybridization) or with tissue sections. After hybridization of the probe to the target mRNA, antibodies directed against the epitope tag are added. These antibodies are coupled to an enzyme that catalyzes a color reaction to allow detection.

Commonly used reporter proteins in plants are β -**glucuronidase (GUS)** as well as **Green Fluorescent Protein (GFP)** and its many derivatives. These reporter proteins are either expressed under control of the promoter of a gene or they are translationally fused to the amino- or carboxyl-terminal end of the protein under study. Detection of the GUS reporter in plant tissue is based on a colorimetric reaction; in contrast, GFP signal is detected through the use of fluorescent or confocal microscopes.

Genome-wide approaches used for the detection of differentially expressed genes are microarray analysis and RNA sequencing. **Microarrays** (see figure) are based on single-stranded DNA probes that are complementary to gene transcripts. These probes are usually synthesized chemically and then spotted and immobilized onto glass slides. For the detection of transcripts in a sample, mRNA is isolated and reverse-transcribed into cDNA. The cDNAs are then labeled with a fluorescent dye, and the resulting material is incubated with a microarray so the different cDNAs can hybridize to their complementary probes. After washing the microarray thoroughly, it is scanned to reveal and quantitate the fluorescent signals. **RNA-sequencing (RNA-Seq)** is based on the direct sequencing of cDNA libraries using ultra high-throughput DNA sequencing technologies. This technique is likely to supersede microarray analysis for the genome-wide detection of gene expression because it is more sensitive and does not require the time-consuming and expensive preparation of DNA probes.

cues. Many different experimental approaches have been established to study gene expression in plants (see Box 9.9).

To understand the importance of differential gene expression for plant growth and development, it is important to take a look at how different cell types are formed through the process of **cellular differentiation**. It is now well-established throughout the biological kingdom that, with few exceptions, cellular differentiation does not involve loss of genetic information. This was demonstrated first in the plant kingdom by classic experiments on carrot and tobacco, where tissue explants or isolated cells from a mature plant could be induced to regenerate into a complete plant that was identical to the root

cell donor. This notion of the **totipotency** of nuclei from adult cells was replicated in frogs by the demonstration that the cytoplasm of an enucleated frog egg is capable of development when guided by the genome of a nucleus transferred from a differentiated frog cell. These classic experiments have now been superseded by the isolation first of embryonic stem cells from mice, humans, and other animal species and the more recent demonstrations of reprogramming of differentiated adult mammalian cells by transfection with an appropriate suite of transcriptional regulators. Cell differentiation that accompanies an organism's development can therefore be seen as the orchestrated activation and repression of appropriate

sets of genes in different organs and tissues over developmental time. How is this process controlled to ensure that certain gene sets are active only at specific stages of development or in certain parts of the plant body? The answer to this question involves the regulatory regions of the genome, the promoters of genes.

9.4.4 Promoters are composed of regulatory DNA sequence elements

A promoter contains various sequence elements that collectively recruit the protein factors that regulate the transcription of a gene. Each class of RNA polymerase binds to its cognate promoters to initiate transcription. Promoters consist of two types of regulatory elements, **basal elements** and **cis-elements**. Basal elements are necessary for RNA polymerase binding and positioning and generally lie within 50 bp up- or downstream of the transcription initiation site. They are often relatively conserved between different genes and together form the **core promoter**. One example for a basal element is the TATA box (see Section 9.4.2), and other examples for elements in core promoters are the **TFIIB recognition elements** (BREs), which are found immediately upstream and downstream of TATA boxes (Fig. 9.18) and recognized by the general transcription factor TFIIB, and the **downstream promoter element** (DPE), which is located around 30 bp downstream of the transcriptional start site and bound by subunits of the TFIID complex. Not all types of basal elements

are always present in a given promoter; instead, the composition of core promoters shows a large degree of variability. In contrast to other eukaryotes, basal elements are as yet not well defined in plants due, at least in part, to the limited sequence data of precisely defined transcription start sites.

Unlike basal elements, which show some degree of conservation between different genes, *cis*-elements vary greatly from gene to gene. “*Cis*” (from Latin, meaning “on the same side”) refers to the fact that these regulatory elements are located on the same DNA molecule as the genes they control. *Cis*-elements are responsible for the activation, repression or modulation of gene expression. They are bound by **trans-acting factors**, proteins encoded elsewhere (“*in trans*”) in the genome that can interact directly with the basal transcriptional machinery (for example, with components of the TFIID general transcription factor complex) or indirectly through **mediator**, a large protein complex that acts as a transcriptional coregulator (see Fig. 9.17). This, in turn, influences the rate at which transcription by the appropriate RNA polymerases occurs. The *trans*-acting factors that bind *cis*-elements are usually transcription factors. They are also called **specific transcription factors** to distinguish them from the general transcription factors discussed above.

Most *cis*-elements in plants lie within 1–2 kb of sequence upstream of the transcription start site (Fig. 9.18). However, they may also be found further upstream, in a gene’s introns or exons, or downstream of the site where termination of transcription occurs. *Cis*-elements are usually short (<10 bp) in sequence and vary greatly in their base composition (Table 9.4).

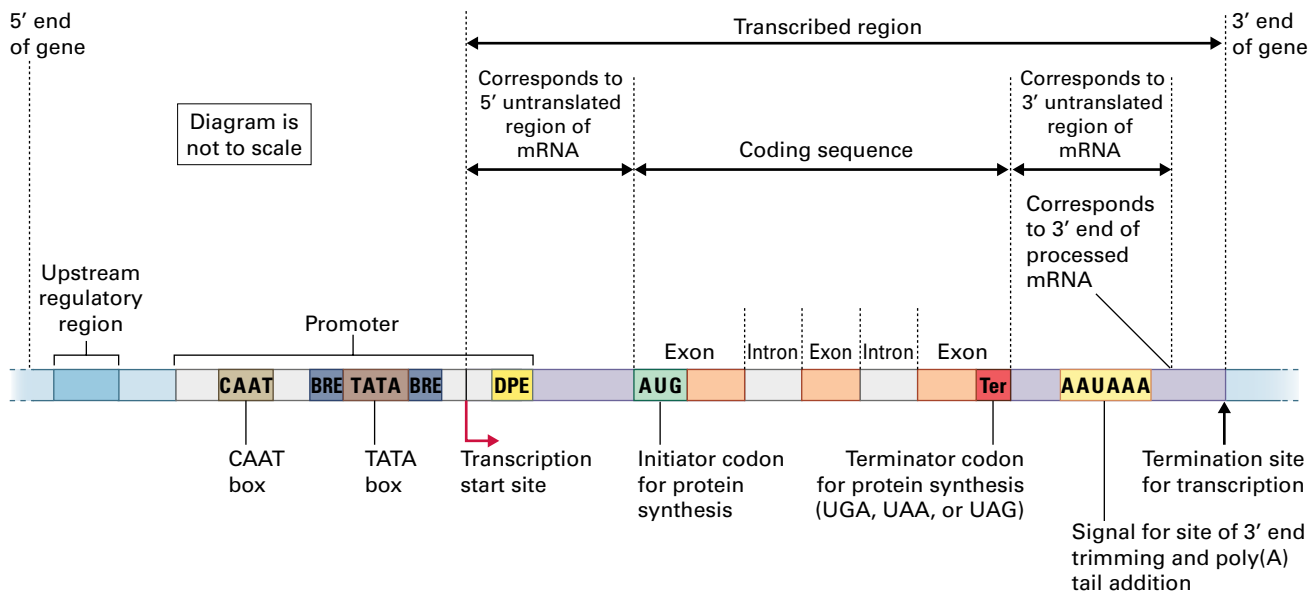

FIGURE 9.18 Structure and organization of a eukaryotic gene. A gene is divided into several functional units. The transcribed region acts as a template for synthesis of mRNA, which is then edited and translated into the protein product of the gene. The transcribed region is interspersed with noncoding sequences that partition the region into coding sections (exons) and noncoding sections (introns). The transcribed region is flanked on either side by noncoding sequences that play a role in regulation of the gene. Most of the regulatory sequence elements are in the 5' flanking region. The first 1,000 bp or so of the 5' flanking region is referred to as the gene promoter, as it contains sequence motifs important for the “promotion” of transcription. One of the most highly conserved regulatory elements is the TATA box, which is usually found within the first 50 bp of the transcription start site. The TATA box coordinates the recruitment of RNAPII to the gene.

TABLE 9.4 Examples for DNA sequence motifs bound by *Arabidopsis* transcription factors, and their functions in plant growth and development.

Motif name	Sequence	Bound by	Function
ABA-responsive element (ABRE)	CACGTGGC	ABRE-binding factors (bZIP proteins)	ABA response
Auxin response element (ARE)	TGTCTC	Auxin response factors	Auxin response
CaRg box	CC(A/T) ₆ GG	MADS domain proteins	Flower development, etc.
Evening element	AAAATATCT	Certain MYB proteins	Gene regulation by the circadian clock
G box	CACGTG	bZIP and bHLH proteins	Light response, etc.
GATA promoter motif	(A/T)GATA(G/A)	GATA transcription factors	Various

FIGURE 9.19 Example for the function of cis-regulatory modules and enhancers. A cis-regulatory module in the promoter of a gene is bound by several transcription factors. This transcription factor complex, together with an input from a distal cis-regulatory element (CRE), which acts as an enhancer, leads to the recruitment of a co-activator complex and ultimately, to the promotion of transcription.

A promoter can contain several different *cis*-elements, and more than one copy of the same element can be present. These elements often cluster together to form **cis-regulatory modules**. The function of these modules likely allows the cooperative action of several (different or identical) transcription factors in the regulation of gene expression by bringing them in close proximity to one another (Fig. 9.19). *Cis*-regulatory modules are often classified as **enhancers** or **silencers**, depending on whether they promote or inhibit the expression of a gene. Some biologists use the terms enhancer and silencer to refer to regulatory elements that are located a great distance away from the transcribed region of a gene to

distinguish them from **proximal promoter elements** (regulatory elements found in the vicinity of the transcription start site). *Cis*-regulatory modules can also function as **insulators** to block signals from enhancers and silencers and prevent them from influencing gene expression activities of certain genes (Fig. 9.20).

Cis-elements can mediate expression of specific genes during development or in response to internal or external signals. One example is the auxin response element (AuxRE; sequence: 5'-TGTCTC-3'), which is found in the promoters of genes controlled by the phytohormone auxin (see Chapter 18). The occurrence of specific *cis*-elements in a

promoter, therefore, determines where and when a gene is expressed in a plant. Hence, the capacity of cells for differential gene expression is hardwired into the genome in the form of a *cis*-regulatory code.

9.4.5 Diverse transcription factor families control gene expression

As discussed above, *cis*-elements are bound by transcription factors that in turn promote or inhibit gene expression by interacting with components of the transcriptional machinery. These transcription factors usually bind DNA in a sequence-specific manner so that a given transcription factor targets a specific *cis*-element; for example, the ARE mentioned above is bound by members of a family of transcription factors called auxin response factors (ARFs).

FIGURE 9.20 Function of genetic insulators. The effect of a *cis*-regulatory module (CRM) on a gene (A) can be blocked by the presence of an insulator (B). Insulators can also limit the effects of a CRM on a specific gene, preventing neighboring genes from responding to CRM activity (C).

FIGURE 9.21 Three major types of DNA binding domains. (A) Helix-loop-helix motif. (B) Basic leucine zipper. (C) Zinc finger domain. Each model illustrates the DNA/protein complex.

Transcription factors are typically composed of at least two domains with different functions. The **DNA-binding domain** mediates the recognition of and binding to a *cis*-element, while the **transactivating domain** interacts with the transcriptional machinery and determines the activity of the protein. Transcription factors also typically contain a **nuclear localization sequence** (NLS), which allows the proteins to enter the nucleus after they have been synthesized in the cytoplasm.

Several different types of DNA-binding domains have been identified, and their structures have been resolved in atomic detail, yielding detailed insights into how they interact with DNA (Fig. 9.21). For example, **zinc finger** transcription factors are characterized by a domain that carries a duplicated set of projections that insert into the major groove of the DNA double-helix. The projections are created by coordinating a zinc ion with four amino acids (often a combination of two histidine and two cysteine residues). Another structural motif frequently found in transcription factors is the **basic leucine zipper** (bZIP) domain. Proteins with this domain form dimers that bind to the major groove of the DNA molecule. Each bZIP monomer contains an α -helix in which every seventh amino acid residue is a leucine. The leucine residues face each other in the dimer and their structural arrangement “zips” the helices together into a coiled coil arrangement. The coiled coil holds the dimer together and holds the basic region in place within the major groove. Compared to DNA-binding domains, transactivating domains are structurally not well defined (note that a transactivating domain, despite its name, can also act to repress the transcription of a gene).

Transcription factors can thus be divided into **repressors** and **activators**, depending on their effect on gene expression. However, some transcription factors carry both repressor and activator function. These proteins are said to be **bifunctional**. Which of the two functions dominates in the control of a given gene may depend on the presence of additional transcription factors at that gene’s promoter or on posttranslational modifications of the bifunctional transcription factor that render one of the transactivating domains inactive.

TABLE 9.5 Examples for transcription factor families in *Arabidopsis* and rice. The number of family members, and whether the families are plant specific, is indicated.

Family	<i>Arabidopsis</i>	Rice (<i>Oryza sativa</i>)	Plant specific
AP2/ERF	147	161	No*
bZIP	74	94	No
GRAS	32	57	Yes
MADS	108	77	No
MYB	198	182	No
NAC	100	149	Yes
WRKY	71	109	No*

*But predominantly found in plants.

The pivotal role of transcription factors for the regulation of plant growth and development is demonstrated by the large number of transcription factor-coding genes in plant genomes. For example, the *Arabidopsis* genome contains approximately 2,000 genes that encode transcription factors. This number corresponds to roughly 6% of all *Arabidopsis* genes, considerably higher than that observed in many other model organisms. The different transcription factors found in higher plants can be grouped into 50 or so families, depending mainly on sequence similarities. The names of these families sometimes refer to common structural features (e.g., **basic helix–loop–helix proteins** (bHLH) contain a DNA-binding domain composed of two α -helical segments separated by an intervening loop) (Fig. 9.21), but they are also often named after their physiological function in the plant (e.g., the ARFs mentioned above) or after the founding member(s) of a family (e.g., the **AP2-like transcription factors**, which constitute one of the largest transcription factor families in plants, were named after the APETALA2 (AP2) protein, a key regulator of flower development).

Many plant transcription factor families are also found in other eukaryotes (e.g., bZIP and MYB proteins) (Table 9.5); however, the number of family members is often considerably enlarged or reduced in plants when compared to those of animals or fungi. One example is the family of **MADS domain transcription factors** (named after the four founding members of the family), which has over 100 members in *Arabidopsis*, but only two in *Drosophila*. At the same time, the *Drosophila* genome encodes many more zinc-finger transcription factors than *Arabidopsis* despite having fewer genes. In addition to evolutionary conserved transcription factor families, plants contain many transcription factors that are not found outside of the plant kingdom, including, for example, the ARFs mentioned above.

The large number of transcription factors in plants implies a high degree of complexity in the regulation of gene expression activities. This complexity is further increased by the fact that many transcription factors, such as the bZIP proteins, act as dimers. In addition to **homodimers** (pairs of identical proteins), many transcription factors also form **heterodimers** (pairs of different transcriptional regulators). Because a single transcription factor can form heterodimers with many different partner proteins, the number of possible transcription factor complexes is staggering. Moreover, the activities of transcription factors can be regulated through a plethora of posttranslational modifications that often occur in response to the activation of a specific signal transduction pathway (see Chapter 18). For example, phosphorylation of a transcription factor by a specific protein kinase may alter DNA-binding activities or serve as a signal for its degradation. The activities of other transcription factors are controlled by changes in their intracellular localization; while retention of a transcription factor in the cytoplasm renders it inactive, the induction of its nuclear import leads to its activation.

A key problem in regulatory biology is identifying the genes that a transcription factor controls and the *cis*-elements to which it binds. To address this problem, a number of experimental approaches have been developed to locate the binding site of a transcription factor in a genome. A particularly powerful technique for the identification of **target genes** of transcription factor is **chromatin immunoprecipitation** (ChIP; see Box 9.10). The results of genome-wide analyses of binding sites of several transcription factors in *Arabidopsis* suggest transcription factors can bind to hundreds, if not thousands, of regions across the genome. At the same time, not all binding events result in changes in gene expression, perhaps because these sites lie outside of functional *cis*-regulatory modules.

9.5 Chromatin and the epigenetic regulation of gene expression

9.5.1 Nuclear DNA is packaged into chromatin, a dynamic structure

The nuclear genomes of many plants are exceptionally large, and to fit this amount of DNA into a nucleus that is only a few micrometers in diameter, the nuclear DNA is condensed to reduce its length. This efficient packaging strategy is made possible through the association of DNA with different types of proteins into **chromatin**. The most important and abundant of these proteins are the histones. Histones are relatively small proteins that contain many basic amino acid residues in their sequence, resulting in a high positive net charge that allows them to bind strongly to the negatively charged DNA. As described earlier (see Section 9.1.1), the main function of histones is the formation of nucleosomes (see Fig. 9.1).

BOX
9.10

The binding sites of transcription factors can be identified through chromatin immunoprecipitation (ChIP)

A chromatin immunoprecipitation (ChIP) assay begins with fixation of plant tissue with a crosslinking agent such as formaldehyde, which covalently attaches DNA-binding proteins to the nucleic acid. Subsequently, chromatin is isolated from the cells and broken into small fragments. These chromatin fragments are then incubated with antibodies against the protein of interest. After purifying the DNA–protein–antibody complexes, for example, through the use of immobilized protein A, which has a high affinity for certain antibody types, the crosslinks are reversed and the immunoprecipitated DNA is isolated. The genomic fragments can then be tested for an

enrichment of specific genomic regions through real-time PCR (“ChIP-qPCR”), or on a genome-wide scale through the use of DNA microarrays (“ChIP-chip”) or ultra-high-throughput DNA sequencing (“ChIP-Seq”) methods. Genomic regions found to be overrepresented in the immunoprecipitated chromatin relative to negative control regions (i.e., regions that are not bound) likely contain binding sites of the protein of interest.

The ChIP procedure can also be employed for epigenetic marks (especially histone modifications) using antibodies directed against these chromatin modifications.

The high degree of condensation of nuclear DNA within chromatin poses a considerable challenge for the process of gene expression (as well as for other processes, such as DNA replication), because transcriptional units and promoter sequences are inaccessible for RNA polymerases and transcription factors. Early studies on the correlation between gene expression and chromatin structure established that active genes are generally more sensitive to digestion by the nuclease DNase I than are inactive genes (Fig. 9.22). These

differences are due to the fact that chromatin surrounding a transcriptionally active gene is less condensed than genomic chromatin as a whole and is thereby more accessible to nuclease digestion. Regions of DNA that are hypersensitive to DNase I are thought to be nucleosome free, allowing transcription factors greater access to promoter *cis*-elements. These regions of low chromatin condensation are also termed **euchromatin**, whereas regions that are highly condensed are referred to as **heterochromatin**.

FIGURE 9.22 DNase I hypersensitive sites in the maize Alcohol Dehydrogenase 1 (*ADH1*) promoter. As a gene becomes transcriptionally active, regions of the promoter become less condensed, to accommodate transcription factors. This opening of the promoter chromatin can be visualized as an increase in accessibility to DNase I digestion. DNase I is an endonuclease with very little sequence specificity. DNA held in a condensed chromatin configuration is difficult for DNase I to access, but when the chromatin of a gene promoter becomes less condensed—to afford access to the transcriptional machinery—it also becomes more accessible to DNase I. Thus, hypersensitivity to DNase I is a hallmark of the less-condensed chromatin configuration necessary for a gene to become transcriptionally active. (A) The *ADH1* gene promoter is less accessible to DNase I in cells where the gene is “off” (uninduced, U) than in cells where it is transcriptionally active (induced, I). The transcriptionally active promoters from induced cells show more regions of DNase I hypersensitivity (indicated with the filled triangles) than do those where the gene is not being transcribed (C is the control). (B) The hypersensitive region may reflect a nucleosome-free region, a state potentiated by the binding of one or more transcription factors.

The existence of euchromatic and heterochromatic regions implies that chromatin structure can be modified or remodeled. In fact, chromatin is a dynamic entity that can undergo considerable structural change. Chromatin structure is directly remodeled through the activity of at least two different protein classes, **histone chaperones** and **ATP-dependent chromatin remodeling enzymes**. Histone chaperones, such as chromatin assembly factor 1 (CAF-1), are involved in the deposition of histones during DNA replication and remodeling. They are also thought to prevent misfolding and aggregation of histones. Chromatin remodeling enzymes alter the position of nucleosomes in chromatin to reduce or increase the accessibility of other proteins to the DNA. They contain a DNA-dependent ATPase that is the powerhouse of the system. Classic examples of chromatin remodeling proteins are the products of the *SWI* and *SNF* genes in yeast, which affect mating type switch (*SWI*) and the ability to ferment sucrose (*SNF*), respectively, and actually function together in the same complex. Homologs of *SWI*/*SNF* have been identified in plants and are involved in the control of diverse developmental processes.

The ability of a cell to modify the structure of its chromatin raises the question as to how this process is controlled at the molecular level and what signals determine the locations within chromatin targeted by remodeling enzymes.

9.5.2 Gene expression may also be controlled by epigenetic mechanisms

The traditional view of the relationship between genotype and phenotype is that all the heritable traits that determine the patterns and timing of gene expression, and hence an individual’s phenotype, are encoded in the primary sequence of its DNA. Over the decades, there have been sporadic examples of heritable changes that apparently do not involve alterations in an organism’s primary DNA sequence. Such changes are said to be **epigenetic** (literally: “on top of genetics”).

Early examples of epigenetic phenomena are **paramutation** (Fig. 9.23) and **cosuppression**, but epigenetic

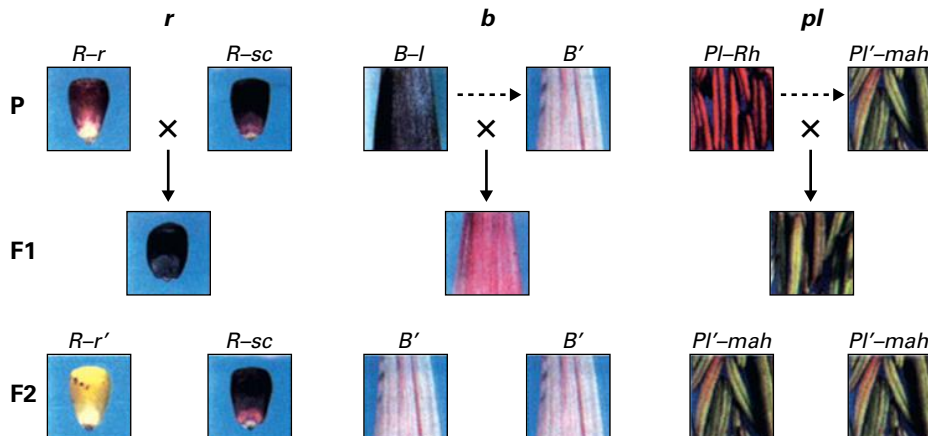

FIGURE 9.23 Paramutation describes an allelic interaction whereby the expression of one allele in a heterozygote is altered by the presence of the other. Several cases of paramutation have been described for loci that control pigmentation in *Zea mays*. The examples shown are those affecting coloration of seed (*r* expression), husk (*b* expression), and anther (*pl* expression). Parental, F1, and the resulting segregant phenotypes are represented in successive rows of the figure. (A) Activity of the paramutable *R-r* allele is heritably reduced after exposure to the paramutagenic *R-sc* allele in the F1 heterozygote. The *R-r* and *R-sc* alleles are structurally distinct from one another and the *R-sc* allele is always strongly expressed. (B) Weakly expressed paramutagenic *B'* states can arise spontaneously from strongly expressed paramutable *B-l* alleles (dashed arrow). *B-l* alleles change exclusively to *B'* when exposed to *B'* in the F1 heterozygote. (C) Weakly expressed paramutagenic *Pl'-mah* (*Pl'*) states can arise spontaneously from strongly expressed paramutable *Pl-Rh* (*Pl*) alleles (dashed arrow). *Pl-Rh* alleles change exclusively to *Pl'-mah* when exposed to *Pl'-mah* in the F1 heterozygote.

FIGURE 9.24 Covalent modifications of histones H3 and H4. “M” symbolizes methylation, “Ac” acetylation, and “P” phosphorylation. Modified amino acid residues (single letter abbreviations are used) and their positions relative to the N-terminus of a protein are indicated.

mechanisms play key roles in many cellular and developmental processes and in particular in the regulation of gene expression. Epigenetic mechanisms are largely based on a multitude of different types of covalent chromatin modifications, which are also called **epigenetic marks**. These include DNA methylation, as well as an array of posttranslational

FIGURE 9.25 Cytosine methylation. A methyltransferase (*MTase*) transfers a methyl group from *S*-adenosyl methionine (*SAM*) to cytosine, resulting in the formation of 5-methylcytosine.

histone modifications that occur preferentially at the amino- (Fig. 9.24) and carboxyl-terminal tails of these proteins. While epigenetic mechanisms in plants and animals show many commonalities, there are also some differences, some of which will be briefly touched on below.

DNA methylation is based on the methylation of cytosine bases in the nuclear DNA by enzymes called **DNA methyltransferases** (Fig. 9.25). Unlike in animals, where the methylation of cytosines is found mainly in the context of CG dinucleotides, in plants, cytosines in the context of CHG and CHH (recall that in the IUB code, H = C, T, or A) sequences are also targets of DNA methyltransferases. DNA methylation is an attractive model for epigenetic changes because mechanisms exist to ensure both mitotic and meiotic inheritance of specific DNA methylation patterns. Newly replicated DNA that contains hemi-methylated sites is a strong substrate for methyltransferase activity that ensures the maintenance of preexisting methylation patterns in both daughter

FIGURE 9.26 Histones can be modified by acetyltransferases and deacetylases to influence the degree of chromatin condensation. Both histones within the nucleosome and the linker histone H1 can be modified at the N-terminal region by acetyltransferases. An acetyl group on a histone creates steric hindrance for surrounding structures, thereby generating a local region of decondensation. Decondensation of chromatin can facilitate recruitment of transcription factors to the surrounding sequence. Histone deacetylases (not shown) remove acetyl groups to allow the N-termini of histones to interact more tightly with DNA.

chromosomes. Three distinct pathways of DNA methylation with overlapping functions have been characterized in *Arabidopsis* and likely exist in many, if not all, plant species. METHYLTRANSFERASE 1 (MET1), a homolog of mammalian DNMT1, primarily maintains methylation at CG sites while CHROMOMETHYLASE3 (CMT3), which is plant-specific, maintains methylation at CHG sites. The third pathway involves DOMAINS REARRANGED METHYLASES 1 and 2 (DRM1/2; homologs of mammalian DNMT3a/3b) and maintains cytosine methylation in all sequence contexts. This process requires the active targeting of sites by siRNAs (see Chapter 6).

The occurrence of DNA cytosine methylation can be studied through **bisulfite sequencing**. This technique is based on the treatment of genomic DNA with sodium bisulfite, which converts cytosines, but not of methylated cytosines, into uracil. The subsequent sequencing of the treated DNA can then distinguish between cytosines that were methylated or not. Using this approach, it has been shown that about 20% of the *Arabidopsis* genome is methylated and that the proportion of methylated DNA increases with genome size and repeat content. The largest fraction of methylated DNA occurs within transposons and other repeats. In fact,

methylation plays an important role in silencing transposon activity, as evidenced by the observation of genome-wide transcriptional activation of transposons in mutants lacking maintenance methylation activity. The effect of DNA methylation on gene expression varies according to the location of the methylated cytosines. Promoter methylation is usually associated with decreased transcription, whereas methylation in the body of a gene often correlates with moderate to high expression levels.

Post-translational modifications of histones include, for example, methylation, acetylation, and phosphorylation (see Fig. 9.24), and of these, the best understood are histone acetylation and methylation.

Histone acetylation occurs via the transfer of the acetyl group from acetyl coenzyme A to the ϵ -amino group of different lysine residues of mainly histones H3 and H4 by enzymes known as **histone acetyl transferases** (HATs). Acetylated histones regulate transcription through interaction with proteins that contain a **bromodomain**, a 110 amino acid sequence motif present in a variety of transcription factors as well as in some chromatin remodeling complexes. In general, histone acetylation is thought to activate gene expression by reducing chromatin condensation (Fig. 9.26). Histone acetylation can be reversed by a class of enzymes called **histone deacetylases** (HDACs).

Histone methylation occurs predominantly, but not exclusively, on lysine residues of histones H3 and H4 and is carried out by **histone methyl transferases** (HMTases) that use S-adenosyl methionine as the methyl donor. Unlike histone acetylation, where only single acetyl groups are added, histone methylation can lead to the addition of either mono-, di- or tri-methyl groups. The effects of histone methylation on gene expression depend on the amino acid residues in the histone tails that are modified. While methylation of certain residues increases gene expression, methylation of other residues has the opposite effect. For example, tri-methylation of lysine 27 of histone H3 by **polycomb repressive complex 2** (PRC2) leads to the repression of genes. In contrast, tri-methylation of lysine 4 of histone H3 through **trithorax** group (trxG) proteins counteracts PRC2 activity and leads to gene activation. For other residues in histones, the exact methylation status determines the effect on gene expression. One example is the di-methylation of lysine 9 of histone H3, which serves as a repressive mark, whereas tri-methylation of the same residue is commonly associated with actively transcribed genes.

9.5.3 Epigenetic mechanisms are often based on an interplay with transcription factors

As described above, a bewildering array of different epigenetic marks exist that can have opposite effects on the transcription of a gene. How does a cell use this wealth of

FIGURE 9.27 Chromatin states. A combination of specific epigenetic marks in a genomic region leads either to chromatin condensation or to a more relaxed chromatin configuration. These changes in chromatin structure prevent or facilitate transcription.

information to control gene expression activities during development or in response to environmental stimuli? The now generally accepted view is that different combinations of epigenetic marks can be read and interpreted by specialized proteins that then activate or repress the expression of a gene for example through the modification of chromatin structure. This idea was initially put forward as the **histone code hypothesis**, which has now been incorporated into the more generally applicable concept of the **epigenetic code**.

Because of the multitude of different epigenetic marks, the number of combinations that could theoretically occur in a genome is staggering. However, analyses of the epigenomes (i.e., the genome-wide distribution of epigenetic marks) of plants and animals have led to the realization that not all possible combinations actually occur in vivo. Instead, certain patterns of epigenetic marks, the so-called **epigenetic states**, are prevalent (Fig. 9.27). The number of different epigenetic states appears to be relatively small, but this view may change in the future when further in-depth studies are conducted and the epigenomes of specific cell types are analyzed.

One key question in regulatory biology is how epigenetic mechanisms are linked to the activity of transcription factors. The emerging picture suggests that transcription factors provide the general inputs for the control of gene expression, and enzymes that set or erase epigenetic marks use the information from these inputs to modify chromatin structure. At a molecular level, there is ample evidence that these enzymes are targeted to genes through the direct or indirect interaction with transcription factors. One example for an indirect mechanism involves **transcriptional**

FIGURE 9.28 Mechanism of transcriptional co-repressor function. Binding of a co-repressor to a transcription factor complex leads to the recruitment of a histone deacetylase (HDAC) to a target gene promoter. The HDAC then removes acetyl groups from histone H3 in specific positions. This change in chromatin state inactivates transcription.

co-repressors (Fig. 9.28). These proteins bind to certain transcription factors and then recruit histone deacetylases to the promoters of genes, which leads to the removal of acetyl groups from histones and ultimately to changes in chromatin structure.

9.5.4 Epigenetic mechanisms control plant growth and development

As briefly mentioned above, epigenetic mechanisms control many cellular and developmental processes during plant development (see also Chapter 19). One well-studied

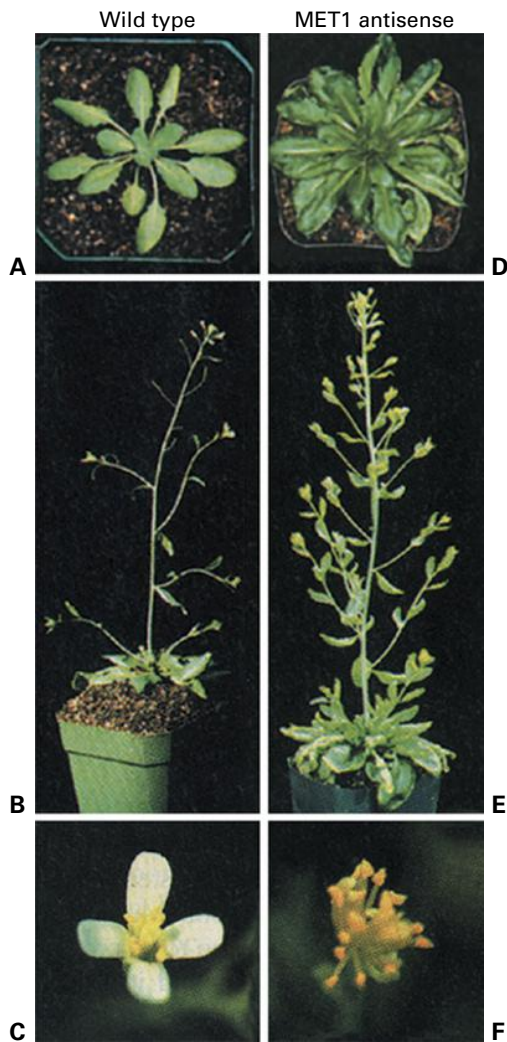

FIGURE 9.29 Interference with DNA methyltransferase activity. Phenotypic comparisons of wild-type (A–C) and a *MET1* antisense line (D–F) of *Arabidopsis thaliana*. Interference with cytosine methylation activity by an antisense knockout approach for the *MET1* gene is associated with abnormal phenotypes during vegetative (A, D), inflorescence (B, E), and floral (C, F) development.

Summary

The genome of a plant contains the blueprint for the structure and function of the organism. Starting with the concept of genes as units of inheritance and chromosomes as the visible carriers of these genes, our understanding of genome structure has progressed over the last century from cytogenetics, through increasingly sophisticated microscopy methods to DNA sequencing. Our view of the genome was dramatically refined by the first complete sequence of a plant genome (*Arabidopsis*) and subsequently by many others. Plant genomes vary

considerably in size, with the larger genomes containing more repetitive DNA in the form of transposable elements and other sequences. Movement of transposable elements has played roles both in genome evolution and diversity within species. Most plant genomes appear to contain 25,000–50,000 genes, somewhat more than animal genomes (including humans) and larger gene families. This is due to one or more whole genome duplications that have occurred in different lineages from a few million to a hundred or more million years ago. DNA

example is the regulation of flowering time in *Arabidopsis*. In winter annuals (plants that typically germinate in fall, survive the winter period, and then flower in spring), the gene *FLOWERING LOCUS C (FLC)* represses the initiation of flowering. This repression is removed during winter, when the plant experiences a prolonged cold period, through a process termed **vernalization**. The underlying molecular mechanism appears to depend mainly on the activity of the polycomb repressive complex 2 (see Section 9.5.2), which represses the *FLC* gene by tri-methylation of lysine 27 of histone H3. Once *FLC* expression is turned off, flowering can commence in response to certain environmental signals, such as the photoperiod.

Polycomb group (PcG) proteins are also involved in the repression of entire developmental programs (for example, genes that are involved in seed and embryo development). A loss of PcG activity leads to a depression of such genes in vegetative tissue of the plant and can, in extreme cases, result in **somatic embryogenesis**, where embryo formation is initiated by somatic cells (i.e., cells of the plant body) without fertilization.

Another example for involvement of epigenetic mechanisms in the control of plant growth is the role of DNA methylation in a phenomenon called **genomic imprinting**. This term refers to an unusual mode of inheritance, in which alleles are active or inactive, depending on whether they were passed on from the mother or the father. Imprinting is to a large extent based on differences in cytosine methylation patterns between the paternal and maternal genomes. These differences are caused, for example, by the DNA-demethylating glycosylase *DEMETER*, which is expressed primarily in the female gametophyte and reduces the methylation state of the maternal genome.

DNA methylation also has a direct effect on the development of a plant. For example, a disruption of *MET1* activity (see Section 9.5.2) leads to a reduction in genome methylation and to a late-flowering phenotype, as well as to abnormal shoot and flower development (Fig. 9.29).

considerably in size, with the larger genomes containing more repetitive DNA in the form of transposable elements and other sequences. Movement of transposable elements has played roles both in genome evolution and diversity within species. Most plant genomes appear to contain 25,000–50,000 genes, somewhat more than animal genomes (including humans) and larger gene families. This is due to one or more whole genome duplications that have occurred in different lineages from a few million to a hundred or more million years ago. DNA

sequencing has also allowed us to associate specific sequences with cytological features such as centromeres, telomeres, and nucleolar organizer regions.

The expression of genes in a genome gives a plant its life, its form, and its ability to respond to environmental cues and stimuli. A great deal is now known about the basic mechanisms of transcription and about how specific transcription factors regulate gene expression in

temporally, spatially and environmentally specific fashions by interacting with regulatory elements in the promoters of genes. There is now ample evidence that a multitude of epigenetic mechanisms, which are based on covalent modifications of histones and of the DNA itself, contribute to the regulation of gene expression and are involved in controlling various physiological and developmental processes in plants.

Protein Synthesis, Folding, and Degradation

Judy Callis, Karen S. Browning,
and Linda Spremulli

Introduction

Proteins constitute a large percentage of plant cellular dry weight and carry out many different and essential cellular functions. Proteins also serve as nitrogen and energy stores in the seed endosperm or embryo of seed plants. Protein metabolism is central to cell growth, differentiation, and reproduction, and cells respond to internal and external signals by regulating both protein synthesis and degradation to adjust the amounts of specific proteins to suit cellular requirements.

Although plants share many features of protein synthesis and degradation in common with other eukaryotic organisms, some aspects are unique to plant cells and photosynthetic single-celled organisms such as *Chlamydomonas* and *Euglena*. This chapter highlights the protein synthetic processes that are distinct from those in other organisms and describes how translation (the “reading” of the messenger RNA, or mRNA, template and “writing” of the corresponding peptide sequence) may be affected by intrinsic, biotic, and abiotic factors. The basic steps of protein biosynthesis outlined in general biochemistry textbooks are directly applicable to plant systems, and the reader is referred to such sources for a general introduction as needed. This chapter also illustrates how the polypeptide chain folds to form a precise three-dimensional structure that can carry out specific biological functions. Finally, this chapter elaborates how all cellular compartments have specific pathways for removing proteins by hydrolyzing peptide bonds.

10.1 Organellar compartmentalization of protein synthesis

In plants, protein synthesis occurs in three subcellular compartments (Fig. 10.1): the cytosol, plastids, and mitochondria each contain distinct protein synthetic machinery. About 75% of cell proteins are made in the cytosol, where mRNAs transcribed from the nuclear genome are translated. About 20% of the proteins in a photosynthetically active cell (e.g., a young leaf cell) are synthesized in the chloroplast using mRNA templates transcribed from the chloroplast genome, and a small amount of protein synthesis (2–5% of total protein) occurs in mitochondria. In the cytosol, more than 25,000 different proteins may be synthesized, whereas in chloroplasts, about 40 proteins are synthesized, though plastid genomes can encode over 200 proteins. The number of proteins synthesized in mitochondria varies widely among species; about 20–40 proteins appear to be synthesized in the mitochondria of the liverwort *Marchantia polymorpha*, for example, whereas the mitochondrial genomes of most plants typically encode far fewer proteins. The overall mechanisms responsible for protein synthesis in the cytosol, plastids, and mitochondria are similar, but are clearly distinct from each other; accordingly, plant cells contain three different types of ribosomes,

FIGURE 10.1 Sites for protein synthesis in a plant cell. A typical plant cell synthesizes proteins in three distinct compartments—the cytosol, plastids, and mitochondria. Translation of mRNAs transcribed in the nucleus occurs in the cytosol, either on soluble or membrane-bound ribosomes. In contrast, both transcription and translation of plastid and mitochondrial mRNA take place within those organelles. Similarly, ribosomes can be membrane-localized in the organelles. Proteins synthesized in the cytosol can be imported into one or more organelles—the plastid, mitochondria, or microbody. Shown here is the leaf-type microbody, the peroxisome (see Chapter 4). Organellar genomes are shown in circular form, but can exist in other conformations.

three groups of transfer RNA (tRNA), and three sets of translation factors for protein synthesis (see Section 10.2).

In many cases, plant plastid and mitochondrial genomes encode tRNAs that are used specifically for protein synthesis within the organelle; there are cases, however, in which tRNAs encoded within the nuclear genome are imported into mitochondria for use in mitochondrial protein biosynthesis. Plastids and mitochondria presumably arose through the endosymbiosis of ancient prokaryotic organisms (see Chapters 1 and 6). Consistent with this theory, the protein synthetic machineries in plastids and mitochondria are closely related to those of bacterial systems, as evidenced by the similarity of ribosome composition and structure (see Table 10.1). However, the capacity of the organellar genomes to synthesize proteins is limited, and, as a result, both organelles require proteins imported from the cytosol after synthesis (see Chapter 4). Most organelle-encoded proteins function in oligomeric protein complexes that contain subunits from both nuclear and organelle genomes. Assembly of such complexes requires close coordination of transcription and translation between the nucleus, cytosol, and organelle.

10.2 From RNA to protein

10.2.1 Protein biosynthesis occurs on ribosomes

Ribosomes are large complexes of proteins and ribosomal RNA (rRNA, see Chapter 6) that hold tRNA and mRNA in position and catalyze the formation of peptide bonds between amino acid residues. They can be isolated intact or as two subunits—one large and one small (Table 10.1, Fig. 10.2)—that reversibly associate and dissociate during protein synthesis. Surprisingly, it is not the protein component, but the largest RNA species of the large subunit that catalyzes peptide bond formation. The importance of this RNA species (a ribozyme) is highlighted by the toxicity of ribosome-inactivating proteins (RIPs), which remove an adenine base from the large subunit RNA to inactivate protein synthesis (see Box 10.1).

The protein composition of eukaryotic ribosomes is highly conserved. Plant cytosolic ribosomes contain

TABLE 10.1 Summary of the composition and properties of various plant ribosome types.

Ribosome (in S value*)	Subunits (in S value*)	rRNAs (in S value*)	Number of proteins
Plant cytosolic, 80S	40	18	32
	60	28, 5.8, 5	48
Plant plastids, 70S	30	16	≈25
	50	23, 5, 4.5	≈33

orthologs of mammalian ribosomal proteins (RPs) and have one additional plant-specific subunit (the RPP3, a member of the acidic ribosomal protein family, discussed below). Plant ribosomes contain an estimated 80 proteins, each typically encoded by a small gene family. For example, in *Arabidopsis* the number of family members ranges from two to eleven. The multiple isoforms of RPs suggest that there may be a wide diversity of ribosomes, some with specific functions or roles.

Most ribosomal proteins are basic in nature, which facilitates their interaction with the negatively charged rRNA; however, ribosomes also contain a small family of acidic proteins, called P-proteins. In addition to the conserved RPP0, RPP1, and RPP2 proteins found in all eukaryotes, plant ribosomes also contain a unique member, RPP3. RPP3 interacts with RPP1 and RPP2 to form a mobile acidic stalk complex

on the large subunit, which interacts with an elongation factor (eEF2) to promote GTP hydrolysis tRNA translocation within the ribosome following peptide bond formation.

Many ribosomal proteins undergo post-translational modifications. For example, several ribosomal proteins are substrates for various kinases, and phosphorylation of the small subunit ribosomal protein, S6, is affected by various metabolic and environmental conditions including heat, cold, hypoxia, and sugar signaling. The physiological significance of these modifications is of great interest in understanding ribosome heterogeneity. In addition, nonribosomal proteins copurify with ribosomes. One such protein is a scaffold protein called receptor for activated C kinase 1 (RACK1), which binds to the 40S subunit and eIF6, likely facilitating 80S ribosome assembly. RACK1 also has non-ribosomal functions.

BOX

RIP: Ribosome-inactivating proteins (RIPs) have an appropriately grim acronym

Ricin, a toxic protein from the seeds of the castor bean plant (*Ricinus communis*), is the best-known member of a class of plant polypeptides known as ribosome-inactivating proteins (RIPs). Ricin was made famous as the poison used by the Bulgarian secret police to assassinate the defector Georgi Markov in London in 1978. In a plot that reads like a popular spy novel, a dart-tipped umbrella was used to deliver the toxin to its unfortunate victim.

Ricin cleaves the glycosidic bond between the sugar and an adenine residue at a specific position on the 28S ribosomal RNA. Loss of this adenine irreversibly inactivates the ribosome. RIPs are thought to provide protection of seeds and plants from predators and viral infections. RIPs are being investigated as potential therapeutic agents that could be targeted to kill malignant cells, and in particular, ricin, has been implicated as a possible bioterrorism agent.

10.2.2 Initiation of protein synthesis establishes the reading frame on the mRNA and positions the first amino acid for incorporation

Initiation of protein synthesis is a complex series of events that is largely conserved in eukaryotes. The initiation of translation is facilitated by a group of auxiliary protein factors referred to as **eukaryotic initiation factors** (eIFs), which are classified on the basis of the general reaction they promote. Each may consist of a single or multiple polypeptides (Table 10.2), and many mechanisms that regulate cytosolic protein synthesis in eukaryotes affect the activities of one or more of these factors.

Initiation (Fig. 10.3) begins when eIF2 interacts with an initiator Met-tRNA^{Met} in the presence of GTP to generate a tRNA–protein complex called the ternary complex. eIF2 is a heterotrimer of alpha, beta, and gamma subunits. Once formed, the ternary complex binds to a free 40S ribosomal subunit, a process facilitated by several other eIFs (Fig. 10.3). The small subunit of the ribosome, bound to the Met-tRNA and several eIFs, then interacts with the mRNA. This step requires the eIF4 family of initiation factors, which includes eIF4A (DEAD box helicase), eIF4B (RNA-binding protein), eIF4G (protein interactions), and eIF4E (cap-binding protein). The eIF4s facilitate recognition of the cap structure and interaction between the 40S subunit with other associated eIFs and the mRNA. In addition, there is circularization of the mRNA through interactions of eIF4G and the poly(A)-binding protein (PABP) bound to the 3' poly(A) tail. Any secondary structures in the 5' portion of the mRNA are

presumably removed by the helicase and the ATP hydrolysis activities of eIF4A in complex with eIF4F (eIF4G/eIF4E) and eIF4B.

The 40S subunit must then identify the correct AUG codon to begin reading the mRNA. Typically, the 40S subunit carrying the bound Met-tRNA migrates away from the cap along the 5' untranslated region (UTR) of the mRNA in a 5' to 3' direction, a process referred to as **scanning**. Based on model plants, the 5' UTRs range from <10 to >200 nucleotides (nt), but on average are ≈125 nt. mRNAs with 50–75 nt 5' UTRs are over-represented in polysomes, suggesting this is the optimum leader length in protein synthesis. For initiation, the ribosome generally selects the first AUG codon it encounters; however, there are significant exceptions (especially with viral templates; see Box 10.2). AUG selection is facilitated by codon:anticodon hydrogen bonding between the AUG codon and the Met-tRNA bound to the ternary complex on the 40S subunit with the associated factors eIF1, eIF1A, and eIF5B. This pairing fixes the start site on the mRNA and establishes the correct reading frame.

Ribosomal selection of the initiation AUG codon is not strongly dependent on the nucleotide sequence surrounding the codon. A consensus sequence surrounding the AUG translation initiation codon for *Arabidopsis* and rice (*Oryza sativa*) was identified through in silico analysis of predicted translation initiation sites. The consensus sequence is highly degenerate: aa(A/G)(A/C)aAUGGcg and c(g/c)(A/G)(A/C)(G/C)AUGGCg, where lower-case letters are variable and upper-case letters are conserved nucleotides. These sequences are similar to the human translation initiation consensus, with the G following the AUG codon being the most important

TABLE 10.2 Eukaryotic initiation factors (eIFs) and their roles in initiating translation.

Class	Members	General role
eIF1	eIF1, eIF1A	Multiple effects in enhancing initiation of complex formation and AUG selection
eIF2	eIF2, eIF2B*	GTP-dependent recognition of Met-tRNA and nucleotide exchange
eIF3	eIF3 [†]	Ribosomal subunit dissociation; promotion of Met-tRNA and mRNA binding to 40S subunits
eIF4	eIF4A, eIF4B, eIF4F [‡] , eIF(iso)4F [‡] , eIF4H [‡]	Recognition of 5' cap on mRNA, binding 40S subunit to mRNA, and unwinding mRNA secondary structure
eIF5	eIF5, eIF5B*	Promotion of eIF2 GTPase activity, AUG selection, and release of factors from ribosome; joining of the 60S subunit
eIF6	eIF6	Binds to 60S subunits and may function in regulation and assembly of ribosomes
PABP	Poly(A)-binding protein	Binds to poly(A) at 3' end of mRNA and interacts with eIF4F at the 5' end, facilitating circularization

*The presence of eIF2B, eIF5B, and eIF4H in plants is based only on the presence of gene sequences similar to other eukaryotes. eIF2B and eIF4H have not been purified or characterized from plants.

[†]eIF3 is composed of 13 nonidentical subunits (designated a–m) ranging from 180 to 28 kDa.

[‡]These factors are composed of two subunits. eIF4F consists of eIF4G and eIF4E (cap-binding protein); and plant-specific eIFiso4F consists of eIFiso4G and eIFiso4E (cap-binding protein).

residue neighboring the AUG codon. *Arabidopsis* mRNAs that lack the optimal context at the initiator AUG are more likely to be poorly translated in leaves under dehydration stress. Thus, the initiation context may be particularly important when protein synthesis is constrained, such as under suboptimal growth conditions. Other properties of the 5' UTR that can affect translation of its downstream open reading frame (ORF) are the presence of potential secondary structures, such as a loop of self-complementarity, or short ORFs called upstream ORFs (uORFs, see Box 10.3).

Next, the large ribosomal subunit binds to the small subunit, with the mRNA and Met-tRNA^{Met} remaining in the correct position (Fig. 10.3). During this stage, eIF5 acts as a GTPase-activating protein and stimulates the hydrolysis of

GTP by eIF2 present in the ternary complex; eIF2-GDP is then released. The final step of joining of the 60S subunit requires eIF5B, another GTPase that interacts with both the large and small subunits.

This mechanism for the initiation of protein biosynthesis in the cytosol of plants appears to be very similar to that in other eukaryotes. One difference, however, is the presence of two forms of eIF4F, the protein complex involved in recognizing the 5' mRNA cap before the interaction between the mRNA and 40S ribosomal subunit. Plants have two forms of this initiation factor, eIF4F and eIF(iso)4F, each comprised of two subunits, eIF4G/eIF4E or eIFiso4G/eIFiso4E. The purpose of these two forms in plants is not known, but likely reflects the need for specialized translation or regulation of translation for some plant mRNAs.

10.2.3 Initiation of protein synthesis in the cytosol is tightly regulated

In all eukaryotes, translation is primarily regulated at the initiation. In mammals and yeast, phosphorylation of eIF2 by several different kinases prevents the exchange of GDP bound by eIF2. Whether phosphorylation of eIF2 is also a major regulatory event in plant cells is still unknown and an area of active research. Several lines of evidence suggest this regulatory system may function in plants. Unphosphorylated eIF2 α is barely detectable under normal growth conditions, but the phosphorylated form increases in seedlings depleted for amino acids. Concomitantly, overall protein synthesis declines (Fig. 10.4). An *Arabidopsis* kinase (GCN2) that phosphorylates plant eIF2 α subunit has been identified. GCN2 is activated by amino acid deprivation, among other stresses, and eIF2 is phosphorylated in a GCN2-dependent manner under the same conditions (Fig. 10.4). These changes correlate with an overall reduction in protein synthesis; however, a direct effect on initiation of translation by phosphorylation of eIF2 α by plant GCN2 kinase has not been demonstrated.

A second major regulatory pathway in yeast and mammals is through a small protein that competes with eIF4G for binding to eIF4E. These eIF4E-binding proteins, known as 4E-BPs in mammals, are regulated through phosphorylation by kinases in signal transduction cascades. This group of regulatory proteins has not been detected yet in plants, either biochemically or through bioinformatics.

The regulation of translation by small RNAs is a rapidly growing area of research. The exact mechanisms of how small RNAs regulate the translation of targeted mRNAs are still being explored. While microRNAs (miRNAs) were thought to act primarily by degrading mRNAs in plants, it appears that, as in animals, miRNAs can inhibit translation specifically without affecting mRNA levels. Small RNAs may not only downregulate translation of mRNAs; they can also enhance translation under certain conditions.

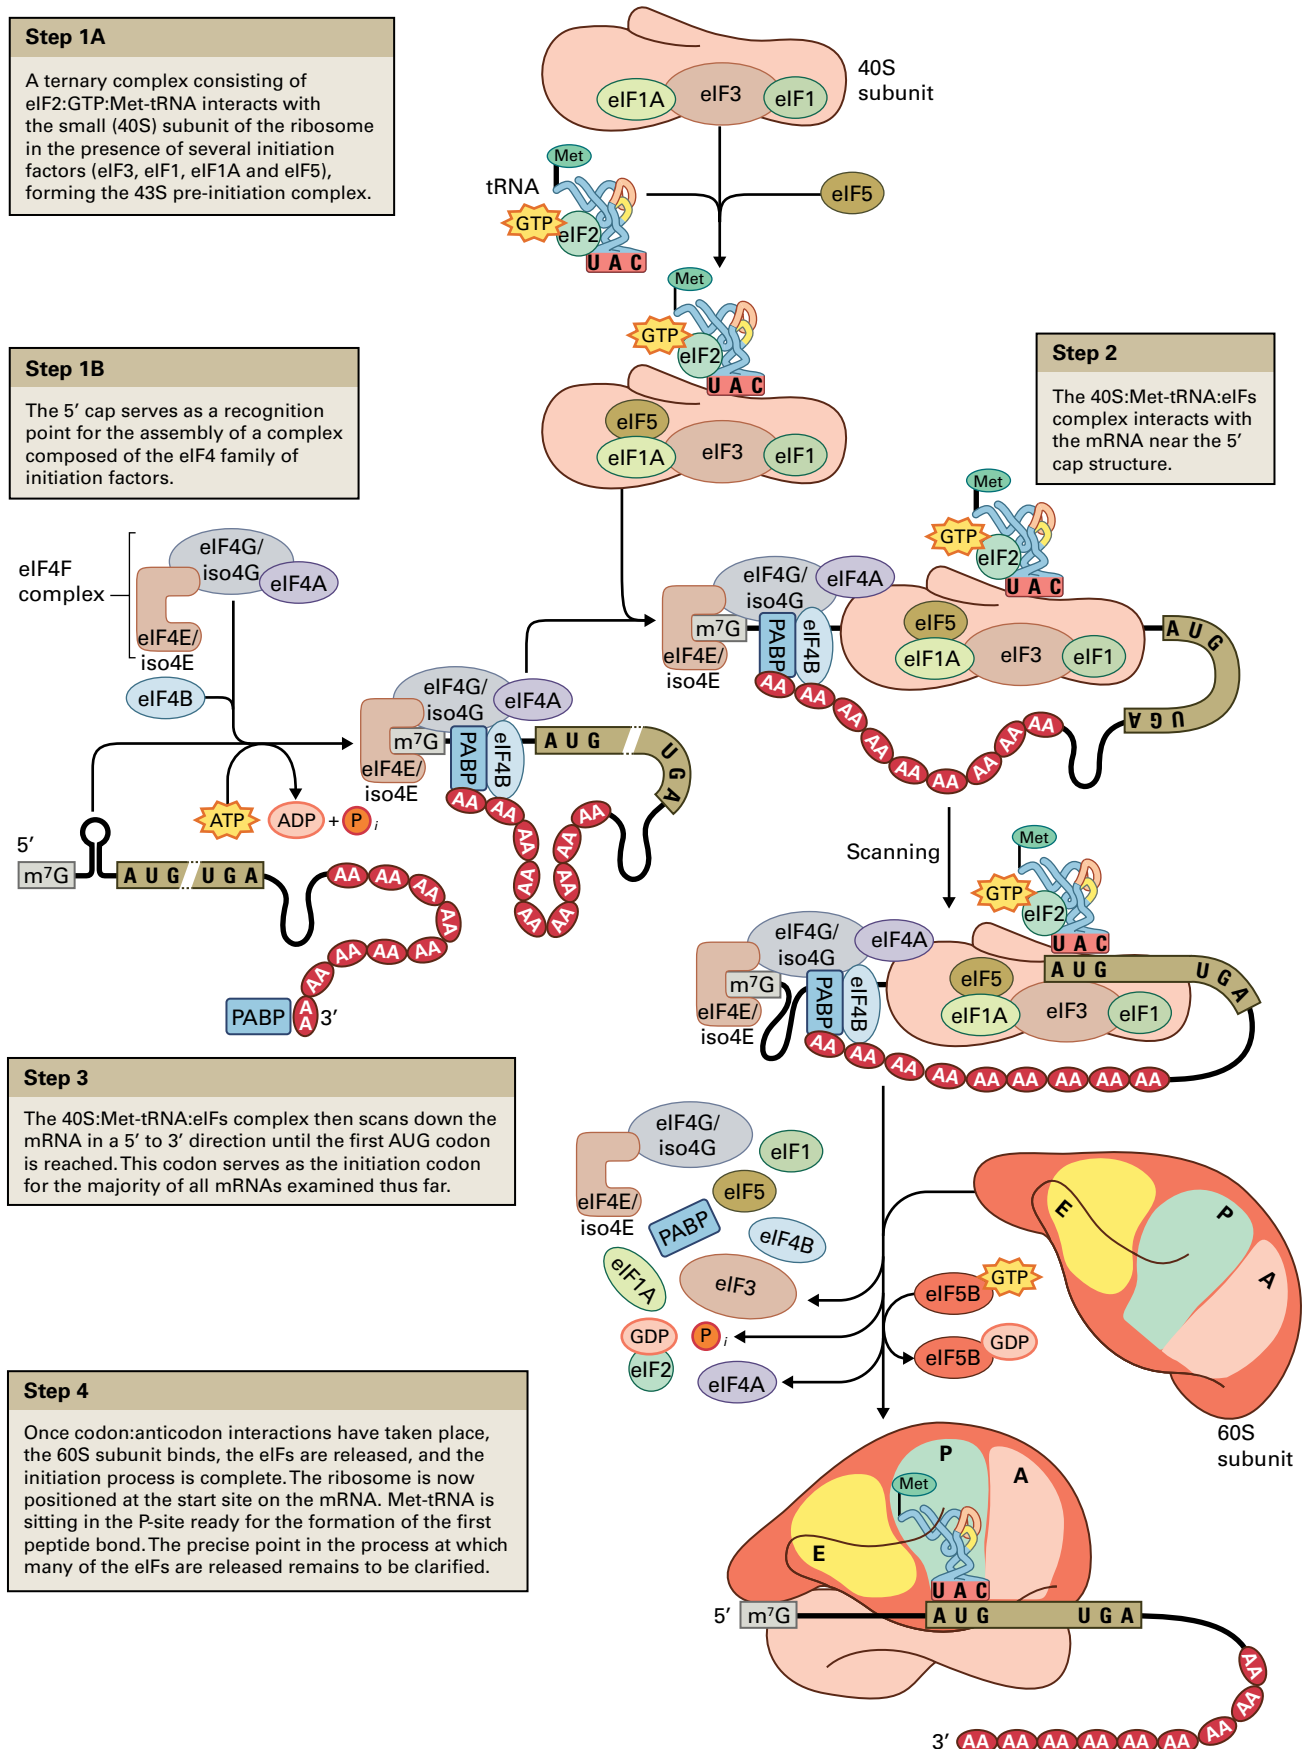

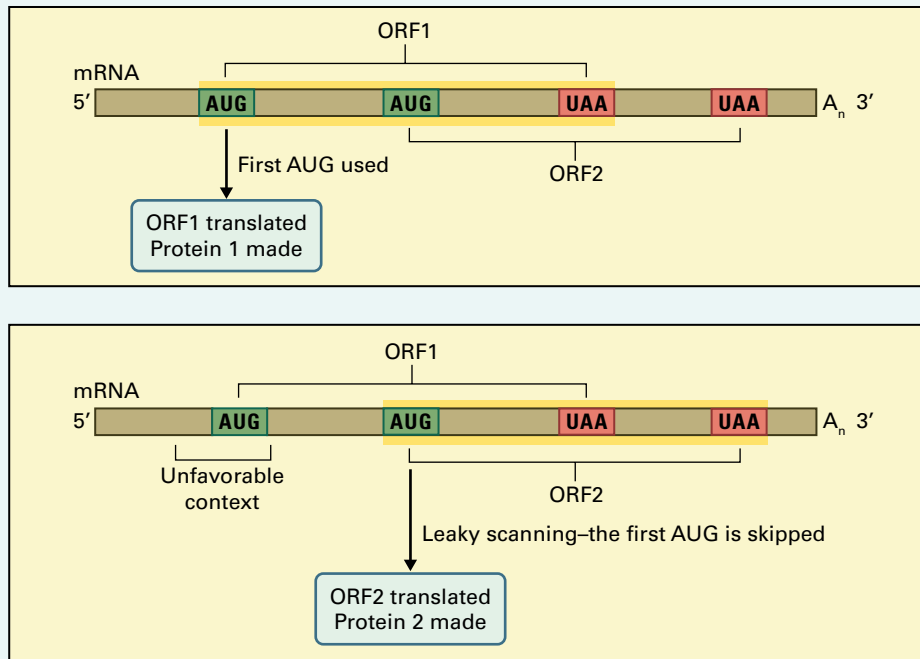

FIGURE 10.3 Overview of the mechanism of polypeptide chain initiation in the plant cell cytosol.

BOX
10.2

Leaky scanning allows plant viruses to translate multiple polypeptides from a single mRNA

Most eukaryotic mRNAs are monocistronic, initiating protein synthesis from the AUG codon closest to the 5' end. Several features of a particular mRNA—including the nucleotide sequence surrounding the first AUG, the secondary structure of the mRNA, and the distance between the cap and the first AUG codon—can affect the efficiency of initiation at the first AUG. If the first AUG is in an unfavorable context, some ribosomes may bypass it

and initiate translation at the second AUG codon, in a process referred to as **leaky scanning**. If the two AUG codons set different reading frames, the two proteins made will have very different sequences and likely carry out different biological functions. Many plant viruses, such as many of the luteoviruses (e.g., barley yellow dwarf virus), use this strategy because it allows the virus to minimize its genome size while maximizing the coding capacity of the genome.

10.2.4 Polypeptide chain elongation involves sequential addition of amino acid residues to the growing polypeptide chain

The sequential addition of amino acids to the growing polypeptide chain involves the use of three sites (the A-, P-, and E-sites, Fig. 10.5) on the fully assembled 80S ribosome. The P-site (peptidyl-tRNA binding site) participates in chain initiation and donates the growing polypeptide chain to the incoming aminoacyl-tRNA (aa-tRNA) in the A-site. The A-site (aa-tRNA binding site or decoding site) exposes the next codon to be read on the mRNA, where the incoming charged tRNA binds. The P-site tRNA occupies the E-site (exit site) after it has released its growing polypeptide chain, just before it leaves the ribosome. These three sites are used

sequentially as the polypeptide chain is synthesized, and a complete cycle requires as little as 0.05 seconds.

The overall chain elongation process occurs in three steps (Fig. 10.5) and requires three elongation factors: eEF1A, eEF1B, and eEF2 function similarly to bacterial elongation factors. eEF1A in the GTP-bound form binds to the aa-tRNA and delivers it to the ribosome, accompanied by GTP hydrolysis. eEF1B exchanges the GDP for GTP on eEF1A to allow recycling of eEF1A. eEF2 catalyzes translocation of the mRNA through GTP hydrolysis after formation of the peptide bond. eEF2, unlike other G proteins involved in translation, such as eIF2 and eEF1A, does not require a recycling factor to replace the GDP for GTP. eEF2 is a target of regulation through phosphorylation and ADP-ribosylation, processes that are conserved across eukaryotes. Both eEF1A and eEF2 are believed to interact with the

BOX
10.3

Translation of certain mRNAs is regulated by upstream open reading frames

Classical eukaryotic mRNA harbors only a single open reading frame (ORF), and ribosomes scan across the 5' untranslated region (5' UTR) to find the main AUG start codon (see text). Thus, it comes as a surprise that an estimated one third of mRNA species contain additional AUG codons within their 5' UTR (5' leader). These upstream AUGs and their associated **upstream open reading frames** (uORFs) complete with a stop codon terminate before the AUG of the major ORF.

uORFs often serve a regulatory purpose. For example, the mRNA for the *Arabidopsis* transcription factor, AtbZIP11, contains a 42-amino acid uORF (uORF2) with

a phylogenetically conserved peptide sequence that represses translation of the main ORF when sucrose levels are high. Given that AtbZIP11 induces transcription of asparagine synthetase mRNA, its uORF may serve to coordinate sugar and amino acid metabolism. The sucrose-regulatory uORF is embedded into a cluster of additional uORFs that fine-tune its regulatory activity. Specific components of the general translation initiation machinery, including 60S ribosomal proteins and subunits of the largest initiation factor, eIF3, allow the ribosome to **reinitiate** translation after terminating at a uORF stop codon. Without such reinitiation, the main ORF could not be translated effectively.

FIGURE 10.4 (A) The alpha subunit of eIF2 is phosphorylated in response to amino acid deprivation (here by treatment of seedlings with the herbicide chlorosulfuron (chlor), an inhibitor of branched amino acid synthesis). Phosphorylation is detected with an antibody that specifically detects the phosphorylated form. eIF2α phosphorylation is not seen in a *gcn2* mutant background, but is restored when a *GCN2* expression construct is re-introduced into the mutant background. Three independent transgenic lines are shown. The tubulin immunoblot (below) indicates that equal protein was present in each sample. (B) Schematic of the proposed control of protein synthesis initiation by eIF2α phosphorylation. Phosphorylation correlates with reduced overall protein synthesis; however, the mechanism of the inhibition has not been shown to be similar to that in mammals and is currently unknown. Source: (A) Lageix et al. (2008). BMC Plant Biology 8:134.

P-protein stalk on the large ribosomal subunit, which is essential for GTP hydrolysis.

As a ribosome starts to read an mRNA, it moves downstream, exposing the start codon and allowing a second ribosome to initiate translation of the mRNA. Thus, mRNAs generally associate with several ribosomes to form structures referred to as polysomes, or polyribosomes (Fig. 10.6). The ribosomes are often spaced as close as 80–100 nt apart on the mRNA. An 80S ribosome occupies about 30–35 nt on an

mRNA. The presence of an mRNA in a polysome suggests translation of that mRNA, although exceptions exist. Recent studies have shown that mRNA associated with polysomes may be a distinct population of mRNA from the total mRNA isolated from cells, and may more accurately represent the protein synthetic activity of the cell. The method of ribosome footprinting can identify not only which mRNAs are actively being translated, but the position of the ribosome on the mRNA.

Step 1

A growing polypeptide chain is covalently attached to the tRNA in the P-site. The A-site is empty, exposing the next codon on the mRNA. The E-site is occupied by the uncharged tRNA from the previous cycle.

**Step 2**

A charged tRNA binds to the ribosomal A-site only if its anticodon matches the exposed codon on the mRNA. When this occurs, the tRNA in the E-site is ejected from the ribosome. A required elongation factor, eEF1, forms a ternary complex with GTP and the charged tRNA and promotes the binding of the charged tRNA to the A-site of the ribosome.

**Step 3**

The ribosome uses the peptidyl transferase center to catalyze the formation of a peptide bond between the growing polypeptide chain and the new amino acid. Recent experiments suggest that rRNA plays a particularly important role as a ribozyme in this catalytic step. The net result of this process is that the nascent polypeptide has been transferred from the tRNA in the P-site to the new amino acid attached to its tRNA in the A-site. The polypeptide is one residue longer, the peptidyl-tRNA now occupies the A-site, and the tRNA in the P-site is free of its amino acid. This tRNA is said to be deacylated.

**Step 4**

The complex must rearrange, exposing the next triplet. This process, called translocation, involves three rearrangements: the deacylated tRNA in the P-site moves into the vacant E-site; the peptidyl-tRNA in the A-site moves into the P-site; and the ribosome moves relative to the mRNA by exactly three nucleotides (one codon), exposing a new triplet in the A-site. Moving one or two nucleotides too little or too much would initiate a new reading frame, probably resulting in an inactive polypeptide.

FIGURE 10.5 The elongation phase of cytosolic protein synthesis in plants.

FIGURE 10.6 Most mRNAs are translated by more than one ribosome at a time. The term polysome refers to an mRNA that binds multiple ribosomes. Sucrose density-gradient centrifugation can be used to separate the mRNAs that bind different numbers of ribosomes. The more ribosomes bound, the more massive the polysome, and the greater the distance traveled during sedimentation.

Polysomes fall into two classes—free and membrane-bound. The proteins synthesized by free polysomes are released after translation and are directed to their final destination by protein sequences that act as targeting signals. By contrast, the protein products of membrane-bound polysomes are inserted directly into the membrane during translation, typically the endoplasmic reticulum (ER), but also the thylakoid and inner membrane of the plastid and mitochondria, respectively. This mechanism is referred to as **cotranslational translocation** (see Chapter 4 for more details).

10.2.5 Termination of protein synthesis occurs at specific signals in the mRNA

Polypeptide elongation ceases when a ribosome reaches one of three stop codons on the mRNA: UAA, UAG, or UGA (Fig. 10.7). Termination of protein synthesis requires two proteins, known as **release factors** (RFs), eRF1 and eRF3, to bind to the A-site. eRF1 is a structural mimic of tRNA, and it recognizes all three stop codons and binds eRF3 and GTP. eRF3 has GTPase activity. RF interaction with the ribosome triggers a series of events, including hydrolysis of the bond between the completed protein and the final tRNA at the P-site. GTP hydrolysis by RF3 stimulates release of the polypeptide and the RFs from the ribosome. The tRNA and the ribosome are also released from the mRNA and become available to participate in another cycle of translation.

Dissociation of the 80S ribosome into 40S and 60S subunits is promoted by eIF6 and ATP-binding cassette E (ABCE1) protein in an ATP-dependent process, and may not occur until 40S subunits are required for preinitiation complex formation. Consequently, 80S ribosomes lacking an mRNA accumulate when initiation of translation is limited, such as under conditions of stress (e.g., hypoxia, heat shock, or dehydration stress).

10.2.6 Translation of plant cytosolic mRNAs is affected by stress conditions

Protein synthesis in the cytosol of plants does not occur at a constant rate. Rather, it is regulated in response to numerous physiological and environmental changes. Stresses such as anaerobiosis, heat shock, or viral infection diminish cytosolic protein synthesis (see Chapters 21 and 22). For example, plants growing in flooded fields can suffer oxygen deficit (hypoxia) as soil gases are displaced by water and less air reaches the roots. During hypoxia, oxidative phosphorylation can no longer provide energy for the cell, and fermentative metabolism dominates. The cell responds by decreasing the synthesis of most of the normal cellular proteins while maintaining synthesis of select enzymes required for glycolysis and ethanolic fermentation. mRNAs for the enzymes involved in anaerobic metabolism remain bound to polysomes, whereas other mRNAs decrease dramatically from the polysome population. Upon reintroduction of oxygen, mRNAs for all cellular processes rapidly return to polysomes. Presumably, this mechanism of reduction of protein synthesis and sequestration of cellular mRNAs during this stress helps to conserve ATP and preserve energy when aerobic metabolism is limited. The regulatory mechanisms that control how the translational machinery responds to physiological and environmental changes are currently the focus of considerable research.

10.3 Mechanisms of plant viral translation

10.3.1 Viral mRNAs are translated despite the absence of a 5' CAP

Many plant viral RNAs lack a 5' cap structure, so the RNA is translated in a cap-independent manner. These viral RNAs harbor a cap-independent translation enhancer or element

FIGURE 10.7 Events during the termination of protein synthesis. Polypeptide chain termination occurs when one of three stop codons appears in the A-site of the ribosome.

FIGURE 10.8 Plant viral RNAs initiate translation differently than cytosolic mRNAs. The viral RNA (right) contains a 3' CITE that binds the eIF4 complex, mimicking the cap structure of cytosolic mRNA (left). The viral cap-like structure interacts with the pre-initiation complex (43S) to position the RNA correctly at its 5' UTR.

Source: W. Allen Miller, Iowa State University.

BOX 10.4

Plants have naturally occurring virus resistance genes

A number of naturally occurring plant virus resistance genes in lettuce, tomato, pepper, pea, melon, rice, and barley correspond to genes encoding the cap-binding complex subunits, eIF4E, eIFiso4E, eIF4G, or eIF(iso)4G. The majority, but not all, of these resistance factors function against RNA viruses (potyvirus, cucumovirus, carmovirus, bymovirus, sobemovirus, polerovirus) carrying a virus-encoded protein (VPg) linked at the 5' end of their genomes. Translation initiation factor-mediated resistance results from a small number of amino acid changes, most of which are not conservative and are on the surface

of the protein (see colored areas in protein images). Interestingly, the mutations (often single amino acid changes) occur at sites generally distinct from the cap-binding region of the host protein, suggesting that cap-binding ability is not affected by the mutation (because eIF4E must still function for host mRNA translation). Although the exact mechanism for viral resistance has not been determined, it appears that these host initiation factor genes are required in some capacity for the translation and/or replication of the viral RNA genome that is mediated by direct interaction with the viral VPg protein.

Select known VPg resistance mutations

(CITE) in a UTR. This RNA tract has a high affinity for translation initiation factors that, in turn, recruit the ribosome to the mRNA.

Plant viral CITEs are usually about 100 nt long and come in a variety of sequences and structures. Those of potyviruses and crucifer-infecting tobamovirus are located in the 5' UTR of the viral mRNA. In contrast, CITEs of viruses in the large, diverse Tombusviridae family (e.g., the Carmovirus, Tombusvirus, and Panicovirus genera) are located in the 3' UTR. Some of these 3' CITEs bind subunits of translation initiation factor eIF4F or eIF(iso)4F, which normally requires a

cap structure on the RNA to bind with high affinity. Most 3' CITEs are known or predicted to base pair to a sequence in the 5' UTR mimicking the circularization of cellular mRNAs by the interaction of eIF4G and PABP (Fig. 10.8). The essential role of translation initiation factors, eIF4E, eIFiso4E, eIF4G, or eIF(iso)4G in the virus replication cycle is made evident by the fact that alleles of genes encoding these factors are often recessive resistance genes (see Box 10.4). This means the wild-type alleles are essential for virus infection. Coordination of translation with replication is a key to successful viral infection (see Box 10.5).

BOX
10.5

Viruses coordinate replication and translation

Why do some viruses have such a complicated system to control translation initiation at the 5' end via a sequence in the 3' UTR? One reason is that it may prevent collisions between ribosomes and the viral replicase during early infection events. All positive-sense RNA viruses must translate the viral replicase-coding region before the viral RNA can be replicated. A problem is that translation must be shut off to allow the replicase to copy the viral RNA without interference from the ribosomes translating the RNA. Replicase initiates complementary RNA synthesis at the 3' end of the viral template RNA. As the replicase moves in the 5' direction

in the 3' UTR of the template, it would encounter and disrupt the CITE structure in the 3' UTR and interfere with CITE base pairing to the 5' UTR, thereby turning off translation initiation at the 5' end. This would depopulate the RNA of ribosomes translating upstream of the replicase. By the time the replicase moves upstream along its template to the translated region, the translated region would be ribosome-free and available to be copied by the viral replicase. Thus, blocking the base pairing between the 3' CITE and the 5' UTR would serve as a molecular switch to turn off translation and promote replication.

10.3.2 Viruses use recoding mechanisms, such as shifting the translation reading frame and reading through stop codons, to increase the diversity of proteins synthesized

Plant viruses often use recoding mechanisms (noncanonical reading of the genetic code) to increase the variety of products they can make. Ribosomal frameshifting allows translation of overlapping open reading frames (Fig. 10.9).

All ribosomes initiate at the same start codon in “zero frame,” and most read only this ORF. In the region of reading frame overlap, however, a small fraction (1–10%) of translating ribosomes change reading frames. The vast majority of programmed frameshifts are into the –1 frame. Frameshifting at –1 occurs at a slippery heptanucleotide that usually fits the consensus XXXYYYZ, where X is any base, Y is A or U, and Z is any base except G. This is followed by a highly structured region, usually consisting of a pseudoknot, beginning six to eight bases downstream. It is thought that, as the leading edge of the ribosome encounters the structured region, the slippery site is positioned inside the ribosome bound to the tRNAs at the A- and P-sites. The tension created by the inability of the ribosome to “melt” the pseudoknot forces the tRNAs in the A- and P-sites to slip one base backward relative to the mRNA and into the –1 frame. tRNAs then repair to the mRNA, the pseudoknot secondary structure is melted, and translation resumes normally.

Many viruses also can incorporate an aa-tRNA instead of a release factor at a stop codon in a process called in-frame stop codon readthrough, or codon redefinition. Like frameshifting, this is an infrequent event performed by <1% to perhaps 10% of ribosomes, depending on the readthrough sequence. It provides a high ratio of the shorter protein encoded by the first ORF to the C-terminally extended version of the protein encoded by the first ORF plus the sequence downstream of the stop codon. Readthrough signals in the mRNA are quite diverse and less well characterized than those that confer –1 frameshifting. Perhaps the best characterized example is that of tobacco mosaic virus

(TMV). Expression of the polymerase gene requires readthrough of a stop codon at the consensus motif UAGCARYYA, where UAG is the stop codon, R is any purine, and Y is any pyrimidine. The mechanism of readthrough remains unknown.

10.4 Protein synthesis in plastids

10.4.1 Plastid protein synthesis shows many similarities to bacterial protein synthesis

Plastid protein synthesis differs from cytosolic protein synthesis in several details. In general, the ribosomes, mRNAs, and auxiliary factors required at each step are not interchangeable between the cytosol and the plastid, and the numbers and functions of specific initiation factors differ considerably between the cytosol and the plastid. Bioinformatic analyses indicate plants have plastid translation factors that can be recognized based on their homology to bacterial translational factors. These include homologs of prokaryotic initiation factors (IF1, IF2, and IF3), elongation factors (EF-Tu, EF-Ts, and EF-G), termination factors (RF1, RF2, RF3), and the ribosome recycling factor RRF (Table 10.3). Very little enzymology has been carried out on the translation factors required in the plastid. The best studied are those of the unicellular photosynthetic organism *Euglena gracilis*, which have many functional similarities to the bacterial factors, but also have a number of unique structural features that may facilitate their function within the chloroplast.

Plastid ribosomes (see Table 10.1) have a single 16S rRNA in the small subunit, but three rRNAs in the large subunit (23S, 5S, and 4.5S); however, the total amount of RNA in plastid ribosomes is only a few nucleotides more than in bacterial ribosomes. Homologs of almost all of the bacterial ribosomal proteins occur in plastid ribosomes, and several

FIGURE 10.9 Recoding mechanisms are used in viruses. Frameshifting occurs when two overlapping ORFs share a start codon but terminate at different sites. The reading frame of one ORF shifts, made possible by a recoding signal positioned at the site where the frameshift occurs. The ribosome slips back one nucleotide (into the -1 frame), then continues until reaching a different stop codon.

TABLE 10.3 Plastid translation factors and their relationship to bacterial translation factors.

Factor	Role in prokaryotes	Approximate conservation between <i>Arabidopsis</i> and bacterial factor	Comments
IF1	Facilitates the functions of IF2 and IF3	≈58% identical to <i>E. coli</i> IF1 after removing the import signal	Very small protein, probably <80 amino acids after import signal removed
IF2	Binds the initiator tRNA (fMet-tRNA) to the ribosome	≈34% identical to <i>E. coli</i> IF2 after removing the import signal	Lengths variable, with the <i>E. gracilis</i> chloroplast IF2 over twice the size of the <i>E. coli</i> factor
IF3	Mediates dissociation of ribosomal subunits, proofreads the initiation complex	≈42% identical to <i>E. coli</i> IF2 after removing the import signal	Generally longer than the bacterial factors, with the <i>E. gracilis</i> chloroplast IF3 over twice the size of the <i>E. coli</i> factor
EF-Tu	Binds aa-tRNA to A-site of the ribosome	≈69% identical to <i>E. coli</i> IF2 after removing the import signal	Generally a highly conserved factor; encoded in chloroplast genome in some species
EF-Ts	Mediates guanine nucleotide exchange with EF-Tu	≈34% similar to <i>E. coli</i> EF-Ts, but percentage unclear due to overall poor alignment	Polyprotein with chloroplast ribosomal protein S7
EF-G	Translocase	≈57% identical to <i>E. coli</i> EFG after removing the import signal	GTPase
RF-1	Release factor 1, recognizes UAA/UAG	≈41% identical to <i>E. coli</i> RF after removing the import signal	Essential gene
RF-2	Release factor 2, recognizes UAA/UGA	≈41% identical to <i>E. coli</i> RF after removing the import signal	Also important for mRNA stability
RF3	Mediates release of RF1 and RF2 from the ribosome	33% identical to <i>Chlamydomonas</i> RF3	Homolog not yet clear in <i>Arabidopsis</i>
RRF	Ribosome recycling factor	≈44% identical to <i>E. coli</i> RF after removing the import signal	Has been isolated from spinach and preliminary enzymology studies done

FIGURE 10.10 Comparison of the cryoelectron microscopy maps of the spinach (*Spinacia oleracea*) chloroplast 70S ribosome at 9.4-Å resolution and the *E. coli* 70S ribosome. (A) The chloroplast ribosome is shown with the 30S subunit in yellow and the 50S subunit in green. (B) The *E. coli* 70S ribosome with the 30S subunit in pale yellow and the 50S subunit in blue. Structural differences between chloroplast and *E. coli* ribosomes are indicated by the red arrows in A. Landmarks of the 30S subunit: h, head; sh, shoulder; and sp, spur. Landmarks of the 50S subunit: CP, central protuberance; H38, 23S rRNA helix 38; L1, protein L1 protuberance; and Sb, stalk base.

plastid-specific ribosomal proteins (PSRPs) have no counterparts in bacteria. The exact number of these varies between the plastids of different organisms. For example, spinach (*Spinacia oleracea*) chloroplast ribosomes have six plastid-specific ribosomal proteins (four in the small subunit and two in the large subunit). Cryoelectron microscopy of these ribosomes (Fig. 10.10) has allowed an estimation of the location of these plastid-specific proteins. One of them (PSRP1) is located on the decoding face of the small subunit and blocks both the ribosomal A- and P-sites to prevent translation. It has been postulated that this protein must be released or moved before initiation occurs, and that this process may be directly involved in the regulation of chloroplast protein synthesis by light (see below).

FIGURE 10.11 The Shine–Dalgarno interaction for selection of the start codon. Initiation at the correct AUG codon is facilitated by hydrogen bonding between a polypurine sequence in the mRNA (the Shine–Dalgarno sequence) and a polypyrimidine sequence near the 3' end of the small subunit 16S rRNA.

Perhaps one of the most fundamental differences between the translation systems found in the plastid and cytosol of plants can be seen in the process by which the initiation signal on the mRNA is selected. As discussed earlier, cytosolic mRNAs have a 5' cap that flags the 5' end for initiation factors. By contrast, plastid mRNAs are not capped and are often transcribed as polycistronic messages that contain several reading frames, similar to bacterial mRNAs.

In bacterial systems, the small (30S) subunit of the ribosome selects the correct AUG codon for initiation. The 16S rRNA in this subunit base pairs with the Shine–Dalgarno sequence, a short sequence found just upstream of the initiation AUG and named after its discoverers (Fig. 10.11); binding this sequence facilitates selection of the start codon. The mechanism by which plastid ribosomes recognize the correct AUG for initiation has been studied most extensively in *E. gracilis*, spinach, and *Chlamydomonas*. Chloroplast mRNAs from these organisms tend to fall into two classes. One group does not contain a Shine–Dalgarno sequence within 20 nt of the start codon. Further, they have no conserved sequence signal in the 5' UTR. The translational start site in these mRNAs is specified by the presence of an AUG codon in an unstructured or weakly structured region of the mRNA (Fig. 10.12) and in many cases probably requires one or more nuclear-encoded *trans*-acting proteins to facilitate initiation. The chloroplast mRNAs in the second group contain a Shine–Dalgarno sequence upstream from the start codon. In this class of mRNAs, the sequences surrounding the start codons demonstrate a greater degree of secondary structure, and the Shine–Dalgarno sequences typically play a role in initiation.

10.4.2 Thylakoid membrane proteins encoded in plastid DNA are translated on membrane-bound ribosomes

The light reactions of photosynthesis occur in the thylakoid membranes, and several of the proteins synthesized by the chloroplast are destined for incorporation into enzyme complexes

FIGURE 10.12 Selection of the start site on chloroplast mRNAs proceeds by one of two routes, as dictated by the mRNA sequence. In the first route (left), the start codon is located in a weakly structured region and may be facilitated by a trans-acting factor. In the second route (right), a Shine–Dalgarno sequence is located near the start codon facilitating its selection for initiation.

FIGURE 10.13 Proteins targeted to multimeric complexes in the thylakoid membrane are synthesized on membrane-bound ribosomes. Translation of these mRNAs is initiated in the soluble portion of the chloroplast (stroma). Signals in the nascent peptides then direct the polysomes to the thylakoid membranes, where protein synthesis is completed.

found in these membranes (Fig. 10.13). Synthesis of chloroplast membrane-bound proteins appears to occur in two steps. Protein synthesis in the chloroplast is believed to be initiated on free ribosomes. Once the nascent protein chain emerges from the ribosome, the amino acid sequence near its N-terminus acts as a signal sequence, directing the ribosome to the thylakoid membrane. This process is mediated by a protein complex, the chloroplast signal recognition particle. Once the ribosome and its nascent chain associate with the membrane, translation continues, and the polypeptide is inserted into the membrane as it

is synthesized. In some cases, it is believed that certain mRNAs are directed to thylakoid membranes directly by binding to membrane-associated RNA-binding proteins.

10.4.3 Chloroplast protein synthesis is regulated by light

Photosynthetically active chloroplasts arise from proplastids as a leaf develops, or from etioplasts in dark-grown tissues upon light exposure. Dramatic morphological and biochemical changes occur within these organelles during these transitions.

In the thylakoids, major protein complexes, most notably photosystems I and II (PSI, PSII), are assembled from nuclear- and plastid-encoded proteins. To achieve this, synthesis of many chloroplast proteins is greatly enhanced during the light-induced greening of the plastid. Translation of certain chloroplast mRNAs increases as much as 100-fold, sometimes without significant changes in the amount of mRNA present. For example, the mRNA for the large subunit of Rubisco (LSU) is present in dark-grown amaranth (*Amaranthus* sp.) and is bound to polysomes, but translation is minimal. When the cotyledons are illuminated, LSU mRNA remains constant, but LSU protein synthesis can be detected within 3–5 hours. Similarly, in barley (*Hordeum vulgare*), initiation complexes with the LSU mRNA are formed both in the light and dark, but the subsequent elongation step is enhanced in the light.

In addition to this translational control, changes in transcription, mRNA stability, cofactor availability, and protein degradation also participate in regulating the synthesis of chloroplast proteins (Fig. 10.14). Each protein shows a distinct pattern of regulation. The synthesis of some proteins appears to be controlled to a large extent by transcription, whereas the quantities of other proteins are regulated by changes in translation initiation rates or protein degradation.

It has become clear that nuclear gene products act as regulators of chloroplast protein synthesis, in some cases affecting the translation of a single species of chloroplast mRNA by interacting with its 5' UTR, or more globally affecting

FIGURE 10.14 Many regulatory processes act together to control the quantities of chloroplast proteins present during different phases of growth and development. (1) Gene expression can be regulated at the transcription of the DNA into RNA. (2) Regulation also occurs in the maturation of the pre-mRNA into the mature mRNA. These steps include processing the 3' and 5' ends, removing introns, and processing polycistronic mRNAs in intergenic regions. (3) The stability of the mRNA is regulated through the action of the nucleases that determine how long the RNA will be available for translation. (4) The translation of the mRNA into protein is regulated in several ways, including through the action of specific mRNA-binding proteins. (5) The rate of protein synthesis and the stability of the nascent chain may be regulated during the cotranslational insertion of the polypeptide into the membrane and by the binding of a cofactor such as chlorophyll. (6) The amount of the final protein product from a gene is also regulated by its maturation (folding, modification, localization) and by sequence signals that regulate its lifespan.

translation of many mRNAs. These protein–mRNA complexes increase in the light, correlating with enhanced translation of the mRNA component (Fig. 10.15, see Box 10.6).

10.4.4 mRNA-binding proteins can be regulated by redox potential

During light-activated protein synthesis, binding of the translational activator proteins must be coordinated with the photosynthetic activity of the chloroplast. At least two pathways

seem to link these processes: The first involves the redox potential of the chloroplast, whereas the second couples translation to the availability of energy in the organelle.

Within the chloroplast, photosynthetic electron transfer generates reducing power and drives synthesis of the energy-rich nucleotide ATP (see Chapter 12). Both of these processes appear to regulate translation of *psbA* transcripts in the chloroplast of *Chlamydomonas*. The *psbA* gene product, the D1 protein, is a core component of PSII. The redox environment of the chloroplast and the availability of ATP are thought to influence the formation of a multiprotein complex that binds to the 5' UTR of the *psbA* mRNA. Formation of this mRNA–protein complex is promoted by light and correlates with a 50- to 100-fold enhancement of *psbA* translation.

During the light reactions of photosynthesis, water is split and its electrons are transferred to NADP⁺ by means of a series of electron carriers. One of these redox-active carriers, the small iron–sulfur protein ferredoxin, can donate electrons to several proteins, including the enzyme ferredoxin-thioredoxin reductase (FTR). While best known for mediating the transfer of electrons from reduced ferredoxin to the regulatory disulfide protein thioredoxin (see Chapters 12 and 13), FTR can also reduce a chloroplast enzyme called disulfide isomerase (RB60), which catalyzes the interconversion of cysteinyl sulfhydryls and disulfides. In the current model for regulation of *psbA* protein synthesis by light in *Chlamydomonas*, the light-dependent reduction of RB60 leads to reduction of disulfides within the mRNA-binding protein RB47 (Fig. 10.16). Reduced RB47 as part of an oligomeric complex can then bind to the 5' UTR of the *psbA* mRNA and upregulate its translation.

In chloroplasts, light-dependent phosphorylation of ADP produces energy for the plant cell. In the dark, ATP concentrations fall while ADP concentrations rise. Exposing leaves to light results in a rapid increase in ATP and a concomitant decrease in ADP. These light-dependent shifts in the ADP/ATP ratio may play a role in linking the status of the light environment to translational activity in the chloroplast.

Synthesis of the *Chlamydomonas* D1 protein encoded by *psbA* provides the best-studied case for regulation of translation by ADP/ATP ratios. When activated by high ADP concentrations, a serine-threonine protein kinase is thought to phosphorylate RB60 in an unusual reaction that transfers the β -phosphate from ADP to the protein (Fig. 10.16). The phosphorylated form of RB60 not only fails to promote the reduction of RB47, but also may actively oxidize this protein, leading to accumulation of the oxidized form of RB47. Because the reduced form of RB47 must bind to the *psbA* mRNA to activate translation, the net result of this process is a decrease in the synthesis of D1. Thus, in the current model, a dual system acts to regulate the translation of the *psbA* mRNA. In the dark, when there is an abundance of ADP, RB60 is phosphorylated, reducing its ability to activate the binding of RB47 to the mRNA; in the light, the kinase is inhibited, and the redox environment of the plastid activates RB60. As a result, the reduced form of RB47 accumulates, increasing the ability of that protein to bind mRNA and activate translation.

FIGURE 10.15 *Trans*-acting factors that bind to the 5' UTRs of chloroplast mRNAs are thought to play a role in light-dependent activation of translation.

BOX 10.6

Binding of proteins to mRNAs can be detected by gel-mobility shift assays

Protein binding to RNA can often be detected by a gel-mobility shift assay, in which the RNA is labeled with radioactivity, and its migration during polyacrylamide gel electrophoresis is detected by autoradiography. If a protein binds to the RNA, the protein/RNA complex migrates more slowly in the gel than the unbound RNA molecules. The *trans*-acting factors that bind to chloroplast mRNAs can be detected by this method.

In a specific example, suppose a portion of *psbA* mRNA is subjected to electrophoresis alone (lane 1) or is incubated with an extract of light-grown cells that contain an mRNA-binding protein (lane 2). A protein-mRNA complex forms that migrates at a slower rate during gel electrophoresis. Much less of the mRNA-protein complex is observed when the mRNA is incubated with extracts of dark-grown cells (lane 3).

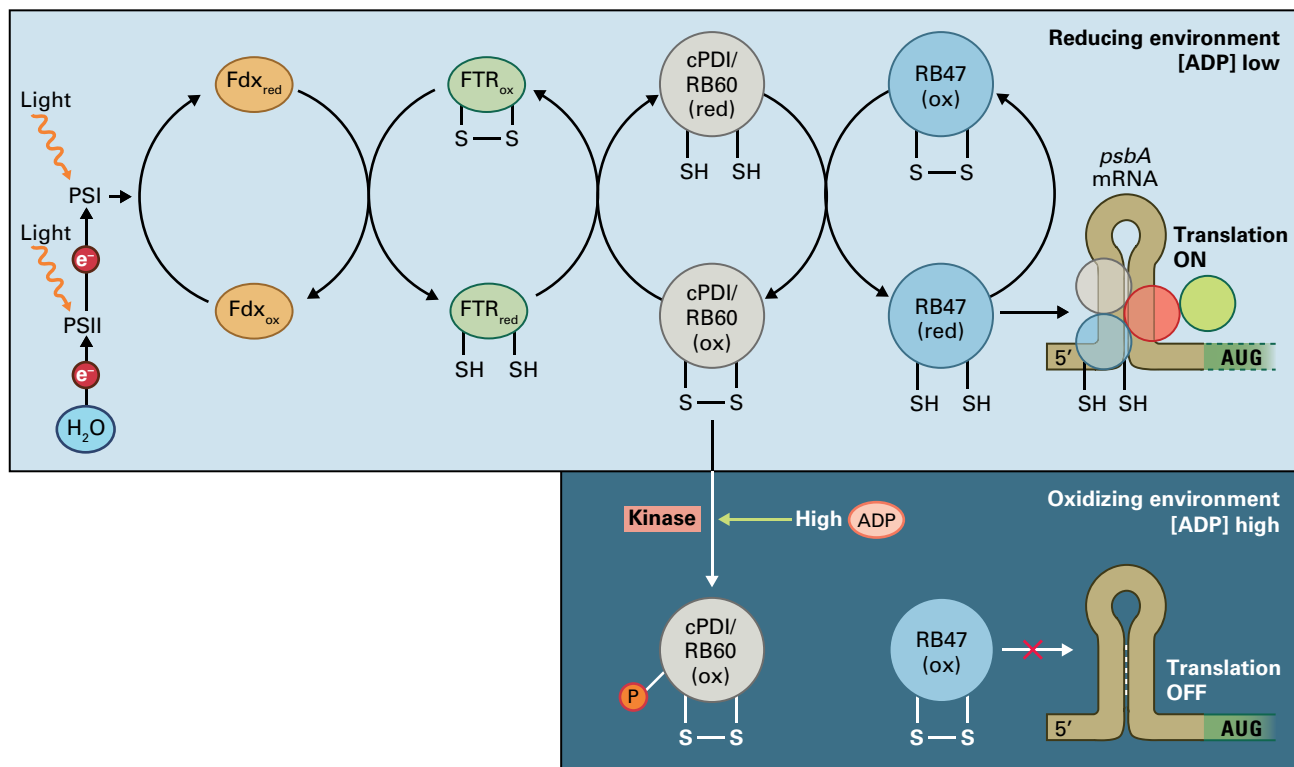

FIGURE 10.16 Model for how light affects synthesis of the chloroplast protein D1, the product of the *psbA* mRNA. In *Chlamydomonas*, a unicellular alga, translation of *psbA* mRNA is enhanced dramatically when a protein complex consisting of at least four distinct polypeptides binds to the 5' UTR. The current model postulates that in the dark, concentrations of reduced ferredoxin (Fdx_{red}) are low and cPDI/RB60 is oxidized. As a consequence, the RB47 mRNA-binding protein is also oxidized and binds poorly to the 5' UTR of the *psbA* mRNA. In the absence of reduced RB47, there is little translation of the *psbA* mRNA. In the light, electrons flow from water to ferredoxin via photosystems (PS) II and I. Fdx_{red} donates electrons to ferredoxin-thioredoxin reductase (FTR), which in turn reduces disulfides in cPDI/RB60. The reduced cPDI/RB60 via PSII and PSI subsequently donates electrons to reduce disulfides in RB47, which can then bind *psbA* mRNA, greatly enhancing its translation. A second level of control is exerted by the concentration of ADP in the chloroplast. In the dark, high concentrations of ADP activate a protein kinase that phosphorylates cPDI/RB60. The phosphorylated form of cPDI/RB60 not only fails to promote the accumulation of reduced RB47 but also appears to actively promote its oxidation. Because the oxidized form of RB47 does not bind well to the *psbA* mRNA, translation is not activated in the dark.

10.4.5 Cofactor insertion often occurs during translation of photosynthetic components

Numerous proteins involved in photosynthesis require prosthetic groups such as chlorophylls, carotenoids, quinones, or hemes to carry out their biological functions. Often, a protein must bind its cofactors before it can accumulate in a stable conformation. Perhaps the best-studied group of proteins in this category is the group that binds chlorophyll. Chloroplast thylakoid membranes include several proteins that bind chlorophyll, six of which are synthesized within the plastid itself. These proteins are essential components of PSI, PSII, and the light-harvesting complexes. In addition to chlorophyll, they also contain several other prosthetic groups, such as quinones (see Chapter 12).

These proteins cannot be detected in cells from emerging leaves and cotyledons before exposure of these organs to light. However, in most plants, mRNA transcripts for these chlorophyll-binding proteins are present whether the plants are kept in the light or the dark. Surprisingly, some of these mRNAs

associate with thylakoid membrane-bound polysomes even in the dark. This indicates that synthesis of chlorophyll-binding proteins is initiated in the dark, but some mechanism prevents the accumulation of mature protein products under those conditions.

Plants must have light to synthesize chlorophyll, since light is required for the conversion of protochlorophyllide to chlorophyll (see Chapter 12). The accumulation of chlorophyll-binding proteins appears to depend on the ability of the chloroplast to complete the process of chlorophyll synthesis. If chlorophyll is not present, the apoprotein is degraded, presumably because it fails to fold properly (Fig. 10.17). In this way, the accumulation of chlorophyll-binding proteins is coupled to the light-dependent synthesis of their cofactors.

To allow time for the chloroplast to coordinate the synthesis of a protein, its insertion into a membrane, and the binding of its required cofactors, the ribosomes pause at discrete sites during the synthesis of the nascent polypeptide chain. The best-studied example of the cotranslational insertion of cofactors is the D1 protein. During its synthesis, the ribosome

FIGURE 10.17 Regulation of protein synthesis by cofactor availability: model for stabilization of a chloroplast protein by cofactor binding. Proteins in the thylakoid membranes bind cofactors such as chlorophyll, quinones, or iron-sulfur clusters. Many proteins that bind chlorophyll do not accumulate in dark-grown chloroplasts, although the mRNA for these proteins is present and is often found in polysomes. Plants require light to complete the synthesis of chlorophyll. Although chlorophyll-binding proteins are believed to be synthesized in the dark, the apoprotein (protein without the bound cofactors) formed is unstable and is rapidly degraded. In the light, the plants make chlorophyll, which binds to the growing polypeptide chain and stabilizes it.

pauses at discrete positions (see Box 10.7), and these pauses facilitate interaction of the nascent chain with the thylakoid membrane, the insertion of segments of the growing polypeptide into the membrane, and assembly of the protein into PSII. The binding of cofactors to the protein occurs during its synthesis and assembly (Fig. 10.18).

10.5 Post-translational modification of proteins

10.5.1 Proteolytic processing can be used to modify the final protein product

Initially, all polypeptides begin with either formylmethionine (in bacteria, plastids, and mitochondria) or methionine (in the eukaryotic cytosol). The formyl group is almost always removed by a ribosome-associated deformylase. In about half of all proteins, the initiating methionine is removed from the nascent chain by a ribosome-associated protease called Met-aminopeptidase. Removal of the N-terminal methionine is

determined largely by which amino acid occupies the second position; small neighboring residues favor removal of the initial amino acid. Occasionally, the second amino acid is also removed, although the protease responsible for this step has not been identified.

As proteins reach their appropriate subcellular location, proteolytic processing may remove any N-terminal signal sequences (see Chapter 4) and other segments of the original polypeptide. One example of proteolytic processing in plant chloroplasts occurs during D1 maturation. Before complete assembly of photosystem II, a C-terminal peptide of D1 (consisting of nine or 16 amino acids, depending on the organism) is removed. The newly formed C-terminus binds to a manganese atom in the oxygen-evolving center, and this interaction is essential for subsequent photosystem function.

Proteolytic processing is also involved in generating active peptide hormones. The 18 amino acid peptide hormone, systemin, is produced in response to wounding in members of the Solanaceae, such as tomato (*Solanum lycopersicum*) and potato (*S. tuberosum*) (Fig. 10.19). Systemin is secreted by wounded plant cells and is transported to other regions of the affected plant to participate in inducing the synthesis of proteins involved in plant defense. Like many peptide hormones

BOX
10.7

Toeprinting can be used to determine where ribosomes pause during protein synthesis

The positions where ribosomes pause on an mRNA can be determined by mapping the edge of the ribosome on the 3' side of the region of the mRNA covered by the ribosome. In this procedure, known as **toeprinting**, mRNAs with ribosomes bound at the stalled position are isolated, and a short DNA primer is hybridized to the mRNA downstream from the predicted pause site. Reverse transcriptase is used to synthesize a cDNA from the mRNA/primer complex. When no ribosomes are present on the mRNA, the reverse transcriptase can potentially copy the mRNA all the way to the 5' end; however, if a ribosome is present between the site where the primer is annealed and the 5' end of the mRNA, the progress of the reverse transcriptase is blocked. When it reaches the edge of the ribosome, the enzyme stops and dissociates from the mRNA, creating a shorter cDNA that locates the leading edge of the ribosome.

in animals, systemin is initially synthesized as a much larger precursor of 200 amino acids, and proteolytic processing produces the active peptide hormone. Phytosulfokines, sulfated penta-, and tetrasulfated peptides discovered for their role in cultured cell proliferation, are produced from an 89 amino acid precursor that includes an N-terminal signal sequence. RALF (rapid alkalization factor) is also synthesized as a pre-protein and undergoes several proteolytic cleavages to produce the biologically active molecule, while others, such as ENOD40 and CLAVATA3, only have an N-terminal signal sequence removed to produce the mature form.

10.5.2 Proteins must fold into a precise three-dimensional structure to carry out their biological function

During or after the completion of translation, the polypeptide chain rearranges to give rise to the well-defined three-dimensional conformation of the protein. Much remains to be learned about this process, but according to the current model, a newly synthesized protein first folds into a structure in which most of the elements of secondary structure

(e.g., α -helices and β -sheets) are present (Fig. 10.20). These structures align with each other so that the orientation approximates the final structure of the folded protein. This partially folded molecule, referred to as a **molten globule**, is the starting material from which the final three-dimensional structure of the protein will emerge after numerous interactions among the amino acid side chains.

In vitro, many proteins can unfold and then refold correctly within a few microseconds, re-establishing their native conformations in the absence of other cellular components. This protein behavior has led to the idea that the primary sequence of the polypeptide contains all the information necessary to confer the correct structure on the folded protein. Similar assumptions have been made regarding the formation of oligomeric complexes. However, high concentrations of cellular proteins and the presence of many surfaces with which a folding protein can interact may interfere with proper folding. In the eukaryotic cytosol, most protein folding occurs cotranslationally. In chloroplasts, at least a portion of protein folding occurs post-translationally. The folding of proteins *in vivo* is regulated by **molecular chaperones**, proteins that promote proper folding of polypeptides and suppress folding patterns that would result in protein aggregation or nonfunctional protein products (Fig. 10.21, see Section 10.5.3).

FIGURE 10.18 Model for cotranslational insertion of cofactors into the D1 proteins. Ribosomes synthesizing D1 pause during translation to allow the protein to interact with the membrane with the correct topology and allow insertion of cofactors such as chlorophyll, pheophytin, and quinones.

10.5.3 Protein-assisted folding occurs in the cell

Molecular chaperones are proteins that bind and stabilize otherwise unstable protein conformations. Through coordinated and repeated binding and release of partially folded polypeptides, chaperones facilitate several processes, including protein folding, oligomer assembly, subcellular localization, and protein degradation. Chaperones do not direct specific folding patterns; rather, they prevent the formation of incorrect interactions within a polypeptide, between polypeptides, or between polypeptides and other macromolecules. Thus, chaperones increase the yield of fully functional proteins.

Chaperones fall into several major classes, including the Hsp70 family (named for their approximate mass in

kilodaltons), and the chaperonin family (Table 10.4 and Fig. 10.21). The Hsp70 family is found in bacteria and in most compartments of eukaryotic cells. Similarly, chaperonins are found in all cells, from bacteria and the eukaryotic cytosol to subcellular organelles, such as chloroplasts and mitochondria.

10.5.4 The Hsp70 family of molecular chaperones maintains polypeptides in an unfolded state

During protein synthesis, stable folding cannot occur until at least one complete domain (i.e., 100–200 amino acids) of a nascent protein chain emerges from the ribosome. These nascent

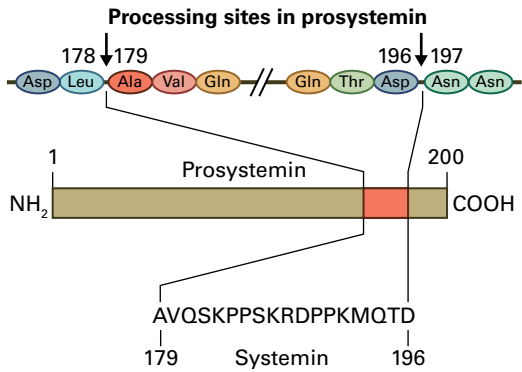

FIGURE 10.19 The 18-amino-acid peptide hormone, systemin, is formed by plant cells in response to wounding. It is produced by proteolytic processing of prosystemin, a much larger precursor polypeptide (200 amino acids).

FIGURE 10.20 Steps in protein folding. Protein folding in the cell cytosol is primarily cotranslational. Many proteins, especially multidomain proteins, fold as they are being synthesized. Each domain folds as it emerges fully from the ribosome. Proteins in bacteria, and at least some proteins in chloroplasts and mitochondria, often fold after the completion of their synthesis (i.e., post-translationally).

chains contain hydrophobic amino acids that tend to aggregate so as to minimize their interaction with the aqueous environment. A cell must maintain these aggregation-prone nascent chains in a nonaggregated, folding-competent state.

Molecular chaperones in the Hsp70 family bind to amino acid chains emerging from the ribosome during protein synthesis (Fig. 10.22). These proteins bind and release hydrophobic segments of unfolded proteins in an ATP-dependent manner. Hsp70 binding stabilizes unfolded proteins and prevents their aggregation. The controlled release of the unfolded protein may permit it to proceed successfully along the folding pathway once a complete domain is synthesized (Fig. 10.23). This process is facilitated by cochaperones such as Hsp40 and GrpE. Hsp40 facilitates the interaction of Hsp70 with the nascent chain, while GrpE functions as a nucleotide exchange factor, increasing the rate of conversion of the Hsp70 family member between the ATP (loose protein affinity) and ADP (tight protein binding) bound conformations (Fig. 10.23).

FIGURE 10.21 Molecular chaperones are divided into two classes. The Hsp70 chaperones function in the early stages of the protein-folding process, often during translation, by recognizing small hydrophobic patches on the surface of the nascent polypeptide. Many polypeptides can fold with the aid of the Hsp70 pathway alone. The chaperonins act later in the process, after translation, and provide a central cavity in which protein folding is facilitated. Both Hsp70 and chaperonin pathways require energy in the form of ATP hydrolysis for proper functioning.

10.5.5 Chaperonins play a crucial role in facilitating the folding of many proteins

In the current model for protein folding in bacteria, chloroplasts, mitochondria, and the eukaryotic cytosol, nascent polypeptide chains interact with the Hsp40/Hsp70 proteins while a portion remains positioned on the ribosome. For some cellular proteins, particularly in chloroplasts and mitochondria, subsequent successful folding requires transfer to a second folding complex, the chaperonin system.

TABLE 10.4 Examples of chaperones found in plants, bacteria, and organelles.

Hsp70 family		Chaperonins	
Bacteria	dnaK	Bacteria	GroEL (cpn60), GroES (cpn10)
Eukaryotic cytosol	Hsp70, Hsp40	Mitochondria	Mt-cpn60
Endoplasmic reticulum	BiP	Chloroplasts	Rubisco-binding protein (ch-cpn60), ch-cpn10
Mitochondria	Grp25	Cytosol	TRiC (or CCT)

FIGURE 10.22 Hsp70 is believed to play a role in preventing improper folding and aggregation of nascent polypeptide chains and newly released polypeptide chains. (A) The three-dimensional structure of a protein often involves interactions between distant segments of the polypeptide chain. As the nascent peptide emerges from the ribosome, the side chains of hydrophobic amino acids cluster together to avoid contact with water. As a result, the protein may fail to fold correctly, or the peptide chain may aggregate with other cellular proteins. (B) Hsp70 and its cochaperone Hsp40 bind to the nascent chain, impeding unfavorable interactions within the nascent chain and between the unfolded polypeptide and other proteins in the cell. Hsp70 thus prevents the protein from becoming trapped in an incorrectly folded conformation and prevents the aggregation of the nascent polypeptide with other proteins in the cell.

Chaperonins are the most varied and structurally complex class of molecular chaperones, and they are divided into two families: the GroEL group (also called the Hsp60, chaperonin 60, or cpn60 group), and the TRiC (TCP-1 ring) family (see Table 10.4). The GroEL group is found in bacteria, mitochondria, and chloroplasts, whereas the TRiC family functions in the eukaryotic cytosol.

The best-studied member of the GroEL family is from *E. coli*, but the organellar chaperonins are believed to share similar structures and functions. All are oligomeric proteins, consisting of ≈ 60 kDa subunits. Bacteria and mitochondria appear to contain one chemical species of GroEL subunit, whereas chloroplasts have two. In plants, plastid and mitochondrial GroEL are encoded in the nuclear genome and imported into the organelle. In mitochondria and chloroplasts, as in bacteria, GroEL chaperonins consist of two stacked rings with seven subunits, arranged in the shape of a barrel ≈ 150 Å

in height and 140 Å in diameter with a central cavity ≈ 50 Å wide (Fig. 10.24). Unfolded polypeptides bind in this central cavity in a collapsed molten globule-like conformation.

GroEL works in cooperation with a smaller protein, GroES. In *E. coli*, GroES consists of 10 kDa subunits that form heptameric rings. The plastid protein is sometimes referred to as cpn10, based on the molecular mass of its subunit in *E. coli*. However, this nomenclature can be misleading because one chloroplast homolog has a molecular mass of ≈ 24 kDa, consisting of two GroES-like units (Fig. 10.25). GroES plays a crucial role in promoting the binding and release of the unfolded polypeptide and induces significant conformational changes in GroEL (Fig. 10.26).

A few polypeptides synthesized in the cytosol are thought to use a chaperonin referred to as the TRiC complex. This complex is not as well understood as the GroEL–GroES complex, but it may play a similar role in folding. In plants, the

FIGURE 10.23 Model for the role of Hsp70 in protein folding. The unfolded polypeptide is bound by Hsp40, a cochaperone that facilitates the interaction of an Hsp70:ATP complex with the unfolded polypeptide. The Hsp70 protein contains two domains: The N-terminal domain contains the ATP-binding site, whereas the C-terminal domain folds into a conformation that can bind short peptide sequences exposed on an unfolded protein. After ATP hydrolysis, a stable ternary complex of the unfolded polypeptide, Hsp70, and ADP forms. A nucleotide exchange factor, often designated GrpE, promotes the exchange of ADP for ATP. In the presence of ATP, the interaction of Hsp70 with the polypeptide is reduced, and Hsp70 dissociates from the folding protein. The protein can then (1) complete its folding and enter the native state, (2) interact with Hsp40 and Hsp70 again to undergo additional folding steps, or (3) be transferred to an additional folding system, the chaperonin system.

FIGURE 10.24 Structures of GroEL and GroES. These space-filling representations illustrate the central cavity in which folding takes place.

TRiC complex contains at least six distinct polypeptides, many of which appear to be related to each other in sequence. As with GroEL, TRiC subunits are arranged in two stacked rings with a hole in the center. Many of the general principles discussed above for protein folding in chloroplasts and mitochondria probably apply to plant cytosol as well. However, much work remains to be done to develop a detailed understanding of this process.

10.5.6 Protein folding is coordinated with transport

Many proteins are secreted from cells or localized in subcellular compartments other than their sites of synthesis. Protein synthesis, transport, and folding events vary according to where the protein is localized. Proteins destined for secretion from the cell or localized to membrane-bound organelles of the secretory pathway are simultaneously synthesized on ER-bound polysomes and translocated into the ER lumen, which contains molecular chaperones that facilitate folding in this compartment. Nuclear-encoded proteins targeted to the plastids, mitochondria, or peroxisomes are synthesized in the cytosol and then imported into their target organelles. In all these examples, protein transport and folding must be tightly

FIGURE 10.25 (A) The chloroplast homolog of GroES (*cpn10*, also referred to as *cpn21*) has an unusual structure. The N-terminal region contains a transit peptide specifying chloroplast localization. The remainder of the protein consists of two sequences of ≈ 100 amino acids, each of which is analogous to the bacterial GroES. These two repeats are separated by a short linker region. (B) In this electron micrograph, *cpn10* can be seen forming a ring-like structure analogous to that observed in bacterial GroES.

coordinated. Chapter 4 examines in detail the synthesis at the ER and folding in the ER lumen, formation of correct disulfide bonds between cysteine residues, and import of newly synthesized proteins into organelles.

10.5.7 Assembly of soluble oligomeric complexes is essential for many biological processes

Many biological processes require oligomeric protein assemblies consisting of more than one copy of the same polypeptide or many different polypeptides. It is crucial that these oligomeric complexes be assembled correctly. Much remains to be learned about the molecular details of the assembly processes.

The chloroplast enzyme Rubisco has been studied as an example of the assembly of a soluble oligomeric protein complex. In plants, Rubisco consists of eight copies of a large subunit (LSU, 53 kDa) and eight copies of a small subunit (SSU, ≈ 14 kDa) (see Fig. 12.39). The large subunits form an octameric core, whereas the small subunits form two layers of four subunits each, on opposite sides of the core. As shown in Figure 10.27, the LSU is encoded by chloroplast DNA and synthesized in the chloroplast, whereas the SSU gene is transcribed in the nucleus, its mRNA translated in the cytosol, and protein imported into the chloroplast.

Rubisco assembly requires the active participation of the chloroplast chaperonin (*cpn60*), another plastid-localized product of a nuclear gene. *Cpn60* forms a large complex with the LSU shortly after the subunit is released from the ribosome. In an ATP-dependent step, folding of the LSU is facilitated. Once folded, the LSU is released from the chaperonin. In cyanobacteria, the protein *RbcX* facilitates Rubisco assembly after chaperonin release by organizing an LSU octamer

capable of associating with SSUs. The generality of this RUBISCO-specific chaperone to higher plants has yet to be established.

10.6 Protein degradation

10.6.1 Protein degradation plays many important physiological roles

Degradation of cellular proteins is a constant and ongoing process that serves a number of physiological roles, one of which might be called “cellular housekeeping.” Abnormal proteins arise in cells as a result of mutations, errors in protein synthesis or folding, spontaneous denaturation, disease, stress, or oxidative damage. If not removed, these damaged proteins eventually poison the cell, often by forming large insoluble aggregates that affect basic cellular processes. Plant cells do not divide rapidly enough to keep concentrations of damaged proteins dilute, so eliminating these proteins is essential. Photoinhibited D1 protein in PSII is a good example of a damaged protein that is proteolyzed during the repair process (see Box 10.8).

A second role for protein degradation is to modulate accumulation of subunits of oligomeric protein complexes in the correct stoichiometry and to maintain the correct ratio of enzymes and their cofactors. One example can be seen in the coordinated accumulation of the large and small subunits of Rubisco. When the concentration of LSUs in the chloroplast decreases—for example, if synthesis is experimentally prevented—SSUs synthesized in the cytosol are rapidly degraded when imported into chloroplasts. Another example is seen with the synthesis of the chlorophyll *a/b*-binding protein: When chlorophyll synthesis is prevented, the apoprotein is rapidly degraded (see Fig. 10.17).

FIGURE 10.26 Model for the roles of GroEL and GroES in protein folding. This type of system is thought to be present in chloroplasts and mitochondria.

FIGURE 10.27 Synthesis and assembly of Rubisco requires the participation of two genomes and two translational systems as well as chloroplast chaperones. The large subunit of Rubisco is encoded in the chloroplast genome, and for correct folding, it requires the chaperonin system consisting of cpn60 (the analog of GroEL) and its cochaperonin cpn10 (the analog of GroES). Both cpn60 and cpn10 are synthesized in the cell cytosol as precursors. After they are imported into the chloroplast, their transit peptides are removed, and the mature proteins assemble into the chaperonin complex. The folding of the large subunit of Rubisco is facilitated by interaction with the chaperonin complex. The small subunit of Rubisco is synthesized in the cytosol as a precursor protein. After transport across the chloroplast membranes, the precursor is processed into its mature form. Eight copies of the folded large subunit must then assemble with eight copies of the small subunit to form the active oligomeric enzyme complex.

BOX 10.8

The D1 repair cycle operates to repair photodamage to PSII

Although light is the source of energy for photosynthesis, it can also cause extensive damage to the photosynthetic apparatus, especially PSII. Light can lead to the inactivation of electron transport and can promote oxidative damage to the reaction centers, particularly to proteins D1 and D2. Plants have evolved a complex and energetically expensive mechanism to repair photoinduced damage, which occurs at a rate directly proportional to the intensity of the incident light. When damage to PSII outpaces the plant's ability to repair itself, photoinhibition results, and this can lead to reduced growth. The severity of photoinhibition varies with the plant species, physiological state, and its life history. The extent of photoinhibition is greatly affected by other environmental conditions, including temperature and water availability.

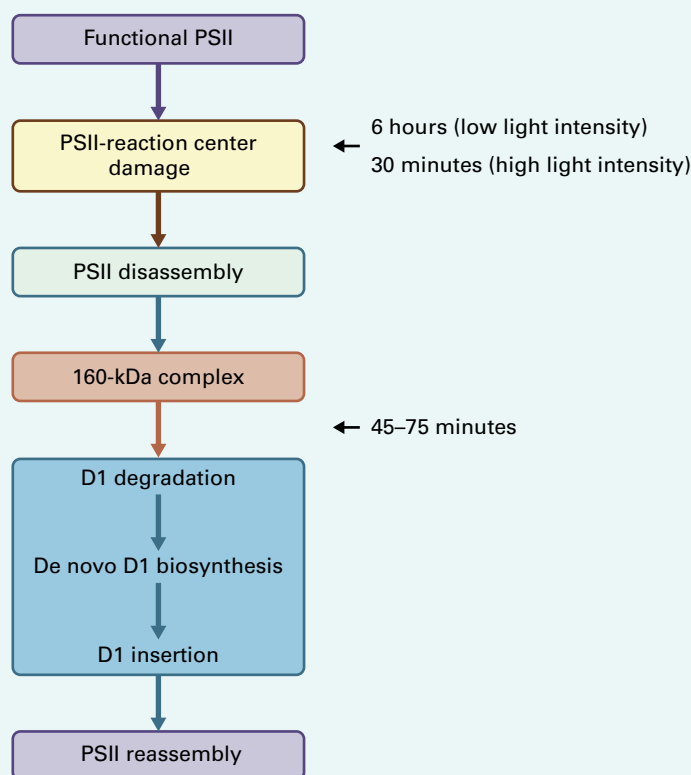

D1 and D2 constitute the core polypeptides of the photosynthetic reaction center of PSII (see Chapter 13). When D1 is damaged during the photochemical reactions of PSII, it is targeted for degradation by

proteolysis. Presumably, oxidative damage to D1 by singlet oxygen or superoxide anion radicals alters its conformation, rendering it vulnerable to proteases. D1 is an integral thylakoid membrane protein with both luminal and stromal loops. The degradation pathway has several steps, and the initial step requires cleavage of a soluble loop in either stroma or lumen. Once D1 has been cleaved, PSII is thought to undergo a partial disassembly. The photodamaged D1 is degraded, new D1 protein is synthesized *de novo* on chloroplast ribosomes and inserted into the thylakoid membrane, and the PSII complex is reassembled. Direct D1 degradation and *de novo* D1 biosynthesis can become rate-limiting under high light intensities, resulting in the accumulation of 160-kDa complexes containing partially disassembled PSII and additional proteins of an unknown nature.

The D1 repair cycle poses significant logistical problems for the chloroplast. Thylakoid membranes

demonstrate lateral heterogeneity. PSII is located primarily in closely adjacent, or appressed, membranes. By contrast, D1 synthesis occurs in unappressed membranes exposed to the stroma, where ribosomes can bind and

insert the growing polypeptide into the membrane during synthesis. How the lateral movement of damaged PSII complexes to unappressed regions to reassemble with newly synthesized D1 remains an interesting question.

Protein degradation probably plays its most important role, however, in regulating numerous biological processes through the degradation of biologically active molecules. In this sense, protein degradation can be viewed as the final mechanism for regulating gene expression, that is, the final regulatory mechanism controlling the levels of protein gene products. As an example, consider enzymes catalyzing the first step or the rate-limiting step of a metabolic cascade. When these enzymes are short-lived because of proteolytic degradation, the plant can alter the output of a particular metabolic pathway simply by decreasing or increasing the rate of proteolysis of the enzyme catalyzing the rate-limiting step. For example, synthesis of the hormone

ethylene is controlled by the activity of ACC synthases (see Chapter 17 for details of ethylene synthesis pathway). These enzymes are short lived in cells and modulation of their degradation rates results in alteration of ethylene production.

Likewise, the concentration of key regulatory proteins such as transcription factors or signaling proteins regulates downstream processes and, as a consequence, these proteins are also almost always subject to proteolytic regulation. In plants, phytochrome A (PhyA) provides a good example (see Chapter 18). Phytochromes exist in two forms that can be interconverted by light. The P_R form of PhyA absorbs red light, has little biological activity, and is long lived in plant cells, whereas the P_{FR}

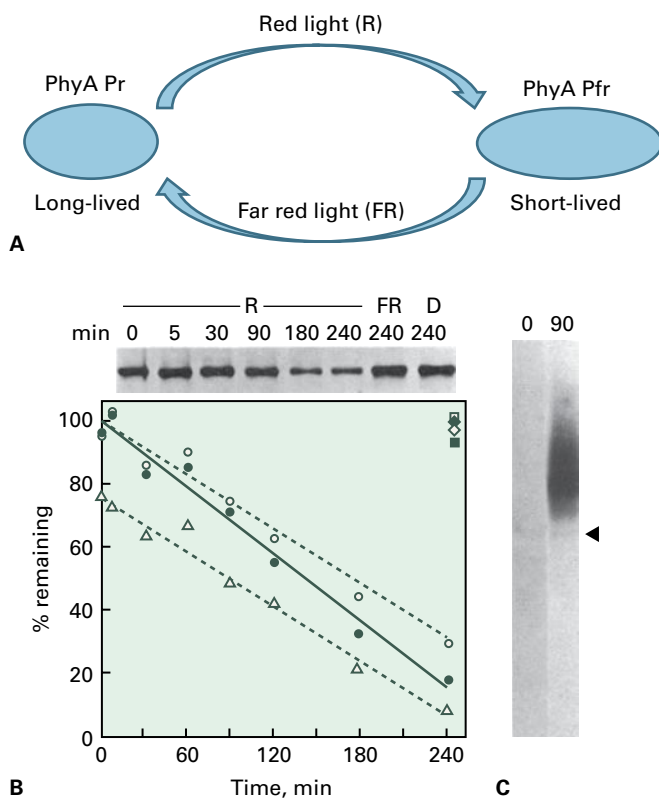

FIGURE 10.28 (A) The conformation of phytochrome in dark-grown (D) seedlings (Pr) is long-lived, while the phytochrome form (Pfr) after red (R) light absorption is short-lived. Pfr reverts back to the Pr long-lived form after absorption of far red light (FR). (B) The rapid loss of Pfr can be detected by measuring amount of spectrally active PhyA (open triangles) or by ELISA and immunoblot assays visualizing PhyA with anti-PhyA antibodies (immunoblot analysis is shown above graph, and represented by open circles in the graph; ELISA assay results are represented by closed circles). The reduction in PhyA is quantified as the percentage remaining as a function of the time of exposure to light. The amount of Pr (spectrally, open symbols, or immunologically, closed symbols), whether from dark-grown seedlings (square symbols) or from far-red light-treated seedlings (diamond symbols) stays the same over time (top horizontal line). (C) Pr and Pfr were isolated from cells by immunoprecipitation and separated by size. The presence of ubiquitinated Pfr, but not ubiquitinated Pr was visualized, indicating that ubiquitination of Pfr correlated with its degradation, suggesting that PhyA in the Pfr form is a substrate of the ubiquitin system. Arrowhead indicates migration of unmodified Pfr. Ubiquitinated species migrate more slowly due to presence of one or more covalently attached ubiquitin proteins. Different species of PhyA have different numbers of ubiquitins attached, giving rise to the heterogeneity in size observed. Source: (B, C) Shanklin et al. (1987) PNAS 84:359–363.

form absorbs far-red light, acts as a photoreceptor to initiate many light-regulated developmental processes, and is rapidly degraded (Fig. 10.28). Another well-characterized example is the DELLA family of proteins. These proteins function as negative regulators of gibberellin signaling, and their degradation is required for proper response to this hormone (see Chapter 17).

Proteolysis in plants also supplies amino acids necessary for maintaining cellular homeostasis and for new growth. Approximately half of the complete set of proteins in a plant

is replaced every 4–7 days, and in many cases, new proteins are synthesized from recycled amino acids. A good example of the role of proteolysis in supplying amino acids is seed germination (see Chapter 19). During germination, most of the amino acids required for growth of seedlings are supplied by degradation of seed storage proteins synthesized during embryo maturation. In senescing leaves, some proteases play an important role in activating the senescence process, whereas others likely produce amino acids for use by other parts of the plant (see Chapter 20).

10.6.2 Proteases are classified by catalytic mechanism

In contrast to other enzymes, proteases are classified by their catalytic mechanism, not by the nature of their substrate or biological function. The aspartate-, cysteine-, serine/threonine-, and metalloproteases have the side chain of the indicated amino acid or a metal ion (often zinc) in the active site to catalyze peptide bond hydrolysis. Chemicals can inhibit a specific protease class or subset of classes, and class-specific inhibitors are useful in protease identification. For example, metalloproteases are inactive without a bound metal cation, so incubation with a metal chelator inhibits metalloprotease activity, leaving aspartate, cysteine, and serine/threonine activities unaffected.

Another distinction among proteases is whether they catalyze peptide bond hydrolysis at the end of the protein (either N- or C-terminus) or at an internal site. This property separates the exoproteases, which release either a single amino acid residue or di- or tripeptides located at the ends of a polypeptide, from the endoproteases that cleave peptide bonds further within. The exoproteases process the termini of proteins or remove peptides remaining after endoprotease action.

10.6.3 Proteolysis can be selective or nonselective

At specific times, degradation of proteins occurs without reference to the nature of the protein. For example, during autophagy (self-digestion, see Chapter 20) new membrane structures are produced that encircle cytoplasmic contents inside a closed vesicle. Proteins and membranes trapped within the vesicle are degraded independent of identity. Both the encapsulation and subsequent digestion in the vacuole by resident proteases do not show preference for any specific protein.

In contrast, most proteins are selectively degraded, that is, the protein is specifically recognized and degraded while proteins in the same compartment and presumably accessible to the same proteases are not. One can easily imagine the advantages of this selectivity. A single plant cell may contain more than 5,000 different proteins at any given time. It is imperative that cells have precise mechanisms for targeting individual proteins for degradation. Without such regulation, proteolytic enzymes would degrade cellular proteins indiscriminately.

Multiple proteases require ATP hydrolysis for activity. Because the hydrolysis of peptide bonds is energetically favorable and thus does not require coupled ATP hydrolysis, ATP is thought to act to increase specificity. The addition of an ATP requirement necessitates accessory proteins to link ATP hydrolysis to proteolysis. Thus, protease systems are complex, including both catalytic and specificity activities.

10.6.4 Protease activity is highly regulated

It also is evident that unregulated protease activity could have dire consequences, for example, by removing a substrate protein at inappropriate times. So, in addition to a high degree of specificity, protease activities are controlled by similar mechanisms that control the activities of other cellular proteins; some of these include control of synthesis, compartmentalization of the protease away from substrate until proteolysis is desired, synthesis as an inactive precursor, or changes in the activity of the protease by modification, such as phosphorylation, or by interaction with ligands. This is only a partial list of the possible ways that protease activity is regulated in cells to prevent unwanted destruction of its substrates.

10.6.5 Plant cells contain a large number of proteases that are found at several sites in the cell

An indication of the significance of proteolysis is the large number of genes in a single organism dedicated to the processing and cleavage of proteins. For example, in rice (*Oryza sativa*) and *Arabidopsis*, whose genomes have been extensively annotated, bioinformatics studies identify approximately 700 and 800 predicted proteases, respectively. In addition, predicted components of the proteolytic pathway called the ubiquitin pathway (see below) that are not proteases per se, but are required for proteolysis, add approximately another 1,000 proteins. This large number of genes encoding proteases and/or components of proteolytic pathways within a single organism indicates the diversity and significance of protein processing and degradation throughout the life of an organism.

Proteases are localized to multiple cellular compartments (Fig. 10.29). Thus, distinct systems are present in vacuoles, in the cytosol, in the nucleus, in chloroplasts, and in mitochondria. The proteolytic machinery in each compartment reflects the evolutionary origin of that compartment. Thus, the proteolytic mechanisms observed in chloroplasts and

FIGURE 10.29 Most subcellular compartments in a plant cell (the cytosol, nucleus, chloroplasts, mitochondria, ER, and vacuole) contain proteases. In addition, many plant cells secrete proteases.

mitochondria are more closely related to bacterial systems than to those localized in the plant cell cytosol.

Vacuoles are very conspicuous organelles and may occupy as much as 95% of the plant cell volume. Rich in hydrolytic enzymes, vacuoles perform a variety of functions. The proteases they contain may play a role in protein degradation similar to that of lysosomes in animal cells. During nutrient starvation, the vacuole is the site of digestion of autophagic vesicles, where proteins are degraded to generate needed amino acids in an autophagic process (see Chapter 20). In seed-reserve tissues, specialized vacuoles called protein bodies have been observed. Proteins deposited in the protein body during seed maturation remain there in a stable state until the seed germinates. During germination, protein bodies fuse with a different vacuole containing proteases, and the storage proteins are degraded, supplying amino acids to the new seedling.

Plastids contain a complement of proteases distinct from the cytosol. In addition to processing proteases, there are proteases involved in protein removal. In *Arabidopsis*, bioinformatic analyses predicted 11 different protease types in chloroplasts encoded by ≈ 50 genes. Three different types of ATP-dependent proteases with prokaryotic relatives have been experimentally verified to reside in the chloroplast. They are named after the homologous proteins in *E. coli*: Clp, FtsH, and Lon, each encoded by multigene families in plants. In addition, chloroplasts contain ATP-independent proteases, including the Deg family, involved in removal of damaged PSII proteins (see Box 10.8).

The ATP-dependent proteases contain both proteolytic and ATPase activities, either on a single polypeptide or on different proteins. Clp is a stromal multimeric enzyme complex, consisting of multiple catalytic subunits; these ClpP or ClpP-like proteins in are a heterotetradecamer subcomplex that interacts with a regulatory subunit possessing the ATP hydrolysis activity (Fig. 10.30). FtsH is a homomultimeric complex bound to thylakoids and is also involved in damaged D1 proteolysis. In addition to degradation inside the chloroplast, recent evidence suggests that during autophagy, portions of the chloroplast segment into vesicles, which fuse with the tonoplast. Once inside the vacuole, chloroplast-derived components are degraded.

Other plant organelles, including mitochondria, microbodies, such as peroxisomes, and the ER also have the ability to degrade proteins, but the mechanisms are poorly understood in plants. In the case of ER-localized proteins, in yeast and mammals, translocation of proteins from the ER to the cytosol occurs before breakdown, but such a mechanism has not yet been described in plants.

10.6.6 The ubiquitin pathway is a major intracellular pathway for selective proteolysis in the cytosol and nucleus

The ubiquitin pathway is the major proteolytic pathway in the cytosol and nucleus. It is unusual because it requires prior modification of the substrate protein by another protein,

FIGURE 10.30 Representation of chloroplast Clp protease complex. The P subunits are active serine proteases, R subunits are related inactive subunits, which form two heptameric rings. Names of the individual subunits in *Arabidopsis* are indicated to the right; the P ring subunits P3, P4, P5, and P6 are in a 1:2:3:1 stoichiometry. The R ring contains ClpP, the only chloroplast-encoded subunit and R proteins R1, R2, R3, and R4 subunits in 3:1:1:1 stoichiometry. ClpC1, ClpC2, and ClpD form a hexameric RING, hydrolyzing ATP to unfold proteins and feed them into the internal chamber and access to protease active sites. ClpT2 proteins are thought to play a role in assembly.

ubiquitin (Fig. 10.31), which is not degraded, but is recycled for future attachment (Fig. 10.32). This conserved eukaryotic pathway is essential, likely because of its role in modulating the abundance of key regulators of the cell cycle and of developmental transitions. The ubiquitin pathway includes all enzymes required for ubiquitin attachment, the protease complex that hydrolyses the substrate and removes ubiquitin intact, accessory proteases that hydrolyze various ubiquitin linkages, and the myriad of proteins that modulate any one of these processes (Fig. 10.32). The number of genes in this pathway in a single organism is estimated at $>1,200$, and new components are still being identified.

Conjugation of ubiquitin to a substrate requires ATP and is carried out by a multienzyme pathway (Fig. 10.33). This pathway first catalyzes the formation of an isopeptide bond between the C-terminus of ubiquitin and typically the ϵ -amino group on the side chain of a lysine residue on a substrate protein. Proteins with a single attached ubiquitin are known, but many have multiple covalently bound ubiquitins. Additional ubiquitin molecules typically are added onto an ϵ -amino lysyl group of a previously attached ubiquitin, forming an ubiquitin chain. Ubiquitin has seven lysine residues (see Fig. 10.31), and all have been found in ubiquitin-ubiquitin linkages formed *in vivo*, although the major site of ubiquitin attachment to ubiquitin is lysine 48. In addition, multiple lysine residues on the substrate protein can be conjugated in this manner, giving rise to more than one ubiquitin chain on a single protein.

The enzymes responsible for ubiquitin conjugation, E1 (ubiquitin activating enzyme), E2 (ubiquitin conjugating

FIGURE 10.31 Ribbon (left and center, opposite faces) and space-filling (right) models of ubiquitin. Ubiquitin consists of a compact globular domain with a flexible protruding C-terminal segment, where it attaches to proteins. The three hydrophobic residues on the surface are indicated in blue, and these residues function in noncovalent protein–protein interactions with other components of the ubiquitin pathway. The seven lysine residues that serve as attachment sites for a second ubiquitin are indicated in red, with the major attachment site, lysine-48 indicated in magenta. Source: Vijay-Kumar et al. (1987). *J. Mol. Biol.* 194:531–544.

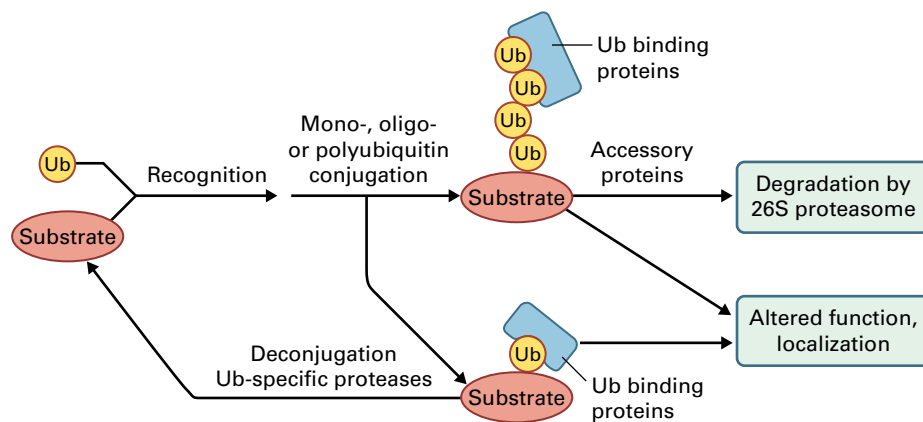

FIGURE 10.32 Modification of proteins by covalent ubiquitin addition has diverse consequences. Typically, polyubiquitylation via ubiquitin lysine-48 targets a protein for proteasomal degradation. Monoubiquitylation can affect the protein's subcellular localization, intermolecular interactions, enzymatic activity, and possibly other properties.

enzyme), and E3 (ubiquitin ligase) act sequentially (Fig. 10.33). E1 activates the C-terminus of ubiquitin through adenylate formation, transfers the ubiquityl moiety to a cysteinyl group on itself to form thioester-linked ubiquitin, and then transfers the ubiquitin to a cysteinyl group on an E2, the second protein in the cascade. The E2 with a thioester-linked ubiquitin then binds to E3, and ubiquitin is transferred to the substrate, either directly or indirectly. In one type of E3, the HECT type, ubiquitin is first thioester-linked to the HECT E3 and then transferred to a peptide linkage on the substrate. For all other E3s, ubiquitin transfer is directly from the E2 to the substrate (Fig. 10.33). Hence, interaction of the substrate with the E3 is a key step, and modulation of this interaction provides a means of controlling the rate and extent of ubiquitylation.

It is not surprising, then, that the largest group of proteins in the ubiquitin pathway is the E3 ligases (Table 10.5).

These proteins can be divided into two mechanistic types: The HECT E3 type covalently attach ubiquitin prior to substrate ubiquitylation, whereas the RING/U box E3 type serves as a scaffold to position the substrate protein adjacent to the E2 carrying a thioester linked ubiquitin (Fig. 10.34). RING proteins and U box proteins are named after the domain that interacts with the E2. RING and U box domains form similar structures using different mechanisms, Zn chelation and hydrophobic interactions, respectively. Some E3s are multimeric, of which the cullin-RING ligases (CRLs) are the best characterized in plants. In one type of CRL (the SCF type), one subunit (F-box protein) interacts with the substrate protein, while the other SCF subunits position the E2 for optimum ubiquitin transfer (Fig. 10.34, Table 10.5). Other CRL E3 ligases are similar, with one subunit serving the substrate interaction function (Table 10.5).

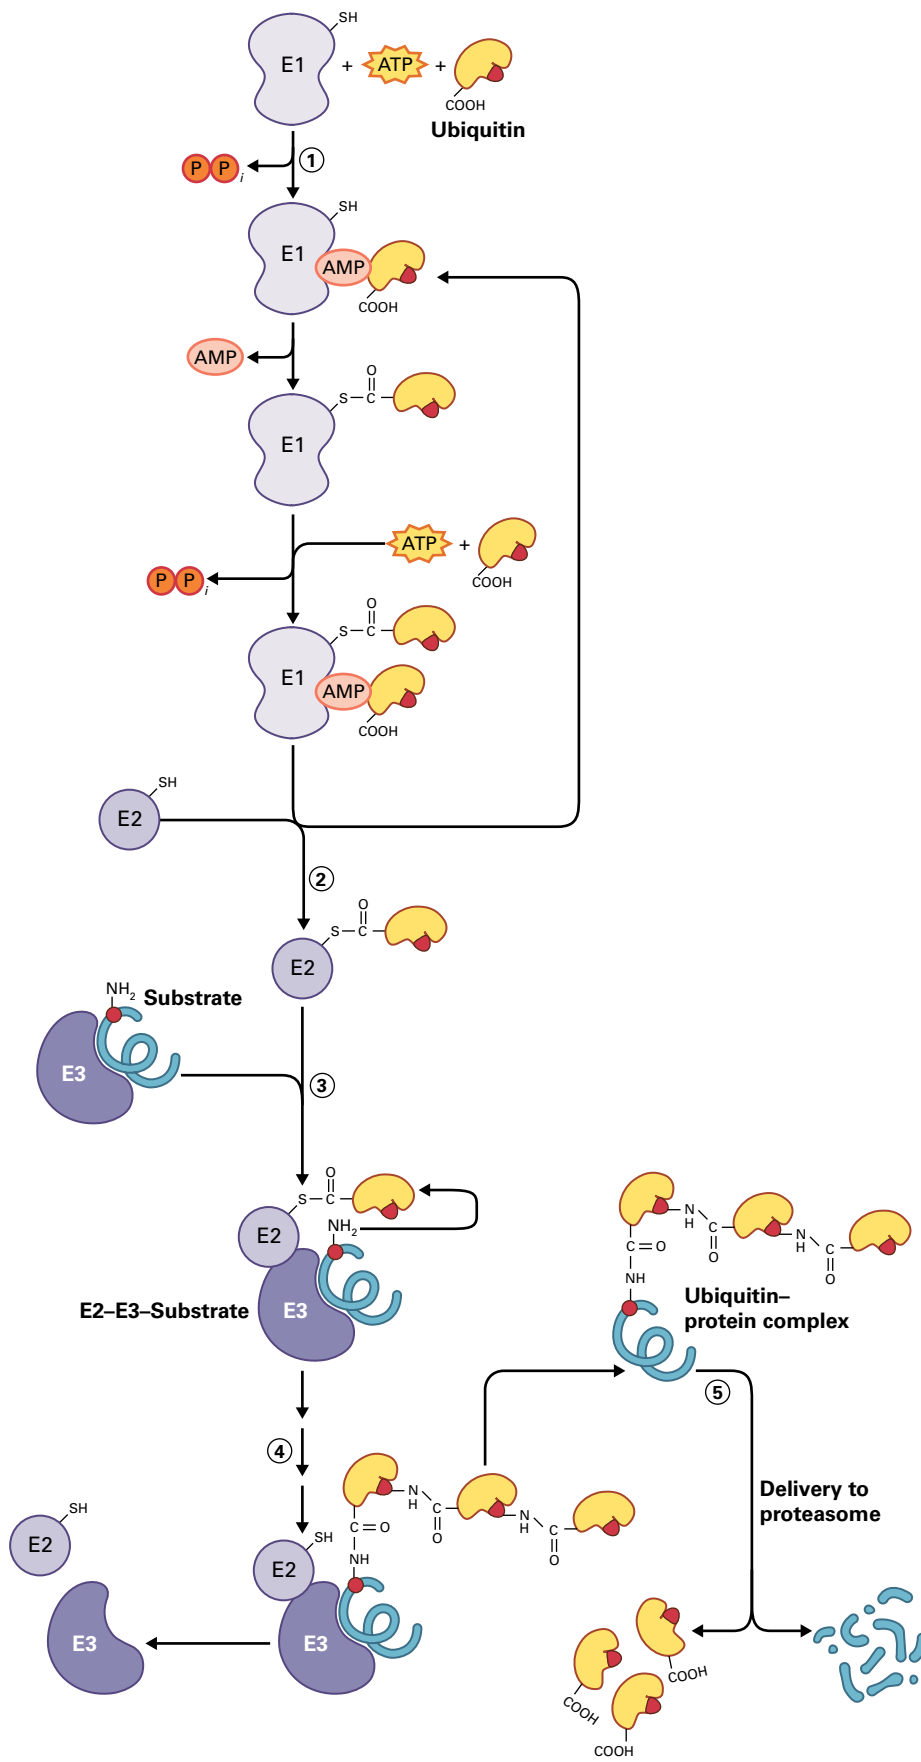

FIGURE 10.33 Covalent attachment of ubiquitin to substrate proteins requires three enzymes, E1, E2, and E3. The first step is activation of the ubiquitin C-terminus, which is analogous to amino acid activation in amino acyl tRNA synthesis and fatty acid activation (see Fig. 10.8). Using ATP, E1 (ubiquitin activating enzyme) forms an ubiquitin adenylate, releasing pyrophosphate. The C-terminal carboxyl of ubiquitin is then covalently attached to the Cys residue sulfhydryl of E1 in a thioester linkage similar to that found in acyl CoA esters. In step 2, the ubiquitin

FIGURE 10.33 (Continued) is transferred to a Cys residue, a sulfhydryl of E2 (ubiquitin carrier enzyme). In step 3, the protein targeted for modification is bound by E3 (ubiquitin ligase). An E2 with a thioester-linked ubiquitin also interacts with the E3. Thus, the E3 brings ubiquitin and the substrate in close proximity, and evidence suggests that conformational changes occur upon E2 binding that facilitate ubiquitin transfer from E2 to the substrate. The ubiquitin is attached to the substrate protein through an isopeptide bond between the C-terminal carboxyl of ubiquitin and typically the side-chain amino group of a lysine (shown as a red dot). In step 4, multiple additional ubiquitin residues are added to the substrate protein. The C-terminal carboxyl of each additional ubiquitin is attached to an internal lysine residue (red dot) of the preceding ubiquitin chain. In general, a series of about four ubiquitins must be attached to the substrate protein before it can be delivered to the proteasome effectively. Some proteins are only modified with a single ubiquitin. In step 5, the ubiquitin-conjugated protein is delivered to the proteasome for degradation.

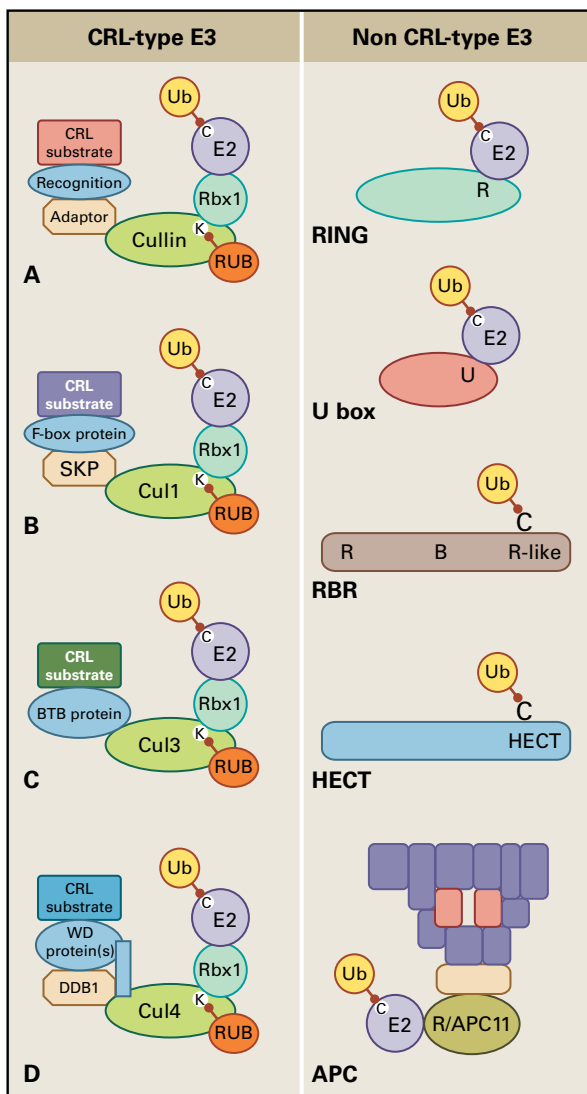

FIGURE 10.34 Two major types of ubiquitin E3 ligases: CRL-type (left) and non-CRL-type (right). E3 ligases interact with both the substrate and E2. Many different proteins are ubiquitin-modified, and different E3s modify a specific protein or group of proteins. CULLIN-RING-ligase (CRL)-type E3s (left) are multimeric. One subunit interacts with the substrate, the other binds E2, and the CULLIN protein in between serves as a scaffold. (A) The generic architecture of CRLs is shown. All share the same RING protein (RBX) and for full activity *in vivo*, all CULLINs must be modified by a single ubiquitin-like protein (RUB). CUL1-based CRL is called an SCF (SKP-CULLIN1-F box); F-box proteins bind substrate (B). CUL3-based CRL with BTB proteins as the substrate binding subunit are shown (C), and the CUL4-based CRL (D). The exact composition of CUL4 CRLs is uncertain, but WD-repeat containing proteins in some cases are substrate-interacting subunits. Non-CRL types (right) include RING, U box, RBR and HECT types, named for the domains that interact with the E2 (in the case of RING and U box) or carry ubiquitin in a thioester linkage (HECT domain). RBR proteins are named after the 3 RING-like domains, the first binds E2 and the third contains a catalytic cysteine that carries activated ubiquitin, similar to the HECT domain E3s. Evidence suggests these non-CRL ligases could be oligomeric, but little is known. The anaphase promoting complex (APC) is multimeric E3 with several substrate-binding subunits, and the small RING protein APC11 binds the E2. It functions to modify cell cycle regulators, such as cyclins.

10.6.7 The 26S proteasome is a unique protease complex that recognizes ubiquitylated proteins

Ubiquitylated proteins are processed to peptides by the 26S proteasome, an extremely large oligomeric protein complex with a molecular mass of >1.5 megadaltons (MDa). The proteasome is an assembly of complexes, most notably the 20S core proteasome and the 19S regulatory complex, or 19S cap. The 20S core consists of four stacked rings, each made of seven subunits (note the similarity to the GroEL chaperone). The active sites for proteolysis face inward, into a channel through the center of the stacked rings (Fig. 10.35). Placement of these catalytic centers inside the channel limits accessibility. The pores into the channel are normally in a closed configuration, and binding of the 19S cap and ATP hydrolysis are required to switch the pores to the open configuration. The 19S cap also binds ubiquitylated proteins, helps unfold substrate proteins using ATP hydrolysis, removes ubiquitin, and inserts the unfolded, de-ubiquitylated polypeptide into the channel within the stacked ring structure, where peptide bond hydrolysis occurs.

Thus, a major fate of ubiquitylated proteins is delivery to the proteasome for degradation. Several types of ubiquitin-binding proteins facilitate the interaction between ubiquitylated proteins and the proteasome. Some of these ubiquitin-binding proteins are part of the regulatory particle, while others only transiently interact.

10.6.8 Ubiquitin attachment is highly regulated

Ubiquitin attachment is highly regulated to prevent unwanted or excessive ubiquitin attachment. Substrate interaction with ligases is regulated by multiple mechanisms. In some cases, modification of the ligase occurs, either a covalent modification, such as phosphorylation, or by interaction with an activator or inhibitor subunit. Alternatively, the substrate protein can be covalently modified or interact with another protein or small molecule to promote interaction with the ligase. Additionally, the presence or absence of specific pathway components can regulate ubiquitylation. For example, upon phosphate starvation in *Arabidopsis*, the miR399 miRNA targets the RNA encoding the E2 enzyme UBC24/PHO2 for degradation, reducing UBC24 synthesis. Although the molecular mechanism is not known, reduction of UBC24 allows plant roots to respond to conditions of low phosphate by enhancing uptake of external phosphate and conserving internal sources.

10.6.9 The ubiquitin pathway is essential in plant hormonal responses

The CRLs are essential ubiquitin ligases in all organisms, including plants where they are implicated in numerous processes, including hormonal responses, progression through

FIGURE 10.35 Structure of the 26S proteasome. The core 20S proteasome has a distinctive hollow cylindrical shape created by the assembly of four stacked rings. Each ring contains seven polypeptides. A 19S regulatory subunit binds to the ends of the 20S proteasome, forming the 26S proteasome. Ubiquitylated proteins are delivered to the proteasome for degradation, likely by ubiquitin-binding proteins either free or bound to the proteasome. The regulatory subunit contains ATPases and ubiquitin-specific proteases for unfolding the substrate and removing the ubiquitin, respectively.

FIGURE 10.36 SCF^{TIR1} is an auxin-regulated E3 ligase. (A) Schematic representation of a specific SCF E3 ligase containing the F-box protein TIR1. This ligase interacts with the Aux/IAA proteins (called IAA proteins in Arabidopsis) in an auxin-dependent manner, which explains the observation that auxin modulates Aux/IAA degradation rates. The rate of ubiquitylation would be modulated by auxin, and in turn the rate of recognition and degradation by the proteasome then depend on auxin. (B) X-ray structure of TIR1 in complex with the substrate adaptor, ASK1, and a peptide of an Arabidopsis IAA protein, IAA7. The peptide-binding pocket requires auxin (in green) at the base. (C) Expanded view of the IAA-auxin-TIR1 binding site, with the IAA peptide in a space-filling model. (D) Schematic model of the requirement for auxin to facilitate IAA interaction with TIR1. Auxin has been coined the "molecular glue" that holds together the substrate, IAA proteins, and E3 ligase subunit. This is an example of ligand-regulated degradation, where auxin is important for the ubiquitylation reaction, which is required for substrate degradation by the proteasome.

the cell cycle, and biotic responses. The substrate-recognizing subunit of one type of CRL, the F-box protein of the SCF-type of CRL, is encoded by a large gene family, presumably because each F-box protein interacts with a different substrate protein or protein family. The best characterized F-box protein is TIR1, which was first identified genetically as an auxin response mutant. The X-ray crystal structure of TIR1 has been solved, and members of the Aux/IAA protein family have been identified as substrates. The Aux/IAA proteins are transcriptional regulators of the auxin response. Some of these proteins are short-lived in cells, and their degradation rates are modulated by the level of auxin. Remarkably, auxin itself binds to TIR1 and helps form the Aux/IAA-binding site. These results provide a molecular explanation for the ability of auxin to change proteolytic rate through changing the rate of ubiquitylation (Fig. 10.36).

The stimulation of ubiquitylation by the auxin-TIR1-Aux/IAA interaction is not an isolated example of how small molecules regulate proteolysis. Multiple hormone signaling pathways utilize regulated proteolysis. The jasmonate signaling pathway requires proteolysis of JAZ transcription factors, and binding of a jasmonate conjugate to the F-box protein called COI1 regulates degradation of JAZ proteins.

Gibberellin (GA) signaling requires the inactivation of the DELLA family of proteins, and a major mechanism of down-regulation is through proteolysis. Active GAs and DELLAs bind to a receptor, and this GA-DELLA-receptor complex interacts with the SLY F-box protein to facilitate ubiquitylation of DELLA proteins and promote their degradation. Thus, direct modulation of the ubiquitin pathway enzymes by small molecules appears to be a reiterated theme, rather than an exception in plants.

10.6.10 Ubiquitylated proteins can have fates other than proteasome-mediated degradation

The consequence of marking proteins with ubiquitin is not limited to hydrolysis by the proteasome. There is evidence with yeast and mammalian proteins that, in addition to proteolysis, ubiquitylation can affect subcellular location and activity. In these aspects, ubiquitin functions as a posttranslational modification. Studies on the nonproteolytic role of ubiquitin are in their infancy in plants.

Summary

Plants have three compartments in which proteins are synthesized. Protein synthesis mechanisms differ among these compartments, probably reflecting their distinct evolutionary origins. Protein synthesis is carefully regulated in response to the physiological needs of the plant. This regulation is particularly apparent in chloroplasts, where protein synthesis is coordinated with the photosynthetic activity of the

organelle. After synthesis, proteins must be localized to the appropriate cellular location and may also be modified. Chaperones are required for the proper folding of proteins in cells. Protein folding and localization are coupled. Proteins are degraded to modulate the quantities of key metabolites, to provide amino acids, to modulate signaling pathways and to remove improperly folded proteins.

Cell Division

Dirk Inzé and Lieven De Veylder

Introduction

Every cell originates from the division of an existing cell. This process is regulated precisely to ensure cells divide only at appropriate times and replicate critical cellular components with high fidelity.

The cell cycle consists of two events: **cell division**, during which a cell replicates its genome and partitions it to daughter cells, and **cell growth**, during which cells increase their mass by synthesizing proteins, membrane lipids, and other essential components. Whereas cell growth and most biochemical processes are continuous, the cell cycle proceeds in discrete, incremental steps. Eukaryotic cells have evolved specialized protein kinases, phosphatases, and proteases that function as switches to impose this stepwise mode of progression on the processes of DNA replication and partitioning of the duplicated genetic information in two daughter cells during **cytokinesis**. This network of regulatory proteins involved in monitoring cell cycle progression is also suited for coupling cell cycle stages with environmental conditions, such that cell divisions only occur when conditions are favorable.

In addition to regulating the timing of cell division, cell cycle control mechanisms perform a quality control function to prevent transmission of incompletely replicated or damaged genomes to daughter cells. Incomplete genome replication, rereplication of DNA without division, DNA damage, or division before DNA has been completely replicated can all wreak havoc on the cell's progeny. To prevent such errors, all

organisms utilize molecular mechanisms to monitor cell division progress at specific steps in the cell cycle, called **checkpoints**.

The basic mechanisms governing cell division arose early in eukaryotic evolution and are highly conserved. Though the basic principles of cell cycle control are similar in all eukaryotes, plants possess a number of species-specific modifications in the mechanisms that regulate cell division. This chapter provides an overview of the basic principles that control cell division, with an emphasis on plant-specific modifications.

11.1 Animal and plant cell cycles

The last common ancestor of plants, animals, and fungi lived over 1.5 billion years ago, well after eukaryotes had evolved. Despite the great evolutionary distance and distinctly different appearances of modern multicellular organisms, the cellular machinery that performs fundamental functions, including the molecules that regulate the division cycle, is highly conserved in all extant eukaryotes. Among these conserved molecules are the protein kinases that control major cell cycle transitions and their regulatory subunits, the enzymes responsible for DNA replication, the cytoskeletal structures necessary for chromosome movements during mitosis, and the components of the ubiquitin-dependent

pathway for protein degradation, which plays essential roles during the cell cycle (see Chapter 10). Somatic cells also share the fundamental four-phase subdivision of the cell division cycle. Although all eukaryotic cells employ a similar molecular machinery to duplicate themselves, animal and plant cells have also evolved distinct mechanisms for controlling cell division, and these are related to the structural and developmental features that differ between plant, mammalian, and fungal cells.

One notable distinction is that during mitosis in mammals, chromosomes move toward a discrete pole, and when the two daughter nuclei move apart, this process involves progressive constriction of the plasma membrane at the central contractile ring. In plant cells, the two daughter nuclei become separated by a **cell plate** that grows at the equator of the mother cell. The cell plate ultimately fuses with the plasma membrane and cell wall that now surround both daughter cells. To generate these two daughter cells, plants have developed two unique cytoskeletal structures, the **preprophase band** and the **phragmoplast** (Fig. 11.1).

Plant cells also differ from mammalian cells in that they have a rigid cell wall and cannot move. Plant organogenesis, therefore, depends on cell division and cell expansion at the site of new organ formation. In addition, cell division in plants is mostly confined to specialized regions called **meristems**, which produce new cells that differentiate as they move away from the meristem (Fig. 11.2). Meristem cells are pluripotent, meaning they allow their progeny to become committed to a spectrum of developmental fates. During the plant life cycle, the identity of the shoot meristem itself can change from a vegetative to a reproductive program, resulting in the formation of flowers (see Chapter 19).

Also in contrast to mammals, plants and plant organs develop their characteristic shapes and functions after the embryo emerges from the seed. The root–shoot axis becomes established and the first leaves (the cotyledons) develop during embryogenesis, but most plant growth occurs after germination by iterative proliferation at the meristems. Because of the sessile life of plants, development and cell division are strongly influenced by environmental factors, such as light, gravity, nutrients, and biotic and abiotic stress conditions. All these specific features contribute to the plant-specific regulation of the factors controlling cell division.

11.2 Historical perspective on cell cycle research

DNA replication and chromosome segregation are the fundamental processes required for cell division. Proliferating cells alternate between these two mutually incompatible states, and the transitions between these states are regulated by cell cycle control mechanisms. Elucidation of these mechanisms has been an active area of research for many years.

11.2.1 The beginnings of cell cycle research can be traced to important discoveries in several areas of biology

In 1869, DNA was discovered to be the major component of the nucleus, and by the end of the 19th century, microscopic examination had revealed that proliferating cells alternate between two stages: **interphase** and **mitosis**. In interphase, no substantial nuclear structures are discernible, whereas in mitosis, chromosomes become visible, are distributed to opposite poles of the cell, and disappear again when the newly formed cells separate by division. By 1944, DNA was shown to be the genetic material, highlighting the importance of the nucleus in cell division. Later, DNA synthesis was found to occur during interphase in bean root tip cells. Together with the discovery of “gap phases” in which cells grow, and of the fact that progression to the next cell cycle phase can be controlled by a variety of intracellular and extracellular signals, the cell cycle was determined to consist of four phases, rather than two: interphase is subdivided into a synthesis phase (S) and two gap phases (G1 and G2) that separate DNA synthesis from mitosis (M). In the sequence G1, S, G2, M, the four phases constitute one complete round of the cell cycle (Fig. 11.3). The discovery in 1953 by James Watson and Francis Crick that the nucleotide bases of DNA are arranged as a complementary double helix immediately suggested a likely mechanism for how the encoded genetic information is replicated during S phase. The stage was set for the remarkable advances in cell cycle research that have characterized the past decades.

11.2.2 Genetics, biochemistry, and cell biology have been instrumental in elucidating molecular details of the cell cycle

Progress in several fields of biological research has rapidly advanced our understanding of how cells divide. Genetic analysis, biochemical complementation, and cell fusion experiments have provided important pieces of evidence that together reveal a great deal about the cell cycle.

In 1970, cell cycle regulation was dissected genetically in the single-celled budding yeast *Saccharomyces cerevisiae*. Genetic analysis was used extensively to identify the genes encoding the essential components of the cell division machinery and clarify the functional relationships of the gene products. Conditional cell cycle mutants were especially useful because they could grow at permissive temperatures (around 20–25°C), but not at a restrictive temperature (usually 36°C). Fortunately, the cell cycle of budding yeast has a readily visible marker, **bud formation**, which facilitates screening for mutants. The nascent bud, which appears approximately at the time of initiation of DNA synthesis, grows throughout the cell cycle, so a mutant phenotype can

FIGURE 11.1 Mitosis in plants. By the end of the 19th century, microscopy of plant cells had shown that steady increases of cell volume in proliferating cells were punctuated by the disappearance of the nucleus and appearance of condensed chromosomes (prophase), followed by their alignment along the equator of the cell (metaphase). Chromosomes appeared to separate and move toward the cell poles (anaphase), which was followed by reappearance of two nuclei (telophase), and the subsequent formation of separate daughter cells (cytokinesis). Most aspects of mitosis in plant cells are similar to those in animal cells, but the two types of cells differ in their spindle poles (which are more diffuse in plant cells) and in the mechanisms by which daughter nuclei are separated. Animal cells constrict their plasma membrane during telophase, while in plant cells, a cell plate is built that forms the new cell wall.

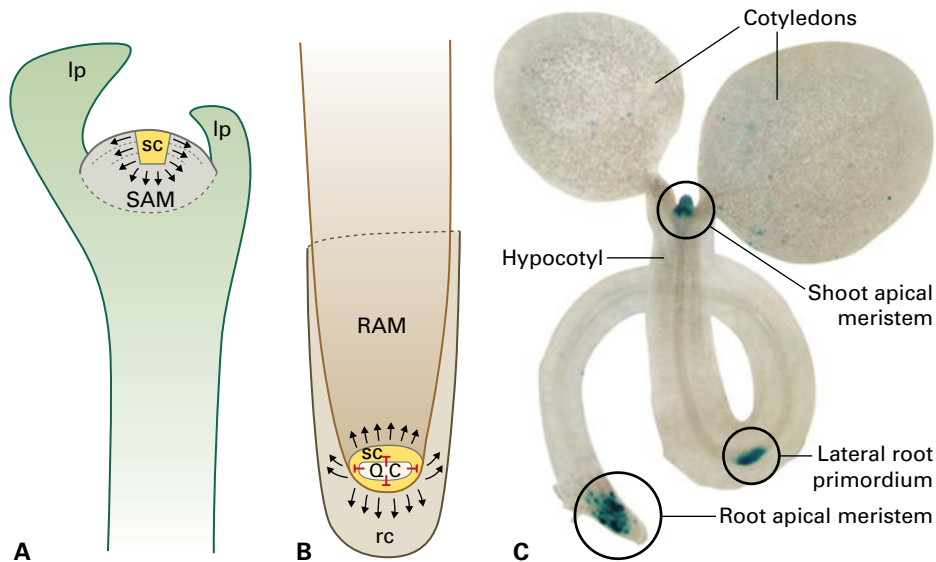

FIGURE 11.2 Continuous development after embryogenesis in plants. Unlike animals, plants can form new organs and tissues continuously throughout their life span. The tissues responsible for maintenance of this open growth mode are shoot apical meristems (SAMs) (A) and root apical meristems (RAMs) (B). Both meristems consist of undifferentiated and dividing cells that deliver new cells to the growing structures. Small populations of stem cells (sc) within the meristems are essential for the self-perpetuating capacity of meristems. After asymmetric divisions, the stem cells form daughter cells with distinct cell fates. One daughter cell will maintain the stem cell fate, whereas the other will receive instructions to differentiate into a specific cell type. However, the final differentiation is postponed and will only occur after several rounds of symmetric divisions that give rise to growing cell files (arrows). In the shoot apex, leaf primordia (lp), also made of dividing cells, are formed in close proximity to the SAM. In the root, no new organs are formed near the RAM and the entire structure is covered by a protective root cap (rc). At the apex cap boundary of the root, a small group of nondividing cells occurs, the quiescent center (QC). Signals emitted by these cells maintain the immediate surrounding cells in a stem-cell fate and prevent them from differentiation. (C) The sites of cell division can be visualized in an *Arabidopsis* seedling by the activity of a CYCLIN–GUS fusion protein produced exclusively in mitotic cells (blue). Next to the SAM and RAM, cell division activity can be observed at the lateral root primordia, sites at which new lateral roots initiate.

FIGURE 11.3 Phases of the cell cycle. Microscopic investigation of the cell cycle reveals two distinct states: mitosis, characterized by chromosome condensation and nuclear division, and interphase, during which chromosomes appear diffuse and cells do not divide. The discovery that DNA synthesis occurs during interphase led to the identification of four cell cycle phases: mitosis (M), DNA synthesis (S), and two gap phases (G1 and G2) that separate these events.

be related to a specific ratio of the volumes of the mother and daughter cells.

The goal of screening for **cell division control** (*cdc*) mutants was to isolate colonies in which growth was arrested at a particular stage when the culture was transferred to the restrictive temperature (Fig. 11.4). In contrast, mutations in genes not related to the cell cycle (e.g., genes encoding metabolic enzymes) were predicted to arrest proliferation at random time points of the cell cycle, that is times at which the cell was deprived of a particular metabolite (Fig. 11.4). The arrest phenotype of the *cdc* mutant identified by time-lapse photography revealed how far the cell cycle could progress without the presence of the wild-type gene product, called the **termination** or **arrest point**; however, it did not reveal when the wild-type gene product was normally required. Accomplishing this task required the use of another technique, **synchronization**.

In a proliferating population, individual cells are in different phases of the cell cycle, making it extremely difficult to study proteins or RNA molecules that are specific to individual phases of the cell cycle. Cell cultures can be synchronized, however, by blocking the progression of cells at a specific point in the cell cycle with drugs that inhibit crucial processes, such as DNA synthesis. Once all the cells in a culture

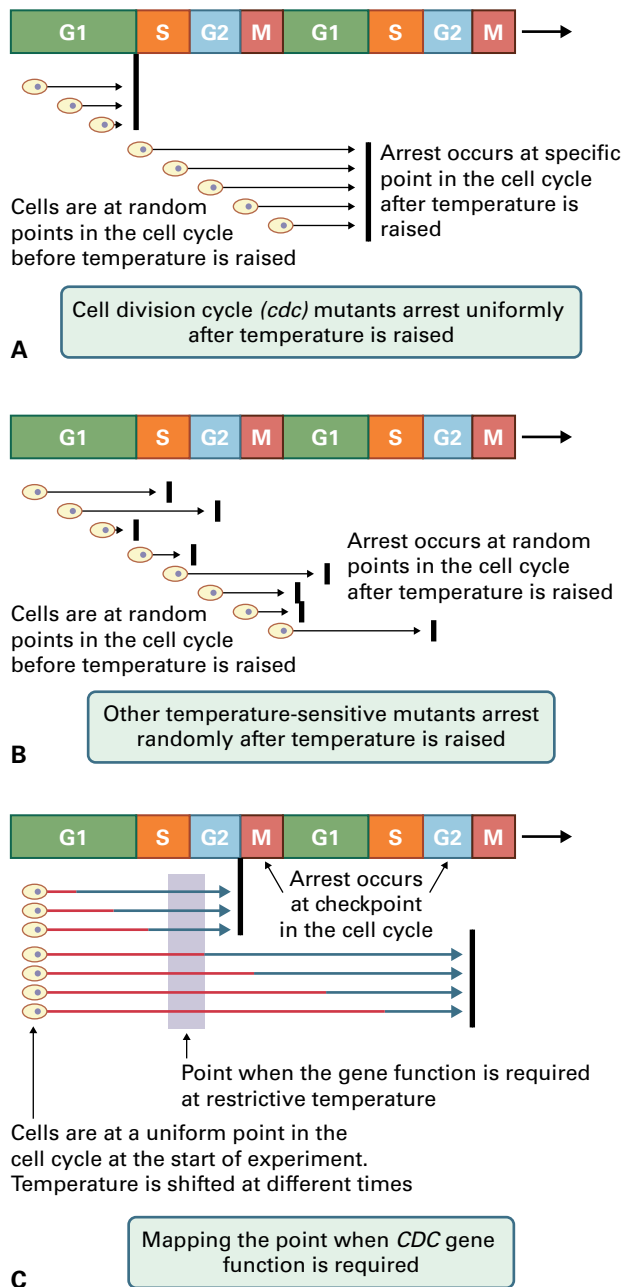

FIGURE 11.4 Genetic screen for identifying conditional cell division cycle (*cdc*) mutants of yeast. Unlike conditional *cdc* mutants (A) that arrest at the same phase in the cell cycle after the temperature is increased to the restrictive temperature, other conditional mutants (B) arrest at random points in the cell cycle after exposure to the restrictive temperature. Such experiments allow identification of the termination, or arrest, point—the point in the cell cycle beyond which mutant cells cannot progress without the gene product. Once a *cdc* mutant is identified, synchronized cell cultures can be used to determine the execution point—the point in the cell cycle at which the gene product is required (C). The temperature is shifted at different times for different synchronized cell cultures, as denoted by the transition of the arrow color from red to blue. Cultures exposed to the restrictive temperature before they reach the execution point arrest at the next termination point, whereas those exposed to the restrictive temperature after they reach the execution point can proceed through another round of the cell cycle before arresting.

have been arrested at the same stage of the cell cycle, the inhibitor can be removed to relieve the cell cycle block and allowing the cells to proceed synchronously through the cell cycle for one or two rounds. By transferring synchronized cells at successive stages of the cycle to a restrictive temperature and monitoring their fate by time-lapse photography, investigators can identify the point in the cycle at which the wild-type gene product is required—the **execution point** (Fig. 11.4).

Biochemical analysis, particularly when used in combination with cell biology, also provides powerful tools for examining the function of specific cell cycle proteins. Two techniques often used together are analysis of phase-specific protein extracts and biochemical complementation (Fig. 11.5). In one experiment, clam oocytes were stimulated to divide, protein extracts from the cells were prepared at different times after stimulation, and the protein patterns were analyzed. This

FIGURE 11.5 Identification of a mitosis-promoting factor (MPF). (A) Extracts are taken from mitotic *Xenopus* oocytes. The extracts contain proteins that induce G2 cells to undergo mitosis. Similar experiments were used to isolate an MPF capable of triggering G2 cells to divide. (B) Biochemical analyses of fractions of cell extracts taken at various stages of the cell cycle reveal the presence of cyclins, soluble protein factors that demonstrate cyclic changes in abundance during the cell cycle. Cyclin abundance correlates with the activity of MPF. Source: (B) Minshull (1989). *J. Cell Sci. Suppl.* 12:77–98.

approach identified a set of unstable proteins called **cyclins**, which appear and disappear at specific phases of the cell cycle. In other experiments, protein extracts from cells undergoing mitosis were fractionated, and the fractions were either combined with extracts from arrested oocytes or were injected into arrested oocytes. Determination of which fractions released the arrested extracts or oocytes allowed identification of a **mitosis-promoting factor** (MPF).

Finally, cell fusion experiments were performed, first with human cell lines and later with plant cells (Fig. 11.6). In these experiments, cells in different stages of the cell cycle were fused to observe how the nuclei responded. When cells in G1 were fused with S-phase cells, the G1 nuclei rapidly advanced into DNA replication. This indicated that although G1 cells were competent to replicate their DNA, this process

required activation by a factor already present in S-phase cells. When G2- and S-phase cells were fused, however, only the S-phase nucleus continued to replicate its DNA. Moreover, the G2 nucleus did not progress into the M phase after this fusion, as it ordinarily would have. This indicated the G2 nuclei were not competent to rereplicate and that a factor in S-phase cells prevented them from entering mitosis. When G2 cells and G1 cells were fused, the G1 nucleus replicated DNA, but on a schedule similar to that of unfused G1 cells, whereas the G2 nucleus did not replicate. Together, these observations demonstrated that S-phase cells contain a labile activator that can stimulate G1 nuclei (but not G2 nuclei) to enter S phase. Cells also contain a repressor of mitosis, which is active in S-phase cells and inhibits DNA rereplication before mitosis.

Observations	Conclusions
G1 nucleus replicates. Early S-phase nucleus continues replication.	G1 nucleus is competent to replicate. S-phase cells contain activator.
G2 nucleus does not replicate. S-phase nucleus continues replication. G2 nucleus does not progress into M phase.	G2 nuclei are not competent and do not rereplicate. G2 cells do not inhibit replication. S-phase nuclei retard mitosis in G2 nuclei.
G1 nucleus replicates at normal time; G2 nucleus does not replicate.	G2 cells do not suppress S-phase entry of G1-phase nuclei.

FIGURE 11.6 Examples of cell fusion experiments. (A) Fusion experiments conducted with animal cells revealed diffusible factors regulate cell division progress, whereas nondiffusible factors associated with chromosomes determine whether the chromosomes are competent to respond to the diffusible factors. (B) Cell fusions of plant cells at different stages of the cell cycle. Plant cell protoplasts, from which cell walls were removed by enzymatic digestion, can be fused together. To readily distinguish the origin of chromosomes in the fused protoplasts, cells from different species with distinct chromosome morphologies are used. In this experiment, mitotic wheat protoplasts (condensed chromosomes, left panel) were fused with rice protoplasts in interphase (chromosomes not condensed and, therefore, not visible, middle panel). After fusion, the rice chromosomes rapidly condensed and became visible (right panel). This suggests the mitotic wheat cells contain diffusible factors sufficient to initiate chromosome condensation in interphase cells.

These different approaches led to the identification of a group of kinases, known as **cyclin-dependent kinases** (CDKs). CDK activity is controlled in a cell cycle phase-dependent manner by the regulatory **cyclin** subunits. The conserved nature of cell cycle control by CDKs is reflected in the fact that a human *CDK* gene can complement a yeast *CDK* mutant despite the 1–1.5 billion years of evolutionary divergence between these organisms. CDKs and cyclins also make up the MPF, an observation that again supports the idea that cell cycle control is conserved among all eukaryotes, including plants. Peak cyclin abundance was later found to correlate well with the maximum biochemical activity of MPF (see Fig. 11.5).

In the following sections, we discuss the molecular components that advance and regulate cell division in plants and illustrate their temporal action in DNA replication and mitosis. The nomenclature of cell cycle proteins, which can be confusing, has been simplified wherever possible. For historical reasons, a protein conserved in many organisms can have many different names in the literature, but only one name is used here for homologous genes or proteins.

11.3 Mechanisms of cell cycle control

11.3.1 Specific kinase complexes facilitate cell cycle progression

Cell cycle progression is controlled by changes in CDK activity. CDK protein complexes are composed of at least two different subunits, one functioning as a protein kinase (CDK) and the other as an activator (cyclin). The protein kinase alone lacks activity; association with a cyclin is the first step in activating the complex. Many single-celled eukaryotes such as yeast have a single CDK, whereas all multicellular eukaryotes appear to have multiple CDKs. All eukaryotic cells also have multiple classes of cyclins, each of which is required for specific regulatory steps during the cell cycle.

In yeast, these different cyclins interact sequentially with the single CDK subunit, thereby changing the substrate

specificity of the enzyme complex during the cell cycle. In multicellular organisms, certain CDKs interact specifically with different classes of cyclins, and these interactions determine the activity and substrate specificity of the CDK complexes at particular points in the cell cycle. Thus, the association of CDKs with specific cyclins is generally thought to be a key regulatory mechanism for advancing the cell through the various stages of the cell cycle.

Cyclins are not, however, the only factors controlling CDK activity. The activity of CDKs also depends on their phosphorylation status and association with other regulatory proteins, such as substrate docking factors and CDK inhibitory molecules. Furthermore, proteases selectively destroy cyclins and CDK inhibitory proteins at defined time points during the cell cycle. The irreversible destruction of these proteins contributes to the unidirectional progression through the cell cycle.

11.3.2 Multicellular eukaryotes have a complex pathway of CDKs

CDKs are a highly conserved class of eukaryotic protein kinases with several characteristic features. When complexed with a cyclin subunit, they phosphorylate substrates on serine or threonine residues within an S/TPXR/K recognition motif found in most CDK substrates. Crystallographic studies have revealed their structure has two lobes, the N-terminal (upper) and C-terminal (lower) lobes, with the catalytic site residing in a deep cleft between the two lobes. Other amino acids required for CDK activity are located throughout the molecule, and they are organized into their appropriate spatial context only after the CDK protein has folded into its three-dimensional structure and interacted with a cyclin subunit.

Cyclin binding is required for entrance of substrates into the catalytic site, which is initially shielded by a flexible CDK domain, called the T-loop. When cyclin binds, the T-loop shifts into an open configuration that is stabilized by the phosphorylation of a conserved threonine residue in the T-loop (Fig. 11.7). This phosphorylation is catalyzed by CDK-activating kinases (CAKs), which are CDKs themselves.

FIGURE 11.7 The structural basis of CDK activation. The activity of CDKs is highly regulated, and association of the CDK catalytic subunit with an activating cyclin subunit is essential for protein kinase activity. Subsequent phosphorylation of the conserved Thr residue at position 161 by a CAK is required for full activity.

Plants have two functional classes of CAKs: CDKDs and CDKFs. CDKD is functionally related to the CAKs of vertebrates, whereas CDKF is a plant-specific CAK with unique enzyme characteristics. The functional diversity between the two CAKs is exemplified by their substrate specificity and cyclin dependence, and the activation of CDKs by CAKs is complex (Fig. 11.8). In addition to activating CDKs for substrate binding, CDKDs phosphorylate the C-terminal domain (CTD) of the largest subunit of the RNA polymerase II, which allows cells to coordinate transcription with cell cycle progression. Unlike CDKD, CDKF activation does not require association with cyclins. CDKF phosphorylates CDKD and, therefore, functions as a CAK-activating kinase. CDKF itself

FIGURE 11.8 Two classes of plant CAKs. CDKF is responsible for phosphorylation and activation of CDKD. Phosphorylated CDKD forms a stable complex with CYCH, and the CYCH-CDKD complex has kinase activity toward both the C-terminal domain of RNA polymerase II (POL-II) and CDKs. The CDK kinase activity of CYCH-CDKD is significantly lower than that of CDKF.

has a conserved site at Thr290, which probably needs to be phosphorylated by an unknown upstream protein kinase before it can phosphorylate CDKD (Fig. 11.8). Such a phosphorylation cascade may link CDK activation to developmental pathways or hormonal regulation.

Amino acid domains required for cyclin binding reside in the N-terminal (upper) lobe of the CDK and are named according to the single-letter codes of the amino acids they comprise. All eukaryotic organisms studied to date have at least one CDK with the PSTAIRE motif. In plants, PSTAIRE-containing CDKs are designated **A-type CDKs** (CDKAs), and they play a pivotal role at both the G1-to-S and G2-to-M transitions. The requirement of CDKA activity for cell division is demonstrated by a reduction in the cell division rate in plants with low CDKA activity, or the arrest of the second mitotic division during male gametogenesis in *CDKA* null mutants (Fig. 11.9).

Other CDKs have variations of the PSTAIRE motif. Plants possess a unique class of CDKs, the **B-type CDKs** (CDKBs), which have either PPTALRE or PPTTLRE motifs, reflecting the two subgroups, CDKB1 and CDKB2. In contrast to CDKAs, expression and activity of CDKBs are more confined to specific phases of the cell cycle, and the two subgroups differ slightly in timing of transcription: *CDKB1* transcripts accumulate during S, G2, and M phases, whereas *CDKB2* expression is specific to the G2 and M phases. Accumulation of CDKB proteins follows their transcription pattern, while their associated kinase activities reach a maximum during mitosis. CDKB1 activity is required for cell cycle progression through mitosis; plant cells with reduced CDKB1 activity arrest at the G2-to-M transition. Moreover, such plants display abnormal stomata and reduced numbers of stomatal complexes (Fig. 11.10). This mutant phenotype indicates CDKB1 has a role in the series of sequential cell divisions required to form a stomatal complex. A role for CDKB2 in cell cycle regulation is illustrated by the abnormal shoot apex and altered phylotaxis of plants with reduced *CDKB2* expression (Fig. 11.10).

FIGURE 11.9 Two rounds of mitotic divisions in wild-type haploid microspores derived from a microspore mother cell. After the first division, the developing gametophyte contains two cells: a vegetative cell with a large nucleus that encloses a generative cell with a small nucleus (2-nucleate stage). Next, the generative cell divides again (mitosis 2) so that the mature pollen contains one large vegetative and two small sperm cells (3-nucleate stage). In *CDKA* null mutants (*cdka1;1*), the generative nucleus fails to progress through the second mitosis, resulting in pollen with one vegetative and only one sperm cell.

FIGURE 11.10 *B*-type CDKs control plant-specific aspects of the cell cycle. (A–B) Plants with reduced *CDKB1* activity have a high number of stomata with aberrant morphology. In contrast to wild-type plants (A), the stomata in these mutants show a unicellular round or kidney-shaped appearance and lack pores (B). Remarkably, the aberrant cells still acquire typical stomatal features, such as guard cell shape formation and cell wall thickening, indicating *CDKB1* activity controls stomatal divisions, but not the differentiation of cells toward their stomatal identity. (C–D) In plants with reduced *CDKB2* activity, the typical meristem organization observed in wild-type plants (C) is disrupted because of a strong inhibition of cell division, which results in an abnormal meristem structure and defects in phyllotaxy (D).

Plants also contain more distantly related CDKs, designated C-type (*CDKC*) and E-type (*CDKE*) CDKs, which do not have a clear role in cell cycle control. *CDKC* may have a role in transcription elongation by phosphorylating the CTD of the RNA polymerase II, as well as in linkage of transcription with RNA splicing. *CDKE* (also known as *HUA ENHANCER3*) controls cell fate specification in floral organs by a currently unknown mechanism.

11.3.3 Cyclins determine the specificity and subcellular localization of CDKs

Association with cyclins is required for CDK protein kinase activity. As mentioned previously, cyclin binding induces structural changes needed for substrate recognition, including the repositioning of the T-loop (see Fig. 11.7). Cyclins also confer substrate specificity to the cyclin–CDK complex and are involved in targeting CDKs to specific subcellular compartments during the cell cycle.

Plants contain more cyclins than other organisms. For example, despite its small genome size, the *Arabidopsis thaliana*

genome encodes up to 50 different cyclins. Plant cyclin nomenclature is based on functional similarities with mammalian counterparts within a **cyclin box**, a largely conserved central domain that interacts with the kinase subunit. Plant cyclins are classified as types A, B, C, D, H, L, P, and T. Until now, a clear role in cell cycle progression has been demonstrated for A-, B-, D-, and H-type cyclins. In a broad sense, D-type cyclins are anticipated to control the G1-to-S transition; A-type cyclins, the S-to-M phase control; B-type cyclins both the G2-to-M and intra-M-phase control; and the H-type cyclins control the activity of CDKs (Fig. 11.11).

D-type (*CYCD*) cyclins diverge largely in their sequence and were originally identified by functional complementation of a yeast strain deficient for G1-specific cyclins. In mammals, accumulation of *CYCDs* is stimulated by growth hormones. Similarly, expression of plant *CYCDs* is modulated by growth factors, such as cytokinins, auxins, brassinosteroids, sucrose, and gibberellins. This indicates these cyclins act as key switches linking the hormonal and nutritional status of plant cells with cell cycle progression. In agreement with this model, expression of *CYCDs* precedes cell division in germinating seeds, and correspondingly, mutant plants with *CYCD*

FIGURE 11.11 The central regulator of the cell cycle is a CDK–cyclin heterodimer. Arabidopsis has five genes encoding CDKs that directly control the cell cycle, and more than 50 cyclin genes encoding mitotic A- and B-type cyclins and D-type cyclins. These classes can be further subdivided in subclasses, for which several of the family members are indicated on the right. They form different combinations of pairs and control progression of distinct cell cycle phases.

loss-of-function alleles show that CYCDs are rate limiting for cell cycle reactivation in the root apex during germination (Fig. 11.12A). Analogously, expression of the *CYCD3;1* gene depends on cytokinin and appears to affect cell division of cytokinin-deprived calli (Fig. 11.12B). Thus, *CYCD* expression seems important for coupling development to nutrient and growth factor availability.

Progression through S phase and entry into mitosis is probably controlled by the **A-type** (CYCA) cyclins and **B-type**

(CYCB) cyclins, respectively. Besides a cyclin box, both types of cyclins also carry a protein domain called the **mitotic destruction box** (D-box) that mediates cyclin degradation late in mitosis. The potential of plant B-type cyclins to trigger the G2-to-M transition was originally shown by microinjection experiments into *Xenopus* oocytes, which illustrated that plant cyclins could overcome the natural G2/M arrest of oocytes. Later, ectopic expression of a *CYCB* was demonstrated to stimulate cell division in roots and trichomes. Promoters of plant *CYCB* genes contain a common *cis*-acting element, called the **M-specific activator** (MSA) element, which is necessary and sufficient to direct G2/M-specific gene expression.

11.3.4 CDK activity is regulated by kinases, phosphatases, and specific inhibitors

The activities of CDK–cyclin complexes are controlled by specialized kinases and phosphatases, which have important functions in regulating cell cycle progression. In yeast, these complexes are subject to inhibitory phosphorylation of the Tyr15 residue in the CDK, whereas in vertebrates CDKs are phosphorylated on both Thr14 and Tyr15. Tyr phosphorylation is catalyzed by the Wee1 kinase, and both Tyr and Thr phosphorylation is counteracted by the dual-specific phosphatase Cdc25 (Fig. 11.13). Thus, Cdc25 and Wee1 act as “on” and “off” switches of CDK activity, respectively, and together play an important role as a timer of M-phase onset.

Plant CDKs are likely also negatively controlled by phosphorylation. Tyr phosphorylation of CDKA has been detected upon cytokinin deprivation, osmotic stress, and DNA damage. This phosphorylation is probably catalyzed by the plant WEE1 kinase, because overexpression of this gene inhibits cell cycle progression. However, no *CDC25* homolog has been identified in a plant genome, indicating the mechanism that controls the timing of M-phase onset is fundamentally different in plants. Likely candidates that have taken over the role of Cdc25 as timer of mitosis are the B-type CDKs or CDK inhibitory proteins (CKIs).

CKIs can be found in all organisms, and they inhibit cell cycle progression through direct association with activated CDK–cyclin complexes, preventing them from phosphorylating substrates. In humans, two different classes of CKIs are known. Members of the INK4 protein family, which operate as important regulators of the G1-to-S transition, are frequently mutated in neoplastic cells that have lost the ability to control proliferation. Members of the CIP/KIP family inhibit a broad range of CDK–cyclin complexes involved in the control of both the G1-to-S and G2-to-M transitions and operate as important effectors of anti-mitogenic stimuli.

Plants also have two classes of CKIs. One class shares a conserved domain with the mammalian CIP/KIP family at

FIGURE 11.12 *D*-type cyclins (*CYCD*) regulate cell cycle progression according to the nutritional and hormonal status of plant cells. (A) Effect of *CYCD* levels on the activation of cell division in the root meristem during germination. *CYCD4;1* loss-of-function mutants (*cycd4;1*) have a delayed onset of cell division activity and fewer dividing RAM cells, resulting in a lower rate of cell division than that of wild-type plants (*Col-Wt*). (B) Effect of *CYCD* levels on hormone-regulated callus formation. Wild-type leaves produce calli efficiently when exogenous cytokinin and auxin are present (top), but in the absence of cytokinin (bottom), only a few, slow-growing calli are formed; these fail to become green, and they degenerate after a period in culture. In contrast, *CYCD3*-overexpressing transgenic plants (*CYCD3^{OE}*) produce healthy green calli in both the presence and absence of exogenous cytokinin.

FIGURE 11.13 The protein kinase activity of a yeast CDK is regulated by phosphorylation and shown here as an example. Phosphorylation by a *Wee1* kinase of conserved threonine and tyrosine residues (*Thr14* and *Tyr15*) near the N-terminus of the CDK catalytic subunit inhibits protein kinase activity. Dephosphorylation by a *Cdc25* phosphatase removes these inhibitory phosphate residues and regulates the timing of entry into mitosis. Although the amino acids are conserved in plant CDKs, it is still unknown if they are regulated by enzymes with similar functions.

the extreme C-terminus that is involved in binding CDKs and cyclins and is essential for CKI activity. Because this conserved domain shares similarity with the N-terminal CKI domain of mammalian CIP/KIP proteins, these plant CKIs are known as **Kip-related proteins** (KRPs). Elevated KRP levels in plants restrain CDK activity and inhibit cell division, resulting in dwarfism and other alterations in plant morphology (Fig. 11.14A,B). The main targets of KRPs are the CDKA-CYCD complexes. Expression of the *Arabidopsis KRP1* gene (also known as *ICK1*) is induced by abscisic acid (ABA), probably contributing to the ability of ABA to arrest cell cycle progression. KRPs are also transcriptionally and post-transcriptionally controlled by other hormones, including auxin, cytokinin, and gibberellin.

The other class of plant CKIs includes the *Arabidopsis* SIAMESE (SIM) and SIAMESE-RELATED (SMR) proteins. The *SIM* gene was originally identified as a suppressor of cell division in trichomes (Fig. 11.14C,D). The SIM and SMR proteins share with KRPs a six-amino acid domain that is essential for cyclin binding and inhibition of CDK activity, and, like KRPs, they inhibit *D*-type cyclin-containing CDK complexes. *SIM* and *SMR* genes respond strongly to diverse

stress conditions, suggesting they play a major role in connecting cell cycle progression with biotic and abiotic stress perception.

11.3.5 Ubiquitin-dependent proteolysis occurs at key transitions in the cell cycle

Proteolysis ensures the unidirectional progression of the cell cycle by rapidly triggering the irreversible breakdown of target proteins. For example, proteolysis of CKIs is necessary to trigger the G1-to-S transition. Similarly, degradation of the cohesion proteins that connect sister chromatids is required for the irreversible transition from metaphase to anaphase. In all cases, the route to destruction runs via the ubiquitin-proteasome system, which uses the highly conserved polypeptide **ubiquitin** as a tag to mark target proteins for degradation by the 26S proteasome (see Chapter 10).

For ubiquitination, polyubiquitin chains must be generated on target proteins through the combined action of ubiquitin-carrying enzymes (E2s) and ubiquitin protein ligases (E3s),

FIGURE 11.14 CDK inhibitors and their effects on plant morphogenesis. (A, B) Wild-type (A) and KRP2-overexpressing (B) plants. KRP2-overproducing plants have narrow leaves that are serrated. These two phenotypes result from a strong reduction in leaf cell number. (C, D) Wild-type (C) and sim mutant (D) trichomes. Wild-type trichomes are unicellular, whereas sim mutants show a high frequency of multicellular trichomes.

Source: (A, B) Based on figure published by De Veylder et al. (2001). *Plant Cell* 13:1653–1668. (C, D) Based on figure published by Churchman et al. (2006). *Plant Cell* 18:3145–3157.

which bring targets and E2s together. Two different E3 complexes are most intimately dedicated to the basic cell cycle control, namely **Skp1-Cullin-Fbox (SCF)-type of E3 ligases** and the **anaphase-promoting complex/cyclosome (APC/C)**, which operate at the G1-to-S transition and in M phase, respectively.

Plant D-type cyclins are likely subjected to degradation in an SCF-dependent manner, as observed for their mammalian counterparts. Many D-type cyclins also contain PEST sequences, regions rich in Pro, Glu, Ser, and Thr that can confer protein instability. Other cell cycle regulators that are targets of the SCF include CDC6, CDT1a, E2Fc, and the KRPs. Among the SCF-type of E3 ligases, the F-box protein recognizes the substrates that need to be degraded. It is still unknown which of the 694 F-box proteins of *Arabidopsis* are involved in the specific recognition of the cell cycle regulatory proteins. An exception is the F-BOX-LIKE 17 (FBL17) protein, which targets the KRP CDK inhibitors for destruction.

The APC/C comprises at least 12 proteins, and recognizes and ubiquitinates several proteins, including proteins that

contain the D-box (mitotic destruction box, see Section 11.3.3). Like SCF, APC/C can occur in several forms with different selector proteins (Fig. 11.15). The activation and substrate specificity of the APC/C complex are in part determined by two adaptor proteins, CDC20 and CDH1. The *Arabidopsis* genome encodes five *CDC20* genes as well as three genes that encode CDH1-related proteins, designated *CCS52A1*, *CCS52A2*, and *CCS52B*. The three *Arabidopsis* *CCS52* genes probably have nonredundant functions: *CCS52B* is expressed from G2 to M, whereas *CCS52A1* and *CCS52A2* are expressed from late M until early G1, suggesting consecutive actions of these APC/C activators in the plant cell cycle. The *CCS52* proteins interact with different subsets of mitotic cyclins, either in free or CDK-bound forms.

Well-characterized target proteins that are ubiquitinated by APC/C are A- and B-type cyclins containing D-box sequences. The destruction of these cyclins is essential for exit from mitosis. Constitutive overexpression of a nondegradable CYCB, lacking the destruction box, causes severe growth retardation and abnormal development due to an abnormal mitosis and inhibition of cytokinesis.

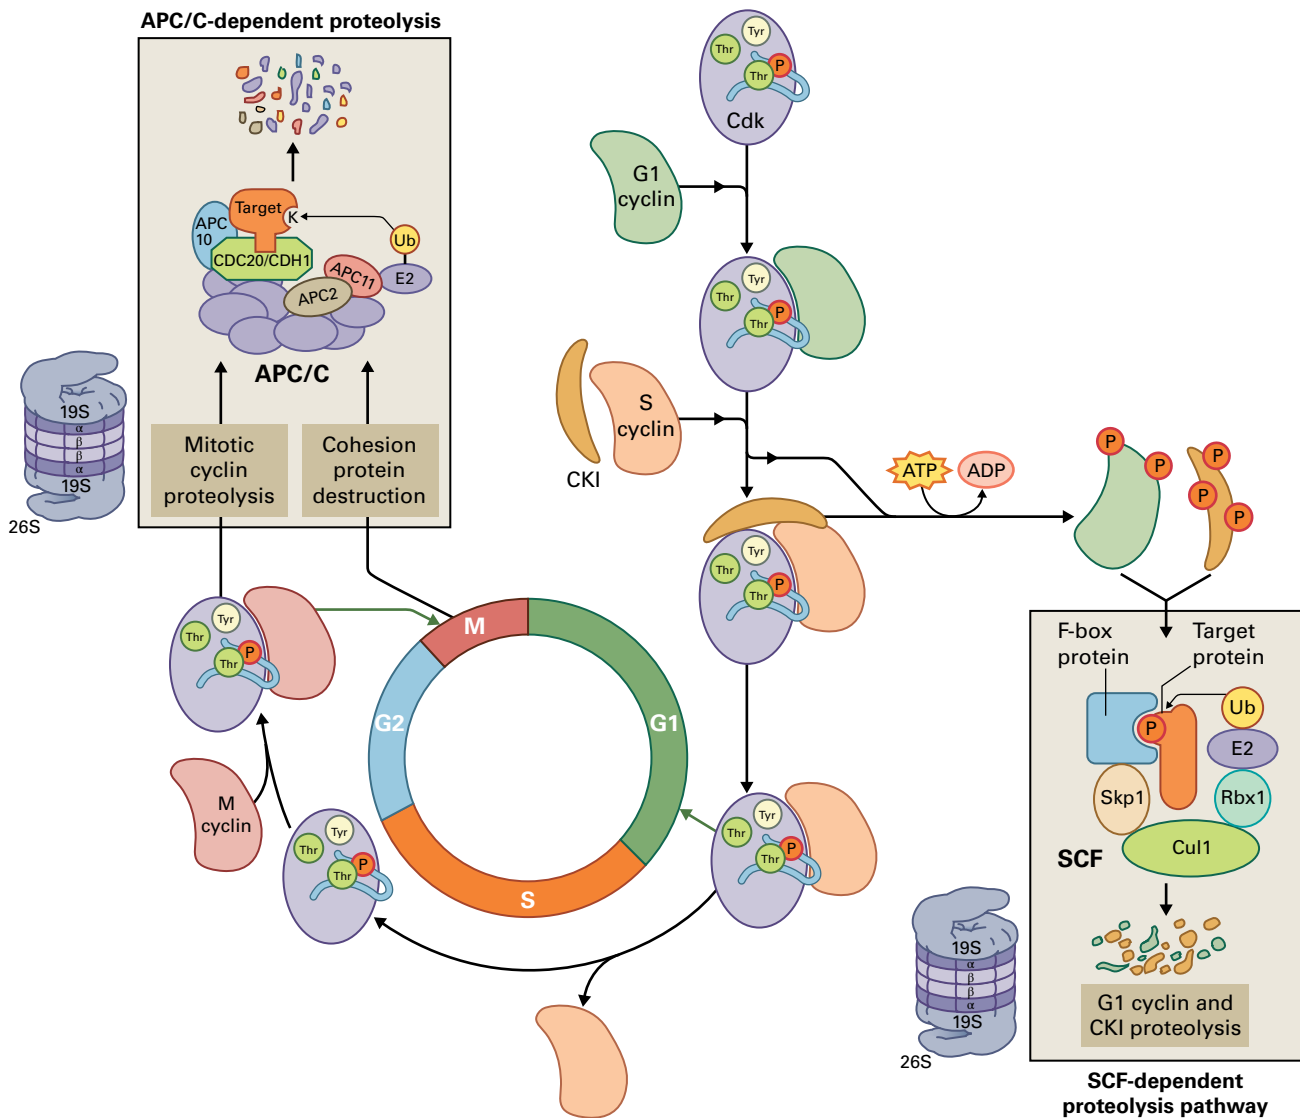

FIGURE 11.15 Protein degradation is instrumental in controlling cell cycle progression at two major transitions. At the G1-to-S transition, two types of cell cycle proteins are substrates for regulatory proteolysis: CKIs, which bind to S-phase cyclin – CDK complexes and prevent CDK activity, and G1 cyclins, which must be degraded to commit the cell irreversibly to the start of a new cycle. CKIs and G1 cyclins are targeted by Skp1-Cullin-F-box (SCF)-type of E3 ligases for degradation in the proteasome. At the metaphase-to-anaphase transition, anaphase-promoting complex/cyclosome (APC/C) complex-controlled proteolysis degrades mitotic cyclins and severs the links between sister chromatids to permit chromosome segregation. SCF-type E3 ligases contain three core subunits, the RING protein Rbx1, a cullin (Cul) protein, and an F-box substrate receptor. The cullin protein functions as a scaffold by bringing together the catalytic module (RBX1 and the E2 enzyme) and the substrate receptors. Recognition by SCF often requires substrate phosphorylation, which creates a signal for interaction between substrate and the SCF complex. The APC/C is the largest and most complex E3 ligase known so far and contains at least 12 subunits. The APC/C requires WD40 activator proteins (CDC20/FZ and CCS52/FZR) and most likely also the APC10 subunit to recruit its substrates and target them for degradation by the proteasome. The RING-H2 finger subunit APC11 interacts with an E2 enzyme to stimulate the ubiquitination reaction. APC/C substrates carry different degradation motifs (degrons), including the well-known destruction box (D-box).

11.4 The cell cycle in action

11.4.1 Control of the G1-to-S transition by the RBR/E2F pathway

In mammals, G1-to-S entry is initiated by the synthesis of D-type cyclins after mitogenic stimulation by serum growth factors. When complexed with specific CDKs, D-type cyclins

initiate phosphorylation of the retinoblastoma (RB) tumor suppressor protein, which negatively regulates cell proliferation through association with members of the E2F transcription factor family (Fig. 11.16).

E2F transcription factors are required for transcriptional activation of genes encoding proteins that are essential during DNA replication. Thus, E2F transcription factors are critical effectors of the decision to pass the G1-to-S restriction point and allow cells to proceed into S phase. When RB binds an

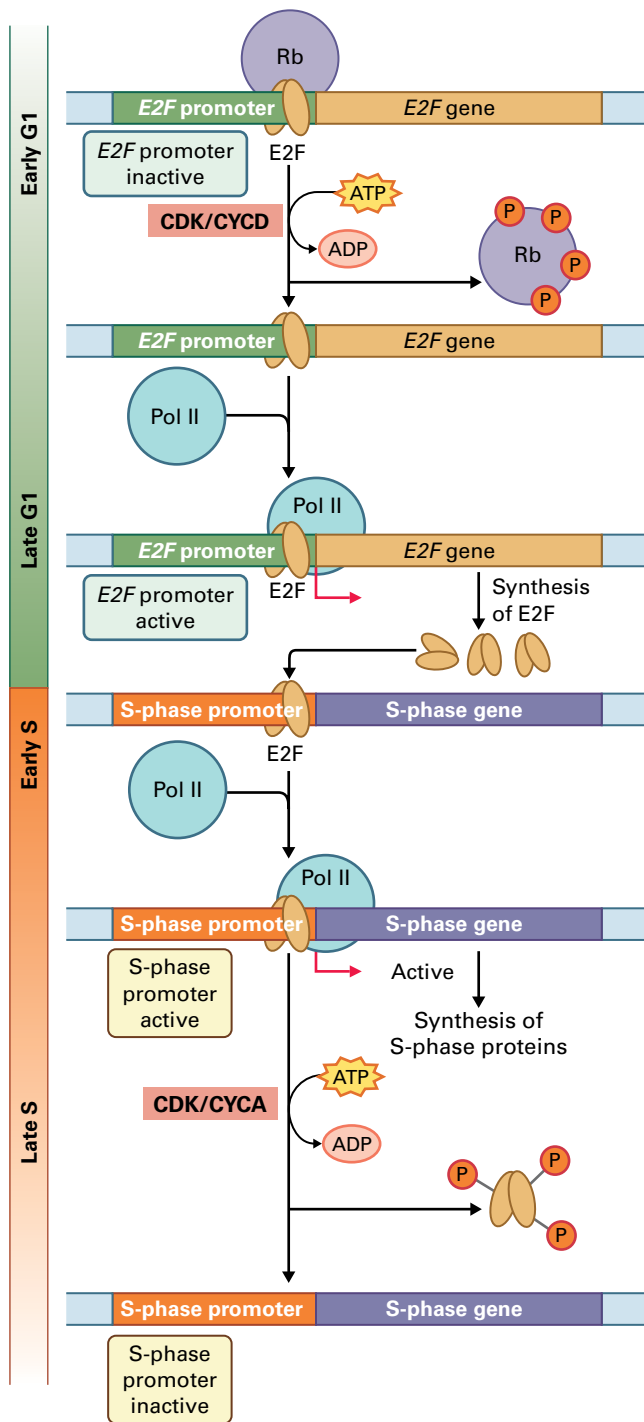

FIGURE 11.16 E2F transcription factor activation at the G1-to-S transition enforces the commitment to S phase. The E2F transcription factor activates its own transcription by binding to a site in its own promoter. In G1, E2F activity is suppressed by binding the retinoblastoma protein (RB). As a consequence of passage through the restriction point, the CDK/CYCD complex phosphorylates RB, resulting in its dissociation from E2F and relieving the inhibition of E2F. This activates E2F transcription, resulting in a positive-feedback loop that leads to accumulation of large amounts of E2F protein as well as other S-phase-specific proteins and subsequent transcription of S-phase-specific genes by RNA polymerase II (Pol II). Phosphorylation of E2F by the CDK–CYCA complex then inactivates E2F-dependent S-phase transcription.

E2F transcription factor, it inactivates it by masking its transcriptional activation domain. Moreover, under certain conditions, RB stimulates the recruitment of DNA-modifying proteins that can repress the promoter activity of E2F target genes by inducing chromatin condensation. RB phosphorylation by CDK–CYCD complexes counteracts the inhibitory function of RB, thereby releasing transcriptionally active E2Fs and, consequently, initiating DNA replication. By this mechanism, RB proteins enforce the decision to proliferate and activate the cell cycle-dependent transcription of genes that encode the DNA synthesis machinery at the G1-to-S transition.

Despite the 1.5 billion years of evolution that separates mammals from plants, both types of organisms use the same RB/E2F pathway to control the G1-to-S transition. Even the canonical DNA *cis*-acting element (TTTCCCGC) recognized by the E2F transcription factors within the promoter region of the E2F target genes is identical. *Arabidopsis* encodes one RB-related gene (*RBR*) and three E2F transcription factors (E2Fa, E2Fb, and E2Fc), which can be classified into two groups. The domain organization of all E2Fs is similar and is characterized by a single, conserved DNA-binding domain, followed by a DP dimerization domain (Fig. 11.17A). Dimerization of the E2Fs with the DP proteins, which contribute a second DNA-binding domain, is a prerequisite for tight sequence-specific binding to the promoter regions of E2F-responsive genes. Both E2Fa and E2Fb possess a transcriptional activation domain and, correspondingly, have been demonstrated to induce cell proliferation upon their overexpression. By contrast, E2Fc lacks a clear activation domain and operates as a negative regulator of E2F-responsive genes, thereby forming a second class within the family of E2F transcription factors. *E2Fc* overexpression inhibits cell division, whereas plants without functional E2Fc show increased proliferative activity.

As in animals, RBR is phosphorylated in a cell cycle phase-dependent manner by CDKs in complex with D-type cyclins; this phosphorylation probably inactivates RBR and subsequently releases activating E2F-DP transcription factors. Simultaneously, CDK-mediated phosphorylation of E2Fc targets E2Fc for destruction in an SCF-dependent manner. Combined, these two events induce expression of genes encoding proteins involved in DNA replication, such as nucleotide biosynthetic enzymes (e.g., ribonucleotide-diphosphate reductase and thymidine kinase) and replication factors (such as DNA polymerases and PCNA).

Upon completion of the *Arabidopsis* genome sequencing project, a new class of E2F-related proteins was discovered that binds E2F target genes in a DP-independent manner through a duplicated DNA-binding domain (Fig. 11.17A). These atypical E2F proteins were first described in *Arabidopsis* as DP-E2F-like (DEL) proteins, but they are also known as E2Fd–E2Ff. Because they lack a transcriptional activation domain, they are postulated to act as repressors and might play a role in a negative feedback loop to repress E2F-activated promoters. Until now, no role for DEL proteins in the timing of S-phase onset has been described. Rather, results obtained

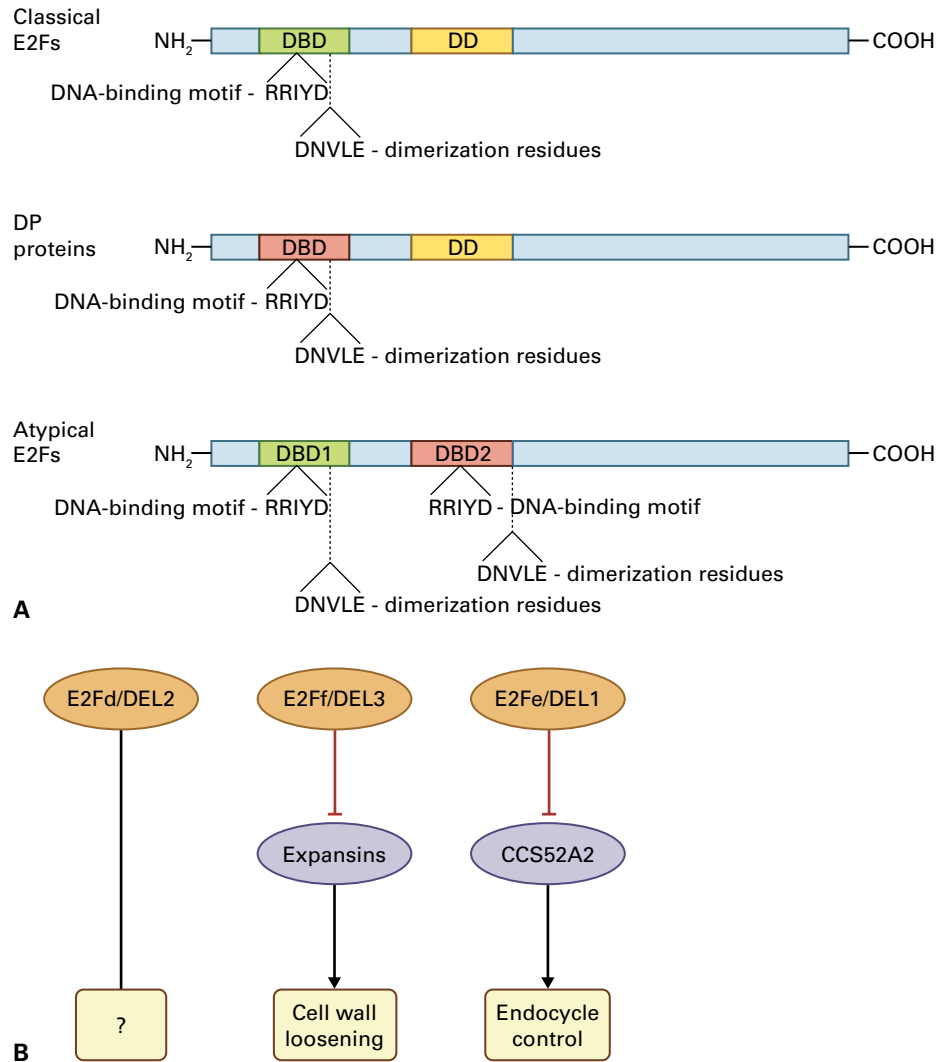

FIGURE 11.17 Typical and atypical E2F transcription factors. (A) Structural differences between typical and atypical E2F proteins. E2F proteins and the related DP proteins have both a DNA-binding domain (DBD) and a dimerization domain (DD). Atypical E2F proteins have two DBDs and no DD. Atypical E2Fs must dimerize with a DP protein to bind DNA, but the two DBDs enable atypical E2Fs to bind DNA as monomers. (B) Overview of identified biological roles of atypical E2F proteins in Arabidopsis. The observed cell elongation and upregulated expression of expansin genes in E2Ff/DEL3 loss-of-function mutant plants suggest the atypical E2Ff transcription factor functions in the control of cell wall loosening. E2Fe/DEL1 expression controls the onset of DNA endoreplication through the transcriptional regulation of CCS52A2, which encodes an APC/C activator protein implicated in the regulation of DNA endoreplication. E2Fd/DEL2 could, therefore, control the balance between cell proliferation and differentiation, but the underlying molecular mechanism is still unknown.

with knockout lines suggest a function in the coordination between cell division and post-mitotic cell differentiation. DEL3 operates as an inhibitor of cell elongation in dividing cells by transcriptional repression of cell wall-modifying enzymes (such as expansins), whereas DEL1 prevents dividing cells from entering the endocycle prematurely (see below) (Fig. 11.17B). After their initial discovery in plants, DEL-related proteins were found in animals, where they play an important role in the coordination between cell proliferation and apoptosis.

RBR also plays an important role outside the cell cycle. Equally important as the control of cell cycle entry for normal plant development are the restraint mechanisms that prevent precocious activation of cell division. RBR is required for cell

differentiation of both male and female gametophytes. In case of embryo development, the central cell of the embryo sac must be kept in a quiescent state until fertilization has occurred, and chromatin remodeling seems to be an important control mechanism in this process. RBR and RBR-binding proteins of the polycomb group, such as FERTILIZATION INDEPENDENT SEED (FIS) and MULTICOPY SUPPRESSOR OF IRA1 (MSI1), form a multi-protein complex that is essential for inducing formation of the heterochromatin that probably silences expression of cell cycle genes. In *RBR1* knockout lines of *Arabidopsis*, this heterochromatin is not formed, resulting in mitotic divisions in the unfertilized egg cell and autonomous endosperm development, with sterility as a consequence. Likewise, RBR-mediated

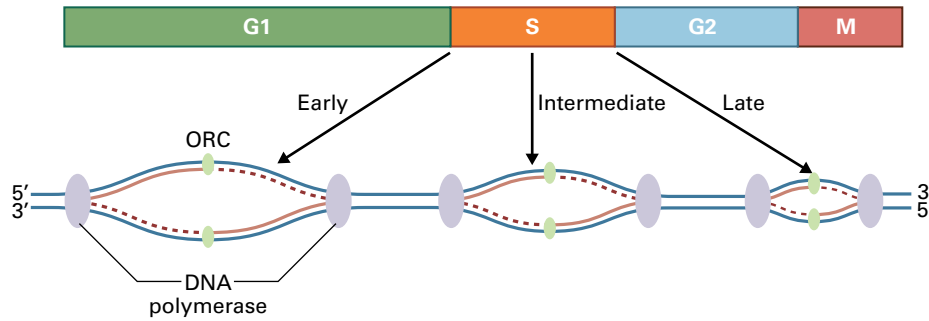

FIGURE 11.18 The origin of recognition complex (ORC) is a landmark that instructs the cell where to initiate DNA replication. The ORC also serves as a docking point for replication proteins. Individual origins initiate replication at different times during S phase (early, middle, and late origins). This model for replication of discrete origins was developed from electron microscopy data. Dotted lines represent lagging DNA strands.

chromatin modeling might dictate the differentiation status of cells, as indicated by the observed delay in cell differentiation in RBR-deficient cells.

11.4.2 Many proteins are involved in controlling S-phase progression

Most of the progress in the field of DNA replication has been made by combining the knowledge obtained by genetic experiments in yeast and biochemical data resulting from work in frog oocytes. Replication is initiated at multiple origins along DNA by a conserved mechanism that consists of four steps: origin recognition, assembly of a **prereplication complex** (preRC), activation of the helicase, and loading of the replication machinery, also referred to as the **replisome**.

Origins of DNA replication are sites in the genome where replication begins. Except for budding yeast, origins of replication are not defined by primary DNA sequences, but by a unique structure dictated by epigenetic determinants. Usually, replication starts at an origin and proceeds bidirectionally, making two Y-shaped DNA structures, called **replication forks**. Eventually, the replicons fuse, resulting in complete genomic duplication. Not all origins initiate DNA synthesis simultaneously at the beginning of S phase; DNA synthesis is initiated throughout S phase. Therefore, origins of DNA replication are classified into early, intermediate, and late types (Fig. 11.18).

Many proteins interact directly and indirectly with the origins of replication to control progression through S phase. DNA replication begins with the assembly of a preRC, which consists of many different proteins (Fig. 11.19). First, an **origin recognition complex** (ORC) binds to DNA in newly replicated chromatin during the S to early G1 phases of the cell cycle. The ORC is a six-protein complex containing ORC1 to ORC6 proteins in equal stoichiometry, and its binding provides a docking platform for additional replication proteins, including the CELL DIVISION CYCLE 6 (CDC6) and CHROMATIN LICENSING AND DNA REPLICATION FACTOR 1 (CDT1). During G1, the CDC6 and CDT1 proteins load the **MINICHROMOSOME MAINTENANCE helicase** (MCM) onto the ORC to complete the preRC. MCM

FIGURE 11.19 Stepwise assembly of the prereplication complex. The ORC is a complex of six proteins, and its binding to DNA provides a docking platform for additional proteins. To prevent premature DNA replication, the proteins that associate with the ORC are assembled in steps. CDC6 and CDT1 proteins bind first, followed by MCM proteins and the CDC45 protein, forming the prereplication complex. The prereplication complex is activated by protein phosphorylation (by CDKs and CDC7 kinase), which commits the cell to a round of cell division, defining the start of S phase. Phosphorylation of MCMs and the GINS complex loads the replisome complex with several other replication proteins including the DNA polymerases, and establishes the replication fork. Subsequent phosphorylation of CDC6 and other origin-binding proteins results in their destruction and ensures that the origins of replication are only activated once in each cell cycle.

proteins, a family of six related and essential proteins, assemble into a large doughnut-shaped complex around the DNA helix, which unravels the DNA at the replication origin and then travels along the DNA with the rest of the replication machinery, unwinding the DNA at the replication forks.

Loading of the MCM helicase onto the DNA is referred to as **DNA replication licensing** to indicate that chromatin-bound MCM proteins give the cell a license for one round of DNA replication.

The actual onset of DNA replication is regulated by the recruitment of the replisome to the origins of replication. The CDC45 protein and a large number of other proteins (e.g., the four-subunit GINS complex, Sld2, and Sld3) are needed for loading of the replisome. The large multiprotein complex that is created at this step is designated the **pre-initiation complex** (preIC), and it opens the DNA helix, stabilizes the formed single-stranded DNA, and allows enzymes (including DNA polymerases) to copy the DNA. Helicase activation and replisome loading are coupled events, ensuring coordinated replication. By a lack of coordination, the helicase might produce unreplicated single-stranded DNA at the fork, which occurs when DNA replication is blocked.

Many other proteins are needed to establish conditions favorable for DNA replication, but they do not regulate DNA replication itself. For example, the biochemical pathways required to synthesize the nucleotide triphosphates used during DNA synthesis are stimulated just before the onset of S phase. During replication, chromosomal DNA remains organized in chromatin, a complex composed largely of histone proteins. Therefore, a substantial amount of new histones must be synthesized in S phase. Histone gene expression and protein accumulation are strongly stimulated in early S phase (Fig. 11.20).

Little is known about how plant replicons are regulated. It is likely, however, that the process of DNA replication is conserved in plants, as evidenced by the presence of genes homologous to most of the key players involved in preRC and preIC formation (e.g., MCMs, ORCs, CDC6, CDC45, and CDT1). Moreover, the embryo- and gametophyte-lethal phenotypes of mutations in genes such as *MCM7* and *CDC45* illustrate their importance in the plant DNA replication cycle.

11.4.3 DNA replication is strictly controlled during the cell cycle

Initiation of DNA synthesis is inhibited during G₂, M, and G₁ phases, and this avoids two major types of cell cycle errors. DNA synthesis in G₂ and early M would lead to a change in **ploidy** (DNA content and genome copy number) and interfere with chromosome segregation, and DNA synthesis in anaphase, telophase, or G₁ would not be coupled to cell growth. The “once-and-only-once” nature of DNA replication is achieved through a temporal separation between the formation of the preRC and preIC.

Although DNA replication is restricted to S phase, assembly of the protein complexes that mediate initiation of DNA synthesis is promoted at late M and early G₁ phases. The chromosomal cycle starts at the transition from metaphase to anaphase, which is accompanied by the activation of the APC/C. The APC/C facilitates the destruction of the mitotic cyclins, causing a dramatic decrease in CDK activity. This

FIGURE 11.20 Histone expression is regulated by the cell cycle. Histones are basic proteins involved in organizing chromatin structure. During S phase, the cellular content of histones must be doubled to assemble with the newly replicated DNA. Therefore, the synthesis of histone-specific RNA (top) and the accumulation of histones (bottom) is strongly stimulated in S phase (0–4 hours in this experiment) but not in M phase (8–12 hours). The activity of cell cycle phase-specific transcription factors is responsible for this peak of histone mRNA accumulation.

Source: Adapted from Reichheld et al. (1998). *Nucleic Acids Res.* 26:3255–3262.

reduced activity allows CDC6, which is otherwise marked by CDK-mediated phosphorylation for protein destruction, to accumulate and interact with ORCs. Thus, CDC6–ORC complexes can form only after M phase is complete and before S phase begins (Fig. 11.19).

In late G₁ phase, the cell decides whether to proceed with proliferation at the **restriction point** (or START in the budding yeast cell cycle). Once the cell has passed this point in the cell cycle, it is committed to S phase. Although replication origins are competent to initiate DNA synthesis at this time, cells are not able to enter S phase before expression of S-phase genes (such as histone genes) has been stimulated. S phase is then initiated when primed preRCs are activated by phosphorylation, which requires the collaborative action of CDKs and the Dbf4-dependent kinase (DDK4).

DDK4 is a heteromeric protein kinase complex that consists of a catalytic CDC7 subunit and regulatory DBF4 subunit.

It is tethered to origins of replication and is activated at the beginning of S phase. DDK4 phosphorylates the MCM2–MCM7 complex, which is thought to cause a conformational change in the MCM5 protein. This triggers the DNA unwinding activity of the MCM complex and signals to preIC proteins to bind, including the CDC45 protein and GINS complex. The GINS complex is phosphorylated by CDKs and together with CDC45 binds the DNA polymerase B subunit. The GINS–CDC45–DNA polymerase B subunit complex then binds chromatin and recruits the replisome, resulting in the start of DNA replication. MCM phosphorylation thus appears to be a key event in switching preRCs to the replicative state. Simultaneously, CDK-dependent phosphorylation of CDC6 and other replication proteins target these proteins for destruction. This ensures the initiated origins of replication cannot be reactivated a second time and the DNA is copied only once.

Thus, replication of nuclear DNA in S phase is the critical event of the chromosomal cycle, but it depends entirely on the cell acquiring competence during the M and G₁ phases to initiate replication later in S phase. Although DNA synthesis remains inhibited during M and G₁ phases, assembly of the protein complexes that mediate the initiation of DNA synthesis is promoted. In contrast, DNA synthesis is promoted during S phase, while assembly of the protein complexes that facilitate the initiation of DNA synthesis is inhibited.

11.4.4 Multiple regulatory factors are required for the G₂-to-M transition

Once DNA replication is complete, synthesis of the M-phase cyclins in late G₂ prepares the cell for mitosis. The rapid increase in mitotic CDK activity at the G₂-to-M transition initiates mitosis and, subsequently, cytokinesis, beginning with chromosome condensation and alignment of the chromosomes at the metaphase plate. In mammals, the G₂-to-M transition is specifically regulated by CDKs that associate with A- and B-type cyclins. In plants, the CDKs that regulate the G₂-to-M transition are probably CDKA and CDKB, as both are active at this transition point. On the basis of their peak of transcription during the G₂ and M phases, both A- and B-type cyclins are probably responsible for the mitotic events.

Plant B-type CDKs and other genes expressed during mitosis (such as KNOLLE and the kinesin NACK) contain a common *cis*-acting element, the **MSA element**, which is necessary and sufficient to direct G₂-to-M-specific gene expression. The MSA element binds two types of MYB3R transcription factors, which are structurally related to animal c-Myb proteins: *MYB3RA*, which displays a cell cycle phase-dependent transcription profile, and *MYB3RB*, the levels of which remain constant during the cell cycle. The MYB3RB protein cannot activate MSA element-containing promoters. A model has been proposed in which MYB3RA and MYB3RB proteins antagonistically control the expression of the G₂-to-M-

FIGURE 11.21 Binding of MYB3R proteins to the M-specific activator (MSA) element. The MSA element is necessary and sufficient for the G₂-to-M-specific transcriptional activation of M-phase genes. In tobacco, three MYB3R proteins are structurally related to animal c-Myb proteins. Whereas the MYB3RA1 and MYB3RA2 genes display a cell cycle phase-dependent transcription profile, levels of MYB3RB remain constant during the cell cycle, and MYB3RB cannot activate MSA-containing promoters. The extent of transcriptional activation of MSA-containing promoters by MYB3RA2 depends on the cell cycle phase and on its C-terminal domain, which is a target for CDK phosphorylation. This implies feedback mechanisms in which the cyclins induced by the MYB3R proteins form a complex with CDKs that activates MYB3R activity. Likewise, controlled proteolysis of cyclins might result in rapid inactivation of MYB3R proteins. Both mechanisms may account for the observed sharp peak of mitosis-specific cyclins during the cell cycle. This feedback mechanism is strengthened by MSA elements in the promoters of MYB3R transcription factors. The initial trigger for transcriptional activation of MYB3RA1 and MYB3RA2 remains unknown.

specific genes (Fig. 11.21). Interestingly, the activity of the MYB3Rs is stimulated by their phosphorylation by CDKs. The cyclins induced by MYB3R proteins form a complex with CDKs that hyperactivates MYB3R activity, and this probably contributes to the sharp peak of mitosis-specific genes during the cell cycle. This positive feedback mechanism is strengthened by the presence of MSA elements in the promoter of the MYB3R genes. The trigger of initial transcriptional activation of MYB3RA remains unknown.

11.4.5 How does a cell become competent for mitosis?

Most of our understanding of the molecules involved in organizing mitosis is drawn from genetic experiments with animal cells and yeast. Although little is known about the nature and regulation of the molecules involved in mitosis in plants, current experimental evidence hints at similarities.

As discussed above, mitosis is suppressed during G₁, S, and G₂ phases, and the stepwise process that promotes mitosis is initiated in S phase. Mitosis commences with the initiation of chromosome condensation and disassembly of

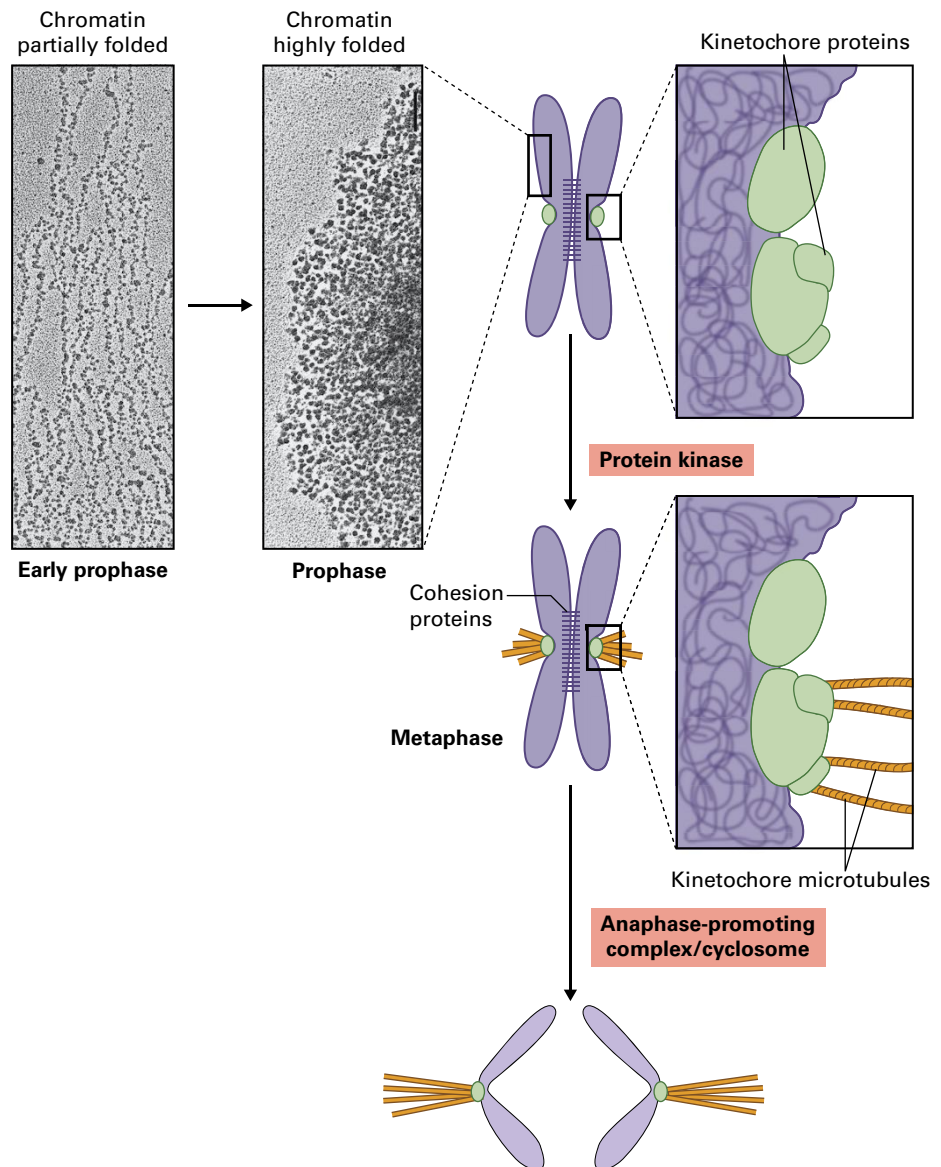

the nuclear envelope that separates the nuclear matrix from the cytoplasm (Fig. 11.22). This is often referred to as the onset of the M phase, but the cells are not yet competent for chromosome segregation. Full competence for separation of the duplicated DNA is achieved only when condensed chromosomes are aligned along a plane in the center of the cell, with each chromosome comprising two **chromatids** that, although attached to each other, are connected by microtubules to opposite ends of the cell. Chromosome segregation is then initiated when the link between sister chromatids is severed.

Several different classes of molecules are involved in establishing the full competence for mitosis. Proliferating cells synthesize proteins collectively called condensins and cohesins, which are essential for assembling the long chromatin fibers into chromosomes and thereby permit the replicated DNA to be segregated without damage. The molecular details of how chromosome condensation and cohesion are achieved have

been discovered mainly in yeast. Cohesion proteins such as SMC1, SMC3, and SCC1 are synthesized during S phase. These proteins interact with both sister chromatids (daughter strands) of a chromosome to establish and maintain their tight linkage until anaphase. Cohesion occurs at both centromeres, where it plays an essential role during chromosome segregation during mitosis and meiosis. Cohesion also locates along the chromosomes, enabling higher order chromosome dynamics and recombination between sister chromatids in response to DNA damage. Plants also have cohesins and condensins, and their inactivation causes a premature arrest in embryo development.

Condensation of chromosomes compacts the chromatids into short, rod-like structures to facilitate their separation during mitosis and meiosis. Condensing chromosomes are assembled around a central axis of scaffold proteins, presumably arrays of cohesin and condensin molecules that bind to long loops of DNA. During the early steps of chromosome

FIGURE 11.22 *Chromosome condensation and the kinetochore complex. In its unpackaged state, the long, fragile DNA molecule would be sheared into pieces during chromosome aggregation and segregation. DNA is packaged into higher order chromatin structures by winding around histones. The chromatin, however, which provides access to transcription factors and RNA polymerase to allow gene expression, is still too diffuse to permit segregation of sister chromosomes in mitosis. Further condensation and disentangling of chromosomes occur in prophase to prepare for chromosome segregation (see photos). The kinetochores are protein complexes that bind to centromeres and serve as attachment points for the spindle microtubules that pull apart the sister chromatids to opposite cell poles. The APC/C, which is activated by protein phosphorylation, tags the mitosis inhibitor securin for proteolysis. This ultimately leads to the destruction of the cohesion proteins that join sister chromatids and results in chromatid separation during anaphase. Source: Photographs: Sitte et al. (1998). Strasburger Lehrbuch der Botanik, 34th ed. Gustav Fischer Verlag.*

condensation, the two sister chromatids condense into one large cylinder. Upon further condensation in late prophase and early metaphase, topoisomerases introduce supercoils into the DNA helix. The supercoils increase the packing density of DNA even further and, at this point, the sister chromatids are distinguishable by light microscopy. The chromosome structure at this phase exposes the cohesins to regulatory factors that break the linkage between sister chromatids in anaphase. Throughout this process, inhibitory proteins such as securin begin to accumulate, and they safeguard against precocious entry into mitosis. Securin binds to and antagonizes the separase protein, which breaks the linkage between sister chromatids and triggers chromosome separation at the onset of anaphase. Genetic analysis in yeast indicates securin must bind to separase for correct targeting to the site where it acts in late metaphase. Thus, securin binding simultaneously suppresses premature activation of separase and ensures its correct localization. Based on sequence similarity, no clear ortholog for securin can be found in plants; however, the separase AESP is required for cohesin removal from meiotic chromosomes and is essential for embryo development.

A second large complex, the kinetochore, attaches to the centromeres of chromosomes. The microtubule network, which is ultimately responsible for congregation of the chromosomes along the metaphase plate and their subsequent movement toward the cell poles, binds to the kinetochores (Fig. 11.22). Kinetochore assembly is coupled with the completion of DNA replication. The molecular composition of the plant kinetochore complex is still poorly understood.

11.4.6 Proteases regulate the initiation of chromosome separation and M-phase exit

The capacity of the cell to undergo ordered mitosis is established during S phase and continues until mitosis is complete. Ordered mitosis begins with insertion of cohesins into the newly replicated helices and removal of catenations that would preclude chromosome separation. Once chromosomes are disentangled and condensed, they are fully competent for segregation. The cell, however, is not competent for mitosis until the sister chromatids are aligned along its equator. Cells at this time also monitor whether the kinetochores of paired chromatids are attached to the opposite cell poles. To prevent premature sister chromatid separation while these processes are in progress, segregation is suppressed during metaphase by inhibition of separase (see above). At the end of metaphase, the protein complexes required for chromosome separation are fully poised, in a state analogous to the primed prereplication complex at the G1-to-S transition.

The metaphase-to-anaphase transition is activated by CDK-mediated phosphorylation of the APC/C, which in turn results in the ubiquitination of securin. Ubiquitinated securin is recognized by the 26S proteasome as a substrate and is degraded. This activates separase, which breaks the cohesin-established linkages between sister chromatids. Once these

bonds are broken, the mechanical forces generated by motor proteins along the kinetochore microtubules draw each “sister” of the formerly paired chromatids to opposite ends of the cell (Fig. 11.22). Activated APC/C also causes destruction of mitotic cyclins, marking the exit from mitosis. Simultaneously, the decline in mitotic CDK activity relieves the repression of the G1 cyclin synthesis, allowing accumulation of A-type cyclins, which had been suppressed from S phase through telophase. Thus, G1 CDK activity can gradually increase, allowing assembly of new replication complexes and maintaining APC/C activity to prevent any residual mitotic CDK activity.

11.4.7 Checkpoint controls are activated by DNA damage or incomplete cell cycle events

Cell proliferation often occurs under unfavorable conditions. Consequently, cells may incur DNA damage or may lag in completing DNA synthesis or in attaching chromosomes to the spindle apparatus. All cells are capable of restoring normal cell cycle activities using special repair mechanisms, but cell cycle progression must be arrested to prevent the damage from progressing to a **mitotic catastrophe**. When damage occurs, cell cycle progression is arrested at a checkpoint. Three major types of checkpoints have been discovered: arrest at a checkpoint can occur prior to the restriction point at the G1-to-S transition, prior to the S-to-M transition that couples mitosis to the completion of DNA synthesis, or prior to sister chromatid separation, at either the G2-to-M or the metaphase-to-anaphase transition. Each of these three checkpoints immediately precedes a committing event that is irreversible (Fig. 11.23).

Although it is still largely unknown how plants control the checkpoints during mitosis, there is clear evidence that the replication-associated checkpoints are partly conserved between animals and plants. When DNA is damaged, two important global cellular responses are needed for survival of the cells: activation of the DNA repair machinery and delay, or even arrest, of the cell cycle progression. This coordinated action ensures that cells repair their damaged DNA before they proceed into mitosis. At the crossroads of both pathways, two related kinases are found, the **ATAXIA TELANGIECTASIA MUTATED (ATM)** and **ATM AND RAD3-RELATED (ATR)** proteins. These proteins are highly conserved and are triggered in response to different types of DNA stress: double-strand breaks (DSBs) activate ATM, whereas ATR primarily responds to single-strand breaks or stalled replication forks. Mutations in *ATM* or *ATR* render organisms hypersensitive to DNA damage-inflicting agents. In plants, the *atm* mutants show growth defects when treated with γ -rays (Fig. 11.24A) or DSB-causing methyl methane-sulfonate. By contrast, the *atr* mutants primarily exhibit hypersensitivity to drugs (such as hydroxyurea and aphidicolin) that inhibit the progression of the replication fork (Fig. 11.24B).

FIGURE 11.23 Checkpoint controls monitor the state of the cell during the cell cycle. If serious DNA damage has been incurred or any biosynthetic process is incomplete, progression of the cell cycle is arrested before any irreversible, committing steps are taken. Checkpoint controls are active before the cell cycle reaches START (in budding yeast) or the restriction point (its equivalent in animals), as well as at the metaphase-to-anaphase transition (in yeast and animals) and at the G2-to-M transition (in animals).

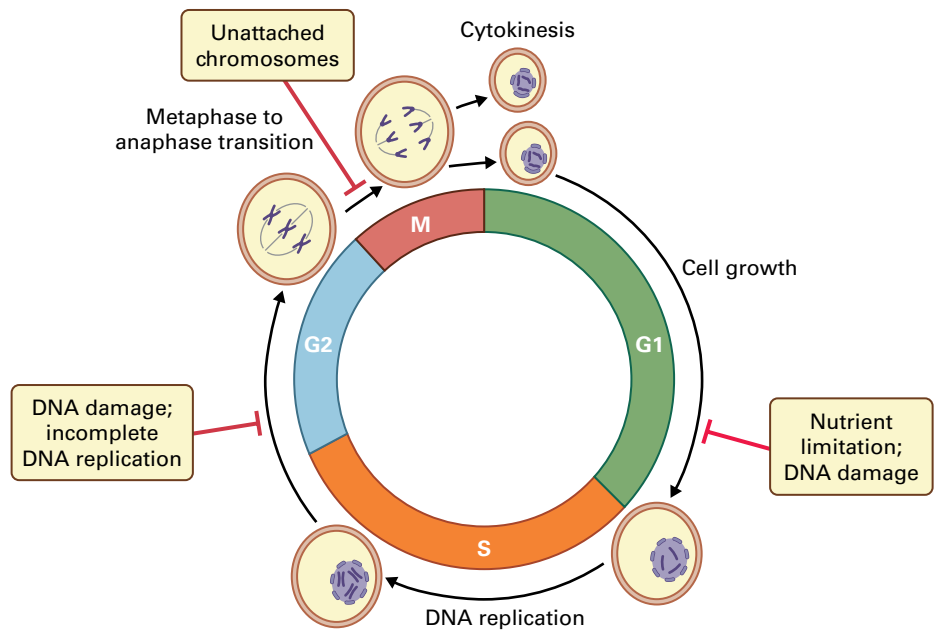

FIGURE 11.24 Hypersensitivity of ATM mutant plants to treatments that induce double-strand breaks, such as irradiation with γ -rays. (A) Five-day-old wild-type (WT) and *atm1* mutant seedlings were either left untreated (0 Gray units, Gy) or subjected to 100 Gy of irradiation. Photographs were taken 21 days after irradiation. The growth of wild-type plants resumes (top right), whereas that of the mutant seedlings is arrested (bottom right). (B) Sensitivity of wild-type (WT) and *atr* mutant plants to replication-arresting agents, such as the nucleotide biosynthesis inhibitor hydroxyurea (HU). Seeds were germinated on control medium or medium supplemented with HU and grown for 3 weeks. Both the wild-type and *atr* mutants grow at similar rates on control plates (left). By contrast, on plates containing HU (right, +HU), wild-type root growth is reduced, whereas that of the *atr* is almost completely inhibited.

B

DNA damage-induced cell cycle arrest is mediated by CDK inactivation. In animals, ATM and ATR signal the tumor suppressor protein p53 and the checkpoint kinases CHK1 and CHK2. Activation of these proteins induces the transcription of CKIs and inactivation of the CDC25 phosphatase, an essential timer of mitosis in nonplant species (see above). In plants, the mechanism by which the cell cycle is arrested in response to DNA damage must be in part different, because a functionally homologous *CDC25* gene is absent. Correspondingly, the counteracting *WEE1* kinase, not *CDC25*, has been shown to arrest the plant cell cycle in times of DNA stress. *WEE1* expression is rapidly induced by DNA stress in an ATM- and ATR-dependent manner, resulting in the Tyr phosphorylation of CDKs and subsequent cell cycle arrest. Likely targets of *WEE1* are the A-type CDKs and CAKs. Plants without a functional *WEE1* gene fail to arrest their cell cycle in response to replication defects, with a growth arrest as a consequence.

Currently, the plant signaling cascades that operate between ATM/ATR and *WEE1* are unknown (Fig. 11.25). The signaling pathways through which ATM and ATR signal DNA stress to the cell cycle machinery must be different from those in mammals, because genes for p53 and functionally homologous CHK1/CHK2 kinases have not been identified in plant genomes. Instead, plants possess a plant-specific transcription factor named *SOG1* that operates immediately downstream of ATM/ATR, suggesting the signaling pathways that activate cell cycle arrest upon DNA damage evolved differently in plants.

FIGURE 11.25 ATR- and ATM-mediated signaling of single- and double-strand DNA breaks. Transcriptional induction of the *WEE1* kinase gene occurs through an unknown pathway (indicated by question marks). *WEE1* phosphorylates CDK–CYC complexes, resulting in their inhibition and preventing mitotic entry.

WEE1 is likely not the only mediator of DNA damage checkpoint. In mammals, checkpoint activation involves transcriptional induction of the CKIs CIP/KIP, but for plants no obvious link between KRPs and DNA stress has been reported. In contrast, some *SMR* genes are strongly induced in an ATM-dependent manner by DNA stress, demonstrating their potential to operate as checkpoint regulators upon genotoxic stress.

11.5 Cell cycle control during development

11.5.1 Cell division is tightly controlled in shoot meristems and during organ formation

Plants, unlike animals, continue to develop after embryogenesis, and new organs and tissues can be formed throughout the entire life span. The tissues responsible for this growth strategy are the apical meristems situated at the tips of shoots (shoot apical meristem, SAM) and roots (root apical meristem, RAM) (see Fig. 11.2). In addition, the cambium is a specialized form of meristem that generates only vascular cells during secondary growth of tissues and is not involved in organogenesis. Lateral roots are generated *de novo* by the induction of cell division in selected root pericycle cells.

Organ formation in shoots occurs on the flanks of the SAM, where cell division activity is generally increased to produce the large number of required new cells (Fig. 11.26A). A slowly dividing population of self-renewing stem cells at the centers of the root- and shoot apical meristems is important not only for maintenance of the meristem, but for ensuring low cumulative mutation rates in long-lived plants such as bristlecone pines, in which meristems can function for millennia.

Several genes essential for SAM function have been identified by mutations that disrupt the structure of the SAM. They all display characteristic expression patterns in the SAM that develops gradually during embryogenesis. Genetic analysis of the SAM has allowed these genes to be grouped into three classes (Fig. 11.26B): one class of genes is required to establish and maintain the indeterminate central zone necessary for self-renewal of the meristem, and the second and third classes direct differentiation and regulated localized cell division in organ primordia, respectively. Mutations in genes of each of these classes affect all aspects of normal shoot meristem activity, indicating that the individual activities of domains in the meristem in which these genes are expressed are not autonomous.

The first class of genes is defined by several different homeodomain-type transcription factors required to establish and maintain meristems. The maize *KNOTTED* gene was the first gene of this type to be discovered. When *KNOTTED1*

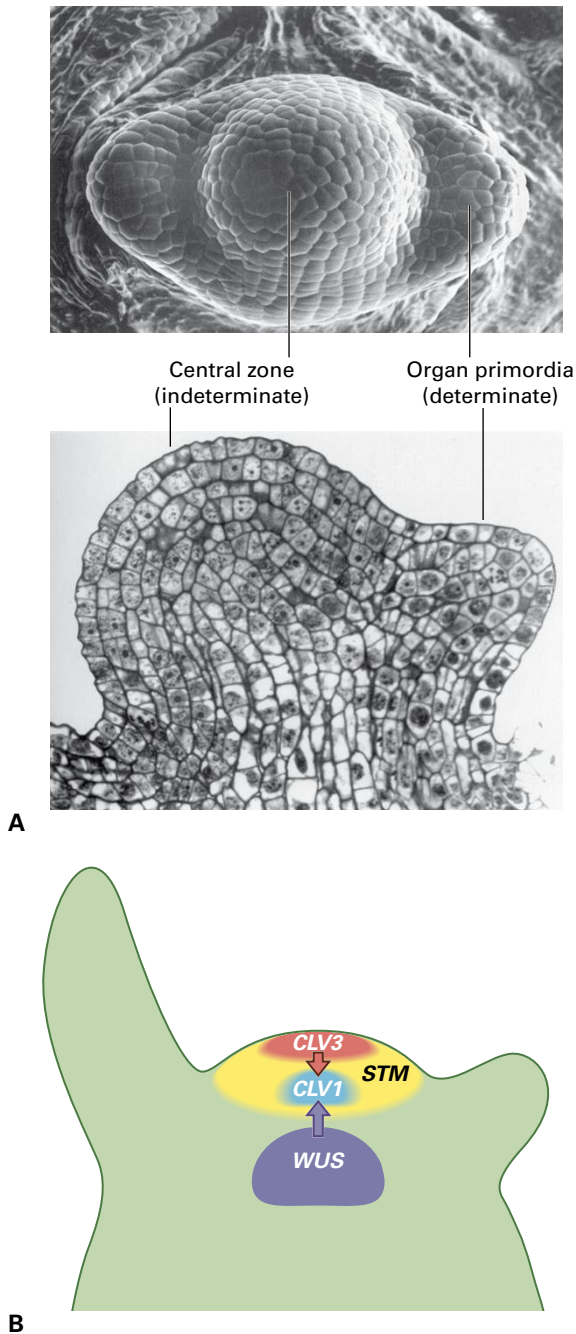

FIGURE 11.26 Organization of the shoot apical meristem (SAM). (A) Two different views of a SAM. The top-down view reveals the incipient organ primordia on the periphery of the meristem. The longitudinal section shows the layered tissue organization of the SAM as well as a developing new organ. (B) Regulatory genes required for the establishment and maintenance of the SAM are expressed in specific domains. The *WUS* gene is expressed at the base of the meristem and is required for expression of the *STM* gene in a domain above it. The products of the *CLV1* and *CLV3* genes (receptor and ligand, respectively) presumably interact to determine the size of the indeterminate central zone of the meristem.

Source: (A) Lyndon (1998). *The Shoot Apical Meristem: Its Growth and Development*. Cambridge University Press, Cambridge UK.

or the related *Arabidopsis* gene *KNAT1* is activated inappropriately, shoot meristems appear ectopically, for example, on leaves. Another *Arabidopsis* gene, *SHOOT MERISTEM-LESS*

(*STM*), is necessary to maintain the capacity for self-renewal or indeterminate growth in the center of the meristem. In the absence of a functional *STM* gene, the SAM disappears and cells at its location differentiate. *STM* appears to keep the shoot meristem cells undifferentiated by promoting cytokinin biosynthesis (cytokinins promote cell division via *CYCD3* expression) and reducing levels of gibberellins. Another homeobox protein, *WUSCHEL* (*WUS*), is also required for meristem maintenance, and its production in a central cell population immediately below the apical layer is necessary for specifying stem cells. *WUS* represses several A-type *ARABIDOPSIS RESPONSE REGULATOR* (*ARR*) genes, which are negative regulators of cytokinin signaling (see Fig. 11.26 and Chapter 18).

Expression of *WUS* is also under the negative control of a second class of genes that promote differentiation in organ primordia. When these genes are disrupted by mutation, the meristem increases in size because cells fail to differentiate. In *Arabidopsis*, loss of *CLAVATA* (*CLV*) gene function results in extremely enlarged meristems and increased organ numbers. *CLV* encodes a receptor-like protein kinase and might function to process intercellular signals. *clv3* mutants have phenotypes very similar to those of *clv1* plants. *CLV3* codes for a short polypeptide that is the ligand for *CLV1*. Currently, little is known about how the various homeodomain proteins control cell cycle activity in the meristems.

Leaf organ primordia initially resemble needles, but they soon broaden in the plane of the future leaf blade. The third class of genes required for meristem function controls proliferation locally in the developing organ. The *PHANTASTICA* (*PHAN*) gene in *Antirrhinum majus* regulates cell proliferation along the upper (dorsal) lamina to generate the leaf blade. The phenotype associated with recessive mutations in this gene is a ventralized, radially symmetrical, needle-like leaf consisting of just the midrib. Furthermore, impaired leaf development in *phan* mutants suppresses proliferation and further organogenesis in the apex, indicating retrograde signaling from nascent organs is important for maintaining shoot meristem function. *ASYMMETRIC LEAVES 1* is the *Arabidopsis* ortholog of *PHAN*.

11.5.2 Specific patterns of cell division might not be required for appropriate root cell speciation

In contrast to the apparently random arrangement of cells in shoot organ primordia, the root apex is highly structured, and tissues derived from the RAM are often organized into long, contiguous cell files. This organization results from an underlying pattern of cell division. The cell files appear to converge onto a central zone within the root apex, the **quiescent center** (QC), in which cells divide only infrequently (Fig. 11.27). The QC is a small group of cells that emit signals to surrounding cells that prevent them from differentiating.

The transcription factors *SCARECROW* (*SCR*) and *SHORT ROOT* (*SHR*) are crucial for specification of the QC.

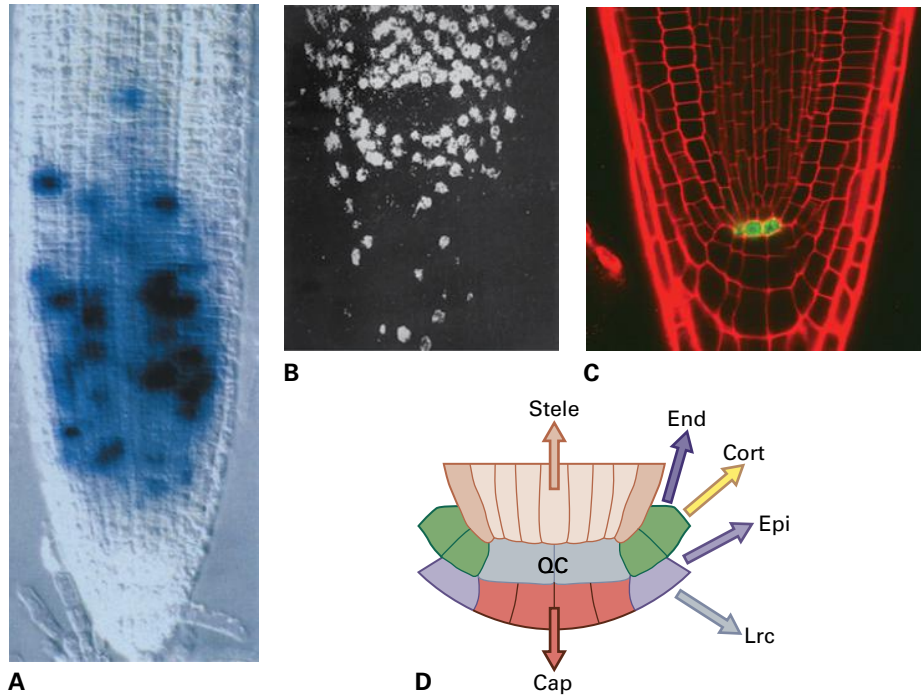

FIGURE 11.27 Mitotic activities in the root apical meristem. (A) A longitudinal section through the root apex of *Arabidopsis*, as viewed by light microscopy. Patterns of mitotic activity are visualized by the activity of a CYCLIN-GUS fusion protein produced exclusively in mitotic cells. (B) Patterns of DNA synthesis in growing *Arabidopsis* roots. Roots were grown in a solution of radioactive thymidine, which was incorporated into the newly synthesized DNA. The longitudinal section was exposed to a photographic emulsion, and white spots represent cells with newly synthesized DNA. Reduced cell proliferation can be seen in the quiescent center (QC), the dark void in the center of the root. (C) A promoter:GFP reporter line highlighting cells of the root QC (green). (D) Organization of the root stem cell niche. Arrows indicate how stem cell division produces regular vertical files of cells. Above and around the QC are the stem cells for the root tissues: lateral root cap (Lrc, purple) and epidermis (Epi, purple), cortex (Cort, green) and endodermis (End, green), pericycle (dark brown) and vascular tissue (light brown). Below are the stem cells for the central portion of the root cap (pink).
 Source: (A) Colón-Carmona et al. (1999). *Plant J.* 20:503–508. (B) O'Brien & McCully (1969). *Plant Structure and Development—A Pictorial and Physiological Approach*. Macmillan, New York.

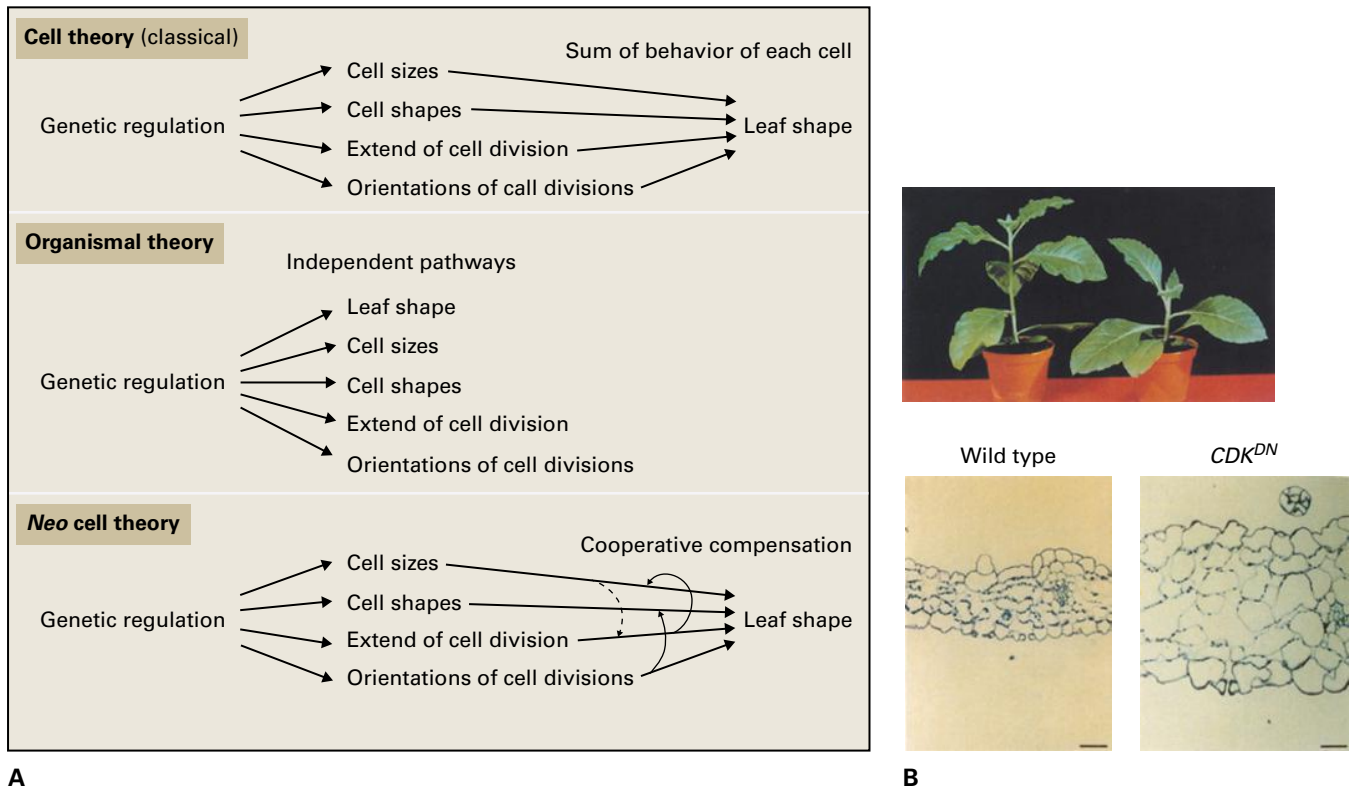

Mutations in *SCR* and *SHR* result in the inability to specify a QC in the root and, as a consequence, all stem cells are lost. Interestingly, QC function and its capacity to produce stem cells can be restored in an *SCR* mutant by reducing *RBR* expression levels. Also, in a wild-type background, local reduction of *RBR* increases the number of stem cells in the RAM, whereas its overproduction results in depletion of stem cells. Likewise, other elements of the RBR-E2F pathway have been found to control the size of the stem cell pool in the root meristem. These data suggest the RBR-E2F pathway operates downstream of *SCR* to determine the stem cell state of cells. *SHR* and *SCR* also regulate the spatiotemporal expression of a specific D-type cyclin involved in formative cell divisions.

The PLETHORA (PLT) group of transcription factors is important for delimiting the meristematic and elongation zones of roots. High and intermediate PLT activity levels promote stem cell maintenance and proliferation, respectively, whereas reduction in activity is required for cells to exit proliferation and enter differentiation. The plant hormone auxin plays an essential role in root patterning, and PLETHORA transcription factors are likely integrators of the auxin gradients in roots. Expression of PLETHORA genes overlap with the auxin maximum in the roots.

11.5.3 Cell division underlies several theories of plant development

The role of the cell cycle machinery in plant development has been the subject of much debate. Obviously, cell division is essential for generating the cells that constitute tissues and organs; however, whether cell division drives growth and development (**cellular theory**) or, alternatively, cell division merely follows a developmental plan (**organismal theory**) is more difficult to answer (Fig. 11.28). Experiments in the late 1950s and early 1960s suggested cell division had little function in growth and morphogenesis. Seedlings from γ -irradiated wheat grains grow to some extent without cell division and resemble untreated seedlings in many aspects of growth. These data provided the first experimental evidence that genetic information, and not the number and orientation of cell divisions, specify the shapes of leaves.

Thanks to the ability to alter cell cycle parameters in transgenic plants, the question of the importance of cell division in determining organ size has been revisited. Transgenic plants that constitutively overproduce any of the KRPs have more than 10-fold fewer cells, but they are, on average, sixfold larger than those of wild-type plants. The reduction in cell

A

B

FIGURE 11.28 Plant growth and cell division are not tightly coupled. (A) A comparison of the cell theory, the organismal theory, and the neo cell theory. The cell theory refers to the concept that cells are the basic units controlling the shape and size of organs, including leaves. The organismal theory holds that the organism, rather than the cell, is the basic unit of life. In this case, genetic information specifies form independently of genetic influences on cell size and shape, or on the number and orientation of cell divisions. The neo cell theory reconciles both theories, taking into account that cells are the unit of morphogenesis and that through regulatory feedback mechanisms each cell is controlled by factors that govern the morphogenesis of the organ in which the cell resides. (B) Altered CDK activity does not significantly affect plant morphology or stature. In transgenic tobacco (*Nicotiana tabacum*) plants, reduction of CDK activity by expression of a dominant-negative mutant (CDK^{DN}) gene that encodes an inactive A-type CDK protein inhibits proliferation. The resulting plant (top panel, right) has fewer, but larger, cells than the wild type, as shown in cross-sections of leaves (bottom panels). The overall stature of the mutant plant is remarkably similar to that of the wild type (top panel), indicating increased cell expansion compensates for decreased proliferation.

Source: (B) Hemery et al. (1995). *EMBO J.* 14:3925–3936.

number is compensated by an increase in cell size. Similarly, overexpression of a dominant-negative *CDKA* (Fig. 11.28B) or a nondegradable *CYCB1;1* in tobacco (*Nicotiana tabacum*) retards the cell cycle and causes formation of larger cells. On the other hand, constitutive overexpression of positive regulators of the cell cycle, such as *E2Fa* or *CYCD3;1*, results in more, but smaller cells; here, the increase in cell number is compensated by a decrease in cell size. All these observations support the organismal theory of plant development, in which the size and shape of an organ or organism is set to some extent by a certain endogenous mechanism independent of the cell division processes. In other words, plants can sense the size of developing organs and compensate for changes in cell division activity with modifications in cell expansion. This phenomenon is known as **compensation**. It is not known what determines the blueprint for leaf shape and size, but hormonal gradients probably play an important role.

However, not all experimental data fit the organismal theory. For example, overexpression of a dominant-negative *CDKA;1* under the control of a seed storage promoter

deregulates embryo development. The strong inhibition of cell division upon *KRP* overexpression results in altered leaf shape. Furthermore, overexpression of *CYCB1;1* under the control of the *CDKA;1* promoter accelerates root growth, as would be expected under the cellular theory. These data suggest the organismal theory might only hold true to a certain degree, and that in extreme situations, growth is controlled both at the level of the organism and of the cell.

To reconcile these contrasting views, the **neo cell theory** was formulated (Fig. 11.28B). This theory states cell division and cell expansion are the building blocks of growing organs, but there is also a regulatory feedback from organ-wide control systems on cell division and cell expansion. Both the short- and long-range signaling components interacting with the cell cycle machinery need to be defined. Numerous genes have been identified that enhance plant organ size, mainly by extending the timing of cell proliferation during organ development. Examples are the transcriptional regulators *AINTEGUMENTA* and *GROWTH REGULATING FACTORS*, which stimulate by an unknown mechanism the expression of cell cycle genes.

11.5.4 Cell division may be independent of cell differentiation

Evidence suggests cell division acts independently of cell differentiation. Neither inhibition nor stimulation of cell division (through overexpression or knockout of cell cycle genes) severely affects cell differentiation. For example, trichome-specific expression of *CYCD3;1* in *Arabidopsis* converts unicellular trichomes in multicellular hairs without affecting differentiation. Another example is found in transgenic plants with reduced CDKB1 activity. In these plants, many stomata, normally built of two guard cells, consist of only one kidney-shaped cell due to inhibition of cell division. These aberrant cells still acquire stomatal identity (see Fig. 11.10), illustrating that cell division and differentiation are uncoupled events.

11.5.5 Totipotency is a rarely used alternative developmental path

In many plant cell cultures and under appropriate conditions, single cells can regenerate an entire plant through two alternative pathways: **organogenesis** and **embryogenesis**. In the former, morphogenesis proceeds by forming shoot organs, followed by root organs. Plants also proliferate asexually in this manner; in many species, roots can generate new shoots, or vice versa. During somatic embryogenesis, embryos are formed directly in the culture. This ability of single cells to recapitulate embryogenesis and pattern formation somatically, without an intervening reproductive phase (flowering), is called **totipotency**.

In some genera (such as *Kalanchoe*), somatic embryogenesis can occur in intact plants and does not depend on the loss of tissue integrity (Fig. 11.29). Thus, organogenesis and

somatic embryogenesis are alternative reproductive strategies to flowering. These asexual mechanisms might be developmental relics that predate the evolution of flowering plants. They may have been preserved in some plant species to allow clonal propagation.

Totipotency has been used in tissue culture to regenerate various plant organs. Even highly specialized plant cells can retain full totipotency, as illustrated, for example, by the stomatal guard cells of sugar beet (*Beta vulgaris*), from which plants can be regenerated. Regardless of the tissue type used as source material, at least three main steps toward plant regeneration are required: cellular dedifferentiation, cell cycle reentry, and induction of redifferentiation.

Cellular dedifferentiation and cell cycle reentry are intimately linked, making it difficult to disentangle these processes at the molecular level. Significant progress has come from studies with protoplast cultures. Plant protoplasts can be obtained from intact tissues by enzymatic removal of the cell wall and, under appropriate conditions, they can be regenerated into intact plants. Before they can reenter the cell cycle, however, protoplasts that originate from differentiated tissues must undergo an abrupt switch from a fully differentiated to a dedifferentiated status. Evidence indicates that this transition is accompanied by a change in the chromatin structure, thereby altering the portion of the genome that is accessible for transcription (euchromatin) versus the one that is repressed (heterochromatin). At the onset of cell division, the proportion of euchromatin increases considerably. It is thought the RBR-E2F pathway is involved in this process, as there is a change in chromatin structure of E2F target genes upon the dedifferentiation of protoplasts. Dynamic changes in chromatin structure are primarily orchestrated by posttranscriptional modifications of the histones in nucleosomes, for example acetylation by histone acetyltransferases.

FIGURE 11.29 Totipotency as an alternative developmental path. (A) Cells from many plant species can be cultured *in vitro* and induced to regenerate vegetative organs by application of suitable combinations of plant hormones. The photograph shows plantlets growing leaves from disorganized tissues called calli. (B) For some plant species (such as *Kalanchoe*), the formation of clonal offspring is a competitive advantage. Small plantlets formed in the axils of serrated leaves are viable and can root if the parent leaf is torn off or when it senesces. FIGURE 11.30 Model for the role of chromatin remodeling in the switch from quiescent to dividing cells. (A) In quiescent (or G1-arrested) cells, the retinoblastoma-related protein (RBR) targets histone deacetylases (HDAC) to the promoters of important regulatory genes required for the G0/G1-to-S transition. RBR itself represses the activity of E2F/DP transcription factors. Through HDAC activity, the chromatin is condensed, thereby obstructing the accessibility of DNA for transcriptional regulatory proteins and preventing transcription of the E2F/DP target genes. (B) Cell cycle entry is facilitated by the activation of CDKA–CYCD complexes that phosphorylate RBR, thereby releasing it and HDAC from the E2F/DP transcription factors. In the absence of HDAC, the activity of unidentified histone acetyltransferases becomes dominant. This results in the acetylation of histones and, consequently, in a less condensed nucleosomal conformation. The DNA in this relaxed chromatin structure is now accessible to transcriptional regulatory proteins. Ac, acetyl group; Pol II, RNA polymerase II.

In maize, the histone deacetylase Rpd3I is associated with the RB-related protein (RBR), and together, these proteins probably repress genes required for cell cycle entry. After stimulation with growth factors, CDKs complexed with D-type cyclins might phosphorylate RBR, which may release both the RBR and histone deacetylase from the promoters of downstream genes that are required for cell cycle entry (Fig. 11.30). This model is supported by the observation that expression of D-type cyclins precedes the resumption of cell division in germinating seeds, and that the knockout of specific D-type cyclins delays cell cycle reactivation in the root meristem. A role for RBR in controlling the differentiation status of cells is corroborated by the delay in cell differentiation by RBR deficiency, whereas its induced expression pushes meristematic cells into the differentiation pathway.

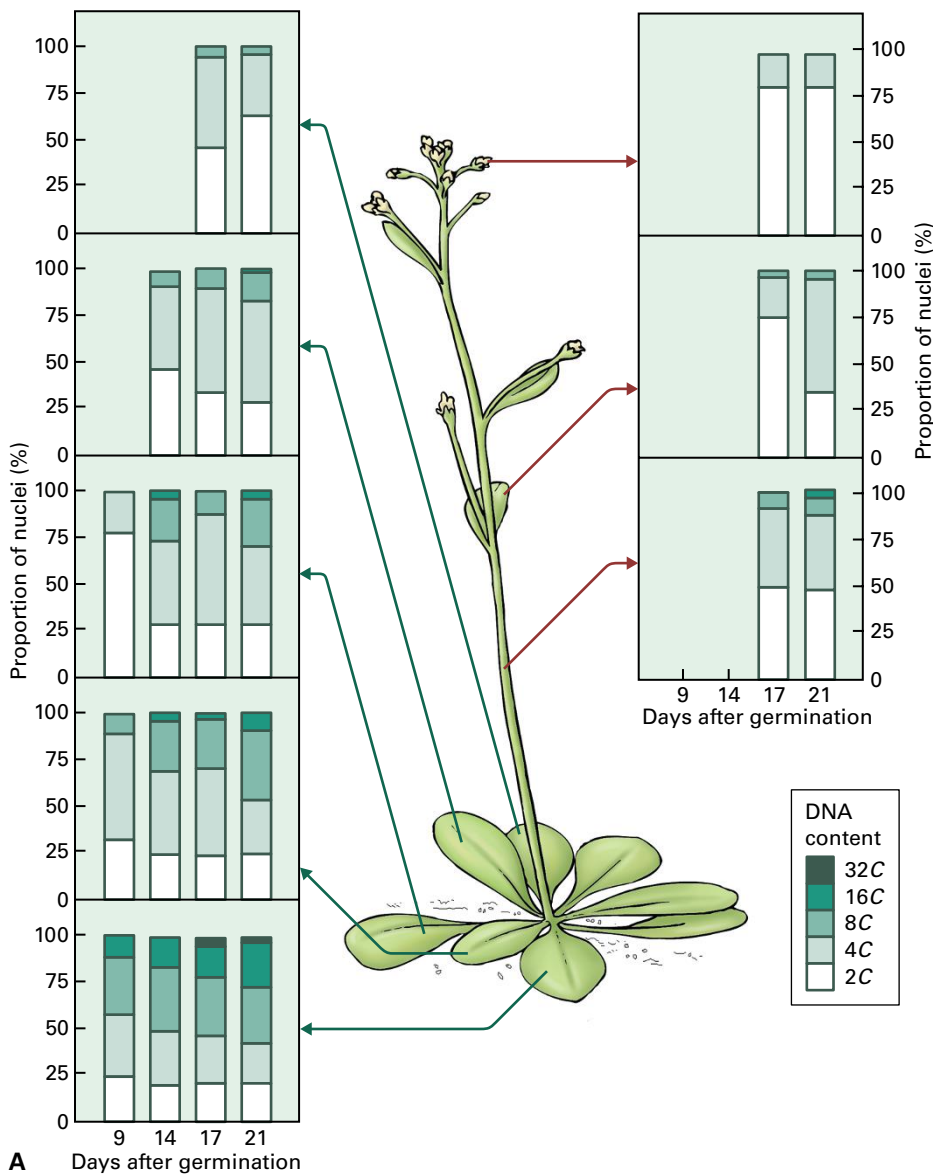

11.5.6 Developmental ploidy increases are common in plants

During development, cells exit the cell cycle and start to differentiate. Exit from the cell cycle is sometimes accompanied by the onset of an alternative cycle, called the endocycle. The endocycle occurs in a wide variety of cell types in arthropods, mammals, and plants. During the endocycle, no cytokinesis occurs between successive rounds of DNA replication, and the DNA content of the cell doubles with every round of replication. These increases can be dramatic: the suspensor cells of *Phaseolus coccineus* go through 12 additional cycles of DNA replication without intervening mitosis, resulting in an approximately 8,000-fold increased DNA content per cell.

The ploidy level of individual cells can increase by various mechanisms. When DNA replication is accompanied by mitosis

but without cytokinesis, polynucleated cells are formed in a process called **endomitosis**. Alternatively, when repeated replication of DNA takes place without formation of new nuclei during telophase, **endoreplication** can result in **polyploidy** or **polyteny**. In polyploid cells, the sister chromatids separate and return to the interphase state as in the mitotic cell cycle, resulting in more chromosomes that retain their individual identity within the original nuclear envelope. On the contrary, polyteny is characterized by the occurrence of chromosome duplication without DNA condensation/decondensation steps and without sister chromatid segregation, forming “giant” multistranded chromosomes with $2n$ chromatids. As a consequence, the number of chromosomes within the nuclear envelope remains the same. In addition, any variation between polyteny and polyploidy is possible.

Endoreplication is often tissue specific (such as in the maize kernel and the tomato fruit), but it can sometimes be found in most vegetative cells, as observed for *Arabidopsis* (Fig. 11.31). The physiological relevance of endoreplication is subject to debate. It probably plays an important role in the differentiation of post-mitotic cells, because endocycle onset usually characterizes the switch between cell proliferation and differentiation. Often, a correlation between DNA ploidy level and cell size is seen (Fig. 11.32). Endoreplication may also provide the increased gene dosage needed to accommodate cell enlargement. As plant species that endoreduplicate are often characterized by a rapid life cycle, endoreplication may also represent an evolutionary strategy to support fast development. Endoreplicating species may combine the advantages of both small- and large-genome species; a small genome allows cells to duplicate quickly at a low energy cost, whereas a large genome enables maintenance of large cells. These features can be valuable under conditions that limit cell division but not cell elongation, such as cold climates.

A Days after germination

B Generic mitotic cycle

C Generic endoreplication cycle

FIGURE 11.31 Control of DNA endoreplication and polyploidy during development. (A) Developmental control of DNA content. Analysis by flow cytometry of interphase nuclei isolated from *Arabidopsis* tissues at different developmental stages shows a strong correlation between polyploid DNA content and increased tissue age. For a given species, C is the mass of DNA present in the haploid genome. (B, C) Roles of CDK–cyclin complexes in mitotic and DNA endoreplication cycles. (B) Typical mitotic cycle. During early G1, CDK activity must be low to allow licensing of replication origins. Late in G1, CDK levels rise due to increasing levels of G1 cyclins until the level of CDK activity is sufficient to inactivate RBR and trigger S phase, including firing of replication origins and S-phase transcription. Maintenance of S phase requires specific CDK–cyclin complexes. During G2, transcription of M-phase cyclins increases until a high level of active CDK–cyclin complexes is reached and M phase begins. In mid-M phase, mitotic cyclins are destroyed by APC/C and CDK levels once again drop to early G1 levels. (C) Typical DNA endoreplication cycle. CDK levels of G1 and S continue to cycle between low levels in a G1-like phase for licensing of the replication origins and the increased levels are needed to trigger S. Mitotic CDK complexes either never form or their activity is suppressed, with CDK activity never reaching the level necessary to trigger M phase as a consequence.

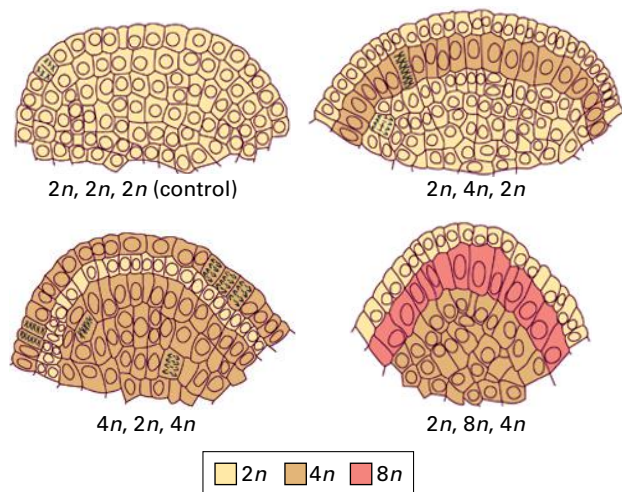

FIGURE 11.32 Correlation of ploidy with cell size. Chimeras (individuals composed of cells with different genotypes) can be readily generated in plants by use of grafting techniques. Analysis of plants with chimeric meristems demonstrates that cell volume is determined not by position but by genome copy number (ploidy, n). A strong positive correlation was observed between increased ploidy and cell size.

The endoreplication cycle can be viewed as a mitotic cell cycle in which the M phase is skipped. In contrast, because cells that divide and endoreplicate both need to duplicate their DNA, they probably share the components required for DNA replication. As each endoreplication cycle has to activate the replication origins, it is not surprising that many proteins controlling the assembly of the preRC (such as CDC6 and CDT1) have an impact on endocycle regulation and progression. Increased endoreplication levels are also observed upon overexpression of E2F transcription factors, suggesting that the E2F-RBR pathway contributes to the endocycle onset.

Elimination of mitotic CDK activity involves transcriptional repression and proteolytic destruction of the G2-to-M-specific CDK/cyclin complexes. CDKs to be inhibited are the B1-type CDKs, as illustrated by the observation that plants with reduced CDKB1 activity display a faster onset of the endocycle. An increase in the activity of CCS52A-activated APC/C probably accounts for the selective destruction of CDKB1-associated cyclins through ubiquitination. Also A-type CDK activity needs to be reduced, a process that likely involves CKIs from both the KRP and SIM families.

11.5.7 Plant cells must replicate and maintain three genomes

Unlike cells of animals or fungi, plant cells have three different genomes in three cellular compartments: the nucleus, the plastids, and the mitochondria. Plant mitochondrial genomes are generally much larger than their animal or yeast counterparts and often range from 200 to 2,400 kb. The

plastid genome is approximately 130 to 150 kb. Genomes in mitochondria and plastids generally encode only a fraction of the proteins required for the functioning of these organelles, which, therefore, depend on the import of proteins encoded by nuclear genes.

Within a plant, the copy numbers of mitochondrial and plastid genomes are surprisingly flexible. The organellar genomes are primarily replicated within meristems and organ primordia. The copy number of the organellar genomes can be very high: 20–100 copies per mitochondrion and 50–150 copies per plastid. In rapidly dividing cells, however, the number of organelles remains relatively low. As post-mitotic cells mature, replication of organellar DNA gradually ceases and mitochondrion/plastid division proceeds, eventually reducing the genome copy number per organelle (Fig. 11.33).

The strict maintenance of plastid populations in dividing plant cells and regulation of plastid numbers in different cell types indicate a mechanism that coordinates plastid division with cellular division. This coordination is strict in species bearing a single plastid, such as some algae and diatoms. In the red alga *Cyanidioschyzon merolae*, inhibition of the degradation of a DNA replication-specific cyclin by a tetrapyrrole-mediated signaling pathway coordinates organellar and nuclear DNA replication. Also in higher plants, inhibition of plastid retrograde signaling affects cell cycle exit and onset of nuclear DNA endoreplication. Nevertheless, the coordination between organellar and nuclear DNA replication is probably less stringent in higher plants as compared to unicellular algae because multiple proplastids are present in every meristematic cell. The replication factor CDT1 also has been proposed to coordinate nuclear DNA replication with proplastid division. The *Arabidopsis* CDT1 protein is targeted to both the nucleus and chloroplasts, and plants with reduced CDT1 levels show defects in plastid size and number. However, the molecular mechanisms by which this replication factor controls plastid division are still unknown.

11.5.8 Plant growth regulators affect the activity of specific cell cycle regulators

Terrestrial plants are **sessile**, attached to an immobile substrate. As plants deplete nearby reserves, they must grow continuously toward new points of access to soil nutrients and light. To fully exploit their environment, plants require flexible growth rates and patterns. Although growth is not the only plant response to a changing environment, cell division and expansion are essential to bringing the plant body into contact with untapped resources.

Like other multicellular organisms, plants use long-range signaling mechanisms to communicate between distant organs (e.g., shoots and roots) and to coordinate their growth. Small molecules play a pivotal role in such mitogenic signaling. Plant growth regulators, including hormones (e.g., auxins, cytokinins, ethylene, ABA, jasmonic acid, strigolactone,

FIGURE 11.33 Replication of chloroplast DNA is not coupled to nuclear DNA replication. Rapidly dividing cells in young leaves contain relatively few chloroplasts but each chloroplast has a high copy number of the circular plastid genome. DNA synthesis in these chloroplasts continues even when nuclear DNA is not being replicated. When cells gradually cease to proliferate and begin to expand during leaf growth, the genome copy number of individual chloroplasts decreases because the chloroplasts continue to divide one or two more times even in the absence of plastid DNA synthesis.

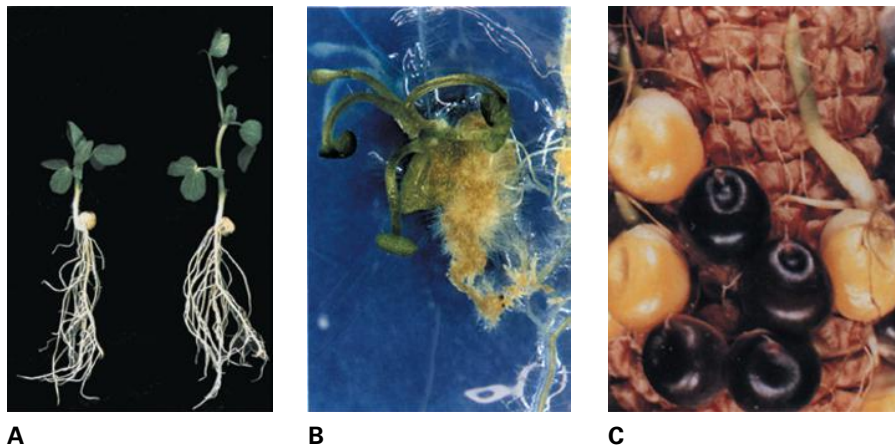

FIGURE 11.34 Abnormalities in hormone synthesis, perception, or response strongly affect plant growth. (A) A block in brassinosteroid synthesis compromises the appropriate expansion of plant cells and affects their ability to respond to light (compare mutant pea plant on left with the wild-type plant on the right). (B) Enhanced synthesis of auxin stimulates excessive lateral root formation. In the *Arabidopsis superroot* mutant, this phenotype is ultimately lethal. (C) The inability of the maize *vp1* mutant to maintain seed dormancy in response to ABA results in premature germination on the ear (vivipary) and jeopardizes the ability of the seed to survive desiccation.

gibberelin, and brassinosteroids), lipo-oligosaccharides (such as nodulation factors), and peptides (such as PSK, GRF, PSY, and CLV), have been implicated in various aspects of growth regulation (see Chapter 18). Mutants defective in hormone synthesis, perception, or response often show drastic changes in their appearance and growth habits (Fig. 11.34).

Auxins and cytokinins are two plant growth regulators with likely roles in cell division regulation. Freshly established plant cell cultures require auxins and cytokinins for continued proliferation; for example, withdrawal of auxin or

cytokinin from the medium of fresh tobacco (*Nicotiana tabacum*) cell cultures results in arrest in G1 or G2, respectively. The lack of cytokinin in tobacco cell cultures is correlated with increased tyrosine phosphorylation of a tobacco CDK that probably inhibits kinase activity. When such arrested cultures are supplied with cytokinins, tyrosine phosphorylation is reduced and cell division activity resumes. In *Arabidopsis*, cytokinin is also necessary to stimulate expression of a D-type (G1) cyclin (*CYCD3*), and constitutive expression of this cyclin relieves the need for cytokinin in

tissue explants (see Fig. 11.12). By contrast, constitutive expression of *E2Fb* can sustain cell division under auxin-limiting conditions.

Treatment of intact plants with plant hormones does not stimulate growth in all tissues. For instance, application of auxins to roots induces branch root formation but inhibits apical meristem activity. Reducing cytokinin concentrations in roots enhances growth, but represses shoot growth. Changes in the expression of cell division regulators such as cyclin and E2Fs and overall cell division activity are early responses to such hormone treatments (Fig. 11.35). Although modifications in the concentrations of auxin or cytokinin clearly affect cell division activity, the nature of the response is not uniform and depends on the tissue.

In contrast to auxin and cytokinin, jasmonic acid exerts an inhibitory affect on cell proliferation, arresting the cell cycle at both the G1-to-S and G-to-M transition points. The G2 arrest correlates with a strong decrease in M-phase genes (such as B-type CDKs, cyclins, and kinesins), but the molecular mechanism involved is unknown. The inhibitory effect of jasmonic acid corresponds with its observed negative impact on plant growth and might represent a mechanism for cross-talk between cell cycle progression and stress perception.

ABA, which is primarily involved in stomatal aperture closure and in signaling drought stress responses, also negatively influences plant growth. ABA concentrations in the root increase during water stress, and the RAM is arrested under such conditions. Expression of the CDK–cyclin complex inhibitor *ICK1/KRP1* is induced, suggesting the inhibitor regulates CDK activity in roots during stress conditions. Similarly, the hormone ethylene is involved in arresting the cell cycle by inhibiting CDK activity upon exposure of plants to mild stress.

Brassinosteroids and gibberellins mostly enhance cell growth and expansion; in the dark, however, brassinosteroids suppress activation of leaf organogenesis, presumably by controlling cell division. Gibberellins stimulate cell division in both *Arabidopsis* root meristems and shoot internodes of deep-water rice, where cells divide and expand rapidly in response to flooding. The role of gibberellins on cell proliferation depends on DELLA proteins (see Chapter 18), which are thought to restrain cell proliferation by enhancing expression of the cell cycle inhibitory genes *KRP2* and *SIAMESE*. In general, much has yet to be learned about how plant hormones and developmental signals control cell cycle activity and tissue and organ sizes.

Summary

In proliferating cells, cell growth is coupled with cell division. The most fundamental roles of cell division are replication of chromosomes and subsequent distribution of the chromosomes to daughter cells. These events are controlled by protein kinases and proteases that have

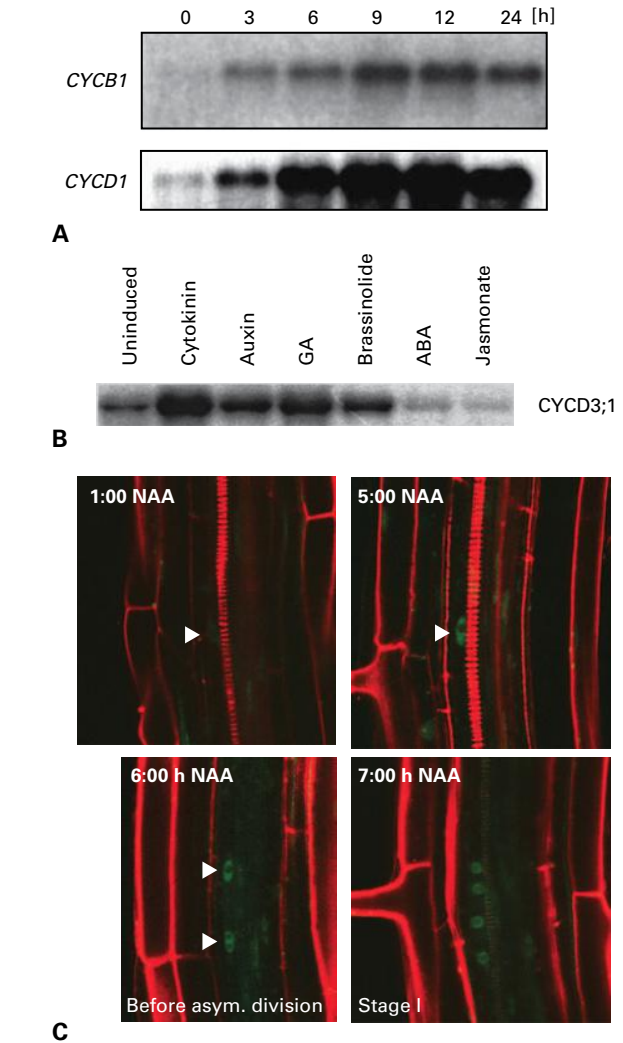

FIGURE 11.35 Plant growth stimulators affect the expression of cell cycle regulators. (A) Accumulation of mRNAs for mitotic (CYCB1) and G1 (CYCD1) cyclins increases after stimulation of *Arabidopsis* roots with auxin. The accumulation is the greatest 12 hours after stimulation and then decreases. (B) Transcriptional induction of CYCD3 in response to different hormone treatments in cell cultures. (C) Accumulation of the E2Fa–GFP fusion protein in lateral root initiation cells after auxin (NAA) treatment. The E2Fa–GFP signal increases rapidly between 1 and 5 hours after NAA treatment, marking the lateral root initiation sites before the occurrence of the first asymmetric cell division that marks the outgrowth of a new lateral root. been identified in plants as well as in other model systems (animals and yeast). Although functional characterization of these regulatory proteins is not complete, initial observations indicate that they function in a similar manner, but might be regulated differently.

ENERGY FLOW

Photosynthesis

Krishna K. Niyogi, Ricardo A. Wolosiuk,
and Richard Malkin

Introduction

The synthesis of organic compounds from inorganic precursors requires energy and reducing power (low-potential electrons). Autotrophic organisms use carbon dioxide (CO₂) as the sole carbon source for production of organic molecules. For **chemoautotrophic** bacteria and the living communities dependent on their activity (e.g., the fauna of deep-sea hydrothermal vents), the ultimate sources of this energy are the chemical bonds found in inorganic molecules. Such organisms are, however, a minority. In nearly all biological systems, the synthesis of organic molecules is driven directly or indirectly by energy from the sun. The overall process whereby plants, algae, and prokaryotes directly use light energy to synthesize organic compounds from CO₂ is called **photosynthesis**.

All photosynthetic organisms are **photoautotrophic**. Some prokaryotes can use light as an energy source for ATP synthesis, but they require organic molecules as sources of carbon for growth; such organisms are **photoheterotrophic**, but not photosynthetic. Photosynthesis sustains most autotrophic producers of organic material, as well as the heterotrophic consumers they support. In addition to providing food, biomass, and fossil fuels, photosynthesis in plants and algae produces the oxygen (O₂) required for respiratory activity by all multicellular and many unicellular organisms.

Photosynthesis encompasses both a complex series of reactions that involve light absorption, light conversion, and electron transfer and a multistep enzymatic pathway that converts CO₂ and water into carbohydrates. This chapter explores these life-sustaining processes in detail. Other topics frequently covered in discussions of photosynthesis are

discussed elsewhere, such as sucrose and starch metabolism in Chapter 13 and photorespiration in Chapter 14.

12.1 Overview of photosynthesis

12.1.1 Photosynthesis is a biological oxidation–reduction process

Most photosynthetic organisms convert light energy into stable chemical products. As shown in Reaction 12.1, photosynthesis is a biological **oxidation–reduction** (or **redox**) process. CO₂ is the electron acceptor, and H₂A is any reduced compound that can serve as the electron donor. (CH₂O) represents the carbohydrate generated by the reduction of CO₂, and A represents the product formed by oxidation of H₂A.

Reaction 12.1: Photosynthesis

In the case of O₂-evolving (**oxygenic**) photosynthesis, the focus of this chapter, water serves as the reductant (Reaction 12.2). Water is oxidized, and the electrons released are energized and ultimately transferred to CO₂, yielding O₂ and carbohydrate. Plants, algae, and prokaryotic cyanobacteria are capable of this light-driven, **endergonic** (energy-requiring) reaction, which has a free energy change (ΔG°') of +2840 kJ mol⁻¹ for the synthesis of hexose. Oxygenic photosynthesis

was an evolutionary innovation of cyanobacteria that led to the accumulation of O₂ in the Earth's atmosphere more than 2 billion years ago.

Reaction 12.2: Oxygenic photosynthesis

Many prokaryotes perform **anoxygenic** photosynthetic reactions that are consistent with Reaction 12.1 but utilize

electron donors other than water. For example, purple sulfur bacteria use electron donors such as H₂S, producing elemental sulfur rather than O₂ as a photosynthetic product (Reaction 12.3). These bacteria retain the capacity to reduce CO₂ to carbohydrate, and in some cases, the carbon fixation reactions are almost identical to those found in oxygenic organisms. Anoxygenic photosynthetic bacteria are essential components of many terrestrial and aquatic ecosystems. In addition, these prokaryotes have served as important models for studying various aspects of photosynthesis (Box 12.1).

BOX 12.1

Model organisms are used to study photosynthesis

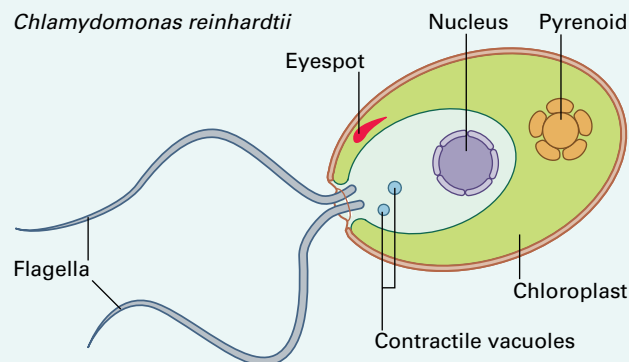

Like other areas of plant biology, contemporary research in photosynthesis has benefited from the development of techniques of molecular genetics and molecular biology. Several model organisms are used in studies of photosynthesis, each of which has characteristics that make it attractive to researchers.

Photosynthetic bacteria have played a major role in the discovery of important concepts in photosynthesis. The anoxygenic purple bacteria (e.g., *Rhodobacter sphaeroides*) and some cyanobacteria (e.g., *Synechocystis* sp. PCC 6803) are metabolically flexible and can grow either photoautotrophically or heterotrophically. In the case of *R. sphaeroides*, most of the genes involved in photosynthesis are located together in the genome in a photosynthesis gene cluster, which facilitates molecular analysis. The functions of specific genes can be tested by constructing deletion mutants. Because these prokaryotic organisms can grow under heterotrophic conditions, they can be used to study mutations of the photosynthetic apparatus that would be lethal in obligate photoautotrophs. Detailed structure–function analysis of the encoded proteins can be performed by transforming cells with strategically modified DNA. Such techniques have been used extensively in studies of photochemical reaction center complexes and electron transfer proteins, providing insight into the specific functions of many individual subunits of these photosynthetic complexes.

In studies of eukaryotic organisms, the requirement for cooperation of the nuclear and chloroplast genomes (see Chapters 6 and 9) in photosynthesis presents additional challenges. *Chlamydomonas reinhardtii*, a unicellular green alga, has emerged as one of the best eukaryotes for molecular studies of chloroplast biogenesis. Like the photosynthetic bacteria described above, *C. reinhardtii* can grow heterotrophically in the dark if supplied with a carbon substrate such as acetate, allowing researchers to study mutations that abolish photosynthesis. Another major advantage of *C. reinhardtii* is its amenability to transformation of both the nuclear and chloroplast genomes. Genome sequencing and phylogenomic approaches have identified hundreds of conserved genes

that are hypothesized to have a role in photosynthesis or chloroplast biogenesis. The functions of these genes are being tested using reverse genetic approaches, such as random insertional mutagenesis of the nuclear genome or targeted mutagenesis of the chloroplast genome (in which targeted deletion mutants can be easily made, as in the photosynthetic bacteria mentioned above).

Although somewhat limited by the lethality of mutations that completely abolish photosynthesis, genetic approaches using plants such as *Arabidopsis thaliana*, maize (*Zea mays*), and tobacco (*Nicotiana tabacum*) have also been very fruitful in photosynthesis research. *A. thaliana* is especially amenable to high-throughput mutant screening approaches and reverse genetics, exploiting the large T-DNA insertion mutant collections that have been developed for this model organism. An advantage of maize is the fact that lethal photosynthetic mutants are easily maintained as heterozygotes, and the large seeds enable substantial growth of nonphotosynthetic seedlings to provide ample material for biochemical studies. In tobacco, chloroplast transformation is also possible, and the use of antisense and other gene silencing technologies to study nuclear genes has been very informative. Concentrations of specific enzymes active in the Calvin–Benson cycle have been diminished through this approach. In some cases, this technique has yielded plants having reduced rates of photosynthesis; in other cases, antisense plants have revealed unknown complexities in the regulation of photosynthesis.

Reaction 12.3: Photosynthetic oxidation of sulfur compounds, such as H₂S

12.1.2 In photosynthetic eukaryotes, photosynthesis takes place in the chloroplast, a specialized organelle

In eukaryotes, the biophysical and biochemical reactions of photosynthesis occur in a specialized plastid, the **chloroplast** (see Chapter 1). All the reactions required for photosynthesis take place in this organelle, which arose from the endosymbiotic association of a protoeukaryotic cell and a photosynthetic bacterium related to modern cyanobacteria (see Chapters 1 and 6). The complex structure of the chloroplast reflects its diverse biochemical functions. Chloroplasts from land plants (Fig. 12.1) are surrounded by a double-membrane system consisting of an **outer and inner envelope** and also contain a complex internal membrane system. The internal membrane system, known as the **thylakoid membrane**, contains distinct regions. Some thylakoids (**granal thylakoids**) are organized into **grana**, stacks of appressed membranes, whereas others (**stromal thylakoids**) are unstacked and are thus exposed to the surrounding fluid medium, the chloroplast **stroma**. The thylakoid membranes are interconnected and enclose an internal space known as the **lumen**.

12.1.3 Photosynthesis consists of light reactions and carbon reactions

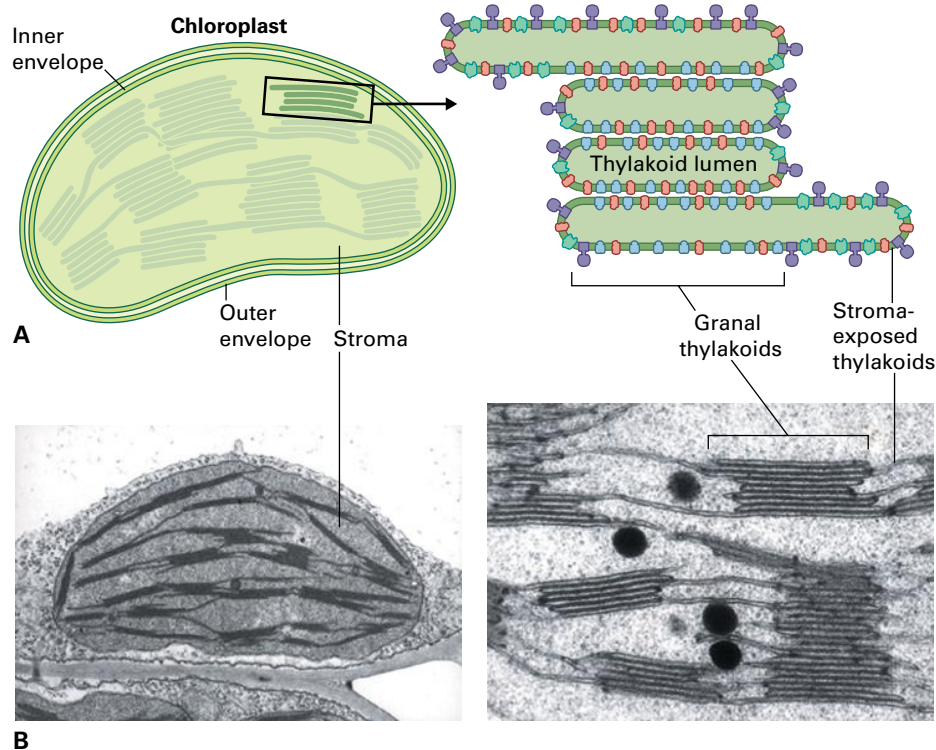

During the 1950s and 1960s, experiments showed that isolated chloroplasts can convert CO₂ to carbohydrate in the light (see Reaction 12.2) and that the photosynthetic process involves two phases: the light reactions, which produce O₂, ATP, and NADPH; and carbon reactions (the carbon reduction cycle, also called the **Calvin–Benson cycle**, after its co-discoverers, Melvin Calvin and Andrew Benson), which reduce CO₂ to carbohydrate and consume the ATP and NADPH produced in the light reactions.

The two phases of photosynthesis occur simultaneously, but they reside in different regions of the chloroplast (Fig. 12.2). The thylakoid membranes contain the multiprotein photosynthetic complexes, photosystems I and II (PSI and PSII), which include the reaction centers responsible for converting light energy into chemical bond energy. These reaction centers are part of a photosynthetic electron transfer chain that also contains a transmembrane cytochrome complex (cytochrome *b₆f*), a water-soluble copper protein (plastocyanin), and a lipid-soluble quinone (plastoquinone). Located primarily in the thylakoids, the photosynthetic electron transport chain moves electrons from water in the thylakoid lumen to soluble redox-active compounds in the stroma (e.g., NADP⁺). This electron transport is coupled to the generation of a **proton motive force** (pmf) across the thylakoid membrane. Using the potential energy of the pmf, ADP is phosphorylated by the chloroplast ATP synthase, a large stroma-exposed protein complex located in thylakoid

FIGURE 12.1 Plant chloroplast.

(A) Schematic diagram showing compartmentalization of the organelle. In a typical plant chloroplast, the internal membranes (thylakoids) include stacked membrane regions (granal thylakoids) and unstacked membrane regions (stromal thylakoids). (B) Transmission electron micrographs reveal plant chloroplast ultrastructure. The higher magnification emphasizes the membrane stacking and includes electron-dense lipid bodies known as *plastoglobuli*.

Source: (B) Staehelin & van der Staay (1996). Structure, composition, functional organization and dynamic properties of thylakoid membranes. In *Oxygenic Photosynthesis: The Light Reactions*, D. R. Ort and C. F. Yocum, eds. Kluwer Academic Publishers, Dordrecht, The Netherlands, pp. 11–30.

FIGURE 12.2 The light and carbon (formerly “dark”) reactions of photosynthesis occur in separate chloroplast compartments. Light is required for the synthesis of ATP and NADPH substrates in a series of reactions that occur in thylakoid membranes of the chloroplast. These products of the light reactions are then used by a series of stromal enzymes that fix CO₂ into carbohydrates during the carbon reactions.

membranes. In contrast, the Calvin–Benson cycle reactions occur in the stroma.

In the past, the Calvin–Benson cycle was referred to as the “dark” reactions of photosynthesis. This terminology may be misleading, because these reactions occur during the day. Furthermore, some of the enzymes involved in CO₂ fixation require activation by light. It is, therefore, more accurate to say the carbon reactions depend on the light reactions, for both high-energy products and regulatory signals.

12.2 Light absorption and energy conversion

12.2.1 Light has properties of both particles and waves

One of the major advances of 20th-century physics was the finding that light, a form of electromagnetic radiation, has properties of both waves and particles. In the case of the quantum mechanical description, radiant energy is visualized as being a stream of energy-carrying particles called quanta (singular: quantum). Each quantum of light, or **photon**, contains a discrete quantity of energy. The energy of a single photon is equal to Planck’s constant, h (6.626×10^{-34} Joule s), multiplied by the frequency of the radiation, ν , in cycles per second (s^{-1}) (see Equation 12.1).

Equation 12.1: Energy is directly proportional to frequency

$$E = h\nu$$

Thus, not all colors of light (wavelengths) have equal energy. The energy of a photon of a particular wavelength can be described by Equation 12.2, where c is the velocity of light (3.0×10^8 m s⁻¹) and λ is wavelength (m). As this relationship indicates, the energy content of light is inversely proportional

to its wavelength. For example, 1 mol of photons of 490-nm blue light has an energy of 240 kJ, whereas 1 mol of photons of 700-nm red light has only 170 kJ. Relating these numbers to the +2840 kJ mol⁻¹ required for CO₂ fixation gives some idea of the minimum number of quanta required to convert six CO₂ molecules to one molecule of hexose sugar. Oxygenic photosynthetic organisms use visible light, with wavelengths of 400–700 nm, whereas many anoxygenic photosynthetic organisms can harness the less energetic wavelengths in the near infrared at wavelengths greater than 700 nm.

Equation 12.2: Energy is inversely proportional to wavelength

$$E = hc/\lambda$$

12.2.2 Light is absorbed by pigment molecules

For light energy to be used by any system, the light must first be absorbed. This is a significant problem for photosynthetic organisms, because shading and reflection can result in large losses of available light. Molecules that absorb light are called **pigments**. The absorption of a photon by a pigment molecule converts the pigment from its lowest-energy (ground) state to an excited state (pigment*):

Reaction 12.4: Pigment excitation

A pigment molecule becomes excited when absorption of light energy causes one of its electrons to shift from a lower-energy molecular orbital, which is closer to the pigment’s atomic nuclei, to either of two more-distant, higher-energy orbitals. The laws of quantum mechanics (Equation 12.3) dictate that transitions to an excited state occur only when the energy exactly matches the energy gap between the ground state energy (E_g) and the excited state energy (E_e)—in this case, the gap between the ground state and the excited state energies of the pigment molecule. That is, not all transitions are allowed.

Equation 12.3: Quantitative requirements for pigment excitation

$$E_e - E_g = hc/\lambda$$

In the case of molecules, in contrast to atoms, the ground state and the excited states have many closely spaced sub-states, the result of molecular vibration and rotations. These are shown in Figure 12.3, along with the first and second excited **singlet states** for a molecule that has two major absorption bands, such as chlorophyll (see Section 12.2.3), which has one absorption band in the blue spectral region

FIGURE 12.3 Energy levels in the chlorophyll molecule. Absorption of blue or red light causes the chlorophyll molecule to convert into an excited state, with blue light absorption resulting in a higher excited state because of the greater energy of blue light relative to red light. Internal conversions or relaxations convert higher excited states to the lowest excited state, with a concomitant loss of energy as heat. Light may be reemitted from the lowest excited state through fluorescence. The spectra for fluorescence and absorption are shown at the right of the figure. The short-wavelength absorption band corresponds to a transition to the higher excited state, and the long-wavelength absorption band corresponds to a transition to the lower excited state.

and one in the red. Excitation causes transitions from the lowest substate of the ground state to any one of these higher-energy substates, depending on the energy relationship shown in Equation 12.3. The existence of this series of substates in molecules yields broad absorption bands rather than the sharp absorption bands found with atoms.

In molecules, two types of excited states can exist. The singlet state is relatively short-lived and contains electrons with opposite (antiparallel) spins; the more long-lived **triplet state** has electron spins that are aligned (parallel). Triplet states generally have much longer lives (take longer to de-excite) than singlet states and are at a lower energy level. Transitions from the singlet state to the triplet state can occur, but these are low-probability events.

Once excited, an electron can return to the more stable ground state by one of several paths, and in each, the energy released may take several forms. In the simplest case, the energy is released as heat during a nonradiative decay (**relaxation**) (Fig. 12.3). A second mechanism involves the emission of a photon in a process known as **fluorescence** (Fig. 12.3). The emitted light has a longer wavelength than the absorbed light because fluorescence always arises from decay from the first excited state to the ground state and is preceded by de-excitation from higher substates to the first excited state via vibrational relaxations. Measurements of chlorophyll fluorescence are used to investigate the efficiency and regulation of photosynthesis (Box 12.2). A third mechanism, **energy transfer**, involves the transfer of energy to another molecule, usually one in close proximity to the excited molecule. This process is an important vehicle for the movement of absorbed light energy through an array of pigment molecules. Finally, the excited molecule may lose an electron to an electron-acceptor molecule through a **charge separation** event, in which the excited pigment reduces an acceptor molecule. This last mechanism, called **photochemistry**, converts light energy into chemical products (Reaction 12.5) and is central to the process of photosynthesis.

Reaction 12.5: Photochemistry

With several avenues of relaxation available, what dictates the fate of the excited state? Simply this: the process with the fastest rate is favored over others and predominates. For many of the pigments found in the photosynthetic apparatus, fluorescence occurs in nanoseconds (ns, 10^{-9} s); however, photochemistry in photosynthetic organisms occurs more rapidly, in picoseconds (ps, 10^{-12} s) (Section 12.3.2). Thus, when the 1,000-fold more rapid pathway of photochemistry is available, little fluorescence is observed and photosynthesis proceeds with high efficiency. The singlet state of the photosynthetic pigment chlorophyll (see Section 12.2.3) participates in energy transfer and photochemistry. The relatively long half-life for triplet-state chlorophyll (as evidenced by how long it takes the molecules in the triplet state to diminish to one-half their original number) suggests that it is not an intermediate in the charge separation events in photosynthesis.

Using Equation 12.4, we can estimate the efficiency of photochemistry in any system by determining the **quantum yield**, Φ , of the photochemical event. According to this equation, a quantum yield of 1.0 would indicate that every absorbed photon is converted into chemical product; lower values indicate other decay pathways diminish the efficiency of the photochemical reaction. In photosynthetic systems under optimum conditions, the measured quantum yield of photochemistry is approximately 1, indicating that other decay routes do not occur to any substantial extent and that almost all absorbed photons are utilized for photochemical charge separation. Losses in efficiency in other steps of the primary photochemical event are associated with the stabilization of some of the photochemical reaction products.

BOX
12.2

Biophysical techniques are used to investigate photosynthesis

Studies of photosynthesis, particularly those related to the light reactions, have benefited from a vast array of techniques used to examine specific components of the photosynthetic apparatus and their function. For example, measurements of chlorophyll fluorescence are used to investigate the efficiency of photosynthesis and energy transfer during photosynthetic light harvesting. At ambient temperatures, most fluorescence comes from chlorophyll *a* molecules associated with PSII. Although the quantum yield of chlorophyll *a* fluorescence in plants is only 0.6–3% under these conditions, it provides useful information about energy transfer, photochemistry, and nonradiative dissipation of absorbed light energy. These mechanisms all involve the singlet excited state of chlorophyll, so changes in these pathways for de-excitation of singlet excited chlorophyll affect chlorophyll fluorescence yield. A pulse-amplitude-modulated (PAM) fluorometer can measure parameters that reflect several aspects of photosynthesis in varying light, such as the maximum efficiency of PSII (F_v/F_m' , where the variable fluorescence F_v is the difference between the maximum fluorescence F_m and the minimum fluorescence F_o in the dark-acclimated state) and the nonradiative dissipation of energy ($\text{NPQ} = F_m/F_m' - 1$, where F_m' is the maximum fluorescence in the light) (A). Chlorophyll fluorescence can also be measured at low temperature (77K), which enables one to distinguish and measure the antenna associated with both PSII and PSI.

Various spectroscopic techniques are also used in studies of the light reactions, taking advantage of the many oxidation–reduction reactions that occur during photosynthesis as a result of light conversion and subsequent electron transfer events. These approaches rely on characteristic “signatures” that distinguish the oxidized and reduced species of a given molecule. When these molecules engage in electron transfer reactions, changes in their redox state can be monitored. Two techniques that have been widely applied to these systems are optical absorption spectroscopy, based on the interaction of light with the molecules, and electron paramagnetic resonance (EPR) spectroscopy, based on the magnetic properties of the molecules.

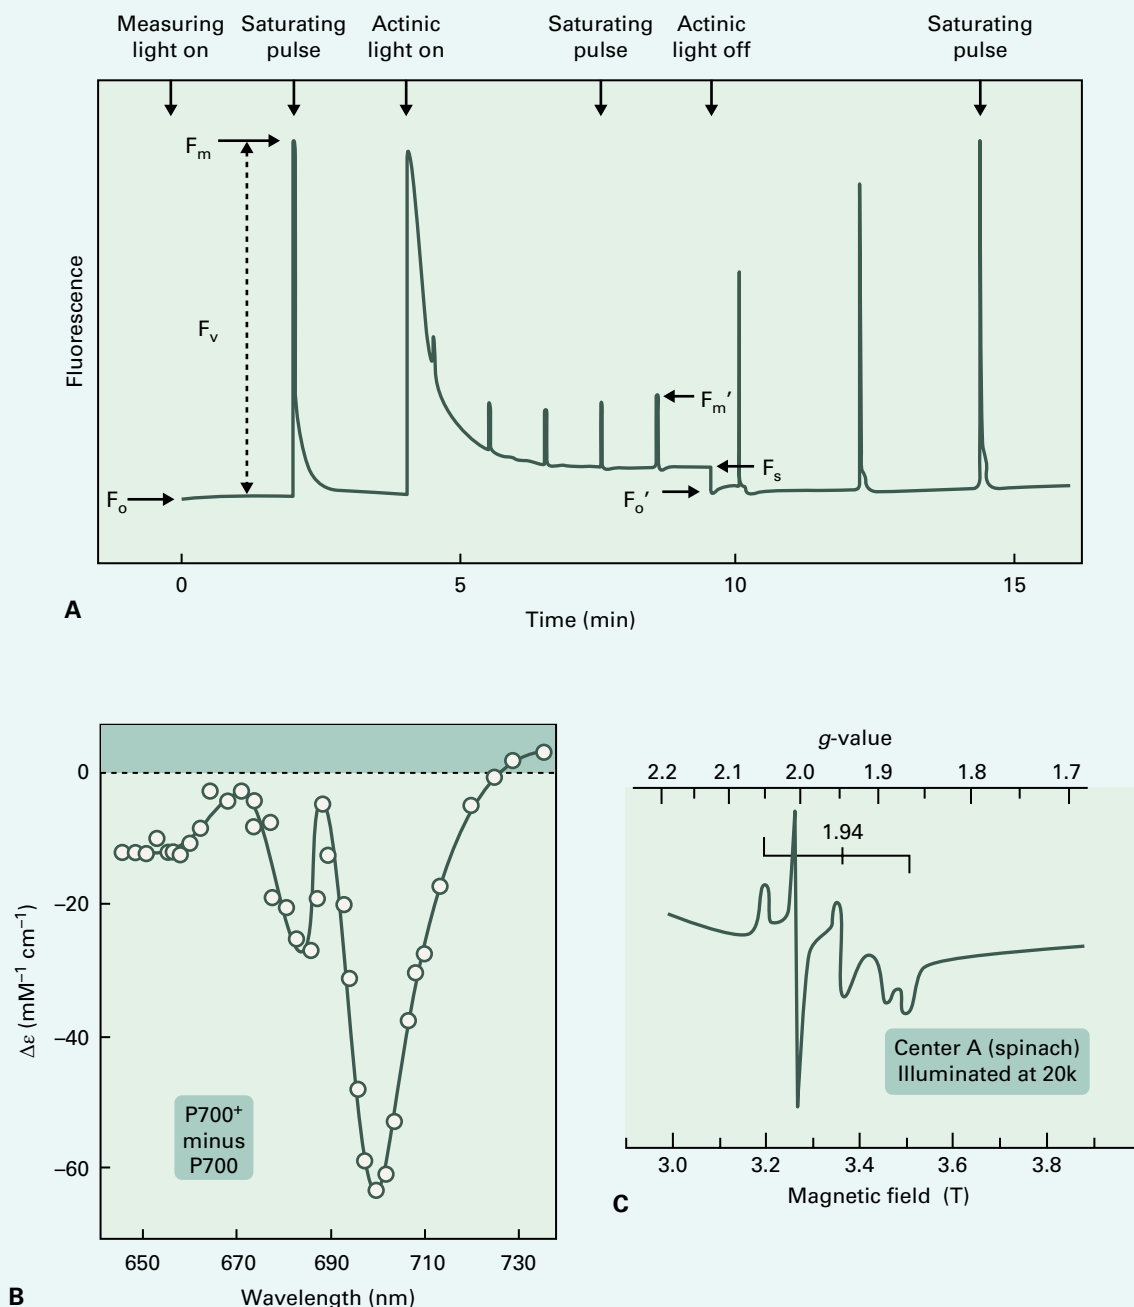

Absorption spectroscopy has been used extensively to detect the state of pigment molecules. Such measurements have provided important details on the kinds of pigments found in photosynthetic membranes and their organizational features. An extension of this technique is absorption difference spectroscopy, which has been applied to the study of pigments that show absorption changes under differing conditions, for example, when they undergo oxidation–reduction reactions in the light. Because the concentration of these

molecules in the photosynthetic membrane is low and is masked by the large absorption of pigmented molecules that do not undergo redox changes, these small absorption changes are difficult to detect. By measuring the difference in the redox state of the molecule in the light versus that in the dark, one can detect these small absorption changes without needing to obtain the absolute spectrum of the component. For example, the reaction center chlorophyll P700 takes its name from such a change, a decrease centered at approximately 700 nm when this pigment undergoes oxidation in the light (B). Other electron carriers also have characteristic absorption changes associated with their oxidation or reduction. This trait allows the monitoring of any individual component in a complex mixture of components, such as are found in a photosynthetic membrane. To obtain these spectra, one can activate the samples by using either steady-state illumination lasting 1 or more seconds or ultrashort flashes, in the range of picoseconds, nanoseconds, or microseconds. The latter technique allows determination of the time-resolved kinetics of a particular redox process. In the case of submicrosecond measurements, the technology is rather sophisticated, using high-energy lasers as the light source. Such measurements have been used to identify early intermediates in the charge separation events in photosynthesis, as well as to monitor the overall kinetics of specific electron transfer events.

Another useful spectroscopic technique applied to photosynthetic systems is electron paramagnetic spin resonance (EPR) spectroscopy, also known as electron spin resonance (ESR). Instead of measuring changes related to the optical properties of molecules as occur during optical absorption spectroscopy, EPR is based on the magnetic properties of paramagnetic molecules, those that contain unpaired electrons. For example, in all photosynthetic reaction centers, both the oxidized and the reduced products of the primary charge separation event are paramagnetic (having been generated by the transfer of a single electron), and both can be detected by the EPR technique. In addition, the process of oxidation and reduction of electron carriers in the electron transfer chain alters the number of unpaired electrons in these molecules. EPR detects transitions that occur between electron spin states that have been established by placing the paramagnetic molecule in a magnetic field. Researchers can use this technique not only to follow the redox state of the electron carrier, but also to gather information on the chemical nature of the paramagnetic species. Different paramagnetic species are characterized by different values for *g* (a unitless number associated with paramagnets). For example, the free electron

(a theoretical construct) has a g -value of 2.0023, whereas the unpaired electron in a photooxidized molecule of the reaction center of chlorophyll has a g -value of 2.0026 and the plastosemiquinone free radical has a g -value of 2.0045. These slight differences are related to the environment of the unpaired electron in each molecule, relative to a free electron not subject to environmental influences. Metal ion-containing centers, such as iron-sulfur (Fe-S) centers found in ferredoxin and PSI, have more-complex EPR spectra because of the involvement of different orbitals for their unpaired electrons compared

with those for free radicals. The first-derivative EPR spectrum of F_A (Fe-S center A) in PSI in liquid helium is shown in C. This Fe-S center is characterized by three g -values: 2.04, 1.94, and 1.86. F_B and F_X , the other Fe-S centers of PSI, have slightly different g -values, allowing for their spectral resolution. Copper-containing proteins in the Cu^{2+} state, such as the oxidized form of the copper-containing soluble protein plastocyanin, have g -values of 2.22 and 2.05, substantially different from the g -values for Fe-S centers. Cu^+ is diamagnetic, so reduction of plastocyanin results in a loss of its EPR signal.

Equation 12.4: Quantum yield

$$\Phi = \frac{\text{number of products formed photochemically}}{\text{number of quanta absorbed}}$$

12.2.3 All photosynthetic organisms contain chlorophyll or a related pigment

All photoautotrophic organisms contain some form of the light-absorbing pigment **chlorophyll**. Plants, algae, and cyanobacteria synthesize chlorophyll, whereas anaerobic photosynthetic bacteria produce a molecular variant called **bacteriochlorophyll** (Fig. 12.4). (Some photoheterotrophic

prokaryotes can synthesize ATP with light as the energy source by using retinal as a pigment bound to a rhodopsin-like protein; these species do not contain chlorophyll and, though fascinating, are tangential to the chlorophyll-based light reactions discussed here.)

Chlorophyll molecules contain a **tetrapyrrole** ring (porphyrin) structure like that found in the heme prosthetic group of hemoglobin and the cytochromes (see Chapter 14, Fig. 14.17). Several steps in the biosynthesis of chlorophyll and heme are shared; however, chlorophyll binds a magnesium (Mg) atom in the center of its tetrapyrrole ring, whereas heme binds an iron (Fe) atom. In addition, a long (C₂₀) hydrophobic side chain, known as a phytol tail, is attached to the tetrapyrrole ring structure of chlorophyll and renders the molecule extremely nonpolar. The biosynthetic pathway for

FIGURE 12.4 Structures of chlorophylls. Chlorophyll molecules have a porphyrin-like ring structure that contains a central magnesium (Mg) atom coordinated to the four modified pyrrole rings. Chlorophylls also contain a long hydrocarbon tail that makes the molecules hydrophobic. Various chlorophylls differ in their substituents around the ring structure. In chlorophyll a, a methyl group is present, whereas in chlorophyll b, a formyl group is present at the same position. Bacteriochlorophyll, found in prokaryotic photosynthetic bacteria, also shows side-chain modifications when compared with the chlorophyll a molecule.

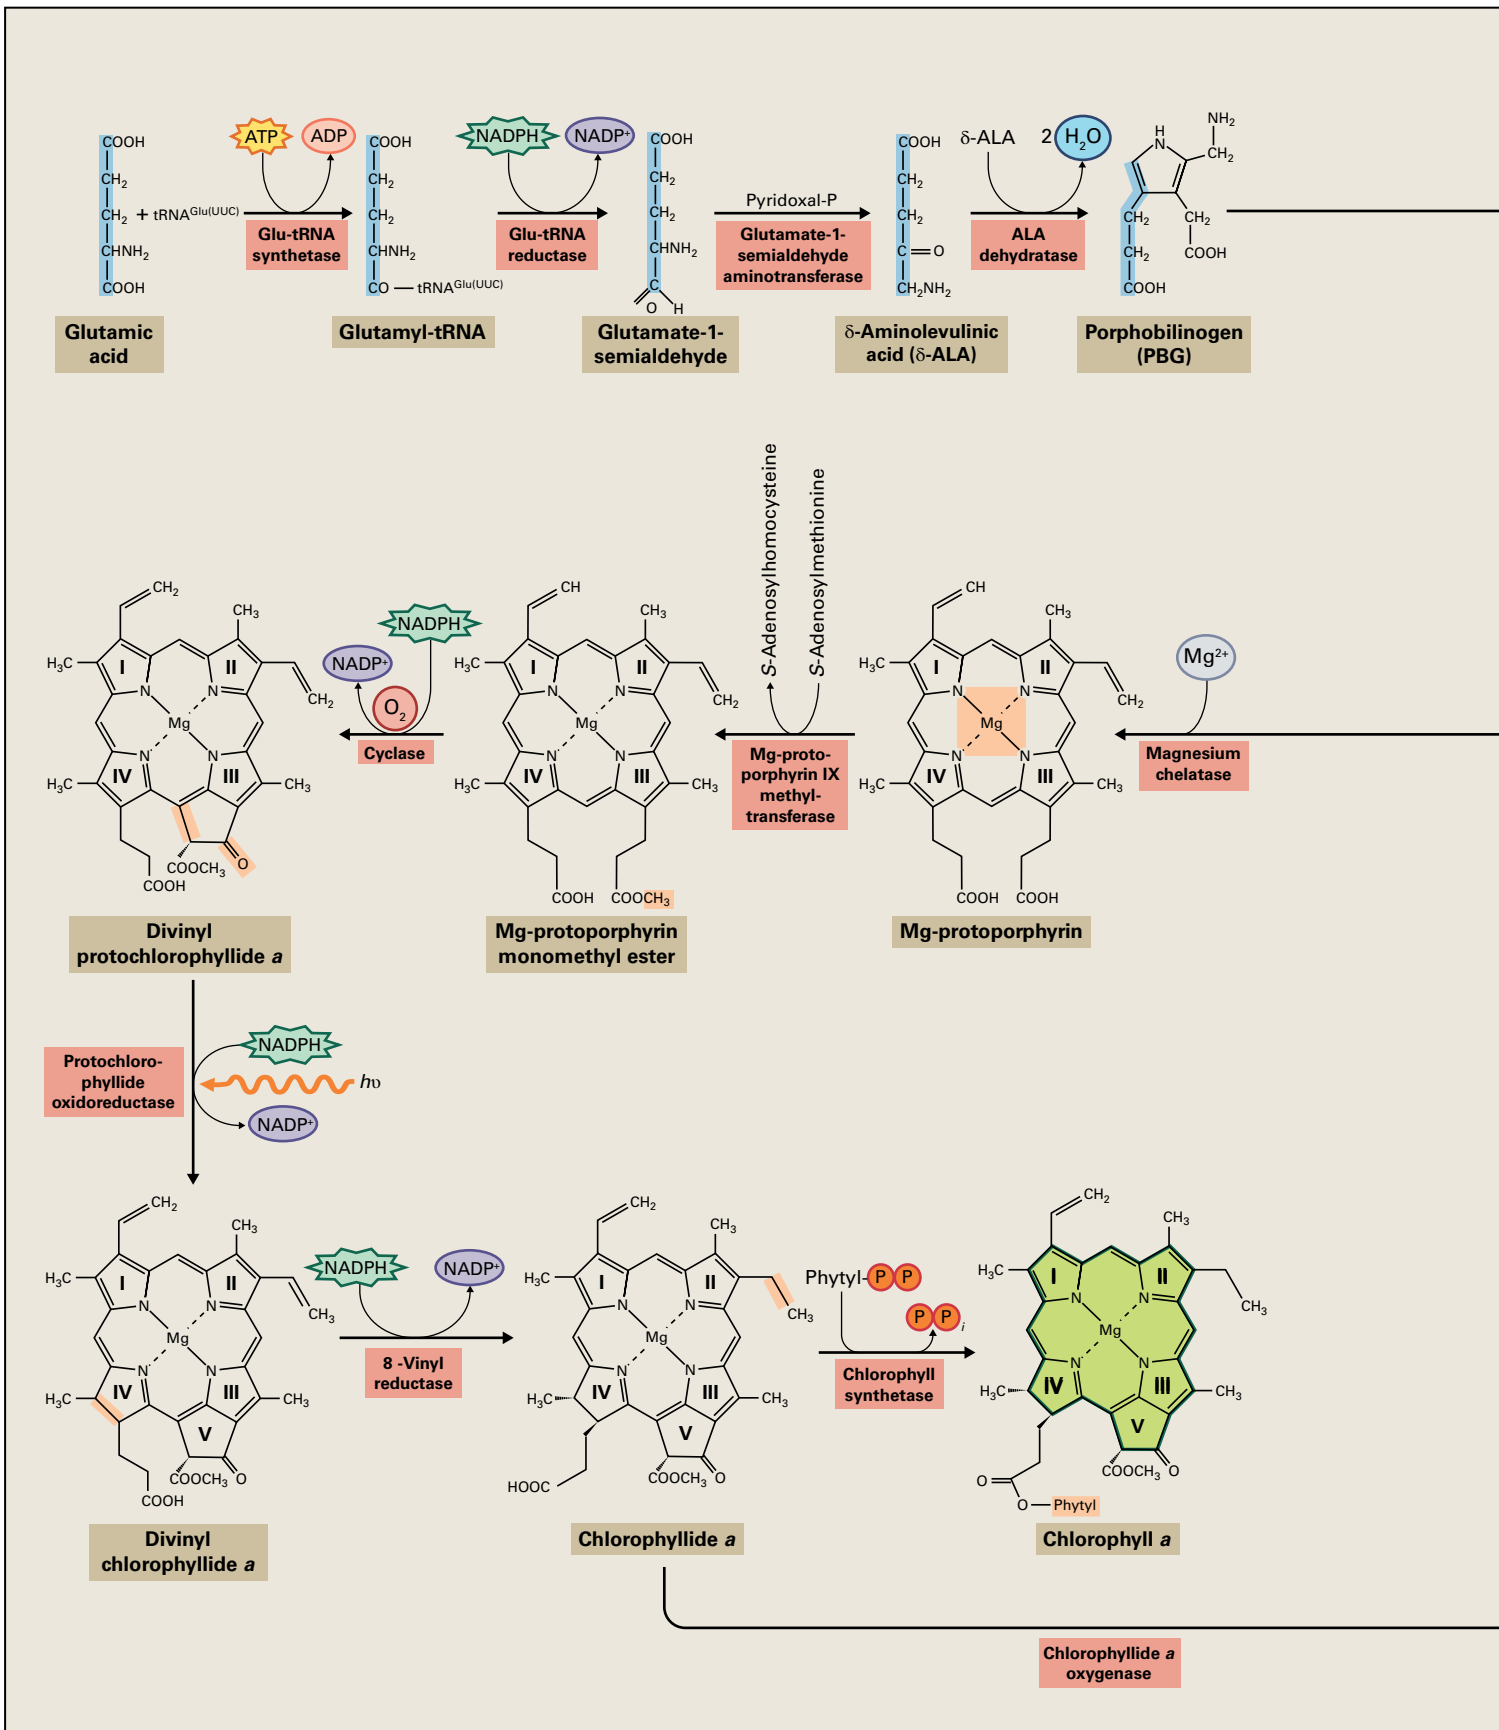

FIGURE 12.5 Biosynthesis of chlorophylls and heme. The biosynthesis of chlorophylls and heme begins with the synthesis of δ -aminolevulinic acid (ALA) from glutamic acid. Two molecules of ALA react to yield porphobilinogen (PBG). Four molecules of PBG form the ring structure of protoporphyrin IX, the common branch point for the synthesis of heme and chlorophyll. To make chlorophyll, a magnesium chelatase inserts Mg into the protoporphyrin IX ring; during heme synthesis, an iron chelatase inserts Fe into the ring. Chlorophyll synthesis involves further modifications of the porphyrin structure, including formation of a fifth ring (V) and attachment of the phytol chain. In angiosperms, synthesis of chlorophyll a requires a light-dependent protochlorophyllide reductase enzyme; synthesis of chlorophyll b is believed to occur with chlorophyllide a as the substrate.

chlorophyll has been elucidated through a combination of labeling studies, enzyme biochemistry, and mutant analysis.

The first committed precursor in the biosynthesis of chlorophyll and heme is δ -aminolevulinic acid (ALA). In plants and cyanobacteria, ALA is produced from glutamate in a series of reactions involving $tRNA^{Glu}$ (Fig. 12.5). Although ALA synthesis differs in plants and animals, the reactions that convert ALA to the branch point intermediate, protoporphyrin IX, are common to both groups of organisms. Protoporphyrin IX can be converted to heme by ferrochelatase, which inserts the iron atom into the center of the ring.

In the first step of the chlorophyll branch of the pathway, magnesium (Mg)-chelatase inserts a magnesium atom instead of iron. Subsequent reactions, including a cyclization to form a fifth ring, convert Mg-protoporphyrin IX into protochlorophyllide, which is reduced to generate chlorophyllide. In angiosperms, protochlorophyllide reduction is

strictly light dependent, whereas gymnosperms, many algae, and photosynthetic bacteria contain light-independent protochlorophyllide reductase, which allows these organisms to synthesize chlorophyll in the dark. The final step in synthesis of chlorophyll *a* involves esterification of the hydrophobic phytol side chain.

The distinct forms of chlorophyll have different side chains on the ring or different degrees of saturation of the ring system (see Fig. 12.4). For example, chlorophyll *b* is synthesized through the action of an oxygenase enzyme that converts a methyl to a formyl side group. These small changes in chemical structure substantially alter the absorption properties of the different chlorophyll species (Fig. 12.6A). Absorption is also affected by excitonic interactions with neighboring pigments and the noncovalent interaction of the molecule with chlorophyll-binding proteins found in the photosynthetic membrane. Chlorophyll is green because it absorbs light in

FIGURE 12.6 (A) Absorption spectra of chlorophylls.

The absorbance spectra of pigments dissolved in nonpolar solvents are shown for chlorophylls *a* and *b* and bacteriochlorophyll *a*. The visible region of the solar spectrum is also diagrammed. Note the spectra of these pigments show substantial shifts in absorption *in vivo*, where they are associated with specific proteins. (B) Absorption spectra of other photosynthetic pigments. The absorption spectrum of the carotenoids is for pigments dissolved in nonpolar solvents; the remaining spectra are for pigments in aqueous solution. UV, ultraviolet; IR, infrared.

the 430-nm (blue) and 680-nm (red) wavelengths of the visible spectrum more effectively than it absorbs green light. The green light not absorbed is reflected, which makes it visible. It is worth noting that some oxygenic photoautotrophs, such as cyanobacteria and red algae, contain additional pigments, called phycobilins, that are linear tetrapyrroles. These pigments absorb green and blue-green light (Fig. 12.6B), enabling utilization of more of the visible light spectrum.

12.2.4 Carotenoids participate in light absorption and photoprotection

A second group of pigment molecules found in all photosynthetic organisms is the **carotenoids** (Fig. 12.7). This class of molecules includes the carotenes, which contain a conjugated double-bond system of carbon and hydrogen, and the xanthophylls, which in addition contain oxygen atoms in their terminal rings.

Carotenoids are tetraterpene (C_{40}) molecules derived from eight isoprene units, the products of the nonmevalonate pathway located in the chloroplast (see Chapter 24). Phytoene, the precursor to all carotenoids, is synthesized from two molecules of geranylgeranyl diphosphate. In plants, two desaturases, phytoene desaturase and zeta-carotene desaturase, and two isomerases, zeta-carotene isomerase and carotene isomerase, catalyze the reactions that convert phytoene to lycopene, which is cyclized on both ends to generate either β -carotene, with two β -ionone rings, or α -carotene, with one β -ionone ring and one ϵ -ionone ring (Fig. 12.7). Hydroxylation of α -carotene produces **lutein**, the most abundant xanthophyll in the plant chloroplast. Hydroxylation of β -carotene results in formation of zeaxanthin. Epoxidation of zeaxanthin yields violaxanthin, which can be converted to neoxanthin by formation of an allene bond and isomerization. Zeaxanthin can also be synthesized by de-epoxidation of violaxanthin in the so-called **xanthophyll cycle**, which is especially important at high light intensities (see Section 12.6.3). Many other carotenoids with diverse structures are synthesized by algae and photosynthetic bacteria.

Several steps of the carotenoid pathway are affected in mutants of plants such as maize (*Zea mays*) and *Arabidopsis*. The genes encoding many enzymes of the plant carotenoid biosynthesis pathway have been cloned by expression in *E. coli*, which does not ordinarily make carotenoids (Fig. 12.8). Carotenoids, which are responsible for the orange-yellow colors observed in the leaves of plants, absorb light between 400 and 500 nm, a range in which absorption by chlorophyll *a* is relatively weak (see Fig. 12.6B). As such, carotenoids play a minor role as accessory light-harvesting pigments, absorbing and transferring light energy to chlorophyll molecules. Carotenoids play an important structural role in the assembly of light-harvesting complexes (LHCs, see Section 12.3.8).

Carotenoids have an indispensable function in protecting the photosynthetic apparatus from photooxidative damage (see Chapter 22). They can accept excitation energy from

both the triplet state of chlorophyll and the singlet state of oxygen. Singlet oxygen, generated by energy transfer from triplet chlorophyll, is toxic and the major type of reactive oxygen species that causes photooxidative damage in plants. If carotenoid biosynthesis is blocked by addition of inhibitors or by mutation, and the organism is then exposed to light in the presence of O_2 , lethal concentrations of singlet oxygen are formed.

12.3 Photosystem structure and function

12.3.1 A photosystem consists of a photochemical reaction center and a light-harvesting antenna system

In photosynthesis, light energy is absorbed and converted into relatively stable chemical products by integral membrane pigment-protein complexes called **photosystems**. All photosystems contain a **reaction center**, where photosynthetic electron transfer begins with a charge separation, as well as an array of light-harvesting, or **antenna**, pigments that are bound by proteins. These antennae absorb light energy and transfer it to the reaction center, where excitation of specially bound chlorophyll (Chl) molecules results in transfer of an electron to an acceptor (A), as shown in Reaction 12.6. This is the primary photochemistry that initiates conversion of light energy into chemical energy.

Reaction 12.6: Photochemistry in a reaction center

The special chlorophyll in the reaction center can be excited directly by absorption of a photon, or it can be excited upon receipt of excitation energy from the antenna. Thus, the antenna, which consists of many pigment molecules, increases the absorption cross-section of the reaction center. Transfer of excitation energy in the antenna from one chlorophyll molecule to another occurs by a mechanism known as Förster energy transfer or resonance (Reaction 12.7). Proximity of the donor and acceptor molecules within the antenna is critical, because the efficiency of energy transfer is inversely proportional to the sixth power of the distance separating the two molecules. For two chlorophylls separated by approximately 10 Å, an energy transfer time of less than 1 ps has been observed. The relative orientation of the two pigments is also significant, and the fluorescence spectrum of the donor pigment and absorption spectrum of the acceptor pigment must overlap for efficient energy transfer. For antenna pigments in close proximity and proper spatial orientation, energy transfer can proceed with high speed and efficiencies approaching 99%.

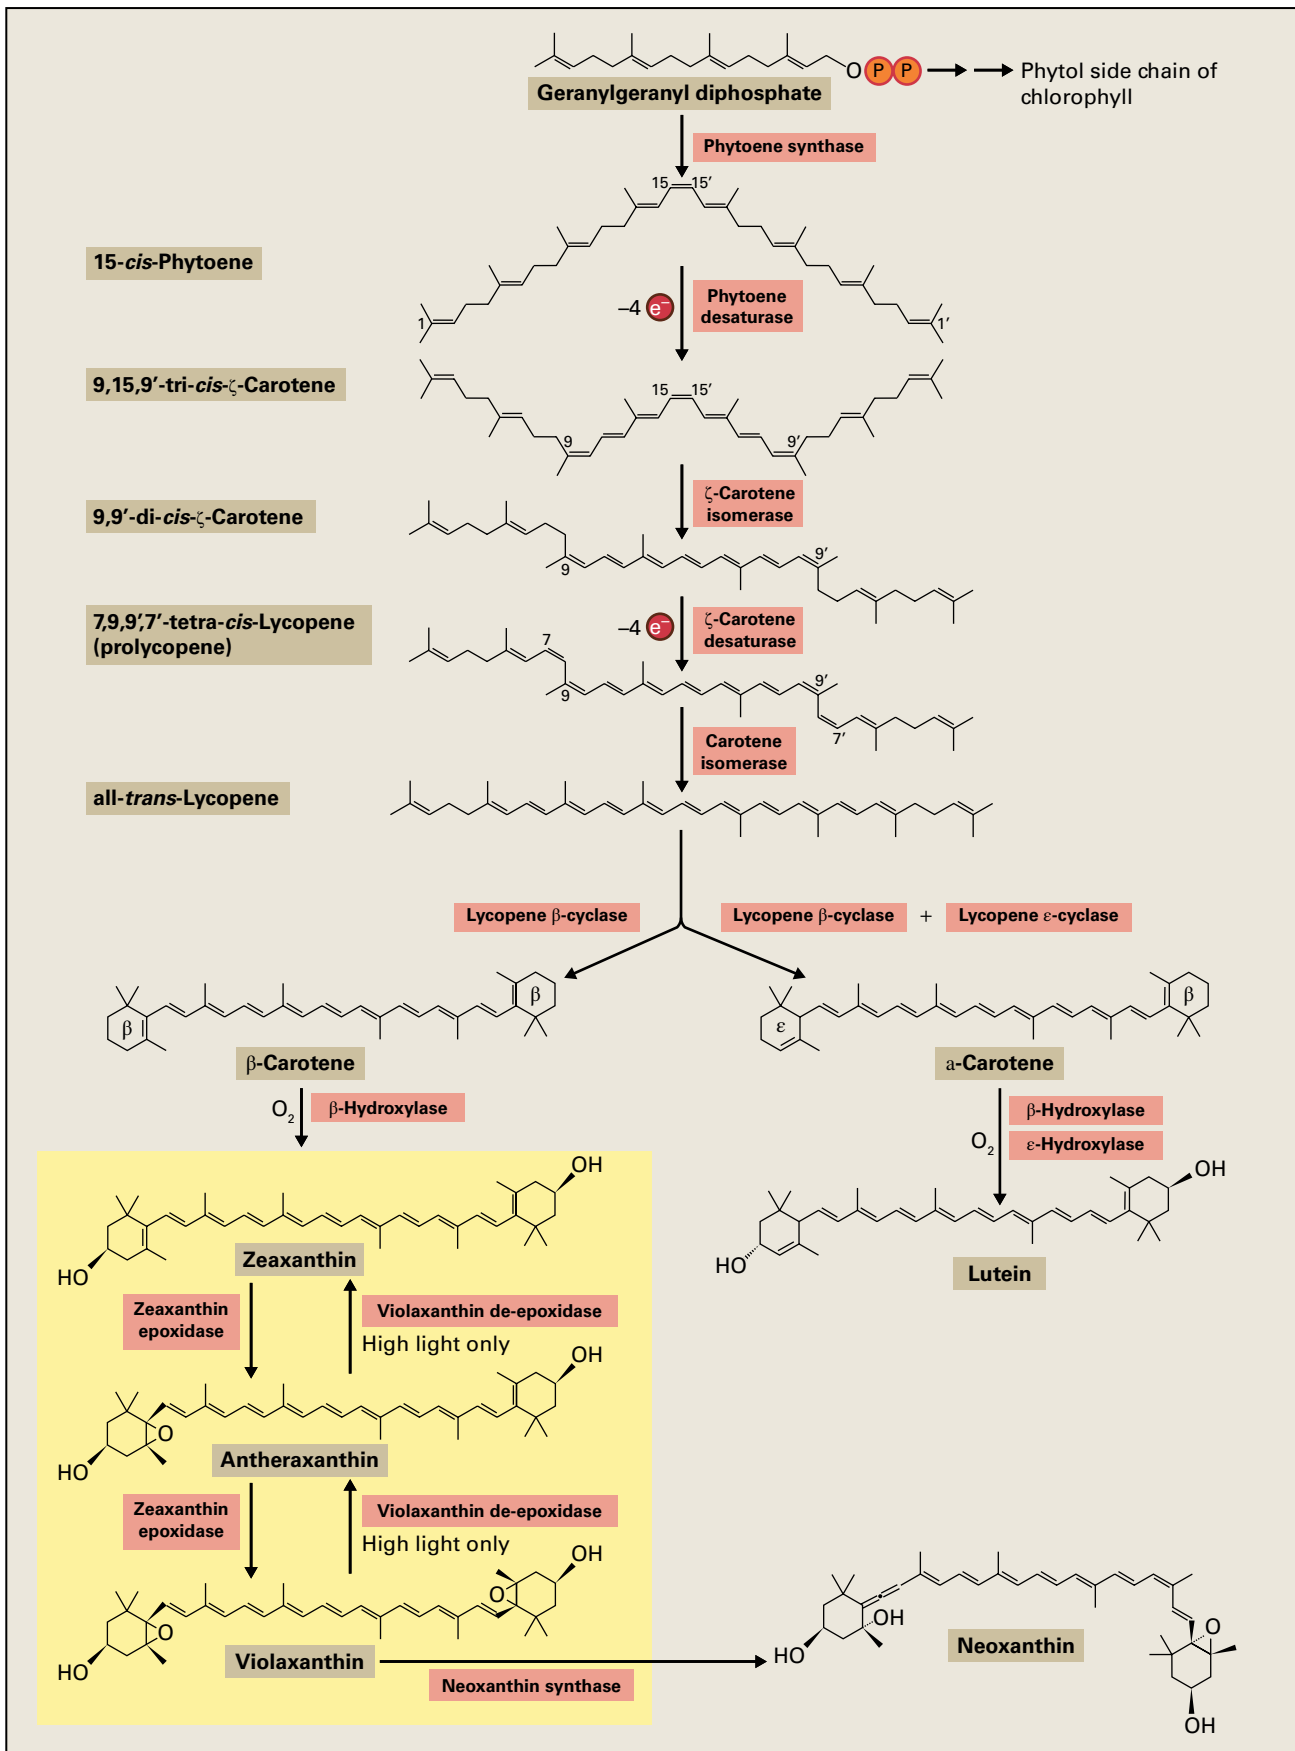

FIGURE 12.7 Biosynthesis of carotenoids and xanthophylls in plants. The pathway for conversion of geranylgeranyl diphosphate to lycopene, shown in the upper half of the figure, involves desaturation and isomerization reactions. Two desaturases, phytoene desaturase (PDS) and zeta-carotene desaturase (ZDS), and two isomerases, zeta-carotene isomerase (Z-ISO) and carotene isomerase (CRTISO), participate in these reactions. The conversion of lycopene to carotenoids and xanthophylls is illustrated in the lower half. The Greek letters β and ϵ designate the ring structures of the two carotene species. The xanthophyll cycle (lower left) protects plants from high light intensities by converting violaxanthin into zeaxanthin, which participates in thermal dissipation of excess absorbed light energy.

Reaction 12.7: Excitation energy transfer

12.3.2 Reaction centers contain both special chlorophyll and electron acceptor molecules involved in energy conversion

Biochemical fractionation of detergent-solubilized photosynthetic membranes has led to the isolation of reaction centers from anoxygenic bacteria, cyanobacteria, algae, and plants that are capable of performing the initial photochemistry in vitro. Spectroscopic studies have indicated that the reaction center chlorophyll participating in the primary charge separation event shown in Reaction 12.7 is composed of more than one chlorophyll or bacteriochlorophyll molecule. In the case of the reaction center complex from the purple bacterium *Rhodobacter sphaeroides*, this pigment is a pair of bacteriochlorophylls that has been named P865 after the wavelength of light for which oxidation-linked changes in absorbance are greatest (Box 12.2). This absorbance change associated with the primary charge separation provides a means to detect and quantitate reaction centers.

In addition to chlorophyll, reaction center complexes contain a series of electron acceptors. The chemical nature of

these acceptor molecules depends on the type of reaction center. A general feature of electron transfer events in all reaction centers is the transfer of an electron from the special chlorophylls, such as P865, to another pigment molecule, such as a bacteriopheophytin (pheophytin is a chlorophyll derivative lacking Mg), or even to another chlorophyll molecule. This reaction is followed by subsequent electron transfer to nonpigment molecules, either quinones or Fe–S centers, that further stabilize the charge-separated state. The generalized sequence of events is described in Reaction 12.8.

Reaction 12.8: Primary charge separation in the reaction center

The kinetics of the primary photochemistry in reaction centers have been studied in great detail. Within several picoseconds of the initial charge separation event of photosynthesis, the light energy conversion reaction is complete and chemical products have been formed. The technique of ultrafast absorbance spectroscopy, in which extremely short laser flashes activate electron transfer components in the reaction center complex, has made it possible to follow the electron transfer steps, from the special chlorophylls to the sequential electron acceptors. In the purple bacterial reaction center, the initial charge separation event, resulting in the formation of oxidized bacteriochlorophyll (P865⁺) and a reduced adjacent bacteriochlorophyll (BCha⁻), takes place in approximately 3 ps. The next step, reduction of the bacteriopheophytin electron acceptor (BPha⁻), occurs in only 1 ps. After an additional 100–200 ps, the electron has been transferred to a bound quinone (Q_A). The terminal quinone electron acceptor (Q_B) is reduced on a slower (microsecond) time scale (Fig. 12.9).

12.3.3 Oxygenic photosynthetic organisms contain two photochemical reaction centers, PSI and PSII

Reaction centers can be divided into two basic types, depending on the nature of the electron acceptor. A reaction center that ultimately reduces an Fe–S cluster is a Type I (or Fe–S type) reaction center, whereas one that reduces a quinone is a Type II (or Q type) reaction center. The photosynthetic membranes of anoxygenic photosynthetic bacteria contain only one type of reaction center, which varies among organisms. For example, green sulfur bacteria and heliobacteria contain a Type I reaction center; purple bacteria have a Type II reaction center.

By contrast, all O₂-evolving organisms, including cyanobacteria, algae, and plants, contain both Type I (PSI) and Type II (PSII) reaction center complexes. Thus, PSII contains electron carriers similar to those in the purple bacterial

FIGURE 12.9 Kinetics of electron transfer in the purple bacterial reaction center. The special pair of bacteriochlorophylls in the reaction center undergoes oxidation in the light. The electron lost from P865 is rapidly transferred to a monomeric bacteriochlorophyll (BChla) and then on to bacteriopheophytin (BPha). These initial reactions occur in only a few picoseconds. In approximately 200 ps, this electron is transferred to one of two ubiquinone molecules, Q_A , and then on to a second ubiquinone, Q_B , on a slower time scale. The electron transfer proceeds unidirectionally through one of the two symmetrical cofactor branches.

TABLE 12.1 Electron transfer carriers in the PSI and PSII reaction centers.

Carrier	PSI	PSII
Reaction center chlorophylls	P700, Chl _A , and Chl _B	P680 and Chl _{D1}
A_0	Chlorophyll <i>a</i>	Pheophytin <i>a</i>
A_1	Phylloquinone	Plastoquinone (Q_A)
A_2	F_x (Fe-S center)	Plastoquinone (Q_B)

reaction center (pheophytin, quinones), whereas PSI contains bound Fe-S centers as stable electron acceptors (Table 12.1). The chlorophylls that undergo light-induced oxidation in PSI and PSII have been named P700 and P680, respectively, referring to absorbance bands in the difference spectra (Box 12.2) for these pigments.

12.3.4 All reaction centers have a homologous core structure

A major advance in understanding the structure and function of reaction centers came with the determination of the structure of the Type II reaction center complex from the

photosynthetic purple bacterium *Rhodospseudomonas viridis* by X-ray crystallography. The core of the structure consists of a heterodimer of two homologous proteins, L and M, each of which has five transmembrane α -helices (Fig. 12.10A). The similarity of L and M suggests they arose by gene duplication of an ancestral reaction center, a homodimer. Together, these two proteins bind all the pigments and cofactors involved in the primary charge separation and electron transfer. The electron carriers are organized in a pseudosymmetrical arrangement of two branches (Fig. 12.10B); however, only one of the two symmetrical pathways available to the electron is used. The second arm remains inactive for reasons that seem to be related to the dynamics of the protein environment.

Subsequent determination of the crystal structures of PSII and PSI from cyanobacteria revealed that these reaction centers share a conserved core structure with the purple bacterial reaction center. The heterodimer in PSII is composed of the D1 and D2 proteins, which are homologous to L and M in the bacterial reaction center. In addition to the symmetrical pair of five transmembrane helices contributed by D1 and D2, two related proteins with six transmembrane helices each (CP47 and CP43) constitute the core antenna of PSII (Fig. 12.10A). In PSI, the cofactor-binding and core antenna domains are combined in the PsaA and PsaB proteins, which have 11 transmembrane helices each (Fig. 12.10A). Although the primary amino acid sequences of the PSII and PSI core proteins have diverged substantially, the arrangement of the transmembrane helices and the positions of the electron carriers are similar (Fig. 12.10). This structural homology suggests that all photosynthetic reaction centers (Type I and Type II) evolved from a common ancestor.

12.3.5 PSII is a light-driven water-plastoquinone oxidoreductase

PSII is an integral membrane complex containing the P680 reaction center, and X-ray crystallography of the cyanobacterial complex confirmed it is a dimer of two reaction centers, as indicated by earlier biochemical studies. PSII from plants is also found as a dimer, but its molecular structure has not been determined.

In addition to the electron transport components involved in the primary charge separation, each monomer in the PSII complex contains more than 20 proteins plus antenna pigments and several lipids. The core of the monomeric form of the PSII reaction center complex is shown schematically in Figure 12.11. As mentioned above, two proteins (D1 and D2) bind electron transfer prosthetic groups, such as P680, pheophytin, and plastoquinone. Other proteins, such as CP43 and CP47, bind core antenna pigments (chlorophyll *a* and β -carotene). Still other PSII proteins on the luminal side of the complex are involved specifically in water oxidation. The functions of many of the remaining low molecular-mass subunits, including cytochrome b_{559} , remain unknown.

FIGURE 12.10 (A) Schematic depiction of the organization of homologous transmembrane helices (shown as circles) in different photosynthetic reaction centers. Photosynthetic purple bacteria, such as *Rhodospseudomonas viridis* and *Rhodobacter sphaeroides*, have a Type II reaction center with a heterodimeric core of L and M subunits, represented by the proteins with five blue and five red circles, respectively. PSII of cyanobacteria and photosynthetic eukaryotes is a Type II reaction center with a heterodimeric core of D1 and D2 subunits (proteins with five blue and five red circles, respectively) and two core antenna subunits (CP47 and CP43, depicted as proteins with six purple and six light blue circles, respectively). In PSI, the core antenna moiety is fused with the core domain in a heteromer of PsaA and PsaB proteins (shown as proteins with 11 blue and 11 red circles, respectively) that constitute a Type I reaction center. Green sulfur bacteria, heliobacteria, and acidobacteria have a Type I reaction center that is homodimeric (depicted as two proteins with 11 circles each). (B) Organization of electron transfer carriers in different photosynthetic reaction centers, based on X-ray crystallography. Each series of electron carriers is organized around a pseudo-twofold axis of symmetry.

Table 12.2 summarizes the properties of some of the polypeptide components of the PSII core complex (most of the smaller and more peripheral subunits are not included). Molecular genetic studies have revealed that several of the low molecular-mass proteins in PSII are required for assembly and stabilization of active PSII complexes.

In the light, PSII functions as a water-plastoquinone oxidoreductase, transferring electrons from water to plastoquinone via only one of the two cofactor branches. The kinetics of the electron transfer reactions in PSII, by which plastoquinone is reduced, are shown in Figure 12.12. Following excitation of the special chlorophylls in the reaction center, the $P680^+Pheo^-$ radical pair is established quickly, within a few tens of picoseconds. Like the purple bacterial reaction center, the PSII reaction center complex binds two quinones, denoted Q_A and Q_B . Q_A is bound tightly to the PSII reaction center and functions as the first relatively stable electron acceptor. Q_B , which is bound more loosely, functions

as a secondary electron acceptor. Reduction of the two quinones proceeds through a five-step process:

- 1 The first electron is released from P680 and transferred to Q_A to produce a plastoquinone, Q_A^- .
- 2 This electron is then transferred to Q_B to yield the semiquinone Q_B^- . The loss of the electron returns Q_A^- to Q_A .
- 3 A second electron is then transferred from P680 to Q_A to produce a second Q_A^- .
- 4 The second electron is subsequently transferred from Q_A^- to Q_B^- to produce a fully reduced Q_B^{2-} molecule. Again, Q_A^- reverts to Q_A .
- 5 Finally, the fully reduced Q_B^{2-} takes up two protons from the stromal side of the membrane, yielding a plastoquinol, Q_BH_2 .

According to this model, under physiological conditions Q_A is capable only of single electron reduction to the semiquinone

FIGURE 12.11 Schematic diagram of the reaction center core of monomeric PSII. The D1 and D2 proteins bind most of the cofactors involved in charge separation and electron transport. Electrons are transferred from P680 to pheophytin (Pheo) and subsequently to two plastoquinone molecules, Q_A and Q_B . The nonheme iron (Fe) does not have a direct role in electron transfer. P680* is reduced by Z, a tyrosine residue in the D1 subunit. Also indicated is the oxidation of water by the Mn cluster, which is bound to the luminal side of the complex and stabilized by a peripheral protein, PsbO (labeled as MSP). CP43 and CP47 are chlorophyll a-binding core antenna proteins. D1 is susceptible to photooxidative damage and undergoes active turnover (see Chapter 10, Box 10.8).

FIGURE 12.12 PSII electron carriers and the kinetics of electron transfer. Pheophytin receives an electron from P680 and transfers it to the first of two plastoquinones (Q_A), which is bound tightly to the complex; the second plastoquinone, being mobile, is able to bind the Q_B site when oxidized (PQ), but not when fully reduced (PQH_2). Transfer of a single electron to Q_A occurs in approximately 400 ps. Reduction of PQ bound in the Q_B site to form the semiquinone $PQ^{\cdot-}$ occurs in approximately 200–400 μ s, whereas the second reduction to form PQH_2 takes place in 800 μ s. Overall, within 1 ms, the oxygen-evolving complex is oxidized by one electron and the quinone is reduced by one electron for each charge separation in PSII.

TABLE 12.2 Protein subunits of the plant PSII core complex. Most of the smaller and more peripheral subunits are not included.

Protein	Gene	Location of gene ^b	Mol. mass (kDa)	Function

level, whereas Q_B can switch between three states: the fully oxidized quinone Q_B , the semiquinone Q_B^- , and fully reduced quinol $Q_B H_2$. After reduction and protonation, $Q_B H_2$ dissociates from the PSII reaction center complex and diffuses into the lipid bilayer of the membrane to function as a mobile electron carrier. The Q_B site on the reaction center complex is filled with another plastoquinone from the pool of quinone molecules diffusing in the membrane.

The reduction of Q_A occurs in about 200 ps because this reaction is linked to the primary charge separation. The reduction of Q_B is slower, requiring 100 μ s. This indicates that Q_B^- must bind to the PSII reaction center complex while waiting to receive a second electron. In contrast, the binding of $Q_B H_2$ is relatively weak: This quinol is easily displaced from its binding site by fully oxidized quinones.

12.3.6 Oxidation of water produces O_2 and releases electrons required by PSII

P680, the reaction center chlorophyll of PSII, undergoes light-induced oxidation to produce the strong oxidant, $P680^+$, which can oxidize water to release O_2 . This implies that the oxidation-reduction midpoint potential of the $P680/P680^+$ couple is greater than +820 mV at pH 7, because splitting water requires at least this much oxidizing potential. In fact, the midpoint potential of $P680^+$ is estimated to be between +1.2 and +1.4 V, making it the most oxidizing molecule in biology. The oxidation of water is not a direct process, but involves a complex series of reactions on the oxidizing (luminal) side of PSII. The oxidation of water involves the transfer of four electrons:

Reaction 12.9: Oxidation of water

Analysis of the thermodynamics of water oxidation has been used to predict that this reaction occurs in either two steps involving two electrons each, or one step involving four electrons. Single-electron transfers would form highly energetic oxidant intermediates that would destroy components of the photosynthetic membrane system. This implies the existence of a charge-storage apparatus on the oxidizing side of PSII that can couple the single positive charges produced in the reaction center at P680 with the multiple positive charges required for water oxidation.

The mechanism of O_2 evolution has been investigated by measuring the amount of O_2 evolved after a series of short flashes of light. With dark-adapted chloroplasts, little O_2 appears after the first two flashes, but maximum amounts of O_2 appear after the third flash and after every subsequent fourth flash. The evolution finally reaches a steady-state level after a large number of flashes (Fig. 12.13).

The S-state model (Fig. 12.14) was proposed to explain these observations. This model postulates a light-driven charge-

FIGURE 12.13 O_2 evolution in flashes. The pattern of O_2 evolution is shown in response to a series of short flashes of light. The maximum amount of O_2 is produced on the third flash, after which a periodic spike is observed after every fourth flash. The flash yield damps out after approximately 20 flashes to a steady-state value.

accumulation mechanism by which the oxygen-evolving machinery of PSII progresses through five successive states of increasing oxidation, S_0 through S_4 , with S_4 being a strong oxidant capable of oxidizing water. Each charge separation event in the P680 reaction center yields $P680^+$, which ultimately oxidizes the charge accumulator, advancing it to the next S-state and increasing its charge by +1. The only state from which O_2 is evolved is S_4 .

In dark-adapted chloroplasts, the charge accumulator is predominantly in the S_1 state, resulting in a maximum yield of O_2 on the third flash, as observed experimentally (see Fig. 12.13). The first flash advances the oxidation state from the dark-adapted S_1 to S_2 . The second flash oxidizes S_2 to S_3 , and the third flash yields the strong oxidant, S_4 , triggering the evolution of oxygen and returning the charge accumulator to the S_0 state. Each succeeding cycle required four flashes because four photons are required per O_2 evolved. The reactions are complicated by “misses” (a flash that fails to oxidize P680), “double hits” (one flash oxidizes P680 twice), and “relaxations” (S_2 or S_3 decays to S_1 in the dark). Such events cause the oxygen yield to stabilize over a series of many flashes. In general terms, however, the S-state scheme has provided an excellent explanation for many of the basic observations on O_2 evolution.

12.3.7 The catalytic site for water oxidation is a Mn_4CaO_5 cluster

The S-state model does not provide a direct biochemical framework for understanding O_2 evolution, so what is the chemical nature of the S-state charge accumulator? Early findings that manganese (Mn) deficiency in algae or chloroplasts affects O_2 evolution, as well as findings in subsequent studies, have led to acceptance that Mn is the main charge

FIGURE 12.14 The O₂ evolution apparatus exists in five different oxidation states (S₀ through S₄). The cycle is advanced sequentially by photons trapped by PSII until the highly oxidized (positively charged) state (S₄) is produced. S₄ is the only state capable of water oxidation. Shown is the light-driven oxidation of P680 and subsequent reduction by electrons that are derived ultimately from water.

accumulator in the S-state model. Mn atoms appear to undergo successive oxidations to yield a strongly oxidizing complex in the S₄ state that is capable of water oxidation. A large number of biophysical measurements have helped define the oxidation state and structure of four Mn atoms associated with the O₂-evolving complex of PSII.

Determination of the structure of cyanobacterial PSII at 1.9-Å resolution has provided important insight into the detailed arrangement of the manganese cluster. As shown in Figure 12.15, the catalytic site for water oxidation is a Mn₄CaO₅ cluster. The structure resembles a distorted chair, with three Mn, one Ca, and four oxygen atoms forming a cubane-like structure (the base of the chair), and one Mn and one oxygen atom as the back of the chair. The oxygen atoms form oxo bridges between the Mn and Ca atoms. In addition, four water molecules are associated with the Mn₄CaO₅ complex (Fig. 12.15), at least one of which is likely a substrate for water oxidation. This structure presumably represents the cluster in the dark S₁ state. Advances in time-resolved X-ray diffraction techniques may enable determination of the structure of the Mn₄CaO₅ cluster in the other S states.

The link between P680⁺ and the Mn₄CaO₅ cluster is indirect. An additional electron carrier intermediate, Z (see Reaction 12.10), is a tyrosine residue in the D1 subunit of the reaction center complex of PSII (Tyr-161). The identity of this

residue has been confirmed by site-directed mutagenesis studies with PSII complexes from cyanobacteria, and the high-resolution crystal structure showed it is linked to the Mn₄CaO₅ cluster by a hydrogen bond network (Fig. 12.15B). To function as an intermediate between P680 and the S-state, the tyrosine radical formed in Reaction 12.10 must be a strong oxidant, capable of advancing the S-state. Measured kinetics of Z⁺ formation and decay are consistent with this proposed role.

Reaction 12.10: Oxidation and reduction of P680 during oxygenic photosynthesis

12.3.8 Plants use light-harvesting chlorophyll *a/b*-binding proteins as their major peripheral antennae

Thylakoid membranes from plants and green algae contain two different forms of chlorophyll (see Fig. 12.4): Chlorophyll *a* is found in all reaction center complexes as well as antennae, whereas chlorophyll *b* is found only in peripheral antenna

FIGURE 12.15 Structure of the water-oxidizing Mn₄CaO₅ cluster in PSII determined at 1.9 Å resolution. (A) Structure of the metal cluster with oxo bridges and water ligands. The bond distances are shown in Å. Hydrogen bonds are depicted as dashed lines. (B) Hydrogen bond network linking the Mn₄CaO₅ cluster and tyrosine Z (D1-Y161).

complexes. These peripheral antennae are in addition to the core antennae associated with the CP47 and CP43 proteins in PSII and the PsaA and PsaB proteins in PSI. Analyses of the total antenna sizes of PSII and PSI show that, in most plants, approximately 250 chlorophyll molecules are associated with each reaction center.

At least 10 different integral membrane **light-harvesting complex** (LHC) proteins that bind chlorophylls and xanthophylls have been identified by fractionation of chloroplast membranes with nondenaturing detergents followed by electrophoresis (Table 12.3). This analysis shows that all of the chlorophyll in thylakoids is associated with specific proteins, some with PSI and others with PSII. All are encoded in the nucleus and must, therefore, be imported into the chloroplast before binding with chlorophyll and associating with their proper photosystem. Similar LHC proteins are found in nearly all photosynthetic eukaryotes.

The major pigment-binding protein in plant thylakoid membranes is a trimeric complex called **LHCII**. Estimated to represent about half of the total protein in the thylakoid membrane, it is arguably the most abundant membrane protein on Earth. The structure of LHCII has been determined at a resolution of 2.5 Å (Fig. 12.16). Each 25-kDa protein monomer has three transmembrane helices that bind eight chlorophyll *a*, six chlorophyll *b*, and four xanthophyll molecules. Two lutein molecules serve as scaffolding for the first and third helices, and a neoxanthin and a violaxanthin are bound more peripherally.

Mild detergent fractionation of plant thylakoid membranes yields intact PSI and PSII complexes with full arrays of pigment molecules. As described in Section 12.3.9, the structure

architecture of PSII, with LHCII connected to the dimeric reaction center core via the monomeric LHC proteins CP29, CP26, and CP24 (Fig. 12.17).

12.3.9 PSI is a light-driven plastocyanin-ferredoxin oxidoreductase

PSI from plants contains approximately 15 protein subunits (Table 12.4). PsaA and PsaB (each ≈ 80 kDa) form the central heterodimer of the reaction center and are involved in binding the major electron transfer carriers, such as P700 and accessory chlorophylls, the chlorophyll *a* acceptor molecule (A_0), phylloquinone (vitamin K1, the A_1 acceptor), and the bound Fe–S center F_X . The low molecular-mass PsaC subunit (9 kDa) binds two additional Fe–S centers, F_A and F_B . Like PSII, PSI contains a large number of protein subunits that do not bind prosthetic groups, many of which have undefined function.

The midpoint potentials of the electron carriers and the kinetics of electron transfer through PSI are shown in Figure 12.18. Unlike PSII, both of the symmetrical cofactor branches in PSI appear to be active, so electron transfer from P700 is bidirectional (Fig. 12.19), with the A branch on PsaA being dominant. The two branches converge at F_X , so there is still only one pathway for electrons exiting PSI via F_A and F_B . The terminal electron acceptor is ferredoxin, a soluble Fe–S protein located in the stroma (a part of ferredoxin is bound to thylakoids in plants such as pea). On the luminal side, plastocyanin is a copper-containing protein that serves as the electron donor to PSI by reducing P700⁺. Thus, the PSI complex functions as a light-dependent plastocyanin-ferredoxin oxidoreductase. Ferredoxin is a very strong reductant with a redox midpoint potential of -420 mV. The reduced ferredoxin generated by PSI is capable of reducing NADP⁺ in a thermodynamically favorable reaction in the physiological pH range.

High-resolution crystal structures are available for PSI from both cyanobacteria and plants. Cyanobacterial PSI is a trimer of reaction centers, with 96 chlorophylls, 22 carotenoids, two phylloquinones, and three 4Fe–4S clusters per reaction center. This structure revealed the detailed structure of the core antenna, the symmetrical cofactor branches, and their interactions with the protein subunits. By contrast, the plant PSI structure shows a supercomplex with a monomeric reaction center core and a peripheral antenna composed of four LHCI proteins (Fig. 12.20). The peripheral LHCI antenna array is located on one side of the reaction center in a crescent shape. The locations of 12 core protein subunits have been determined, ten of which are also found in cyanobacterial PSI. The positions of the electron transfer components and core antenna chlorophylls are conserved between plant and cyanobacterial PSI.

12.4 Electron transport pathways in chloroplast membranes

12.4.1 The chloroplast noncyclic electron transport chain produces O₂, NADPH, and ATP and involves cooperation of PSI and PSII

Between the 1940s and the early 1960s, three seminal findings formed the basis for our current understanding of the coordinated operation of the two photosystems in the chloroplast electron transport chain. The first discovery was of the “red

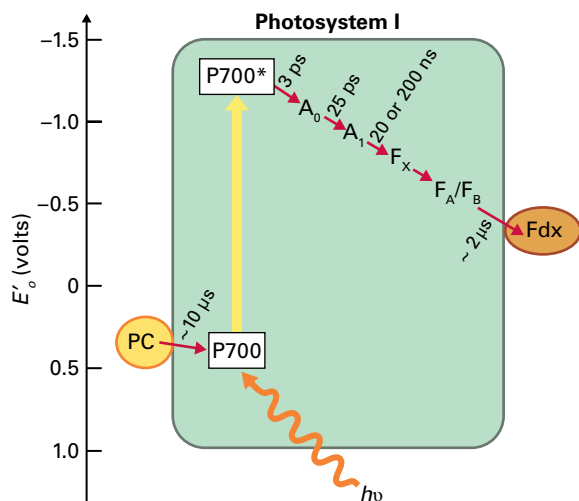

FIGURE 12.18 PSI electron carriers and the kinetics of electron transfer. The pathway of electron transfer through the PSI complex is shown to involve P700, a monomeric chlorophyll a (A_0), a phylloquinone (A_1), and a series of additional electron carriers that include three different Fe-S centers (F_x , F_A , and F_B). Electron transfers through these carriers occur in the time range of picoseconds to nanoseconds, with the terminal electron acceptor, ferredoxin (Fdx), being reduced in approximately 2 μ s. For simplicity, only one path of electron transfer is indicated, and the accessory chlorophyll near P700 is not shown.

FIGURE 12.19 Organization of electron carriers and electron transfer pathways in the PSI reaction center complex. The P700 dimer is located on the luminal side of the structure and two symmetrical cofactor branches radiate out from P700. Each includes an accessory chlorophyll a molecule (A), a monomeric chlorophyll a molecule identified as A_0 , and a phylloquinone (A_1). The two branches converge at the Fe-S center F_x . On the stromal side of the complex, two additional Fe-S centers (F_A and F_B) have been identified on the path to the soluble acceptor ferredoxin (Fdx). The electron donor on the luminal side of PSI is the soluble copper protein plastocyanin (PC).

drop,” where the efficiency of photosynthesis was found to decrease dramatically at wavelengths greater than 680 nm, though there was still substantial absorption of light by chlorophyll. In effect, light of wavelengths longer than 680 nm appeared ineffective in photosynthesis, regardless of absorption by the photosynthetic pigments. Questions raised by the red drop were answered by the second observation, the “enhancement effect.” When red and far-red light were used in combination, the rate of photosynthesis was greater than the sum of the rates achieved by using only red or only far-red light. The third finding revealed that red and far-red wavelengths had an antagonistic effect on the oxidation and reduction of cytochromes in the electron transport chain: red light causing reduction of cytochromes, and far-red causing their oxidation.

These three findings form the basis for the **Z-scheme** (Fig. 12.21), a model of the chloroplast electron transfer chain that takes into account the different pigment and reaction center compositions of the two photosystems. PSI, with its longer-wavelength reaction center P700, is more efficient in far-red light. PSII, however, operates more efficiently in red light because of its relatively shorter wavelength reaction center, P680. For photosynthesis to occur with optimal efficiency, the two photosystems must cooperate.

This cooperation of two photosystems that absorb optimally in different spectral regions explains the red drop phenomenon and the enhancement effect; the efficiency of photosynthesis would be expected to diminish if one of the two photosystems were preferentially activated, as would happen under either red or far-red light alone, but not under both combined. The Z-scheme also explains the antagonistic effects

of red and far-red light. The far-red light that activates PSI photochemistry oxidizes the photosystem, which in turn oxidizes electron carriers located between the photosystems (e.g., cytochromes). By contrast, the red light that activates PSII photochemistry and oxidizes P680 generates reduced compounds, which would reduce subsequent electron carriers in the chain.

The Z-scheme remains the preeminent model of **noncyclic photosynthetic electron transfer** and has been elaborated in detail. In the light, the primary charge separation in PSII produces a strong oxidant ($P680^+$) and a weak, relatively stable reductant, a plastoquinone (Q_A^-); in PSI the charge separation produces a strong, stable reductant (a reduced Fe-S center, F_x^-) and a weak oxidant ($P700^+$). $P680^+$ produced by PSII provides the oxidizing power to remove electrons from water, whereas Q_A^- provides the reducing power that ultimately donates electrons to $P700^+$ via a series of energetically “down-hill” electron transfers involving additional electron carriers,

FIGURE 12.20 Structure of plant PSI. (A) View from the stromal side of the membrane. The peripheral antenna composed of Lhca1-4 proteins is shown on the lower side of the monomeric reaction center core. “Gap chlorophylls” that connect peripheral antenna to the core antenna are evident in the space between the Lhca proteins and the reaction center. (B) Side view within the plane of the membrane. The PsaC, PsaD, and PsaE subunits protrude into the stroma and facilitate electron transfer to the soluble terminal acceptor, ferredoxin.

FIGURE 12.21 Conceptual diagram of the Z-scheme, showing the cooperation of PSII and PSI in the transfer of electrons from water to $NADP^+$. In the light, PSII generates a strong oxidant capable of oxidizing water, and a reductant. Illuminated PSI, in contrast, generates a strong reductant capable of reducing $NADP^+$, and a weak oxidant. The two photosystems are linked by an electron transfer chain (ETC) that allows the PSI oxidant to receive electrons from the PSII reductant.

including the transmembrane protein complex, cytochrome *b_f*. The energy released by this **exergonic** electron transfer contributes to the formation of a proton gradient that can be used for the synthesis of ATP. An intermediate product of P700 oxidation, reduced ferredoxin, serves as an electron donor in many important reactions, including reduction of $NADP^+$, assimilation of nitrogen (see Chapter 8), and reduction of the regulatory disulfide protein thioredoxin (see Section 12.9.4).

A current depiction of the Z-scheme describing the electron carriers in reference to their midpoint oxidation-reduction potentials is shown in Figure 12.22A. A corresponding schematic, Figure 12.22B, illustrates the movement of electrons and protons during noncyclic electron transfer in oxygenic photosynthetic organisms. This electron transfer pathway generates three principal products: O_2 , ATP, and $NADPH$. The two photosystems are connected by a series of electron carriers that include plastoquinone, the cytochrome *b_f* complex, and plastocyanin. Oxidation of water and exergonic electron transport produce a proton electrochemical gradient that drives synthesis of ATP by the transmembrane ATP synthase. A structural view of the protein complexes involved in the Z-scheme is shown in Figure 12.23.

FIGURE 12.22 (A) The current Z-scheme, showing E'_m values of electron carriers. The vertical placement of each electron carrier of the noncyclic electron transfer chain corresponds to the midpoint of its redox potential. These voltage values have been verified experimentally. (B) Membrane organization of the Z-scheme. The components of the chloroplast electron transport chain and the ATP-synthesizing apparatus are illustrated in the thylakoid membrane. Four membrane complexes (PSII, PSI, the cytochrome b_6/f complex, and the ATP synthase) are shown. Electrons are transferred from water to $NADP^+$; accompanying this electron transfer, a proton gradient is established across the membrane. This electrochemical gradient is ultimately utilized for the synthesis of ATP by the ATP synthase. Fdx, ferredoxin; FNR, ferredoxin- $NADP^+$ reductase.

12.4.2 The cytochrome b_6/f complex transfers electrons from reduced plastoquinone to oxidized plastocyanin

Oxidation of plastoquinol occurs by an integral membrane protein complex, the cytochrome b_6/f complex, which is similar in structure and function to the cytochrome bc_1 complex

(Complex III) of the mitochondrial respiratory chain (Chapter 14). Both complexes are dimers, with each monomer containing a conserved core of four electron carriers: a high-potential c -type cytochrome (cytochrome f or c_1), a high-potential 2Fe-2S Fe-S protein (the Rieske Fe-S protein), and a b -type cytochrome (cytochrome b_6 or b) with two b -type hemes (see Figs. 14.20 and 14.22); however, determination of the high-resolution structures of the cytochrome b_6/f complex

FIGURE 12.23 A structural view of the Z-scheme showing structures of the major thylakoid membrane complexes (PSII, cytochrome b_6/f complex, PSI, and ATP synthase) involved in the light reactions of oxygenic photosynthesis. Also shown are the structures of the soluble proteins Fdx and FNR on the stromal side of PSI, as well as PC in the lumen.”

from a cyanobacterium and a green alga revealed several surprising features. In addition to four small protein subunits unique to the b_6/f complex, there is an extra c -type heme bound to cytochrome b_6 , a chlorophyll a molecule, and a β -carotene. Like PSII and PSI, the cytochrome b_6/f complex contains both nuclear and chloroplast gene products (Table 12.5).

The cytochrome b_6/f complex functions as a plastoquinol-plastocyanin oxidoreductase, transferring electrons from plastoquinol to plastocyanin, which resides in the lumen of the thylakoid membrane. This transfer is accompanied by the translocation of protons across the membrane, from stroma to lumen. An unusual feature of the cytochrome complex mechanism permits translocation of two protons for every electron transferred to plastocyanin, facilitating formation of the proton gradient that drives ATP synthesis.

12.4.3 Proton translocation via cytochrome b_6/f is thought to involve a Q-cycle

The most widely accepted mechanism to describe the reactions of the cytochrome complex is the Q-cycle (Fig. 12.24). According to this model, the cytochrome complex contains one quinol-

binding site (Q_p) and one quinone-binding site (Q_n) on opposite sides of the membrane. Quinol oxidation proceeds in two steps at the Q_p site, located at the luminal side of the membrane. At Q_p , quinol is oxidized to the semiquinone by the Rieske Fe–S center, and the released electron passes from the Fe–S center to cytochrome f , then on to plastocyanin. The plastoquinone is then oxidized by one of the two hemes, known as b_l , (b -low potential), located in cytochrome b_6 near the luminal side of the membrane. Accompanying this oxidation, protons are released from the quinol into the lumen. The electron in the b_l heme is transferred across the membrane to the second b -type heme, known as b_h (b -high potential). This electron is then transferred to a quinone molecule that has bound at the Q_n site on the stromal side of the membrane, producing a semiquinone. This cycle repeats itself once again to oxidize a second plastoquinol, with one electron being passed to plastocyanin and the second being transferred to the Q_n site to produce a fully reduced quinol molecule (PQH_2); the fully reduced quinol picks up two protons from the stroma and dissociates from the Q_n site. The net result of this cycle is that a plastoquinol molecule is oxidized to a quinone (PQ ; at the Q_p site), two electrons are transferred to plastocyanin (PC), and four protons are transferred from the stroma to the chloroplast lumen (Reaction 12.11). The arrangement of the electron carriers involved in the cytochrome b_6/f complex is shown in Figure 12.25.

A First turnover

B Second turnover

FIGURE 12.24 The Q-cycle. The transmembrane organization of the cytochrome b_6/f complex is shown schematically. At the quinol-binding site, Q_p , a plastoquinol molecule (PQH₂) is oxidized and two protons are released to the lumen. During the first turnover of the complex (A), one electron released from plastoquinol is passed through the high-potential electron carriers, the Rieske Fe-S protein (RFeS) and cytochrome *f*, to the electron acceptor, plastocyanin. The other electron passes through the cytochrome b_6 hemes (b_h and b_i) to a quinone binding site on the stromal side of the membrane, Q_n , where it reduces a quinone molecule to form a plastoquinone (PQ). During the oxidation of a second plastoquinol molecule (B), the pathways of electron transfer are identical except that the second electron reduces the plastoquinone at the Q_n site to a fully reduced plastoquinol (PQH₂), which takes up protons from the stroma, is released from the complex, and enters the plastoquinone pool.

FIGURE 12.25 Organization of electron carriers and electron transfer pathways in the dimeric cytochrome b_6/f complex. The Q_p site is located near heme b_i and the Rieske Fe-S center on the luminal side of the complex. One electron from oxidation of plastoquinol passes through the Rieske Fe-S center on its way to cytochrome *f* and then plastocyanin. Movement of the Rieske protein is hypothesized to facilitate the electron transfer to cytochrome *f*. The second electron from plastoquinol is transferred to heme b_i and then to hemes b_h and/or c_n near the Q_n site on the stromal side of the complex. It is possible that a two-electron pathway for reduction of plastoquinone occurs at the Q_n site.

Reaction 12.11: The Q-cycle in the chloroplast

The reactions of the cytochrome b_6f complex are among the most important in limiting the rate of electron flux. Whereas $\text{Q}_\text{B}\text{H}_2$ is formed in approximately 100 μs , quinol oxidation occurs in 10–20 ms. Direct measurements of the rate of reactions through the high-potential carriers, including oxidation of cytochrome f by plastocyanin, have shown half-reaction times no longer than 1–2 ms. However, the reactions of cytochrome b_6 , particularly the kinetics of the oxidation of the high-potential heme, b_h , are considerably slower and appear to be the rate-limiting steps in the complex.

12.4.4 Plastocyanin, a soluble protein, links cytochrome b_6f and PSI

The cytochrome b_6f complex reduces the mobile electron carrier plastocyanin, a low molecular-mass (11 kDa), copper-containing protein. Electron transfers involving plastocyanin are very rapid: Its reduction by the cytochrome b_6f complex takes about 100–200 μs , and its oxidation by PSI requires about 10 μs . Docking of plastocyanin to PSI involves electrostatic interactions with the PsaF subunit and hydrophobic interactions with PsaA and PsaB on the luminal side of the reaction center complex.

In some algae and cyanobacteria, the biosynthesis of plastocyanin is controlled by the extent of copper availability in the growth medium. In the absence of copper, these cells are unable to accumulate plastocyanin and instead synthesize a c -type cytochrome, cytochrome c -553, which is functionally interchangeable with plastocyanin.

12.4.5 Electrons from PSI are transferred to NADP^+ in the stroma in a reaction requiring ferredoxin and ferredoxin- NADP^+ reductase

Electrons from PSI are transferred to the 2Fe–2S Fe–S protein ferredoxin in the chloroplast stroma. This electron carrier does not transfer electrons directly to NADP^+ , rather through activity of an intermediate enzyme called ferredoxin- NADP^+ reductase (FNR; see Fig. 12.22 and Fig. 12.23). Evidence indicates that ferredoxin and FNR form a complex through electrostatic interaction. FNR is an FAD-containing enzyme that can be reduced in two single-electron steps: The first electron reduces FNR to the flavin semiquinone state, and the second to the fully reduced state, FADH_2 (see Chapter 14, Fig. 14.6). FNR then transfers the two electrons to NADP^+ . FNR is loosely associated with the thylakoid membrane and is easily dissociated. High-resolution structures of both ferredoxin and FNR are available from X-ray crystallography (see Fig. 12.23), and models for the interaction of the two proteins have been developed from the structural data.

12.4.6 Chloroplasts also contain cyclic electron transport chains that involve PSI

As described above, the noncyclic electron transport chain in chloroplasts links the oxidation of water (O_2 evolution) to the reduction of NADP^+ and production of ATP. Chloroplasts also carry out a cyclic electron transport process that involves PSI, plastoquinone, the cytochrome b_6f complex, and plastocyanin. In a model that describes this pathway (Fig. 12.26), PSI reduces

FIGURE 12.26 Two pathways of cyclic electron transport around PSI in plants. One pathway uses the NADH dehydrogenase-like (NDH) complex, whereas a putative ferredoxin-plastoquinone oxidoreductase activity involving PGRL1 and PGR5 is necessary for the other pathway, which is sensitive to antimycin A (AA). Both pathways involve PSI, reduced ferredoxin, the cytochrome b_6f complex, and plastocyanin. The only net product of the pathway is ATP, which is synthesized by using the proton gradient generated through plastoquinol oxidation.

ferredoxin in the light, but instead of transferring an electron to NADP^+ , reduced ferredoxin donates electrons to the plastoquinone pool. Reduced plastoquinol can then be oxidized by the cytochrome b_6f complex, allowing proton translocation across the membrane. Electrons complete the cycle by returning to PSI via plastocyanin, and the pmf resulting from operation of a Q-cycle (Fig. 12.26) drives ATP synthesis. Thus, cyclic electron transport produces only ATP as a product without net production of NADPH. It seems to be involved in adjusting the ratio of ATP to NADPH production from the light reactions to meet the demands of downstream metabolism.

Biochemical and molecular genetic studies have suggested that two different enzymes catalyze the ferredoxin-dependent reduction of plastoquinone during cyclic electron transport around PSI (Fig. 12.26). One pathway is catalyzed by the **NADH dehydrogenase-like (NDH) complex** in the thylakoid membrane. This large complex is similar to mitochondrial Complex I, except the electron donor appears to be reduced ferredoxin instead of NADH. The formation of supercomplexes of PSI with the NDH complex depends on two minor LHCl antenna proteins, Lhca5 and Lhca6. The NDH pathway is especially prominent during oxidative stress. The second pathway involves a **ferredoxin-quinone oxidoreductase** that is sensitive to antimycin A. This activity depends on a complex of two thylakoid proteins, PGRL1 and PGR5. PGRL1 accepts electrons from ferredoxin and contains redox-active cysteine residues and an Fe-containing cofactor that are necessary for quinone reduction. Thioredoxin m (Trx m , see Box 12.4) has been implicated in the regulation of both types of cyclic electron transport. In the green alga *Chlamydomonas reinhardtii*, PGRL1 has also been found in a supercomplex with PSI, FNR, and the cytochrome b_6f complex.

12.4.7 Specific inhibitors and artificial electron acceptors have been used to study chloroplast electron transport

Several compounds specifically inhibit the chloroplast electron transport chain and act as herbicides (Fig. 12.27). One class of inhibitors binds at the Q_B site on the D1 protein in PSII and prevents the reduction of Q_B . The most widely studied of these is the inhibitor Diuron, 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU). Atrazine also acts at this site. A second class of inhibitors acts at the reducing side of PSI, inhibiting reduction of ferredoxin. The herbicide Paraquat

(methyl viologen) is a member of this class, and its action as a herbicide results from its autoxidizability, which results in the formation of a superoxide radical that is highly reactive and damaging to the photosynthetic apparatus. Paraquat has been used experimentally as a nonphysiological electron acceptor, substituting for ferredoxin.

Another set of inhibitors includes plastoquinone analogs, such as 2,5-dibromo-3-methyl-6-isopropyl-*p*-benzoquinone (DBMIB; or dibromothymoquinone), which block electron transfer by competing with plastoquinol for binding at the quinol oxidizing (Q_p) site in the cytochrome b_6f complex. The site of action of these inhibitors in relation to the electron carriers of the chloroplast noncyclic electron transfer chain is shown in Figure 12.28. In addition to their commercial value as herbicides, these inhibitors are useful for defining the electron transfer events that take place in the photosynthetic membrane. For example, cyclic electron transport is blocked by inhibitors of the cytochrome b_6f complex, such as DBMIB, but not by PSII inhibitors, such as DCMU.

FIGURE 12.27 Chemical structures of three inhibitors of the photosynthetic electron transport chain: DCMU, 3-(3,4-dichlorophenyl)-1,1-dimethylurea; DBMIB, 2,5-dibromo-3-methyl-6-isopropyl-*p*-benzoquinone; and Paraquat.

FIGURE 12.28 Sites of action for the inhibitors of the chloroplast electron transport chain diagrammed in Figure 12.22. DCMU and DBMIB block electron transfer reactions, whereas reduced Paraquat autooxidizes to a radical, resulting in the formation of superoxide and other reactive oxygen species.

12.5 ATP synthesis in chloroplasts

Photophosphorylation, the light-dependent synthesis of ATP, is mechanistically similar to the oxidative phosphorylation processes in mitochondria. Chloroplasts can synthesize ATP using either noncyclic electron transfer, with a concomitant synthesis of O₂ and NADPH, or cyclic electron transfer, in which there is no net utilization of substrate and no end product other than ATP.

12.5.1 Electron transport and ATP synthesis are coupled in vivo

A major feature of both oxidative phosphorylation and photophosphorylation in vivo is that ATP synthesis is energetically coupled to electron transport. This means that no phosphorylation of ADP occurs in the absence of electron transport, and that electron transfer is restricted in the absence of ATP synthesis. In vitro, however, it is possible to obtain high rates of electron transfer in the absence of ATP synthesis under certain nonphysiological conditions, most notably upon addition of compounds known as uncouplers. Uncouplers prevent ATP synthesis but allow electron transfer to proceed unimpeded. Their behavior is explained by the chemiosmotic model (see Section 12.5.2).

There are two coupling sites for energy conservation in the chloroplast noncyclic electron transport chain. These sites involve regions of the electron transport chain where proton accumulation in the thylakoid lumen is coupled to electron transport. One site involves protons liberated when water is oxidized by PSII, given that the protons released are localized in the luminal space of the chloroplast thylakoid membrane system. The second site involves protons released when plastoquinol is oxidized by the cytochrome *b₆f* complex; in this case, the quinol oxidation results in the release of protons into the luminal space.

The amount of ATP synthesized during noncyclic electron transport, expressed as the $P/2e^-$ or $ATP/2e^-$ ratio, has long been a subject of controversy. To some extent, this is because the isolation of well-coupled chloroplasts is challenging. An accurate measurement of the maximum amount of ATP synthesized during electron transfer is difficult to obtain. Values for noncyclic photophosphorylation in chloroplasts are generally in the range of 1.0–1.5 ATP molecules synthesized from ADP and Pi for every two electrons transferred from water to NADP⁺.

12.5.2 Chloroplasts synthesize ATP by a chemiosmotic mechanism driven by a proton gradient

The chemiosmotic model was proposed in the 1960s to explain ATP synthesis in chloroplasts and mitochondria. According to this model, the main energetic driving force for

ATP synthesis is an ion gradient across a selectively permeable biological membrane—in chloroplasts and mitochondria, this is a proton gradient generated as a consequence of electron transfer. This gradient establishes a concentration difference of protons and can also result in a difference in electric potential across the membrane. These sources of potential energy can be used for the phosphorylation of ADP by ATP synthase, an enzyme that can couple this energetically favorable proton flow to the synthesis of ATP (see Fig. 12.22B and Chapters 3 and 14).

Several important features of the chemiosmotic model have been verified experimentally. First, this mechanism requires an intact membrane system with low intrinsic permeability to protons. Second, the electron transport components in the membrane must be arranged vectorially to allow electrons to cross the membrane at defined sites. As electrons pass through this series of electron carriers, protons are also translocated across the membrane at these coupling sites. In chloroplasts, protons move from the stroma to the thylakoid lumen as electrons are transferred along the chain. In the noncyclic electron transport pathway, protons are “deposited” in the lumen at the oxygen-evolving complex of PSII and at the Q_p site near the luminal face of the cytochrome *b₆f* complex, which act to oxidize water and plastoquinol, respectively. This unidirectional proton accumulation results in a high concentration of protons on the luminal side of the membrane and a lower concentration on the stromal side. The resulting gradient supplies the **proton motive force** (pmf).

As summarized by Equations 12.5 and 12.6, there is a linkage between the pH component, arising from a concentration difference of protons across the membrane (ΔpH), and the electrical potential component, arising from a difference in charge across the membrane ($\Delta\psi$). According to the chemiosmotic model, the $\Delta\bar{\mu}_{\text{H}^+}$ (in kilojoules per mole) or pmf (in volts) is the driving force for ATP synthesis.

Equation 12.5: Contribution of pH and membrane potential to the proton motive force

$$\Delta\bar{\mu}_{\text{H}^+} = \Delta\text{pH} + \Delta\psi$$

Equation 12.6: The proton motive force

$$\text{pmf} = \Delta\bar{\mu}_{\text{H}^+} / 96.5 \text{ kJ V}^{-1} \text{ mol}^{-1}$$

The final element in the chemiosmotic model is the presence in the membrane of an ATP synthase capable of using the pmf to convert ADP into ATP. This enzyme complex is oriented in the thylakoid membrane with a hydrophilic head group on the stromal side of the membrane and a hydrophobic channel that allows H⁺ ions to diffuse spontaneously from the lumen to the stroma (Fig. 12.29). The chemiosmotic model predicts a fixed stoichiometry between the number of protons transported across the membrane and the number of ATP molecules synthesized, the H⁺/ATP ratio. Most estimates

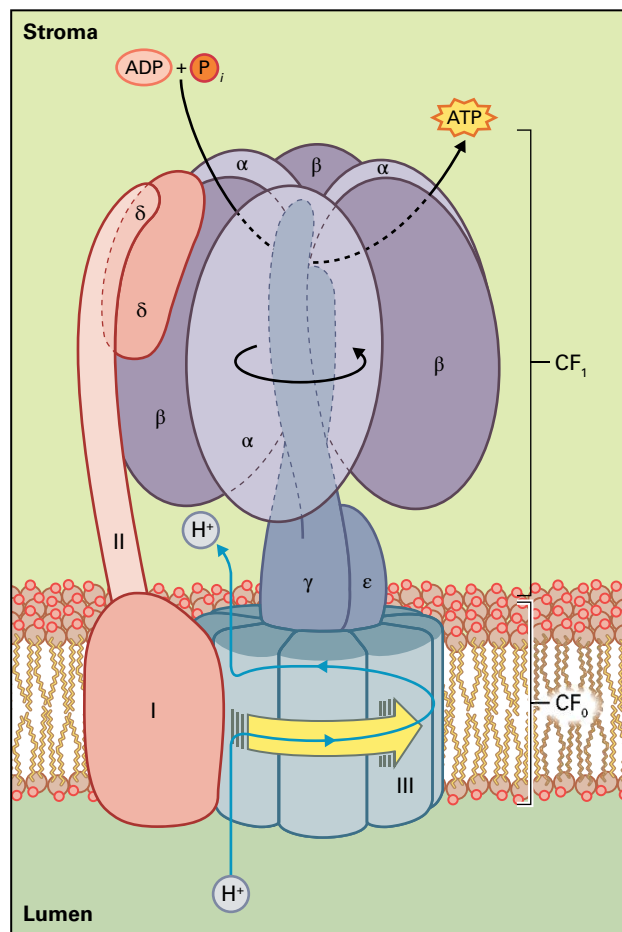

FIGURE 12.29 Model for the chloroplast ATP synthase complex. The subunit structure of the ATP synthase indicates two major regions in the protein: an integral membrane protein portion (CF_0), which functions as a channel for protons passing through the membrane, and an extrinsic portion (CF_1), which contains the catalytic sites involved in ATP synthesis. CF_1 consists of five different subunits (α , β , γ , δ , and ϵ), whereas CF_0 contains four different subunits (I, II, III, and IV, of which three are shown), including 14 copies of subunit III in the membrane.

indicate a value of $4.67 \text{ H}^+/\text{ATP}$. According to the present model of the noncyclic electron transport chain, the net transfer of two electrons through the chain results in the accumulation of six protons in the lumen. These numbers are critical in understanding proton translocation sites, as well as the energetics of ATP synthesis in chloroplasts.

The chemiosmotic model explains many observations of coupled ATP synthesis in both chloroplasts and mitochondria. For example, the coupling of phosphorylation and electron transfer can be understood as a feedback system. As the electron transport chain moves protons into the lumen, the luminal concentration of protons increases, generating a back pressure that slows further proton pumping. As the ATP synthase transports protons out of the lumen, the luminal concentration of protons decreases, relieving the back pressure and facilitating the accumulation of more protons in this space. The ability of nonphysiological uncoupling agents to

overcome this effect is easily understood: Most uncouplers are weak acids that enter the lumen in their unprotonated form and diminish the luminal H^+ concentration by binding protons. Transmembrane diffusion of these bound protons provides an alternative pathway to the reactions catalyzed by the ATP synthase. Thus electron transport proceeds at high rates in the presence of the uncoupling agent, even though no ATP is being synthesized.

The most convincing experimental result in support of the chemiosmotic model was “acid–base phosphorylation.” In this experiment, chloroplasts were first incubated at around pH 4, allowing them to establish this pH internally. The chloroplast suspension was then rapidly adjusted to pH 8 to establish an artificial pH gradient across the membrane. This gradient energized ATP synthesis until the pH difference was insufficient to drive ADP phosphorylation. Acid–base ATP synthesis required no light and was insensitive to electron transport inhibitors, such as DCMU, indicating that a pH gradient alone was sufficient to drive ATP synthesis. However, the acid–base ATP synthesis was sensitive to the addition of uncoupling agents, which affect the proton gradient directly. Subsequent research has confirmed and extended the original observations, and the chemiosmotic model is now widely accepted as the mechanism for ATP synthesis by both chloroplasts and mitochondria.

12.5.3 The thylakoid ATP synthase complex contains numerous subunits

The chemiosmotic model proposed a key role for a vectorial ATP synthase that would use the energy stored in a proton electrochemical potential for the synthesis of ATP. This enzyme was first identified on the basis of its ability to hydrolyze ATP (see F-type ATPase in Chapter 3). In native membranes, the ATPase activity of this enzyme is inactive, allowing for a unidirectional synthesis of ATP in the light. The pmf established across the thylakoid membrane in the light activates the ATP synthase and inhibits the wasteful ATPase activity of this enzyme.

The thylakoid ATP synthase consists of two segments: a transmembrane segment (CF_0) and a hydrophilic segment on the stromal surface (CF_1). CF_0 participates in translocating protons across the membrane to the catalytic portion of the enzyme, CF_1 ; CF_1 is involved in the actual conversion of ADP and P_i to yield ATP, using energy stored in the proton gradient. The enzyme is often referred to as the CF_0 – CF_1 complex (Fig. 12.29).

Chloroplast ATP synthase is a 400-kDa enzyme that contains nine different subunits (Table 12.6) and includes both chloroplast and nuclear-encoded gene products. CF_1 consists of two large subunits ($\approx 50 \text{ kDa}$), α and β , plus three smaller subunits called γ , δ , and ϵ (Fig. 12.29). CF_1 contains three copies of each of the large subunits and one copy each of the other subunits to give an overall stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$. The α and β subunits bind ADP and phosphate and catalyze

TABLE 12.6 Protein subunits of the ATP synthase complex.

Protein	Gene	Location of gene	Mol. mass (kDa)	Function
CF₁				
α Subunit	<i>atpA</i>	Chloroplast	55	Catalytic
β Subunit	<i>atpB</i>	Chloroplast	54	Catalytic
γ Subunit	<i>atpC</i>	Nucleus	36	Proton gating
δ Subunit	<i>atpD</i>	Nucleus	20	Binding CF ₁ to CF ₀
ε Subunit	<i>atpE</i>	Chloroplast	15	ATPase inhibition
CF₀				
I	<i>atpF</i>	Chloroplast	17	Binding CF ₀ to CF ₁
II	<i>atpG</i>	Nucleus	16	Binding CF ₀ to CF ₁
III	<i>atpH</i>	Chloroplast	8	Proton translocation
IV	<i>atpI</i>	Chloroplast	27	Binding CF ₀ to CF ₁

the phosphorylation of ADP into ATP. The δ subunit links CF₀ to CF₁, and the γ subunit appears to control proton gating through the enzyme. The ε subunit blocks catalysis in the dark, preventing the breakdown of ATP, and may also be involved in proton gating through interactions with the γ subunit. The γ subunit also participates in a regulatory mechanism mediated by the ferredoxin/thioredoxin system, which results in activation of ATP synthase in the light at a low pmf and deactivation of the enzyme complex in the dark, thereby blocking wasteful hydrolysis of ATP at night.

The hydrophobic CF₀ portion of ATP synthase is composed of four additional subunits, I, II, III, and IV. These subunits are present as single copies, except for subunit III, which appears to be present in 14 copies per complex in plant chloroplasts. Subunit III may form a pathway for proton translocation from the luminal space to the stroma.

12.5.4 Structural resolution of the F₁ complex from mitochondrial ATP synthase provides insight into the coupling of proton transport and ATP synthesis

Homologous enzymes involved in the synthesis of ATP have been identified in other energy-transducing membranes, such as the inner mitochondrial membrane (F₀-F₁ complex; Chapter 14) and bacterial membranes. A high-resolution structure of the F₁ portion of the mitochondrial enzyme has provided new and important structural information related

to the mechanism of ATP synthesis. An important feature of the structure is the description of the alternating α and β subunits, with the γ subunit extending up through a hydrophobic cavity of the α₃β₃ hexamer of F₁ down into the stalk region. Other low-molecular-mass subunits (δ and ε) were not resolved in the structure. The orientation of the γ subunit is consistent with its proposed role, wherein this subunit transmits the energy of the proton gradient to the catalytic sites for ATP synthesis that are localized on the α and β subunits.

The most widely accepted mechanism of ATP synthesis is the **binding change mechanism** (Fig. 12.30). In this mechanism, conformational changes in the protein are critical and the energy stored in the proton gradient is not directly used to drive the synthesis of ATP in a classical sense; rather, it is used to release a tightly bound form of ATP from its catalytic binding site on the enzyme. The CF₁ portion of the enzyme has three nucleotide binding sites, each of which can exist in one of three conformational states: a loose nucleotide binding (L), a tight nucleotide binding (T), and an open binding site (O), which is free of nucleotides. At any time, all three states are present in the CF₁ complex, each associated with one of the three catalytic centers present in the enzyme. According to the binding change mechanism, ADP and P_i initially bind to an unoccupied site in the open state. As protons move from the lumen to the stromal region through the CF₀ channel, energy is released that results in a rotation of the γ subunit of CF₁, and this rotation causes conformational changes in the three nucleotide binding sites. The T site, which contains bound ATP, is converted to an O site as the ATP is released, while the L site (containing the bound ADP and P_i) is converted into a T site, where the formation of ATP is favored.

FIGURE 12.30 Binding change mechanism of ATP synthesis by the CF_0 - CF_1 complex. Three nucleotide-binding sites are shown on the enzyme—the O-site (open), available to bind ADP and P_i ; the L-site (loose), in which ADP and P_i are loosely bound; and the T-site, a tight nucleotide-binding site where ATP is formed. The movement of protons across the membrane drives rotation of the γ subunit in the enzyme, causing conformation changes that interconvert the three sites.

Evidence from several laboratories supports the binding change mechanism, based on observations of the rotation of the γ subunit within the complex. Assuming one proton is transferred per copy of subunit III, the passage of 14 protons would allow a full rotation of the γ subunit and release 3 ATP molecules. Thus, the structure of the chloroplast ATP synthase suggests a H^+ /ATP ratio of 4.67.

12.6 Organization and regulation of photosynthetic complexes

12.6.1 Protein complexes of the thylakoid membrane exhibit lateral heterogeneity and variable stoichiometry

Two types of internal membranes are present in the chloroplast: stacked or appressed thylakoid membranes (grana) and exposed or unstacked membranes (stromal thylakoids) (see Fig. 12.1). An important organizational feature of thylakoids in plants and green algae is that PSI and PSII are not distributed randomly throughout the membrane system: PSI lies primarily in the unstacked and stroma-exposed membranes, whereas PSII is found mostly in the appressed (stacked or granal) membranes (Fig. 12.31).

FIGURE 12.31 Lateral heterogeneity of the chloroplast membrane complexes. PSII is localized primarily in the stacked membrane regions of the thylakoid membrane, whereas PSI and ATP synthase are almost exclusively localized in the stroma-exposed membrane regions. The cytochrome b_6f complex is distributed evenly throughout the membrane regions. The separation of the photosystems necessitates mobile electron carriers such as plastoquinone and plastocyanin, which shuttle electrons between the spatially separated membrane complexes.

TABLE 12.7 Distribution of photosynthetic components in chloroplast membrane regions.

Component	Thylakoids (%)	
	Appressed	Stroma exposed
PSII	85	15
PSI	10	90
Cytochrome b_6f complex	50	50
LHCII	90	10
ATP synthase	0	100
Plastocyanin*	40	60

* Percentages indicate relative distribution of each component in either appressed or stroma-exposed thylakoid membranes, except in the case of plastocyanin, where localization refers to the lumen of the respective membrane region.

Other protein complexes integral to the thylakoid membrane are also distributed unequally among these two membrane domains (Table 12.7). For example, the ATP synthase is located almost entirely in the stroma-exposed membrane. Even soluble electron transfer proteins such as plastocyanin are distributed unequally within granal and stromal regions of the continuous thylakoid lumen. This **lateral heterogeneity** indicates that the two photosystems, which cooperate in

transferring electrons from H_2O to $NADP^+$ in the electron transport chain, are spatially separated from each other. According to this model, mechanisms for long-distance electron transfer must exist. Note that not all membrane-bound proteins are distributed unequally in the thylakoid. The cytochrome b_6f complex, which transfers electrons between the two photosystems, is distributed evenly (Fig. 12.31).

The concept that PSII and PSI cooperate in the noncyclic transport of electrons from water to $NADP^+$ led to the expectation that the two photosystems would be present in equal amounts in thylakoid membranes. Experimental evidence, however, has not supported this prediction. The ratio of PSII to PSI (photosystem stoichiometry) can vary between 0.4 and 1.7 among various wild-type photosynthetic organisms, such as green and red algae, cyanobacteria, and plants, and the ratio in mutants may vary even more. Photosystem stoichiometry can also be regulated by light quality, demonstrating the ability of the photosynthetic organisms to alter their membrane composition in response to gradients of light quality, such as those observed in a forest canopy or in aquatic environments.

12.6.2 Phosphorylation of LHCII influences the distribution of energy between PSI and PSII

LHCII, the light-harvesting protein complex that functions as a peripheral antenna for PSII, is found almost exclusively in grana (see Table 12.7). Extensive stacking of membranes correlates with the presence of LHCII. Chloroplasts from some mutant plants lacking LHCII have greatly reduced stacking but remain photosynthetically competent. The function of membrane stacking in chloroplasts may be related to the efficient distribution of light energy between PSI and PSII complexes. Because balanced excitation of both photosystems is required for maximum electron transport efficiency, it is critical that one photosystem does not receive preferential photon delivery. The spatial separation of the two photosystems may aid in this regulation. In addition, chloroplasts are able to adjust LHCII association with PSII to regulate distribution of quanta between the photosystems.

A small pool of the total LHCII undergoes reversible phosphorylation in the light. Phosphorylation of LHCII changes the surface charge on the protein. After phosphorylation, LHCII molecules become negatively charged and are displaced from the hydrophobic core of the granal stacks to the less hydrophobic, exposed stromal membrane region. This migration of a portion of the PSII antenna complex decreases light absorption by PSII in the granal membrane by decreasing the antenna associated with PSII (Fig. 12.32).

The most widely accepted model for how chloroplasts sense an imbalance in excitation and phosphorylate LHCII in response involves a redox-activated kinase, STN7. STN7 is activated only when the pool of plastoquinone, a mobile

FIGURE 12.32 Phosphorylation of LHCII controls energy distribution. Excess excitation of PSII relative to PSI increases the level of reduced plastoquinone, which activates a kinase that phosphorylates LHCII. This results in a partial unstacking of the membranes because of electrostatic repulsion of negatively charged LHCII molecules and a migration of some phosphorylated LHCII from the stacked membrane region to the unstacked membrane region, where it can associate with PSI. This effectively reduces the PSII antenna size and favors absorption of quanta by PSI. Excessive PSI activation results in plastoquinol oxidation and kinase de-activation. A phosphatase is able to hydrolyze the phosphate group of LHCII, allowing it to migrate back to the more hydrophobic environment of the stacked membrane region. This mechanism allows for adjustment of the relative excitation of PSI and PSII.

electron carrier that shuttles electrons between PSII and the cytochrome *b₆f* complex, is in a highly reduced state (see Section 12.4). When PSII receives more light than PSI, plastoquinone becomes predominantly reduced, resulting in activation of the LHCII kinase. The kinase phosphorylates LHCII, resulting in migration of LHCII away from the granal region where it can associate with PSI, thereby adjusting the relative excitation of PSII and PSI. As plastoquinone becomes more oxidized by PSI activation, the kinase becomes less active and a phosphatase acts to dephosphorylate LHCII, allowing it to migrate back to the granal membrane, thereby increasing the amount of light absorbed by PSII. This feedback system allows for a subtle control of light distribution between the two photosystems, even though they lie in different parts of the thylakoid (Fig. 12.32).

12.6.3 Light harvesting is regulated by nonphotochemical quenching processes that dissipate excess light energy

Under the high light intensities found in nature, plants may absorb more light energy than they can use for photosynthesis. This excessive excitation of chlorophylls can increase formation of the triplet state of chlorophyll and the singlet state of oxygen (see Section 12.2). Damage caused by singlet oxygen and its reactive products can decrease the efficiency of photosynthesis in a process known as **photoinhibition** (see Box 10.8).

All oxygenic photoautotrophs regulate light harvesting to protect against photoinhibition when light is in excess. In plants, various **nonphotochemical quenching** (NPQ) processes act as safety valves for photosynthesis that dissipate excess absorbed light energy harmlessly as heat (Fig. 12.33). NPQ results in de-excitation of the singlet state of chlorophyll in the antenna of PSII, and it is routinely measured using

chlorophyll fluorescence (Box 12.2). In addition to their photoprotective roles in quenching triplet chlorophyll and singlet oxygen, specific carotenoids (e.g., zeaxanthin and lutein) have been implicated in NPQ.

Several components of NPQ occur with different induction and relaxation kinetics. A flexible, rapidly reversible type of NPQ is induced by the buildup of a high thylakoid Δ pH in the presence of excess light. The resulting low pH in the thylakoid lumen activates an enzyme (violaxanthin de-epoxidase) that converts violaxanthin into zeaxanthin (see Fig. 12.7), and it also leads to protonation of a membrane protein (PSBS) that promotes a dissipative state of LHC proteins in the PSII antenna (Fig. 12.33). This is the major form of NPQ that regulates light harvesting in natural, fluctuating light, and mutants that lack flexible NPQ exhibit decreased fitness. Sustained types of NPQ are more prominent in some plants that experience chronic excess light on a seasonal basis (e.g., overwintering evergreens).

12.7 Carbon reactions: the Calvin–Benson cycle

12.7.1 The Calvin–Benson cycle in the chloroplast stroma utilizes the energy stored in the thylakoid membranes for the assimilation of atmospheric CO₂

Conversion of inorganic carbon into carbon skeletons of organic material (autotrophy) is required for building all the molecules necessary for life (Box 12.3). In plants, light energy drives the oxidation of water, which produces molecular oxygen (O₂) in thylakoid membranes and yields ATP, reduced ferredoxin, and reduced pyridine nucleotide (NADPH). The

FIGURE 12.33 Nonphotochemical quenching regulates light harvesting by PSII. In limiting light, LHC proteins efficiently transfer excitation energy to the reaction center of PSII. In excess light, when the rate of photosynthesis is saturated and protons accumulate to a high concentration in the thylakoid lumen, a flexible type of nonradiative dissipation is induced in the PSII antenna on a timescale of seconds to minutes. Proton binding to the PSBS protein and accumulation of zeaxanthin (not shown) causes a conformational change or reorganization of PSII that switches the antenna into a dissipative state that prevents overexcitation of chlorophyll and overreduction of the electron transport chain.

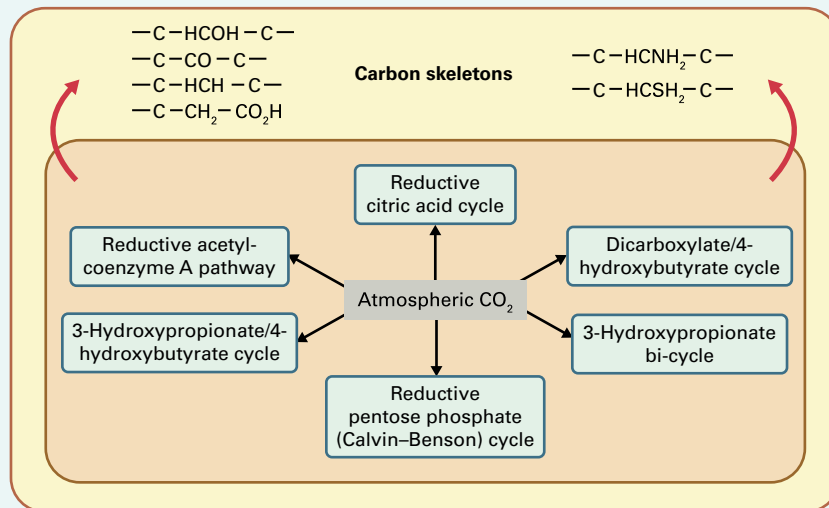

BOX
12.3

Autotrophy is the transition from the inorganic to the organic world

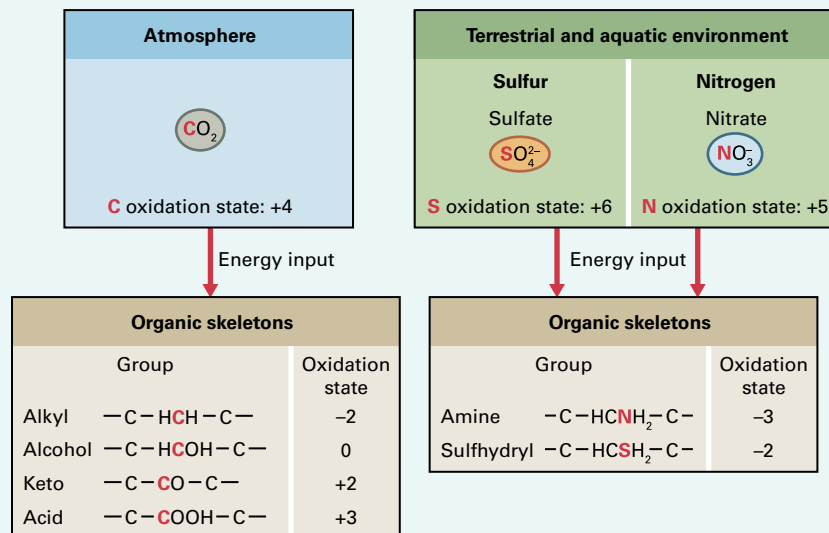

All the organic carbon found in living organisms ultimately comes from inorganic sources, such as gaseous CO_2 and soluble and insoluble HCO_3^- and CO_3^{2-} , the distribution of which in the biosphere depends on environmental parameters, such as temperature, pH, and pressure. Land and marine organisms and many specialized microbes developed the ability to use inorganic carbon as the sole source for building up the organic molecules required to sustain cell metabolism (A). This process, autotrophy, requires a constant flux of energy for converting carbon and other elements from the high oxidation state they hold in the environment (CO_2 : +4) to the low oxidation states of organic molecules that participate in cell metabolism ($-\text{CO}_2\text{H}$: +3; $-\text{CO}-$: +2; $-\text{CHO}$: +1; $-\text{CHOH}-$: 0; $-\text{CH}_2\text{OH}$: -1; $-\text{CH}_2-$: -2; $-\text{CH}_3$: -3; CH_4 : -4) (B).

Two environmental sources provide the energy that sustains autotrophy: chemical compounds (used by chemoautotrophs) and light (used by photoautotrophs). Membrane protein complexes channel the external energy for driving the endergonic flow of electrons. Subsequently, the reducing power is used for the transformation of chemical bonds catalyzed by specific enzymes.

Assimilation of CO_2 proceeds through six different pathways (A): the reductive acetyl-CoA pathway, reductive citric acid cycle (reverse citric acid cycle), dicarboxylate/4-hydroxybutyrate cycle, 3-hydroxypropionate bi-cycle, 3-hydroxypropionate/4-hydroxybutyrate cycle, and reductive pentose phosphate cycle (Calvin-Benson cycle). The former five autotrophic pathways function in prokaryotes and yield acetyl-coenzyme A or pyruvate at

A

B

early stages of CO₂ fixation. Large organic molecules are subsequently built up through unique gluconeogenic pathways. There is renewed interest in these pathways for improving oxygenic photosynthesis through synthetic biology.

The remaining pathway for CO₂ fixation—the reductive pentose phosphate cycle (Calvin–Benson cycle or C₃ pathway)—constitutes the major aerobic mechanism for the formation of biomass (i.e., synthesis of structural and storage polysaccharides). The Calvin–Benson cycle is

used for CO₂ assimilation by many chemo- and photoautotrophic prokaryotes and all photoautotrophic eukaryotes.

Autotrophy. (A) CO₂ assimilation in the biosphere through autotrophic pathways. Atmospheric CO₂ is the building block for carbon skeletons in autotrophic organisms. (B) Oxidation state of carbon, nitrogen and sulfur in the biosphere. The oxidation state of these elements decreases when they are transferred from the environment to the organic molecules of living organisms.

FIGURE 12.34 Three phases of the Calvin–Benson cycle: carboxylation, reduction, and regeneration. Overall, the fixation of three molecules of CO₂ into one molecule of triose phosphate requires six molecules of NADPH and nine of ATP (3 CO₂: 6 NADPH: 9 ATP ≡ CO₂: 2 NADPH: 3 ATP). The net glyceraldehyde 3-phosphate (GAP) formed is utilized either for immediate metabolic needs or converted to a storage form of carbohydrate—starch in the chloroplast or sucrose in the cytosol. 3-PGA, 3-phosphoglycerate.

ATP and NADPH released in the chloroplast stroma are used for the conversion of atmospheric CO₂ to carbohydrates.

The pathway by which this conversion occurs, the Calvin–Benson cycle, is crucial for sustaining most life forms. It was discovered in the 1950s, in experiments in which illuminated green algae (*Chlorella*, *Scenedesmus*) were pulsed with ¹⁴CO₂ and sampled at short intervals by injecting the cell suspensions into boiling alcohol. The ¹⁴C-containing compounds were successively separated by two-dimensional paper chromatography, detected by autoradiography, and analyzed for the exact position of the ¹⁴C label by co-chromatography and degrading the isolated intermediates. The presence of the enzyme activities needed for the photosynthetic CO₂ assimilation in green algae validated the predicted pathway. Some

photosynthetic prokaryotes (photosynthetic bacteria, cyanobacteria) and all photosynthetic eukaryotes (algae and plants) fix CO₂ into biomass using the Calvin–Benson cycle (Box 12.3).

12.7.2 The Calvin–Benson cycle proceeds through 13 biochemical reactions

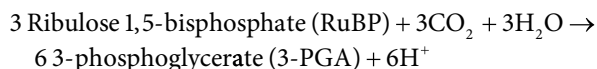

The Calvin–Benson cycle proceeds through 13 biochemical reactions that can be analyzed separately in three highly coordinated phases: carboxylation, reduction, and regeneration (Figs. 12.34 and 12.35).

- Carboxylation of the CO₂-acceptor molecule: ribulose 1,5-bisphosphate (RuBP; five-carbon acceptor molecule) reacts with one molecule each of CO₂ and water to yield two molecules of 3-phosphoglycerate (3-PGA) in the first enzymatic step of the cycle (see Section 12.7.3).
- Reduction of 3-PGA: Photochemically generated ATP and NADPH (see Section 12.4.1) are used in two enzymatic reactions for the reduction of 3-PGA to glyceraldehyde 3-phosphate (GAP) (see Section 12.7.4).
- Regeneration of RuBP: The regeneration of the CO₂ acceptor RuBP closes the cycle through ten enzyme-catalyzed reactions, one requiring ATP (see Section 12.7.5).

12.7.3 Carboxylation of RuBP is the first committed reaction of the Calvin–Benson cycle

In the carboxylation phase, three molecules of CO₂ and three molecules of H₂O react with three molecules of RuBP to produce six molecules of 3-PGA (Reaction 12.12, Fig. 12.35). The enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) catalyzes these reactions (see Section 12.8). Plants that form 3-PGA (a three-carbon molecule) as the first stable compound after feeding with ¹⁴CO₂ in the light are called **C₃ plants**.

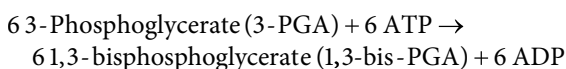

Reaction 12.12: Ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco)

12.7.4 Reduction of 3-PGA follows CO₂ fixation and employs products of the light reactions

The reductive phase of the Calvin–Benson cycle converts the six molecules of 3-PGA coming from the carboxylation stage into six molecules of GAP (Fig. 12.35). This two-step process employs ATP and NADPH, the products of the light reactions. First, the enzyme 3-phosphoglycerate kinase (Reaction 12.13) catalyzes the reaction of ATP with the carboxyl group of 3-PGA, yielding the mixed anhydride 1,3-bisphosphoglycerate (1,3-bis-PGA). Next, NADPH converts 1,3-bis-PGA to GAP and inorganic phosphate (P_i) in a reaction catalyzed by the chloroplast enzyme NADP–glyceraldehyde-3-phosphate dehydrogenase (NADP–GAPD; Reaction 12.14).

Reaction 12.13: 3-phosphoglycerate kinase

Reaction 12.14: NADP–glyceraldehyde-3-phosphate dehydrogenase (NADP–GAPD)

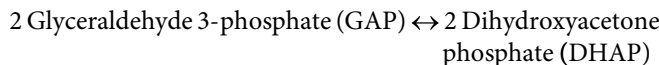

12.7.5 Regeneration of RuBP is necessary for continuous operation of the Calvin–Benson cycle

One of the six molecules of GAP (1 molecule × 3 carbons/molecule = 3 carbons) accounts for the net fixation of three molecules of CO₂ (3 molecules × 1 carbon/molecule = 3 carbons) and represents the newly formed photosynthetic product. The other five molecules of GAP (5 molecules × 3 carbons/molecule = 15 carbons) enter the last and largest set of reactions to regenerate three molecules of RuBP (3 molecules × 5 carbons/molecule = 15 carbons) and allow continuous uptake of atmospheric CO₂.

Ten of the 13 enzymes of the Calvin–Benson cycle catalyze the reshuffling of the carbons from five molecules of GAP to form three molecules of RuBP (Reactions 12.15–12.24, Fig. 12.35):

- Triose phosphate isomerase catalyzes the conversion of two molecules of GAP into two molecules of DHAP (Reaction 12.15). Together, GAP and DHAP are referred to as triose phosphate.

Reaction 12.15: Triose phosphate isomerase

- Aldolase catalyzes the aldol condensation of a third molecule of GAP with one molecule of DHAP, yielding the six-carbon sugar fructose 1,6-bisphosphate (FBP) (Reaction 12.16).

Reaction 12.16: Aldolase

- FBP is hydrolyzed to the sugar monophosphate fructose 6-phosphate (F 6-P) in a reaction catalyzed by a specific chloroplast fructose-1,6-bisphosphatase (Reaction 12.17).

Reaction 12.17: Fructose-1,6-bisphosphatase

- The F6-P molecule donates a two-carbon unit (C₁ and C₂) to a fourth molecule of GAP via the enzyme transketolase,

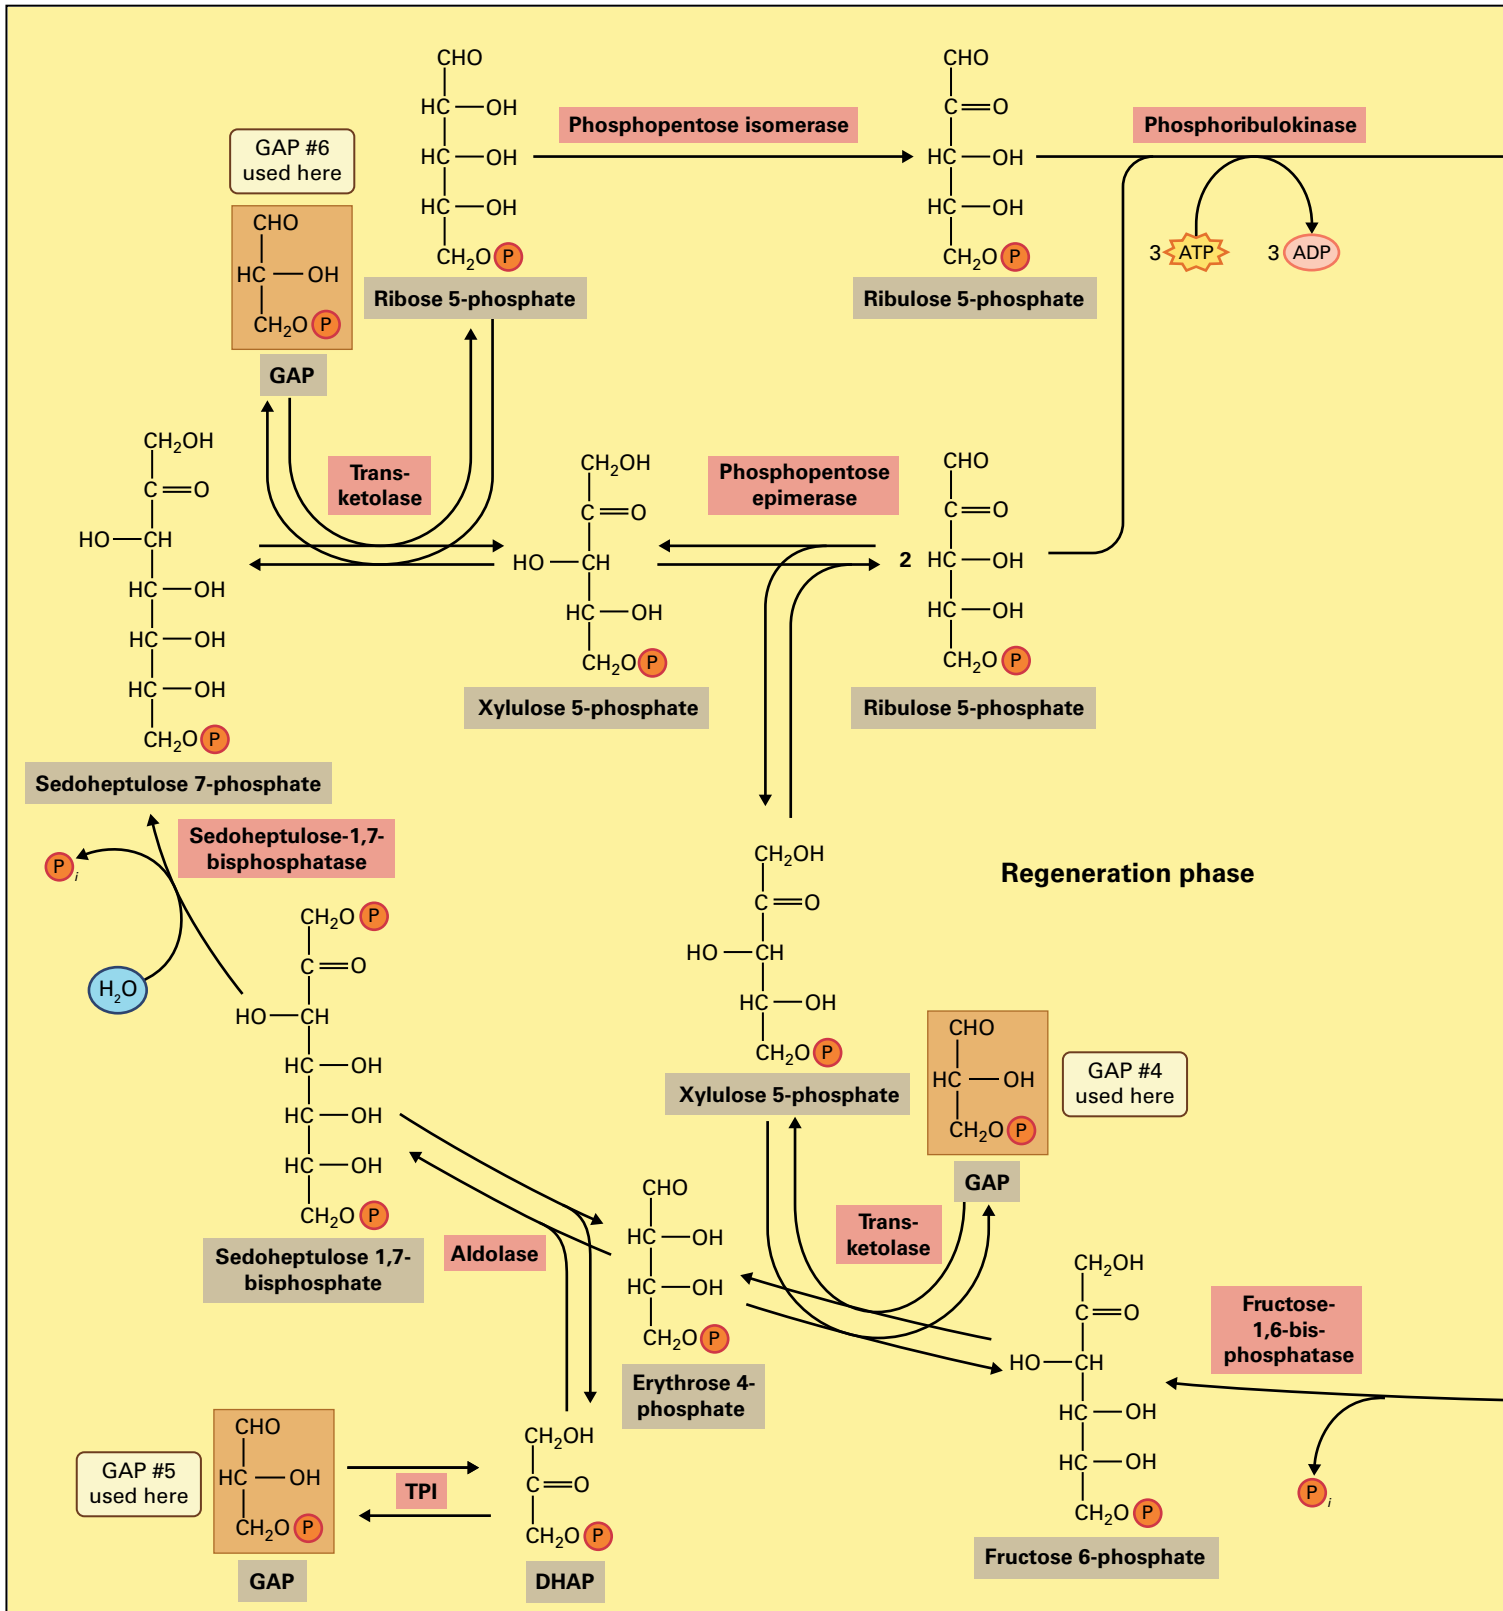

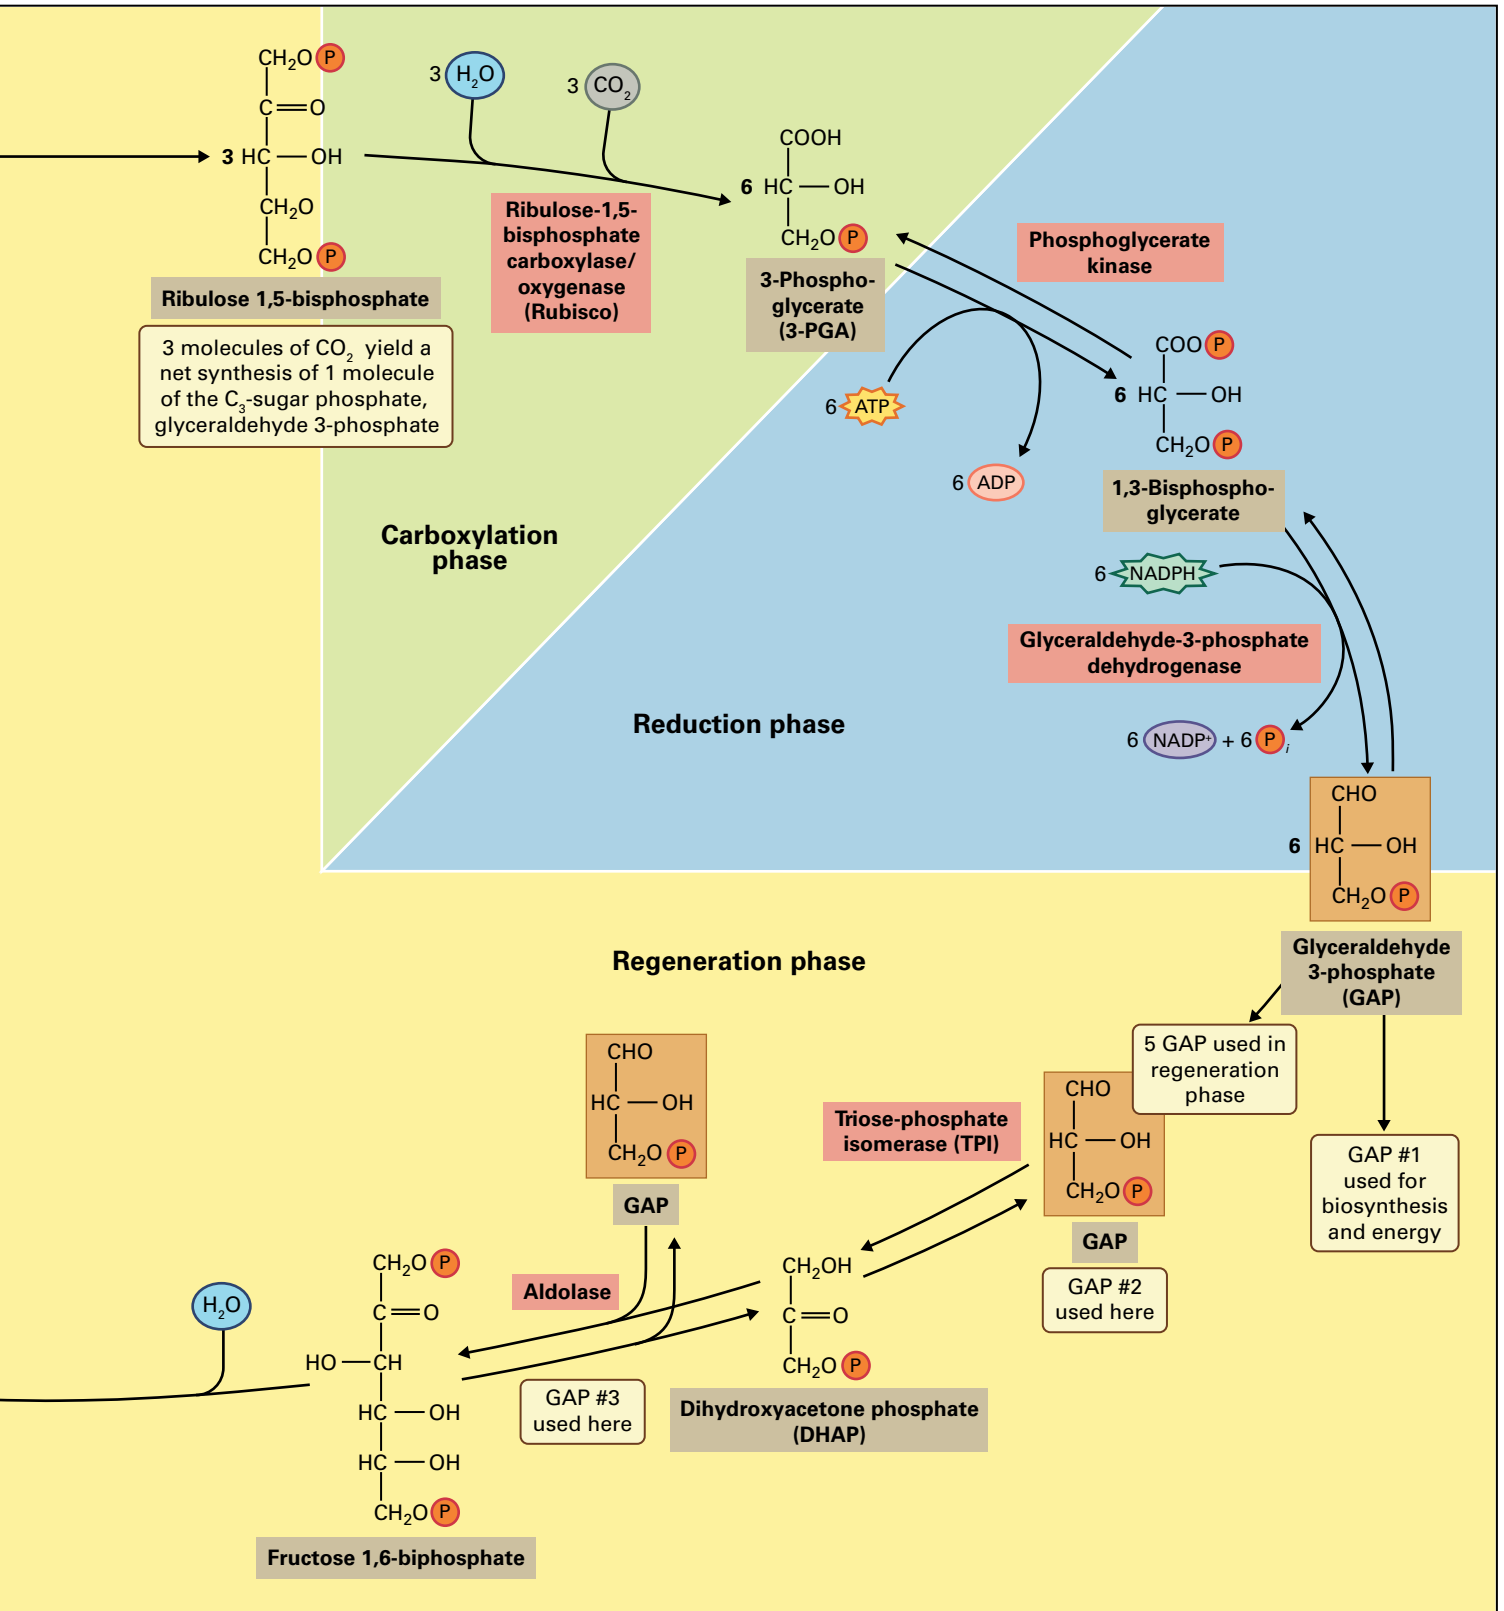

FIGURE 12.35 Individual reactions of the Calvin-Benson cycle.

yielding xylulose 5-phosphate (Xu 5-P). The other four carbons of the F6-P molecule (C_3 , C_4 , C_5 , and C_6) form erythrose 4-phosphate (E4-P) (Reaction 12.18).

Reaction 12.18: Transketolase

Fructose 6-phosphate (F 6-P) + Glyceraldehyde 3-phosphate (GAP) \rightarrow Erythrose 4-phosphate (E4-P) + Xylulose 5-phosphate

- E4-P combines, via aldolase, with the remaining molecule of DHAP to yield the seven-carbon sugar bisphosphate sedoheptulose 1,7-bisphosphate (SBP) (Reaction 12.19).

Reaction 12.19: Aldolase

Erythrose 4-phosphate (E4-P) + Dihydroxyacetone phosphate (DHAP) \rightarrow Sedoheptulose 1,7-bisphosphate (SBP)

- SBP is hydrolyzed to the respective sugar monophosphate sedoheptulose 7-phosphate (S7-P) by a specific chloroplast sedoheptulose-1,7-bisphosphatase (Reaction 12.20).

Reaction 12.20: Sedoheptulose-1,7-bisphosphatase

Sedoheptulose 1,7-bisphosphate (SBP) + H_2O \rightarrow Sedoheptulose 7-phosphate (S7-P) + P_i

- A two-carbon unit of S7-P (C_1 and C_2) is transferred to the fifth (and last) molecule of GAP, via transketolase, producing a second molecule of Xu 5-P. The remaining five carbons (C_3 , C_4 , C_5 , C_6 , and C_7) of the S7-P molecule yield ribose 5-phosphate (R 5-P) (Reaction 12.21).

Reaction 12.21: Transketolase

Sedoheptulose 7-phosphate (S7-P) + Glyceraldehyde 3-phosphate (GAP) \rightarrow Ribose 5-phosphate (R 5-P) + Xylulose 5-phosphate (Xu 5-P)

- Ribulose 5-phosphate epimerase catalyzes the transformation of two molecules of Xu 5-P in two molecules of ribulose 5-phosphate (Ru 5-P) (Reaction 12.22).

Reaction 12.22: Ribulose-5-phosphate epimerase

2 Xylulose 5-phosphate (Xu 5-P) \rightarrow 2 Ribulose 5-phosphate (Ru 5-P)

- Ribose-5-phosphate isomerase catalyzes the conversion of R 5-P into a third molecule of Ru 5-P (Reaction 12.23).

Reaction 12.23: Ribose-5-phosphate isomerase

Ribose 5-phosphate (R 5-P) \rightarrow Ribulose 5-phosphate (Ru 5-P)

- Finally, three additional molecules of ATP phosphorylate the three molecules of Ru 5-P, forming three molecules of RuBP in the reaction catalyzed by phosphoribulokinase (PRK) (also called ribulose-5-phosphate kinase) (Reaction 12.24).

Reaction 12.24: Phosphoribulokinase (PRK)

3 Ribulose 5-phosphate (Ru 5-P) + 3 ATP \rightarrow
3 Ribulose 1,5-bisphosphate (RuBP) + 3 ADP + 3 H^+
Net: 3 CO_2 + 5 H_2O + 6 NADPH + 9 ATP \rightarrow
Glyceraldehyde 3-phosphate (GAP) + 6 NADP $^+$
+ 3 H^+ + 9 ADP + 8 P_i

In summary, the addition of three molecules of CO_2 to three molecules of the five-carbon sugar RuBP yields six molecules of 3-PGA, which in turn generate six molecules of GAP after successive phosphorylation and reduction with six molecules of ATP and six molecules of NADPH, respectively. Five molecules of GAP and three additional molecules of ATP regenerate the three molecules of RuBP that set the Calvin–Benson cycle for another turn of CO_2 fixation. The remaining molecule of GAP formed in the carboxylation and reduction phases of the Calvin–Benson cycle constitutes the net product of carbon fixation that plants use to build storage carbohydrates and other cellular constituents (Fig. 12.35).

12.8 Rubisco

Rubisco, the predominant protein in plant leaves, catalyzes the initial reaction of the Calvin–Benson cycle, the carboxylation of RuBP. In addition, Rubisco catalyzes a competing oxygenation reaction (**photorespiration**, see Sections 12.8.3 and 14.8.2), which reduces the efficiency of photosynthetic carbon fixation. This section describes the structure of Rubisco and mechanisms of its catalysis and regulation.

12.8.1 Four distinct forms of Rubisco are found in nature

Enzyme analyses and genome sequencing projects have revealed distinct forms of Rubisco that are present in organisms that fix CO_2 , as well as in microorganisms that do not use CO_2 as a major carbon source. From a comparison of primary structures, four forms of Rubisco have been identified with different arrangements of large subunits (L, ≈ 50 kDa) and small subunits (S, ≈ 15 kDa) (Table 12.8). Homodimers of the catalytic large subunits are the common unit to all forms. Forms I, II, and III are catalytically competent, while members of form IV lack Rubisco activity and play other roles in metabolism.

Form I is found in most autotrophic organisms. Contributing up to 50% of soluble leaf protein, it is the predominant protein in plant leaves. Its high levels in the photosynthesizing cells of plants and its presence in phytoplankton,

which provide more than 45% of global net primary production annually, make Form I the most abundant protein on earth. Owing to its abundance and importance in plant photosynthesis, we restrict our analysis to aspects of molecular biology and biochemistry of Form I.

Form I is the only type of Rubisco that harbors small subunits, and it consists of eight large and eight small subunits [L_8S_8]: Four dimers of large subunits [L_2]₄ capped by four small subunits at the top and the bottom [S_4]₂ build the hexadecameric structure $\{[S_4] \cdot [L_2]_4 \cdot [S_4] = L_8S_8\}$. Although the hexadecameric L_8S_8 is confined to chloroplasts in photosynthetic eukaryotes, the biosynthesis and assembly of the constituent subunits follow different pathways (Table 12.9). The *rbcL* gene encoding the large subunit is in the plastid genome

of algae and land plants, whereas it is in the nucleus in dinoflagellates. The *rbcS* gene that encodes the small subunit is located in the plastid genome of red and brown algae. In the green lineage of photosynthetic eukaryotes (green algae and land plants), the *rbcS* gene is in the nucleus, and so the latter small subunit is expressed as a pre-protein that translocates to the chloroplast, where its transit peptide is cleaved at the chloroplast envelope prior to assembly with the large subunit into the hexadecameric L_8S_8 . In plants, a suite of nuclear and chloroplast factors modulate the gene expression of chloroplast and nuclear DNA at the posttranscriptional, translational, and posttranslational levels.

TABLE 12.8 Different forms of Rubisco.

Form	Quaternary Structure	Organism(s)
I	L_8S_8	Plants, algae, proteobacteria, cyanobacteria
II	$(L_2)_n$	Proteobacteria, dinoflagellates
III	$(L_2)_n; (L_2)_5$	Archaea
IV	L_2	Proteobacteria, cyanobacteria, archaea, algae

TABLE 12.9 Subcellular localization of DNA encoding eukaryotic Rubisco.

Organism	Quaternary Structure	Subunits	
		Large	Small
Plants, green algae	L_8S_8	Chloroplast	Nucleus
Red and brown algae	L_8S_8	Chloroplast	Chloroplast
Dinoflagellates	L_2	Nucleus	–

12.8.2 The assembly of Rubisco requires molecular chaperones

A conserved nuclear encoded protein (MRL1), found in green algae and plants, regulates biogenesis of Form I (L_8S_8) Rubisco at a posttranscriptional stage through accumulation of the large subunit (L) mRNA. Moreover, prior to formation of L_8S_8 Rubisco, three main processes involving molecular chaperones prevent the misalignment and off-pathway aggregation of large subunits (Fig. 12.36).

12.8.3 Rubisco also functions as an oxygenase

In addition to its role as a carboxylase, Rubisco has an oxygenase activity that uses O_2 as a substrate instead of CO_2 to produce 3-PGA and the two-carbon molecule, 2-phosphoglycolate (Fig. 12.37). All Rubisco enzymes characterized thus far can act as oxygenases, even those isolated from obligately anaerobic prokaryotes that cannot grow in the presence of O_2 . This indicates the oxygenase activity is intrinsic to Rubisco.

The two substrates, CO_2 and O_2 , compete for the same active site on the enzyme, and the activity of the enzyme toward these substrates is dictated by the relative amounts of O_2 and CO_2 in the environment. In air, the carboxylation reaction proceeds approximately three times faster than the oxygenation reaction; the oxygenase activity, however, proceeds at a rate that can have profound effects on the overall

FIGURE 12.36 Chaperones assist the assembly of Rubisco subunits. (1) Chaperonins GroEL and GroES sequester and ensure the correct folding of the newly synthesized large subunit (L). (2) The assembly chaperone (RbcX)₂ binds the large subunit and provides positional information for proper association of large subunit dimers to form the $L_8-((RbcX)_2)_8$ complex. (3) The small subunit (S) associates with $L_8-((RbcX)_2)_8$, triggering a conformational change in RbcL and eliciting (4) the release of (RbcX)₂ and formation of the catalytically mature Rubisco holoenzyme $[L]_8-[S]_8$.

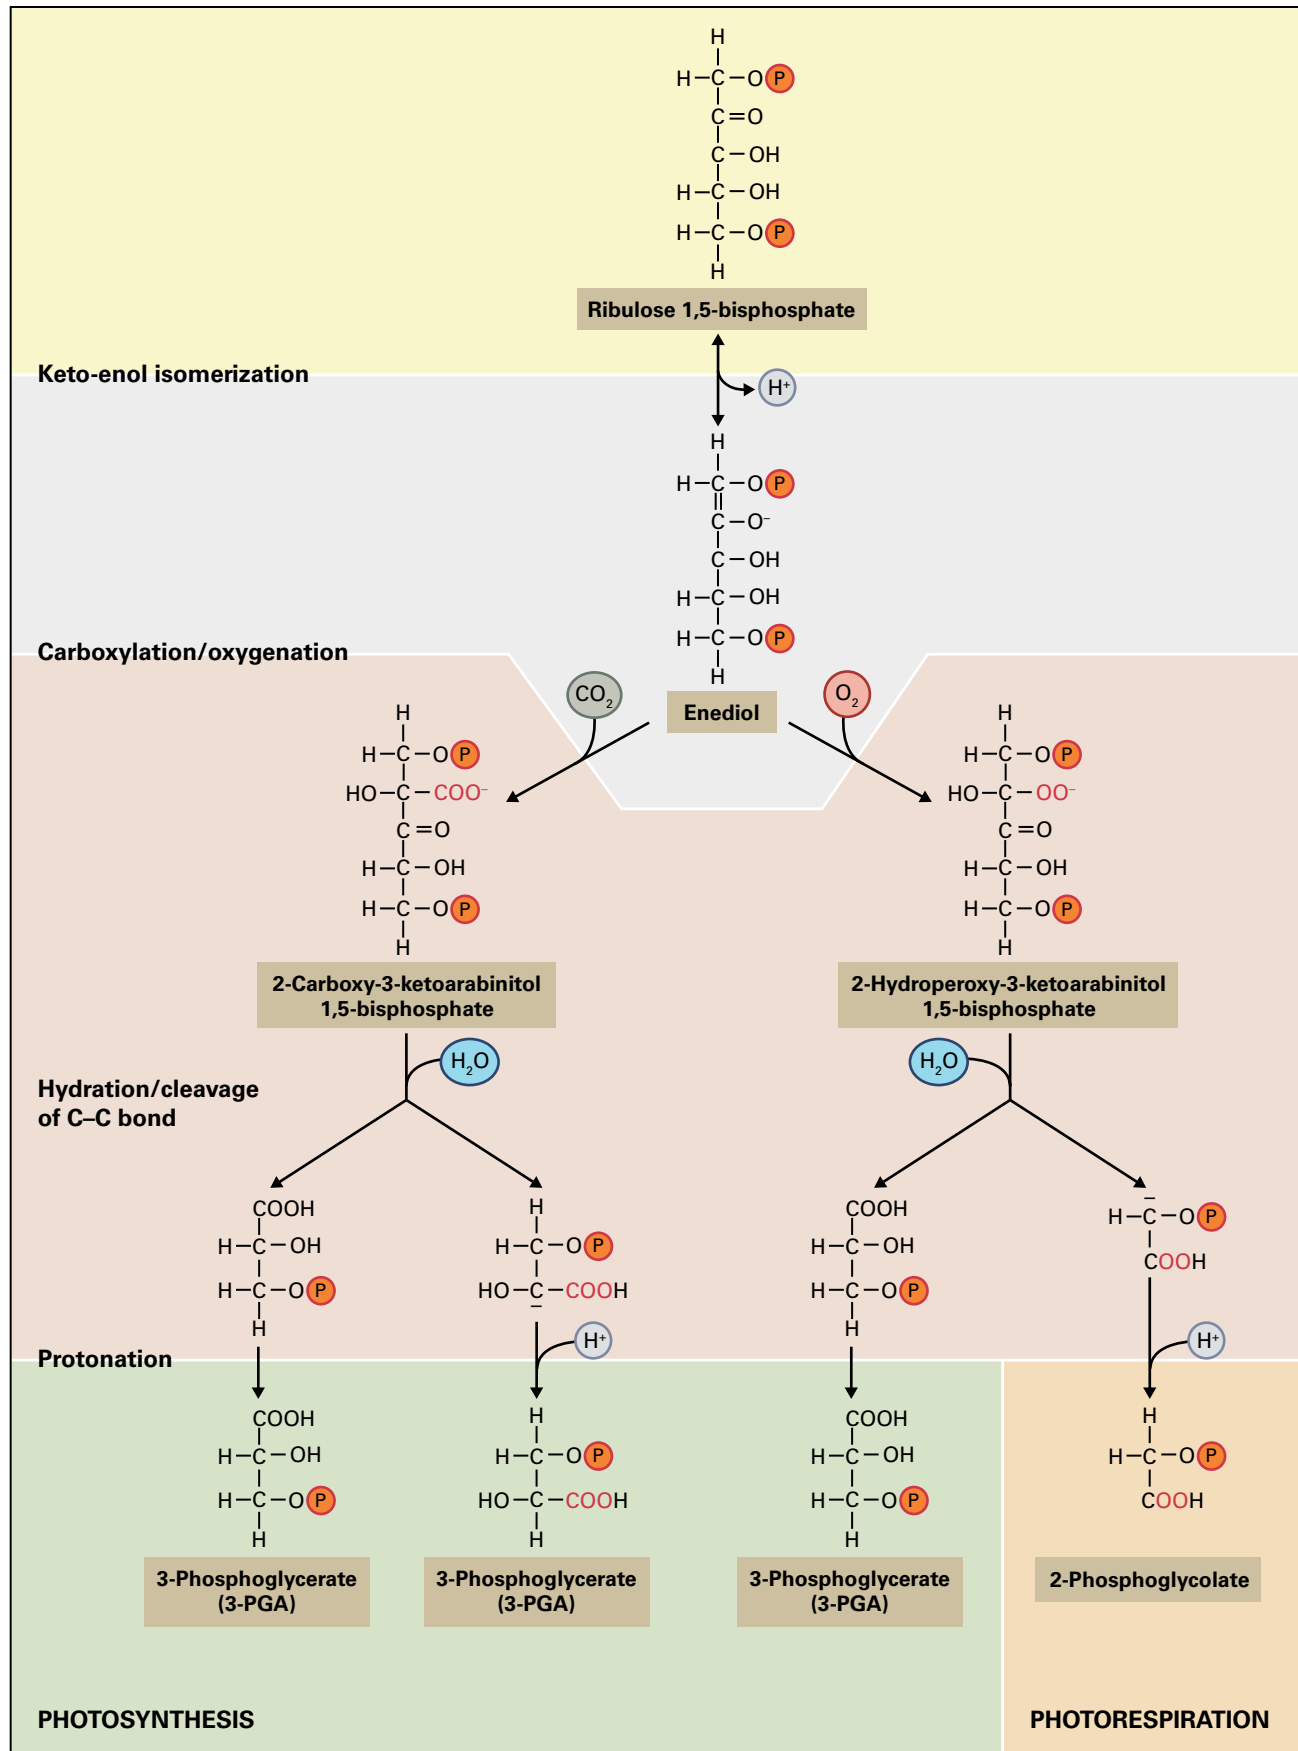

FIGURE 12.37 Rubisco-mediated carboxylation or oxygenation of RuBP. The 3-PGA and 2-phosphoglycolate formed are metabolized through the Calvin-Benson cycle and the C_2 oxidative photosynthetic carbon cycle, respectively.

efficiency of CO₂ fixation in C₃ plants: in some cases, an estimated 50% of CO₂ fixed via photosynthesis is lost through this process of photorespiration (see Section 14.8).

12.8.4 Rubisco catalyzes carboxylation or oxygenation in five steps

The active form of Rubisco catalyzes carboxylation or oxygenation reactions in five steps that involve intermediates of variable stability (Fig. 12.37):

- 1 Enolization of RuBP: Carbamylated Rubisco with bound Mg²⁺ binds to and attracts a proton from the C₃ of RuBP, yielding the 2,3-enediolate form of RuBP linked to Rubisco (the five-carbon-enediol–Rubisco complex) (see Section 12.9.3).
- 2 Carboxylation or oxygenation of the 2,3-enediolate: Addition of gaseous CO₂ (or O₂) to the unstable Rubisco-bound enediolate intermediate discriminates the carboxylase and oxygenase activities. The competing reactions—carboxylase and oxygenase—are an inevitable consequence of the enzyme mechanism, because both CO₂ and O₂ react with the 2,3-enediolate form of RuBP bound to the active site of Rubisco. CO₂ and O₂ yield 2-carboxy-3-ketoarabinitol 1,5-bisphosphate (carboxylase activity) and 2-peroxy-3-ketoarabinitol 1,5-bisphosphate (oxygenase activity), respectively.
- 3 Hydration of the resulting ketone: the resulting ketone is hydrated to produce unstable intermediates.
- 4 Cleavage of a specific carbon–carbon bond: the carbon–carbon bond between C₂ and C₃ of the RuBP is cleaved.
- 5 Protonation of the resulting carboxylate: the carboxylate product is protonated, yielding two molecules of 3-PGA (carboxylase activity) or one molecule of 3-PGA and one molecule of 2-phosphoglycolate (oxygenase activity).

The reaction of the enediol–RuBP bound to Rubisco with CO₂ initiates the Calvin–Benson cycle for inorganic carbon assimilation; its reaction with O₂ initiates the process of photorespiration (see Chapter 14).

12.9 Regulation of the Calvin–Benson cycle by light

Light regulates flux through the Calvin–Benson cycle. This regulation is critical because the chloroplast stroma contains enzymes of the Calvin–Benson cycle that catalyze carbohydrate synthesis as well as oxidative enzymes of pathways that catalyze carbohydrate degradation. To prevent futile cycling and ensure optimal activity of these competing pathways, it is essential for the synthetic apparatus to be “on” and the degradative apparatus “off” in the light.

Chloroplasts ensure appropriate rates of biochemical transformations through modification of both the level and catalytic activity of enzymes. Specific regulatory mechanisms activate enzymes of the Calvin–Benson cycle when needed in the light and turn them off at night; degradative enzymes, such as glucose-6-phosphate dehydrogenase of the pentose phosphate pathway, behave in the opposite manner and are inactive in the light and active in the dark, adjusting production of triose phosphates and preventing futile cycles caused by competing processes (see Chapter 13).

12.9.1 Light modulates the levels of stromal enzymes encoded in nuclear and chloroplast genomes

The levels of stromal enzymes encoded in both the nucleus and chloroplast depend on the rates of their gene expression and protein synthesis. Like the Rubisco small subunit, nuclear-encoded polypeptides are translated on cytosolic 80S ribosomes and have an N-terminal transit signal that is removed at the chloroplast envelope as the mature form of the enzyme enters the plastid and is released into the stroma. Like the Rubisco large subunit, plastid-encoded proteins are translated in the stroma on prokaryotic-like 70S ribosomes. To build up the correct amount of each enzyme for the plastid, nuclear gene expression must be coordinated with the expression of other components of the photosynthetic apparatus encoded in the plastid DNA. Upon stimulation by light, the synthesis of both chloroplast and nuclear mRNAs is coordinated, ensuring that new polypeptides are present together and in sufficient amounts for the function of pathways.

Most of the regulation between nucleus and plastids is **anterograde**: products of nuclear genes control the transcription and translation of plastid genes. For example, the precursor of the small subunit of Rubisco is encoded in the nuclear genome, whereas the large subunit is encoded in the chloroplast. The abundance of the small subunit in the stroma controls the translation of the large subunit mRNA, thereby achieving efficient stoichiometry of Rubisco subunits in the hexadecameric complex (L₈S₈).

In other cases, signal transduction mechanisms can be **retrograde**: The signals flow from the chloroplast to the nucleus. For example, plastidial ferrochelatase I catalyzes the synthesis of heme, which in turn regulates the expression of nuclear-encoded, chloroplast-targeted proteins in greening leaves.

12.9.2 Light-linked posttranslational modifications of enzymes regulate the Calvin–Benson cycle

Whereas accumulation of chloroplast enzymes causes slow changes in overall catalytic rates, posttranslational modifications change catalytic rates rapidly in response to

BOX
12.4

Thioredoxins occur in multiple forms and have conserved structures to interact with target enzymes

Biochemical and genomic studies have uncovered isoforms of Trx in different organisms. The nuclear DNA of land plants, for example, has genes coding for seven different types of thioredoxin (*f*, *m*, *x*, *y*, *z*, *h*, *o*). Trx *f*, *m*, *x*, *y*, and *z* are located in the chloroplasts, *o* in mitochondria, and *h* in the cytosol, endoplasmic reticulum, and plasma membrane. The proteins are characterized by a canonical disulfide active site consisting of Cys-Gly-Pro-Cys and a common tertiary structure called the thioredoxin fold, which consists of five antiparallel beta sheets sandwiched between three alpha helices (A). Surface charges contribute to specificity for interacting with partner enzymes, such as the interaction between Trx *f* and regulatory enzymes of the Calvin–Benson cycle.

Chloroplast enzymes interacting with Trx appear to have evolved from redox-insensitive counterparts inherited from heterotrophic ancestors by acquiring regulatory cysteines. The most extensively studied chloroplast enzymes regulated by Trx have specific sequences at the N- or C-terminus (NADP-malate dehydrogenase) (B) or in the core of the polypeptide (fructose-1,6-bisphosphatase) (C). This structural information has made possible the introduction of specific regulatory sequences through genetic engineering to convert nonregulatory enzymes to regulatory forms that show activity changes following Trx-linked redox transitions.

B NADP-MDH

C CFBPase

modifications in the chloroplast stroma that are coupled to photosynthetic electron transport.

Enzymes of the cycle can acquire different catalytic rates via one of two mechanisms that alter protein structure: (1) Rubisco activase regulates the activity of Rubisco through removal of bound, inhibitory sugar derivatives (see Section 12.9.3), and (2) the ferredoxin–thioredoxin system (FTS) regulates the activity of four enzymes (fructose-1,6-bisphosphatase, sedoheptulose-1,7-bisphosphatase, PRK, and NADP–GAPD) by the reduction of specific disulfide bonds (Box 12.4 and Section 12.9.4).

12.9.3 Rubisco activase modulates Rubisco activity

The unique mechanisms that regulate Rubisco activity are related to the enzyme's slow capacity for CO_2 fixation (1–12 CO_2 fixations per second, per active site).

Prior to catalysis, Rubisco must be activated by a molecule of CO_2 (modulation, Fig. 12.38A), which reacts with the

$\epsilon\text{-NH}_2$ group of a specific lysine within the active site through carbamylation. The carbamate derivative then binds Mg^{2+} to yield the catalytically active enzyme. In catalysis, the ternary complex $[\text{E}-\text{CO}_2^-\cdot\text{Mg}^{2+}]$ binds another CO_2 molecule (the substrate) in the active site, which then reacts with RuBP to yield two molecules of 3-PGA.

Both decarbamylated and carbamylated Rubisco are inhibited by sugar phosphates, even by the substrate RuBP (Fig. 12.38B). The natural sugar phosphate, 2-carboxyarabinitol 1-phosphate (CA1P), which resembles the six-carbon intermediate of the carboxylation reaction, is a strong inhibitor that reversibly inhibits both uncarbamylated and carbamylated Rubisco. CA1P and the other bound sugar phosphates are specifically removed by the ATP-dependent enzyme, **Rubisco activase**, which prepares Rubisco for the catalytic cycle.

Many plant species contain two different Rubisco activases (42 and 47 kDa) that are the results of alternative splicing of a unique pre-mRNA. The two isoforms are identical, except for the extra peptide at the C-terminal region of the longer form, which contains two cysteines that alternate reversibly between the sulfhydryl and disulfide forms in a reaction catalyzed by

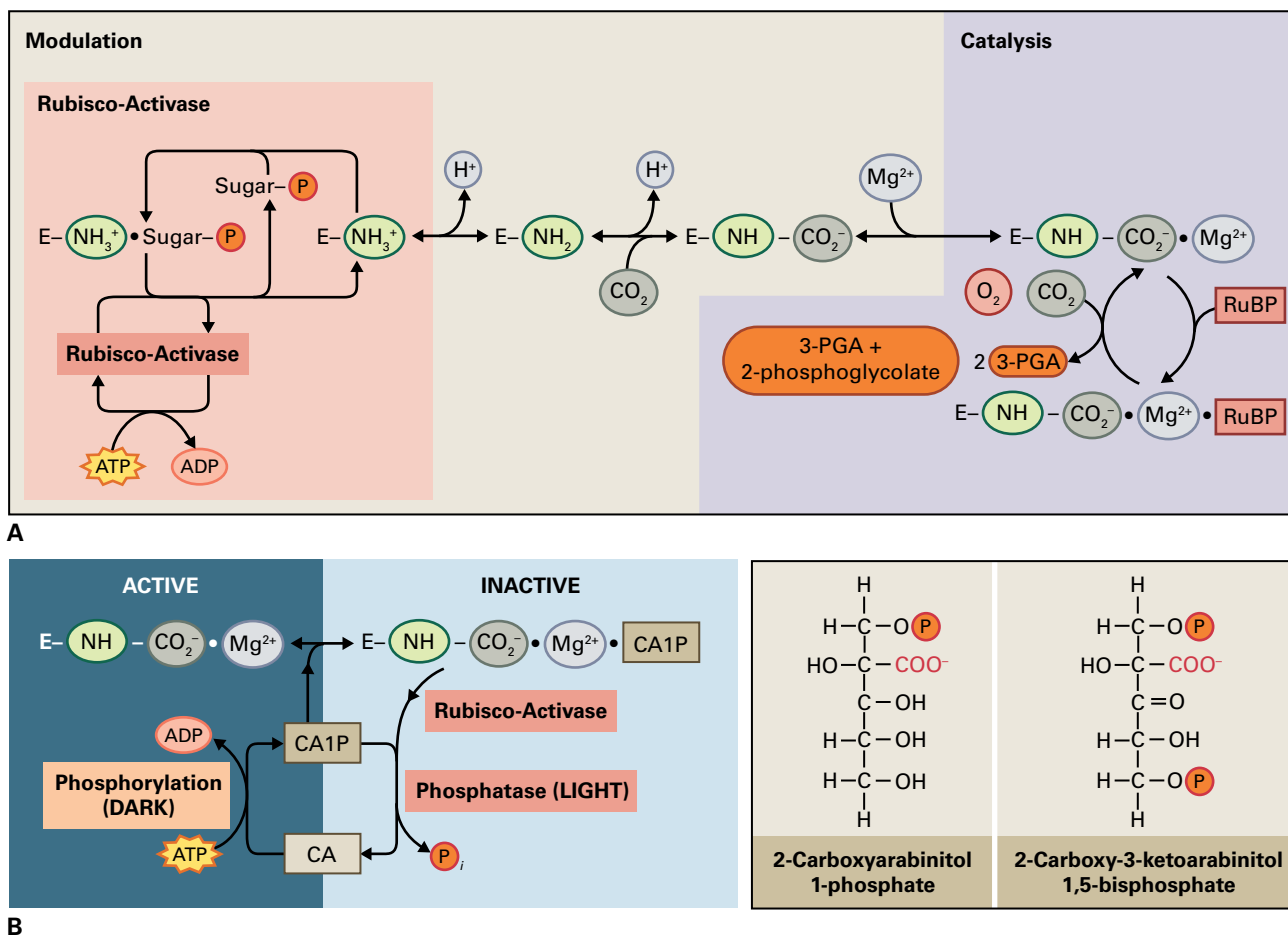

FIGURE 12.38 Regulation of Rubisco activity. (A) The CO_2 molecule plays a dual role in the activity of Rubisco (E): it transforms the enzyme from an inactive to an active form (modulation) and is the substrate for the carboxylase reaction (catalysis). (B) Rubisco is inhibited by tightly bound sugar phosphates, including the natural inhibitor 2-carboxyarabinitol 1-phosphate (CA1P), that is a structural analog of the six-carbon intermediate of the carboxylation reaction (see Fig. 12.37). CA1P turns the enzyme off at night in some plants and Rubisco activase removes these inhibitory sugar derivatives.

Proteomics has greatly increased our understanding of redox regulation in plants

Experimental advances in proteomics have uncovered the role of Trx far beyond the regulation of the Calvin-Benson cycle as was originally envisaged. With this approach, specific disulfide bonds of proteins linked to Trx can be identified by one of two procedures.

One procedure is to label target proteins chemically with a thiol-specific reagent, such as monobromobimane (mBBr) after reduction with Trx (A). An alternative strategy relies on the mechanism of the dithiol-disulfide exchange reaction taking place between reduced Trx and oxidized target proteins (B). Immobilized, mutated Trx in which the internal cysteine has been replaced by a serine (–Trp-Cys-Gly-Pro-Ser–) binds covalently to specific proteins through a disulfide bond; however, the column does not release the heterodisulfide intermediate because the substitution of the second (resolving) cysteine with serine interrupts the dithiol-disulfide exchange reaction. Elution with a disulfide-reducing agent, such as dithiothreitol, provides an enriched fraction of proteins sensitive to Trx reduction. In both approaches, Trx-sensitive proteins are isolated by

two-dimensional gel electrophoresis and identified by mass spectrometry (C).

By applying these proteomics approaches, more than 300 potential Trx-linked targets proteins have been identified, many of which have been confirmed biochemically or genetically. These proteins occur throughout the plant and participate in processes as diverse as chloroplast development and hormone synthesis. Some are redox-regulated enzymes that are deactivated in the light by reactive oxygen species. Once these toxic oxidants are scavenged, the enzymes are reduced again to restore the original activity. Upon oxidation, enzymes regulated oxidatively typically bind glutathione (see Chapter 14) through a disulfide linkage by a mechanism known as glutathionylation, which stabilizes the deactivated form and gives it protection against oxidative damage. In some cases, the bound glutathione is removed by Trx, but more often, the related protein glutaredoxin acts in this capacity. Glutaredoxin is a widely distributed dithiol oxidoreductase that is reduced by the reduced form of glutathione.

thioredoxin (see Section 12.9.4). Both isoforms of the activase activate Rubisco. Studies with transgenic *Arabidopsis* plants indicate that photosynthesis in plants expressing only the longer isoform is more sensitive to inhibition by heat stress than photosynthesis in the wild type or in plants expressing only the shorter isoform; however, whether these isoforms are associated with thermal tolerance is unclear.

12.9.4 The ferredoxin–thioredoxin system regulates enzymes by redox transitions

During the day, light-mediated electron transport generates intermediates with highly reducing potential that transform oxidized inorganic precursors into reduced metabolites; simultaneously, a network of redox pathways transfers information from thylakoid membranes to the stroma for the regulation of enzymes. The ability of cysteine residues to reversibly form intra- and intermolecular disulfide bonds is of primary significance for the dynamic regulation of enzyme activity in response to redox conditions of chloroplasts. This post-translational modification, in which disulfide (-S-S-) bonds are reduced to the sulfhydryl (-SH) level in the light, has been the subject of intense research in plants since the discovery of the **ferredoxin–thioredoxin system** in the 1970s (Box 12.5).

During photosynthesis, electrons flow from the photosynthetic electron transport system to regulatory disulfide bridges of target proteins (Fig. 12.39). This change is achieved by the ferredoxin–thioredoxin system, which is made up of Fdx (Section 12.4.5), the Fe-S enzyme ferredoxin–thioredoxin reductase (FTR), and the small protein–disulfide oxidoreductase, thioredoxin (Trx) (Box 12.4). These three proteins form a complex (Fig. 12.40A) that converts reducing power originating from light-dependent electron transport in the thylakoid membranes to a regulatory thiol signal in the stroma to change the activity of target enzymes.

The redox transformations begin with the light-dependent reduction of Fdx, which then transfers electrons to FTR, cleaving its disulfide bond (see Fig. 12.40B, reactions 1 and 2). Next, FTR converts the disulfide bond of Trx to two sulfhydryl groups, forming the Trx-FTR complex (Fig. 12.40B, reactions 3 and 4). X-ray diffraction studies of crystals have

demonstrated that the electron donor –Fdx– and the electron acceptor –Trx– dock on opposite sides of the FTR molecule (Fig. 12.40A). Fdx then delivers two successive transfers of one-electron through the [Fdx•FTR] complex to the two-electron acceptor, Trx (Fig. 12.40B, reaction 5). In the reduction of Trx, the [4Fe–4S] cluster of FTR stabilizes a one-electron-reduced intermediate that prevents the release of reactive intermediates. The light-induced redox transformations are complete once reduced Trx converts the disulfide bonds of target chloroplast enzymes to the sulfhydryl level, thereby leading to a change in activity (Reaction 12.25, see Fig. 12.39).

Reaction 12.25

The mechanisms that restore Trx-reduced (active) enzymes to the oxidized (less active) forms in the dark are not clear. Trx becomes oxidized when electron flow from Fdx to the enzyme ceases in the dark.

12.9.5 Light-mediated changes in noncovalent interactions of enzymes also control the Calvin–Benson cycle

Noncovalent interactions of enzymes with other proteins and metabolites can also alter catalytic activity within minutes of a light–dark transition. Moreover, the assembly of noncovalently linked complexes causes rapid responses of the associated enzymes to subtle changes in the intensity and quality of sunlight (for example, those caused by cloud cover or canopy shading). Enzymes of the Calvin–Benson cycle undergo intramolecular and intermolecular noncovalent interactions when they associate with regulatory proteins and yield supra-molecular complexes, bind chloroplast metabolites (e.g., ATP, NADPH), respond to ionic composition of the cellular milieu (e.g., pH and Mg^{2+}), and bind to the surface of thylakoid membranes. Overall, these noncovalent mechanisms act in concert with posttranslational modifications to rapidly control the structure and activity of individual enzymes.

FIGURE 12.39 The ferredoxin–thioredoxin system (FTS) provides a mechanism for light-dependent activation or deactivation of enzymes. Photosynthetic electron transfer by PSI leads to reduction of ferredoxin (Fdx). In turn, reduced Fdx reduces thioredoxin (Trx), a regulatory disulfide protein, via the Fe-S enzyme ferredoxin–thioredoxin reductase (FTR). Reduced Trx can then reduce the disulfide bonds of numerous target proteins, modulating their activity. In the dark, O₂ oxidizes both the target enzymes and Trx (not shown) by an unknown mechanism.

FIGURE 12.40 Details of the ferredoxin-thioredoxin system. (A) Structure of the Fdx-FTR-C49S Trx-f complex. Fdx, the catalytic subunit of FTR, the variable subunit of FTR, and C49S Trx-f are colored blue, beige, brown, and green, respectively. (B) Mechanism proposed for the catalytic activity of FTR. Light reduces Fdx via the photosynthetic electron transport chain (reaction 1). Cleavage of the disulfide bond linking Cys57 and Cys87 of FTR takes one electron from one molecule of reduced Fdx, while the second electron comes from the reduced prosthetic group $[4\text{Fe}-4\text{S}]^{2+}$ of FTR (reaction 2). Cys 57 yields a thiolate anion and Cys 87 is stabilized by forming the fifth ligand to the newly oxidized cluster $[4\text{Fe}-4\text{S}]^{3+}$. The thiolate form of Cys57 and a proton cleave the unique disulfide bond of Trx yielding the heterodisulfide complex $[\text{FTR}-(\text{Cys}57)\text{-S-S-Trx}]$ (reaction 3). A second molecule of reduced Fdx provides one electron for the reduction $[4\text{Fe}-4\text{S}]^{3+} \Rightarrow [4\text{Fe}-4\text{S}]^{2+}$ releasing the Cys87 of FTR from binding to the prosthetic group (reaction 4). The thiolate form of Cys87 and a proton cleave the heterodisulfide complex, releasing reduced Trx and restoring the disulfide bond of FTR for another catalytic cycle (reaction 5). In summary, FTR drives the reduction of Trx using two electrons from reduced Fdx and two protons from the surrounding stroma. Subsequently, the reduced Trx reduces a target enzyme, thereby leading to a change in activity.

Phosphoribulokinase and NADP-glyceraldehyde-3-phosphate dehydrogenase bind to the small protein CP12

In addition to being regulated by Trx, plastid phosphoribulokinase (PRK) and NADP-glyceraldehyde-3-phosphate dehydrogenase (NADP-GAPD) are regulated by noncovalent associations with the nuclear-encoded chloroplast protein CP12 (an ≈ 8.5 -kDa protein found in cyanobacteria, green algae, and plants) in supramolecular complexes. In the light (reducing conditions), chloroplasts of land plants and most algae contain active NADP-GAPD (which forms a homotetramer), active PRK (which forms a dimer harboring cysteines), and the reduced form of the CP12 protein, which harbors four sulfhydryl groups (Fig. 12.41).

In the dark (oxidizing conditions), sulfhydryl groups of both PRK and CP12 are oxidized to disulfides, and these oxidized forms recruit the NADP-GAPD homotetramer for the formation of a supramolecular complex. Both enzymes exhibit marginal enzyme activity when associated with CP12 in the supramolecular complex. Illumination of dark-adapted cyanobacteria and chloroplasts activates the ferredoxin-thioredoxin system, which cleaves the disulfide bonds of PRK and CP12. This reduction releases the constituent enzymes from the complex, imparting full catalytic capacity to both NADP-GAPD and PRK (Fig. 12.41).

While CP12 assembles with NADP-GAPD and PRK in dark-adapted pea (*Pisum sativum*) leaves, suppression of CP12 in tobacco (*Nicotiana tabacum*) by genetic manipulation causes minor changes in both photosynthetic carbon

fixation and the activity of the two enzymes. However, it leads to significant changes in plant growth, carbohydrate partitioning, and morphology. This considerable heterogeneity between species indicates that the role of CP12 extends beyond regulation of the Calvin-Benson cycle.

The ferredoxin-thioredoxin system also regulates NADP-GAPD itself

Chloroplasts of land plants contain not only the NADP-GAPD homotetramer, $(A_4)\text{-NADP-GAPD}$, and its associated regulatory system, but also a second form of the enzyme, the heterotetramer $(A_2B_2)\text{-NADP-GAPD}$. Although the primary structure of the B subunit is homologous to the A counterpart, it holds a C-terminal extension with two cysteines that are controlled by the ferredoxin-thioredoxin system (Fig. 12.41). In the light, NADP-GAPD is catalytically active because the cysteine residues are reduced $\{[A_2] \cdot [B-(\text{SH})_2]\}$; in the dark, formation of disulfide bonds promotes aggregation of heterotetramers into enzymatically inactive hexadecamers $\{[A_8] \cdot [B-(\text{S})_2]_8\}$.

Light actuates changes in stromal pH and Mg^{2+} concentration

When dark-treated chloroplasts are exposed to light, the pH of the stroma increases as protons are translocated from that compartment to the thylakoid lumen. As light drives H^+ into the thylakoid lumen, Mg^{2+} is released from the lumen to compensate for the influx of positive charges. As a consequence, the stromal pH increases from 7 to 8, and the concentration of Mg^{2+} increases from 1–3 mM to approximately 3–6 mM. Changes in

FIGURE 12.41 Regulation of NADP-glyceraldehyde 3-phosphate dehydrogenase (NADP-GAPD) and phosphoribulokinase (PRK). Two forms of NADP-GAPD function in the Calvin-Benson cycle: the homotetramer (A_4)-NADP-GAPD and the heterotetramer (A_2B_2)-NADP-GAPD. (A) The activity of the homotetramer (A_4)-NADP-GAPD depends on the small protein CP12. Under light conditions, the high ratio $[\text{Trx}-(\text{SH})_2]/[\text{Trx}-(\text{S})_2]$ reduces disulfide bonds of CP12 and PRK, making (A_4)-NADP-GAPD and PRK catalytically active. Under dark conditions, the low ratio $[\text{Trx}-(\text{SH})_2]/[\text{Trx}-(\text{S})_2]$ allows the formation of intramolecular disulfide bonds in CP12 and PRK. The oxidized states of CP12 and PRK recruit the homotetramer (A_4)-NADP-GAPD for the formation of the heterocomplex $[\text{CP12}\cdot\text{PRK}\cdot(\text{A}_4)\text{-NADP-GAPD}]$. Both PRK and (A_4)-NADP-GAPD are catalytically inactive in this supramolecular complex. CP12 regulates the activity of GAPD and PRK in some photosynthetic organisms (for example, in cyanobacteria, diatoms, red and green algae, and certain plant species such as pea and spinach, but not in others like tobacco). (B) The activity of the heterotetramer (A_2B_2)-NADP-GAPD depends on the C-terminal extension of (A_2B_2)-NADP-GAPD. Under light conditions, the high ratio $[\text{Trx}-(\text{SH})_2]/[\text{Trx}-(\text{S})_2]$ causes the reduction of the B subunit of (A_2B_2)-NADP-GAPD, thereby (A_2B_2)-NADP-GAPD exhibits maximum activity. Under dark conditions, the low ratio $[\text{Trx}-(\text{SH})_2]/[\text{Trx}-(\text{S})_2]$ promotes formation of disulfide bonds in the C-terminal extension of the heterotetramer (A_2B_2)-NADP-GAPD. The oxidized state of (A_2B_2)-NADP-GAPD contributes to the self-association into the hexadecameric complex A_8B_8 that is catalytically inactive.

stromal pH and Mg^{2+} concentration complement the ferredoxin-thioredoxin system and are important for the activation and maximum catalysis of enzymes such as Rubisco, fructose-1,6-bisphosphatase, sedoheptulose-1,7-bisphosphatase, and PRK.

12.10 Variations in mechanisms of CO_2 fixation

12.10.1 Some autotrophic bacteria and archaea do not fix carbon via the Calvin-Benson cycle

Although the Calvin-Benson cycle is the mechanism for conversion of CO_2 into carbohydrates that sustains most life in the biosphere, it is not universal. In some prokaryotes, CO_2 fixation proceeds by five other pathways. These variants of microbial autotrophy synthesize organic acids from atmos-

pheric CO_2 , employing acetyl-CoA as an intermediate, and have survived eons of evolution in specific ecological niches (see Box 12.3).

12.10.2 In plants, C_4 and CAM metabolism increase the efficiency of Rubisco carboxylation

As described in Section 12.8.3, Rubisco catalyzes both carboxylation and oxygenation of RuBP, and photosynthetic organisms have developed strategies to overcome the problems caused by photorespiration. Land plants have adapted two different mechanisms to suppress photorespiration and increase the use of atmospheric CO_2 (Fig. 12.42): **C_4 photosynthetic carbon fixation** (see Section 12.10.3) and **Crassulacean acid metabolism (CAM)** (see Section 12.10.7). These two mechanisms are additions to the Calvin-Benson cycle that separate the uptake of atmospheric CO_2 from the

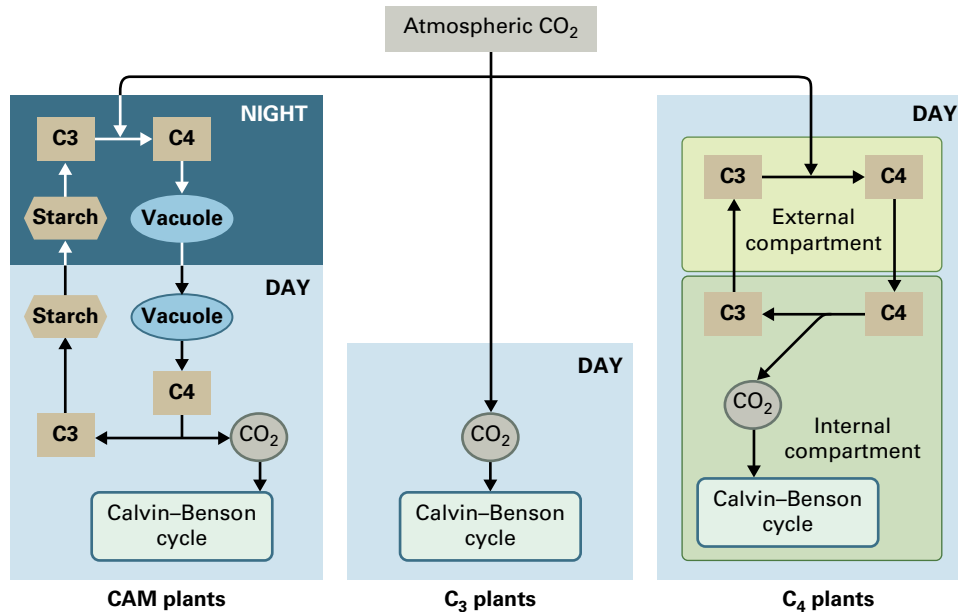

FIGURE 12.42 Photosynthetic CO₂ assimilation in C₃, C₄, and CAM plants. The C₄ cycle and CAM are additions to the Calvin–Benson cycle for the efficient capture of CO₂. The C₄ cycle and CAM separate spatially and temporally, respectively, the capture of atmospheric CO₂ from the CO₂ fixation by the Calvin–Benson cycle.

supply of substrate to Rubisco inside the leaf. They act as CO₂ pumps to increase the concentration of CO₂ around the carboxylation site of Rubisco, thereby reducing the competing effect of O₂.

12.10.3 C₄ plants utilize two distinct metabolic compartments for fixing CO₂

Not all organisms that contain the Calvin–Benson cycle produce 3-PGA as the first stable photosynthetic intermediate. Studies in the 1960s identified several plant species that form large amounts of four-carbon organic acids as the first products of CO₂ fixation when supplied with ¹⁴CO₂. On this basis, plants are classified as C₃ or C₄ plants based on the primary product of carbon fixation in photosynthesis: three-carbon (3-PGA) and four-carbon (oxaloacetic acid, OAA) compounds are the primary products of carbon fixation in C₃ and C₄ plants, respectively (Fig. 12.42).

C₄ photosynthesis involves the primary carboxylation of a three-carbon precursor (phosphoenolpyruvate, PEP) to OAA, catalyzed by PEP carboxylase, followed by the decarboxylation of the four-carbon intermediate prior to secondary (final) carboxylation at the active site of Rubisco. These two biochemical functions are separated between two intracellular compartments, which allow the primary and the secondary carboxylations to occur simultaneously.

Sugar cane (*Saccharum* sp.), maize (*Zea mays*), and numerous tropical grasses are among the species that exhibit the C₄ labeling pattern. The leaves of these and almost all C₄ species exhibit an unusual anatomy involving two different types

of chloroplast-containing cells: mesophyll cells surround enlarged bundle sheath cells, which in turn are arranged concentrically with respect to vascular tissues (Fig. 12.43). Reduced interveinal distance and limited leaf thickness maximize the contact between mesophyll and bundle sheath cells. The 19th-century German botanists who originally described this feature called it **Kranz anatomy** (German: wreath). The biochemical differentiation of mesophyll cells and bundle sheath cells is essential for the effective operation of C₄ photosynthesis: PEP carboxylase (PEPCase) accumulates in the cytosol of mesophyll cells (external compartment), and Rubisco in the chloroplasts of bundle sheath cells (internal compartment). The biphasic C₄ system reduces photorespiration dramatically by increasing levels of CO₂ near Rubisco to enable Rubisco carboxylation to outcompete the oxygenation reaction. The low photosystem II activity in the bundle sheath also minimizes the Rubisco oxygenation reaction.

C₄ photosynthesis also occurs, however, in numerous organisms devoid of Kranz anatomy, including a number of aquatic and land plants. In some of these cases, photosynthetic enzymes and dimorphic chloroplasts occur in separate cytoplasmic domains within a single photosynthetic cell (Fig. 12.44). The subcellular localization of photosynthetic functions in *Bienertia sinuspersici*, for example, revealed that chloroplasts of peripheral and central compartments differ and function in an analogous manner to the mesophyll and bundle sheath chloroplasts of Kranz anatomy. Thus, diffusion gradients between and within cells shuttle metabolic intermediates of the C₄ cycle between the two compartments. In addition to the mechanisms employed by plants, cyanobacteria and green algae have also developed alternative CO₂ concentrating mechanisms for increasing the availability of CO₂ for Rubisco.

FIGURE 12.43 Leaf (Kranz) anatomy of C_4 plants. (A) Electron micrograph showing the leaf anatomy of maize (*Zea mays*). The closely spaced vascular bundles are surrounded by large bundle sheath cells. (B) Electron micrographs comparing the chloroplasts of a bundle sheath cell (bottom) and a mesophyll cell (top) in sorghum. The chloroplast morphologies reflect their biochemical functions. The bundle sheath chloroplasts lack stacked thylakoids and contain little PSII. In contrast, the mesophyll chloroplasts contain all the transmembrane complexes required for the light reactions of photosynthesis but little or no Rubisco. Source: (A, B) Newcomb, University of Wisconsin, Madison; previously unpublished.

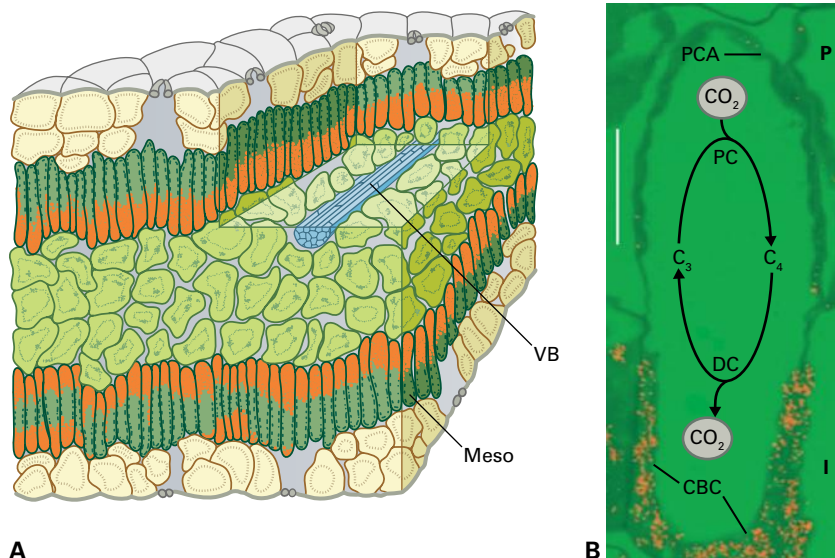

FIGURE 12.44 Leaf anatomy of single-cell C_4 plants. (A) Three-dimensional drawing of the leaf anatomy of *Borszczowia aralocaspica*, a single-cell C_4 plant. Meso, mesophyll; VB, vascular bundles. Note the lack of differentiation in the cells. (B) Immunolocalization of Rubisco at the internal region (I) of a photosynthetic cell from *Borszczowia aralocaspica*. Red chloroplasts containing the Calvin-Benson cycle (CBC) are functionally equivalent to C_4 bundle sheath chloroplasts. Chloroplasts containing PPKK, which are functionally equivalent to C_4 mesophyll chloroplasts, are situated at the peripheral region (P) where they contribute to the photosynthetic carbon assimilation (PCA). PC and DC refer to the initial carboxylation catalyzed by PEPCase and the decarboxylation of C_4 acids, respectively.

12.10.4 The C_4 pathway increases the concentration of CO_2 in internal compartments close to vascular tissues

The C_4 pathway of CO_2 fixation requires a complex interaction between two different compartments and involves the following steps (Fig. 12.45):

- 1 Primary carboxylation: fixation of HCO_3^- by PEPCase in the outer compartment (for example, mesophyll cells) to yield OAA.
- 2 Transformation of OAA into another four-carbon acid (malate or aspartate) and transport of the four-carbon acids from the outer to the internal compartment (e.g., bundle sheath cells)
- 3 Decarboxylation: release of CO_2 from the four-carbon acid.
- 4 Secondary carboxylation: subsequent refixation of the CO_2 by Rubisco and the Calvin-Benson cycle.
- 5 Transfer of the three-carbon intermediates (pyruvate or alanine) resulting from decarboxylation of the four-carbon acids back to the outer compartment.

FIGURE 12.45 General aspects of the C₄ pathway. Atmospheric CO₂ enters the peripheral region and is converted to HCO₃⁻ for reaction with PEP, yielding OAA (primary carboxylation). OAA is transformed to a second C₄ acid (malate or aspartate) that flows across a diffusion barrier to the internal region. There, the C₄ acid is decarboxylated, yielding CO₂ and a C₃ acid (pyruvate or PEP) (decarboxylation). The released CO₂ is fixed by Rubisco in the Calvin-Benson cycle (secondary carboxylation) and converted to carbohydrate for export to other parts of the plant. The remaining C₃ acid is transported back to the external region to regenerate PEP (regeneration).

TABLE 12.10 Variations in C₄ photosynthesis.

C ₄ acid transported to bundle sheath cells	C ₃ acid transported to mesophyll cells	Decarboxylase	Plant examples
Malate	Pyruvate	NADP-ME	<i>Zea mays</i> (maize), <i>Saccharum officinarum</i> (sugarcane)
Aspartate	Alanine	NAD-ME	<i>Panicum miliaceum</i> (millet)
Aspartate	Alanine, PEP, or pyruvate	PEPCK	<i>Panicum maximum</i> (Guinea grass)

- 6 Conversion of the three-carbon intermediates to PEP to reinitiate the fixation of HCO₃⁻.

Biochemical fractionation analyses have shown that OAA is generated from HCO₃⁻ and PEP in the cytosol of the outer compartment (i.e., mesophyll cells), whereas enzymes unique to the Calvin-Benson cycle are located only in chloroplasts of the internal compartment (i.e., bundle sheath cells). In accordance with distinct functions, electron micrographs of bundle sheath and mesophyll chloroplasts (see Fig. 12.43) show structural differences: chloroplasts of (internal) bundle sheath cells lack stacked membranes and exhibit little PSII activity, whereas chloroplasts of (peripheral) mesophyll cells have retained stacked membranes as well as PSII and PSI activities (see Fig. 12.43B). Significantly, the function of chloroplasts in the internal and peripheral compartments of single-cell C₄ species (*B. sinuspersici*) is analogous to that of land plants showing Kranz anatomy.

In the context of the two-cell C₄ pathway, all carbon fixation begins in the cytosol of mesophyll cells, where carbonic anhydrase catalyzes the conversion of atmospheric CO₂ into HCO₃⁻ (Reaction 12.26) for subsequent β-carboxylation of PEP to yield OAA, catalyzed by PEPCase (Reaction 12.27). Use of HCO₃⁻ but not CO₂ as the one-carbon substrate for PEPCase has two advantages for a more efficient initial fixation step: First, the aqueous equilibrium of these two species strongly favors HCO₃⁻ ion over CO₂, and second, PEPCase cannot fix O₂, which has a structure similar to that of CO₂ but not to HCO₃⁻.

Reaction 12.26: Carbonic anhydrase

Reaction 12.27: Phosphoenolpyruvate carboxylase (PEPCase)

12.10.5 Three different types of C₄ photosynthesis are known

Three types of C₄ photosynthesis are known, differing both in the four-carbon acids transported between mesophyll and bundle sheath cells, and the mechanism of decarboxylation in the bundle sheath cells (Table 12.10). These variants are

named on the basis of the enzymes employed for decarboxylation (Reactions 12.28, 12.29, 12.31, Fig. 12.45). Although the intracellular compartmentation and energetic requirements for each of these three types differ, in all cases the CO_2 released in the bundle sheath cell is refixed by the Rubisco localized within the chloroplasts of the same cells.

In **NADP-malic enzyme (ME) C_4 photosynthesis**, OAA is transported from the cytoplasm of mesophyll cells to the chloroplasts for reduction to malate by NADP^+ -malate dehydrogenase (Fig. 12.46A). Malate leaves the mesophyll chloroplasts for the bundle sheath chloroplasts, where NADP-ME catalyzes the oxidative decarboxylation of malate to CO_2 and pyruvate (Reaction 12.28). CO_2 is refixed by Rubisco via the Calvin–Benson cycle, and pyruvate is transported back to mesophyll cells and taken up into mesophyll chloroplasts for regeneration of PEP. The phosphorylation of pyruvate is catalyzed by pyruvate-phosphate dikinase (PPDK, Reaction 12.29), and mesophyll chloroplasts release PEP into the cytosol to start a new cycle of CO_2 fixation.

Reaction 12.28: NADP⁺-dependent malic enzyme (NADP-ME)

Reaction 12.29: Pyruvate-phosphate dikinase (PPDK)

In **NAD-ME C_4 photosynthesis** (Fig. 12.46B), cytosolic aspartate aminotransferase in mesophyll cells converts OAA to aspartate, using glutamate as donor of the amino group (Reaction 12.30). Aspartate moves to the mitochondria of bundle sheath cells, where it is converted back to OAA by aspartate aminotransferase. The mitochondrial NAD-malate dehydrogenase reduces OAA to malate, which is oxidatively decarboxylated by mitochondrial NAD-ME (Reaction 12.31). CO_2 is refixed by the Calvin–Benson cycle in the bundle sheath chloroplasts, and the newly formed pyruvate leaves the mitochondria for conversion to alanine in the cytosol of bundle sheath cells by alanine aminotransferase (Reaction 12.32). Alanine returns to the mesophyll cells, where it is deaminated to pyruvate by the alanine aminotransferase. Pyruvate regenerates the acceptor PEP in the chloroplasts of mesophyll cells as described for NADP-ME C_4 plants. The aspartate/alanine shuttle between mesophyll and bundle sheath cells ensures an adequate balance not only of organic carbon, but also organic nitrogen.

Reaction 12.30: Aspartate aminotransferase

Reaction 12.31: NAD⁺-dependent malic enzyme (NAD-ME)

Reaction 12.32: Alanine aminotransferase

PEP carboxykinase (PEPCK) C_4 photosynthesis is more complex than the other two types, because two complementary cycles shuttle C_4/C_3 metabolites between mesophyll and bundle sheath cells (Fig. 12.46C). Some of the OAA is converted to aspartate in the cytosol of the mesophyll cells (similar to the NAD-ME type), and the aspartate is transported to the cytosol of bundle sheath cells and converted to OAA by transamination. The decarboxylation of OAA catalyzed by PEPCK yields CO_2 , using ATP provided by mitochondrial respiration (Reaction 12.33). The CO_2 is fixed by the Calvin–Benson cycle in the chloroplasts of bundle sheath cells. PEP, the other product of the PEPCK reaction, returns to the mesophyll cells for a new round of CO_2 fixation. In addition to the pathway shown, some of the OAA enters the chloroplast, where NADP-malate dehydrogenase catalyzes the reduction to malate. The malate is transported from mesophyll cells to bundle sheath cells and is converted to pyruvate and CO_2 in the mitochondria (similar to NADP-ME type). CO_2 diffuses to chloroplasts of bundle sheath cells, where it is assimilated by the Calvin–Benson cycle. The pyruvate leaves the mitochondria and is converted to alanine by transamination; the alanine is transported back to mesophyll cells and converted to pyruvate by transamination. Pyruvate yields PEP in chloroplasts for another cycle of CO_2 assimilation.

Reaction 12.33: PEP carboxykinase (PEPCK)

The NAD-ME and PEPCK types of C_4 photosynthesis, but not the NADP^+ -ME pathway, use mitochondrial NAD-ME to decarboxylate malate (Fig. 12.46B,C). The flow of carbon through the bundle sheath mitochondria in the NAD-ME type of C_4 photosynthesis is much greater than that of the respiratory and the photorespiratory pathways in C_3 plants. This unique capacity of plant mitochondria reflects the evolution of the central organelle of heterotrophic metabolism to support autotrophy in photosynthetic eukaryotes.

12.10.6 The C_3 and C_4 pathways have different energy costs

In C_3 plants, the Calvin–Benson cycle consumes nine ATP and six NADPH to assimilate three molecules of CO_2 into triose phosphate (3 ATP : 2 NADPH : 1 CO_2). In C_4 photosynthesis, continuous operation of the C_4/C_3 shuttle requires restitution of PEP in mesophyll cells, which consumes two additional molecules of ATP in the successive reactions catalyzed by PPDK and adenylate kinase ($\text{AMP} + \text{ATP} \rightarrow 2 \text{ADP}$). Thus, at least five molecules of ATP and two molecules of NADPH are needed for assimilation of one molecule of CO_2 (5 ATP : 2 NADPH : 1 CO_2).

A NADP⁺-malic enzyme type

B NAD⁺-malic enzyme type

C Phosphoenolpyruvate carboxykinase type

- ① PEP carboxylase
- ② NADP⁺-malate dehydrogenase
- ③ NADP⁺-malic enzyme
- ④ Pyruvate-orthophosphate dikinase (PPDK)
- ⑤ Aspartate aminotransferase
- ⑥ NAD⁺-malic enzyme
- ⑦ Alanine aminotransferase
- ⑧ PEP carboxykinase

FIGURE 12.46 Three types of C_4 photosynthetic plants: (A) NADP-malic enzyme-type, (B) NAD-malic enzyme-type, and (C) phosphoenolpyruvate carboxykinase-type. All types start with the initial fixation of HCO_3^- by PEPCase in the cytosol of mesophyll cells. However, the transformation of the C_4 dicarboxylic acid OAA proceeds through different organelles and biochemical pathways (see Section 12.10.5 for a description of the organelles in which the indicated reactions take place). The three types of C_4 plants show different mechanisms for the shuttle C_4 (amino)-acid/ C_3 (amino)-acid between mesophyll and bundle sheath cells and the decarboxylation of the C_4 acid. Asterisks mark the enzyme that identifies the C_4 type.

C_4 photosynthesis evolved to minimize energetically wasteful photorespiration; however, avoidance of photorespiration came with a penalty for photosynthetic efficiency. Flow of metabolites across membranes requires establishment and maintenance of a thermodynamic disequilibrium among different compartments, which demands continuous input of energy. In keeping with an increased metabolic flux across the envelope membranes of C_4 chloroplasts, substrate-specific transporters of these membranes are more abundant in C_4 than in C_3 plants.

12.10.7 Critical enzymes of the C_4 pathway are also regulated by light

Light-mediated regulation of enzymes coordinates the activities of mesophyll and bundle sheath cells to ensure that four-carbon acids are available for CO_2 fixation in bundle sheath cells. In C_4 photosynthesis, regulation of Calvin–Benson cycle enzymes by light is similar to C_3 plants. In addition, light also controls the C_4 cycle enzymes NADP-malate dehydrogenase, PEPCase, and PPDK: Light activation of NADP-malate dehydrogenase involves the ferredoxin–thioredoxin system (see Fig. 12.39), while PEPCase and PPDK are regulated by allosteric effectors and protein phosphorylation.

PEPCase is essentially inactive in the dark; it is not phosphorylated and so has a low affinity for PEP and is inhibited by low concentrations of malate (Fig. 12.47A). In the light, PEPCase-kinase catalyzes phosphorylation of PEPCase, rendering the enzyme less sensitive to malate. The kinase is regulated by light at the level of the gene via a complex signal transduction chain involving phospholipases C and D. When dark returns, PEPCase is converted back to the non-

phosphorylated form by protein phosphatase 2A; in parallel, PEPCase-kinase is deactivated by an unknown mechanism.

PPDK catalyzes the phosphorylation of pyruvate by ATP and phosphate to yield PEP, pyrophosphate and AMP (see Reaction 12.29). A regulatory protein (PPDK-RP) regulates PPDK through dark-induced phosphorylation (deactivation) and light-promoted phosphorolysis (activation) of a threonine residue in the active site of PPDK (Fig. 12.48). The substrate of PPDK-RP for the phosphorylation of PPDK is ADP, not ATP [$PPDK + ADP (AMP-P) \Rightarrow (PPDK-RP) \Rightarrow PPDK-P + AMP$]. The absence of light suppresses ATP production and increases the concentration of ADP, promoting PPDK phosphorylation and abolishing the catalytic activity of PPDK. In the light, the concentration of ADP drops and facilitates the phosphorolysis of phosphorylated PPDK [$PPDK-P + P_i \Rightarrow (PPDK-RP) \Rightarrow PPDK + PP_i$], increasing the proportion of nonphosphorylated, active PPDK.

PPDK-RP is a unique regulatory enzyme because it catalyzes the phosphorylation of PPDK using ADP as phosphoryl donor, rather than ATP, and the phosphorolytic dephosphorylation of the $(PPDK)\text{-Thr-O-P}$ with formation of pyrophosphate, rather than the hydrolysis employed by most protein phosphatases.

12.10.8 CAM photosynthesis involves the temporal separation of CO_2 capture and carbon fixation

Another modification of the C_3 pathway occurs in plants utilizing Crassulacean acid metabolism (CAM). Named after the *Crassulaceae* family of succulent plants, this pathway has evolved mechanisms for maximizing carbon uptake under

FIGURE 12.47 Regulation of PEP carboxylase (PEPCase). Phosphorylated PEPCase is catalytically more active and less sensitive to inhibition by malate than the nonphosphorylated form. PEPCase-kinase catalyzes the phosphorylation of PEPCase. (A) C_4 plants. Diurnal phosphorylation of PEPCase regulates incorporation of HCO_3^- into PEP. Light stimulates PEPCase-kinase activity, but in the dark, PEPCase returns to the inactive form because PEPCase-kinase is inactivated and a phosphatase releases the phosphoryl group from PEPCase. (B) CAM plants. Nocturnal phosphorylation of PEPCase controls primary carboxylation. PEPCase-kinase transcripts accumulate during the night, controlled by the circadian oscillator and metabolites.

FIGURE 12.48 Catalytic activity of PPDK and its phosphoregulation by the PPDK-regulatory protein (PPDK-RP). The phosphorylation of an essential histidine residue shown in black [PPDK-(His-P)-(Thr)] during catalysis predisposes PPDK to reversible inactivation by PPDK-RP via the ADP-dependent phosphorylation of a specific threonine residue shown in red [PPDK-(His-P)-(Thr-P)]. PPDK-RP catalyzes the reactivation of PPDK through the phosphorolytic cleavage of the phosphorylated Thr (P_i -dependent/ PP_i -forming).

environmental conditions that limit productivity, such as high temperature or shortage of water. Thus, CAM photosynthesis is commonly associated with plants that inhabit arid environments (e.g., succulents, including cacti and some commercially significant plants, such as pineapple and agave). To enhance water conservation, these plants have evolved anatomical and morphological structures, such as thick cuticles, that prevent water loss. They have also evolved mechanisms for ensuring a high concentration of CO_2 at the active site of Rubisco to minimize photorespiration.

The biochemical pathway of CO_2 fixation in terrestrial CAM plants is similar to the C_4 pathway, but instead of a spatial separation of the two carboxylations necessary for CO_2 fixation, terrestrial CAM plants use a temporal separation of the initial fixation reaction from the assimilation by Rubisco (Fig. 12.49). At night, when it is cold and leaf stomata are open, CO_2 is fixed initially into OAA and then malate via PEPCase and NADP-malate dehydrogenase. The malic acid is stored in vacuoles, where it can reach high concentrations. During the day, stomata close to prevent the loss of water, and malic acid is transported out of the vacuole. At this stage, NADP-ME catalyzes the decarboxylation of malate, yielding CO_2 and pyruvate, and the released CO_2 is fixed by Rubisco via the Calvin-Benson cycle, while pyruvate is used to form starch. The starch confined to photosynthesizing tissues of terrestrial CAM plants, named **transitory starch**, is broken

FIGURE 12.49 Crassulacean acid metabolism (CAM). At night, both atmospheric and respiratory CO_2 provide HCO_3^- for carboxylation of PEP catalyzed by PEPCase (reaction 1). NAD-malate dehydrogenase catalyzes the reduction of the C_4 organic acid—oxaloacetic (OAA)—to malate (reaction 2). Malate is stored in the vacuole overnight. During the day, the stored malate is decarboxylated by NAD(P)-ME yielding NAD(P)H, pyruvate, and CO_2 (reaction 3). In the chloroplast, pyruvate and CO_2 are used for synthesis of carbohydrates via gluconeogenesis and the Calvin-Benson cycle, respectively.

down at night via glycolysis and serves as a source of PEP for the fixation of CO_2 via PEPCase. In this circadian rhythm, the opening/closing of stomata, variations of organic acids and storage carbohydrates, and the activities of carboxylation and decarboxylation enzymes modulate the proportion of CO_2 taken up via PEPCase at night and Rubisco during the day.

A notable feature of terrestrial CAM plants is the alternation between stomatal opening and closing. Stomata remain open during the cool and relatively humid night, allowing uptake of atmospheric CO_2 while sustaining minimal water loss. During the heat and dryness of the day, the stomata close, preventing not only water loss but also the entry of atmospheric CO_2 . Malate becomes the internal source of CO_2 in leaves. The decarboxylation of malate raises the concentration of CO_2 to high levels because CO_2 cannot escape through the closed stomata. These high concentrations of CO_2 further increase the efficiency of Rubisco as a carboxylase. The Calvin–Benson cycle is regulated as in C_3 plants.

For aquatic plants, water is readily available, but the concentration of CO_2 is low for some that exhibit CAM photosynthesis. Freshwater CAM plants (*Isoetes*, *Littorella*, *Crassula*, *Sagittaria*, *Vallisneria*) lack stomata and capture CO_2 24 hours a day. Generally, the concentration of HCO_3^- in most freshwaters exceeds that of CO_2 ; however, CO_2 is the preferred source of inorganic carbon of submerged CAM plants because it is more readily taken up. More importantly, respiratory CO_2 makes a substantial contribution to the nocturnal uptake of carbon through CAM when dissolved levels of CO_2 are depleted. Freshwater CAM plants thus capture CO_2 derived from both the surrounding milieu and respiration for transformation to HCO_3^- used in the primary fixation catalyzed by PEPCase. In short, aquatic CAM photosynthesis maximizes carbon uptake in plants that prosper in water with a highly

variable supply of inorganic carbon by (i) concentrating CO_2 released in the decarboxylation reaction and (ii) preventing the loss of respiratory carbon.

12.10.9 CAM PEPCase is active in the dark

CAM photosynthesis provides a fascinating example of enzyme regulation. CAM PEPCase must function at night and reduce its activity during the day, so the mechanisms that inhibit its activity in dark-treated C_4 plants do not operate here. Endogenous circadian rhythms, rather than exogenous light–dark signals, mediate PEPCase activation at night and deactivation during the day (see Fig. 12.47B). Conversions between nocturnal and the diurnal forms correlate with the cessation and onset of malate accumulation. Malate, which is present at high concentrations when it leaves the vacuole, inhibits the diurnal form of the enzyme, whereas the nocturnal form is insensitive to malate, thereby allowing the accumulation of this metabolite.

The regulation of the nocturnal and the diurnal forms of CAM PEPCase also involves protein phosphorylation by PEPCase-kinase and dephosphorylation by phosphatase 2A. The activity of PEPCase-kinase is high in the nocturnal period when PEPCase is phosphorylated, and low during the light period when PEPCase is dephosphorylated. Complementary experiments showed the functioning of PEPCase-kinase at night requires RNA and protein synthesis, indicating that the nocturnal phosphorylation of CAM PEPCase is largely controlled by a circadian oscillator at the level of protein synthesis and degradation (Fig. 12.47B).

Summary

Photosynthesis produces organic compounds from inorganic carbon by using the energy of sunlight. These redox processes are carried out in plants, algae, and various bacteria. In all cases, the photosynthetic reactions may be divided into two phases: the light reactions and the carbon reactions. In eukaryotic organisms, photosynthesis takes place in the chloroplast. This organelle is surrounded by a double membrane and contains (i) a complex internal membrane system, the thylakoid membranes, and (ii) a soluble fraction called the stroma. The two phases of photosynthesis occur simultaneously but take place in different regions of the chloroplast, with the light reactions being localized to the thylakoid membranes and the carbon reactions to the stroma.

The light reactions of photosynthesis involve the photosynthetic pigments, the photosynthetic electron transport chain, and the ATP synthesis machinery. Light is absorbed by pigments localized in pigment–protein

complexes (photosystems) within the thylakoid membrane. This light energy can be transferred from antenna pigments to special pigment–protein complexes, known as reaction centers, where the light energy is converted into chemical products (photochemistry). Within the reaction center, a special chlorophyll undergoes oxidation, with the transfer of an electron to an electron acceptor during the primary reaction of photosynthesis.

Oxygenic photosynthetic organisms contain two reaction centers and two photosystems, PSII and PSI. In plants the two photosystems are spatially separated: PSII is localized in appressed thylakoids, and PSI is localized in stroma-exposed thylakoids. During noncyclic electron transfer, the two photosystems cooperate in the transfer of electrons from water to NADP^+ via a series of redox reactions that are mediated by both mobile and integral thylakoid membrane components of the photosynthetic electron transfer chain. During these reactions,

PSII oxidizes water and produces molecular oxygen within the thylakoid lumen. The concerted action of PSII and PSI are tuned to meet the demands of downstream metabolism. These reactions provide the O_2 for aerobic forms of life.

In addition to O_2 , reduced ferredoxin, and NADPH, the noncyclic electron transfer reactions are coupled to the formation of ATP. ATP synthesis is driven by a proton gradient established across the thylakoid membrane in the transport of electrons from water to ferredoxin. During electron transport, the lumen becomes acidified by protons that are either translocated from the stroma during electron transport or released by water oxidation. Use of this electrochemical gradient as an energy source requires the ATP synthase complex. This enzyme is composed of two components—one intrinsic to the membrane and involved in transporting protons through the membrane, and the second, extrinsic, functional in the actual conversion of ADP and P_i into ATP. The synthesis of ATP appears to be accompanied by complex conformational changes in ATP synthase, driven by the movement of protons through the enzyme.

In addition to the noncyclic mechanism for ATP synthesis, chloroplasts synthesize ATP via two cyclic pathways that involve only PSI. Cyclic electron transport generates a proton gradient that is used for the synthesis of ATP, but does not yield O_2 or NADPH. In both pathways, the buildup of the proton gradient and the ensuing synthesis of ATP are enhanced by operation of the Q-cycle.

The reduction of CO_2 to carbohydrates requires the reduced ferredoxin, NADPH, and ATP that are synthesized by the photosynthetic light reactions. All plants

employ the C_3 photosynthetic pathway (Calvin–Benson cycle) to fix CO_2 , using the enzyme Rubisco to convert CO_2 and RuBP into the C_3 product, 3-PGA. This multi-enzyme cycle occurs in three phases—carboxylation, reduction, and regeneration—and requires three ATP and two NADPH molecules per molecule of CO_2 fixed. Reactions of the Calvin–Benson cycle reactions are catalyzed by soluble enzymes localized in the chloroplast stroma. Regulation of the cycle is linked to multiple light-dependent mechanisms, including the active removal of Rubisco inhibitors, changes in pH and Mg^{2+} , and disulfide redox transitions catalyzed by the ferredoxin–thioredoxin system.

Variants of C_3 photosynthesis exist in many plants. In one variation, the C_4 pathway, plants fix CO_2 into a C_4 acid in mesophyll cells, and transport this fixed CO_2 to anatomically distinct bundle sheath cells, where the CO_2 is released, refixed, and assimilated by Rubisco and other enzymes of the Calvin–Benson cycle. This sequence of reactions enhances the productivity of C_4 plants by (i) providing a higher concentration of CO_2 for Rubisco in the bundle sheath cell, and (ii) decreasing the oxygenase activity of Rubisco—a reaction that competes with the fixation of CO_2 in C_3 chloroplasts. In another variant, CAM metabolism, CO_2 is fixed at night into malate, which is decarboxylated during the day to provide CO_2 for Rubisco. CAM photosynthesis aids in the retention of water and enables plant to grow in arid environments. Several photosynthetic enzymes in C_4 and CAM plants are regulated to ensure efficient interaction of the CO_2 -concentrating mechanisms with the Calvin–Benson cycle.

Carbohydrate Metabolism

Samuel C. Zeeman

Introduction

Plants are carbohydrate specialists. They are autotrophs and synthesize carbohydrates through **photosynthesis**, then use them to create biological macromolecules. Plant-derived carbohydrates (e.g., cellulose) dominate the biosphere and serve as a key sink for atmospheric carbon dioxide (CO₂). They also dominate animal nutrition, including our own (e.g., sugars and starch). Thus, the global importance of plant carbohydrate metabolism cannot be overstated.

Although many of the reactions involved in carbohydrate metabolism are similar in most organisms, plants have evolved enzymes and pathways that are not found in other organisms. Some distinguishing features of plants help explain their unique metabolic configuration.

- **Plants are photosynthetic.** Apart from a few parasitic species, plants harness light energy and use it to convert simple nutrients such as CO₂, water, and inorganic ions into all the intermediates required for their autotrophic lifestyle. The primary use of the captured energy is the fixation and reduction of CO₂ via the **Calvin–Benson cycle** (see Chapter 12). The resulting triose phosphates are used by photosynthetic cells for the biosynthesis of nucleic acids, proteins, lipids, and polysaccharides, as well as coenzymes and a wealth of secondary metabolites (natural products). Assimilated carbon is also converted to sugars (principally sucrose) or sugar alcohols (e.g., sorbitol) for export to other parts of the plant. Thus, plant carbohydrate metabolism simultaneously feeds many anabolic pathways (Fig. 13.1). Other activities associated with the capture of

light energy include nitrite and sulfate reduction, ammonia assimilation, and numerous other biosynthetic pathways that are supplied with reducing equivalents and ATP from photosynthesis (Fig. 13.2).

Because photosynthesis and the processes associated with light absorption are diurnal, plants must cope with major variations in the supply of energy and assimilated nutrients. At night, photosynthetic carbon assimilation stops, and energy and reducing power must be produced, as it is in nonphotosynthetic organisms, through respiration of stored carbohydrates (Fig. 13.3). Consequently, this imposes a need for flexibility in the pathways and regulation of metabolism in plants that is not seen in other organisms.

- **Plants contain plastids.** Plastids are organelles found only in plants and algae. They can occur as several different types that fulfill different, specialized roles in various plant tissues (see Chapter 1). Plastids are intimately involved in carbohydrate metabolism, and they perform many of the essential biosynthetic reactions that occur in plant cells, including photosynthesis in chloroplasts. Some metabolic pathways are duplicated; they occur in both the cytosol and plastids by the presence of distinct isoforms of each enzyme in the two compartments. To coordinate plastid metabolism with that of the rest of the cell, the plastid envelope contains a suite of transporters that shuttle metabolic intermediates between the two compartments (Fig. 13.4). The complement of transporters differs between plastid types and depends on the specific functions of the plastid. Besides linking cytosolic and plastid metabolism, these transporters also play an important role

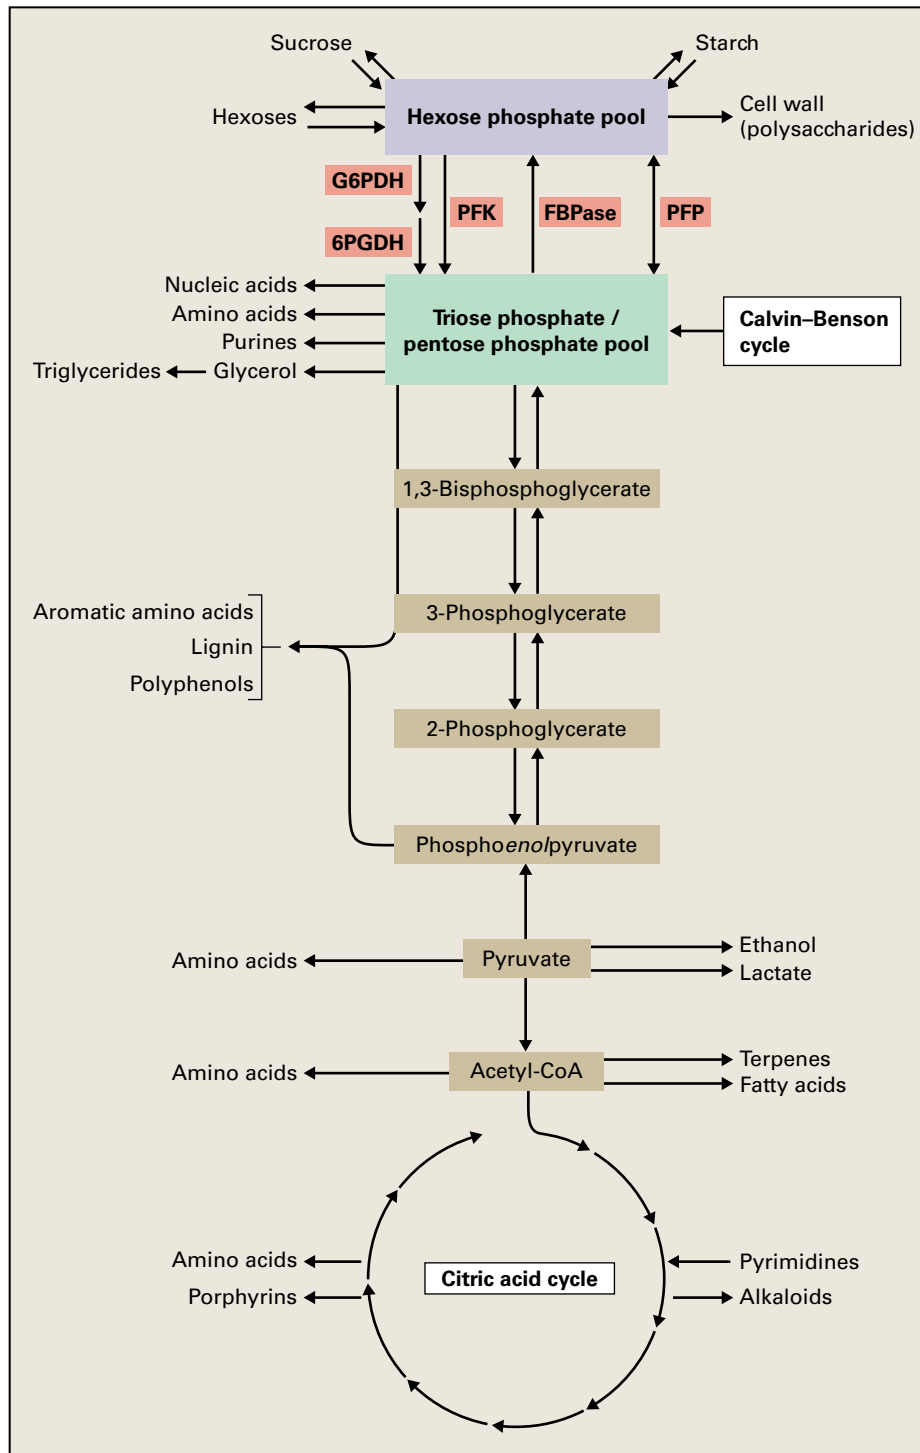

FIGURE 13.1 Central role of carbohydrate metabolism and respiratory pathways in the supply of carbon skeletons for biosynthetic reactions. G6PDH, glucose-6-phosphate dehydrogenase; 6PGDH, 6-phosphogluconate dehydrogenase; PFK, ATP-dependent phosphofructokinase; FBPase, fructose-1,6-bisphosphatase; PFP, pyrophosphate-dependent phosphofructokinase.

in metabolic regulation by communicating changes in metabolites levels in one compartment to another. The segregation of biosynthetic reactions into different cellular compartments also means that the required energy (ATP) and reducing power (NAD(P)H) must be transported between them (Fig. 13.5).

- **Not all plant cells are photosynthetic.** Many cell types lack chlorophyll and so are heterotrophic. Subterranean roots, for example, have no photosynthetic cells and rely on sugars translocated from the shoot. Even within a green leaf there are many cells (e.g., epidermal cells) that rely on their neighboring photosynthetic cells for

FIGURE 13.2 Photosynthetic electron transfer generates ATP and energy-rich reductants that are used to assimilate carbon, nitrogen, and sulfur. Fdx, ferredoxin.

FIGURE 13.3 During the day, carbon dioxide (CO_2) is assimilated through photosynthesis. Some is used for growth, and some is stored. At night, stored carbohydrate is used to support respiration and continued growth.

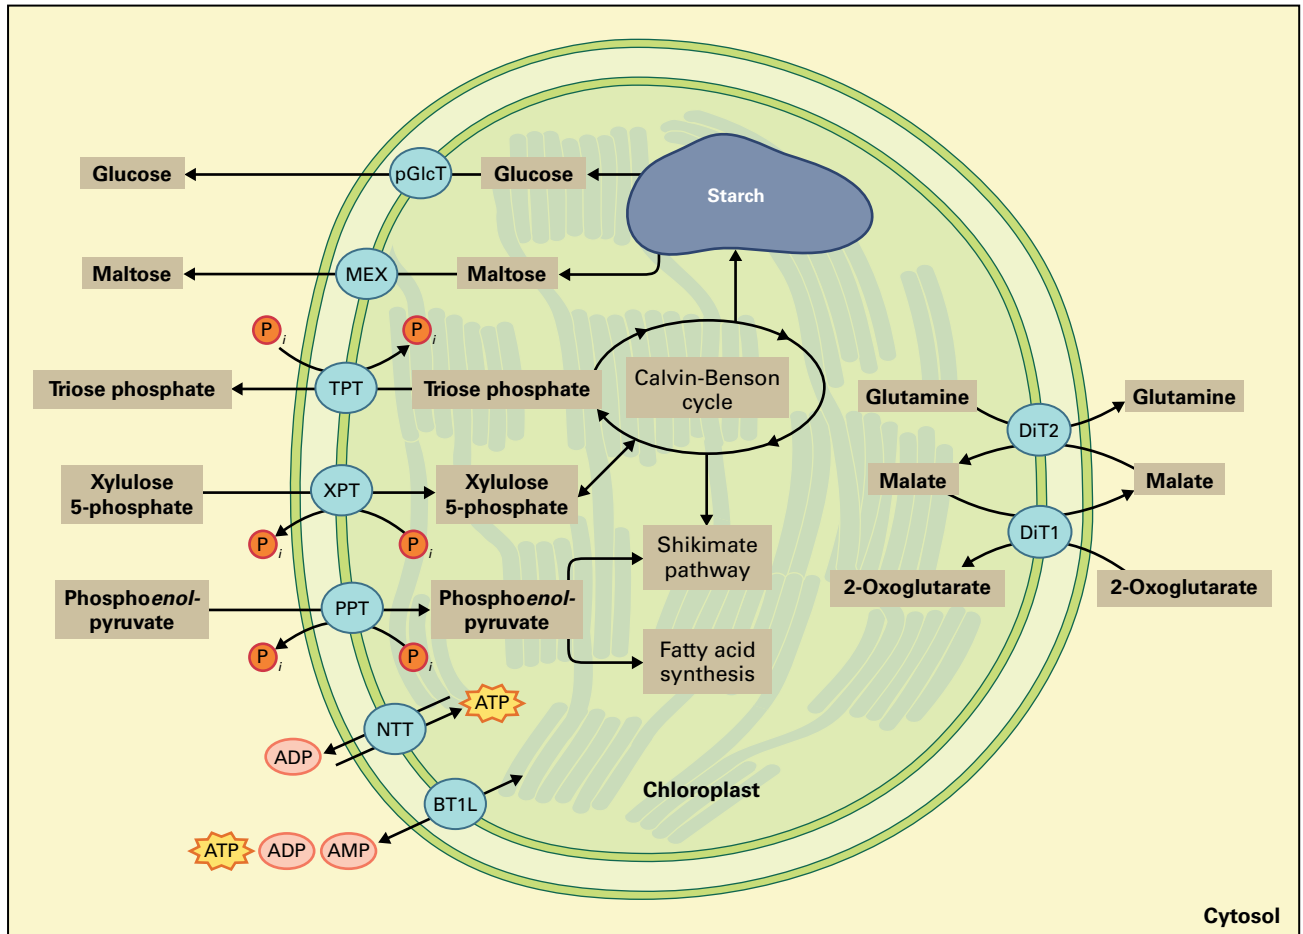

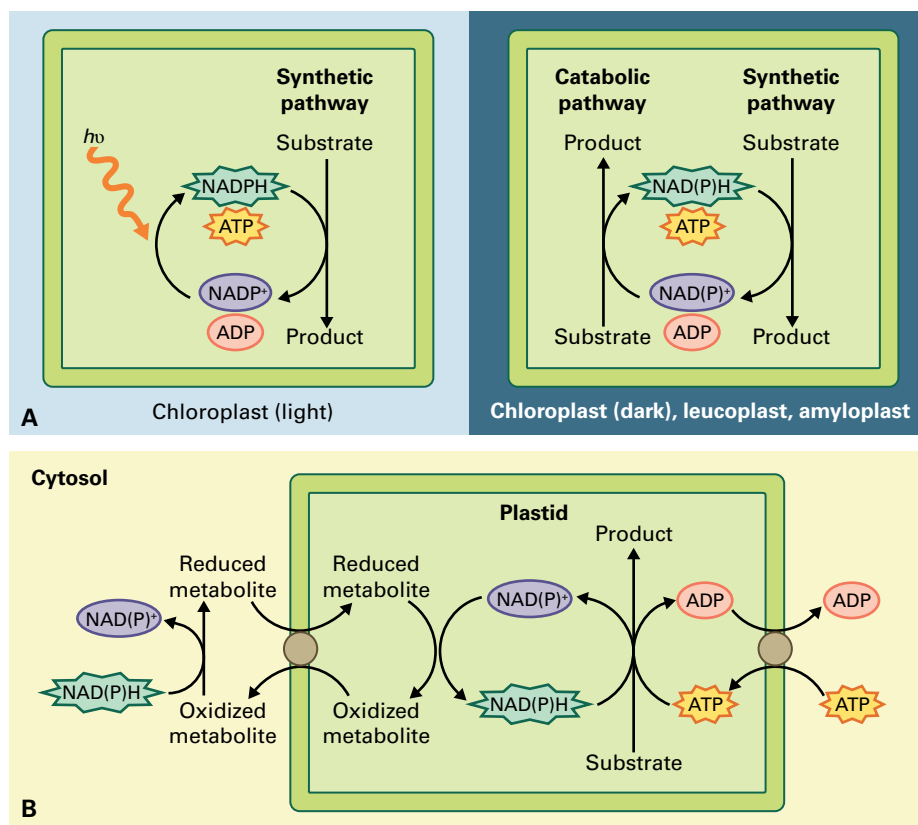

FIGURE 13.4 Transporters located in the inner envelope membranes of plastids exchange metabolites between the cytosol and the plastid stroma. In the transport processes illustrated here, photosynthetic chloroplasts export triose phosphate in exchange for inorganic phosphate (P_i); this is a major flux in photosynthesis. Transporters also exchange pentose phosphates and phosphoenolpyruvate for P_i and nonphotosynthetic plastids also have transporters mediating the movement of hexose phosphates (not shown). Adenylate cofactors can also be transported across the chloroplast envelope, as can maltose and glucose (the products of starch breakdown) and intermediates involved in nitrogen assimilation. All the transporters are reversible, and the direction of transport depends on the concentrations of metabolites on each side of the envelope.

FIGURE 13.5 Mechanism for supplying cofactors to plastids. Cofactors such as NADPH or ATP are required for biosynthetic pathways. (A) Cofactors can be generated within the plastid using light energy ($h\nu$) in the case of the chloroplast or via catabolic pathways located in the organelle. (B) A simple shuttle system for the transfer of reducing equivalents into a plastid. Cofactors may be imported from the cytosol either by direct transport (e.g., exchange of ADP for ATP) or indirectly via shuttles, as shown here.

carbohydrates. Consequently, fluxes through the pathways of carbohydrate metabolism may differ significantly even in adjacent cells.

In other ways, all cells in a plant are alike. For example, each cell is surrounded by a **cell wall** composed primarily of carbohydrates (**cellulose**, **hemicellulose**, and **pectin**; see Chapter 2). Synthesis of these polysaccharides and other cell wall components (e.g., lignin) represents a major sink for carbohydrates, and their production can account for 30% or more of cellular carbohydrate metabolism. That said, cell wall biosynthesis for a cell may be limited to a defined phase of growth and expansion, and once the cell is fully expanded, other metabolic pathways dominate.

- **Plants are sessile organisms.** Terrestrial plants are unable to move to a new location when faced with physical or chemical stress. They must tolerate herbivory and adapt to changes in temperature and in the availability of light, water, and nutrients. This sessile nature renders plants potentially vulnerable to environmental changes. To ensure survival in unforgiving circumstances, plant metabolism is flexible, and changes in chemical composition form an important part of their acclamatory or adaptive responses. For example, when subject to herbivory, plants expend considerable resources in the production of defensive compounds to deter the herbivores.

Combined, these features mean that plant carbohydrate metabolism is complex, flexible, and subject to precise regulation.

13.1 The concept of metabolite pools

Carbohydrate metabolism is frequently depicted in terms of discrete anabolic and catabolic pathways. While this can help in grasping the basic elements of each pathway, it inevitably simplifies the true picture of metabolism, in which many pathways are interconnected and share intermediates. Parts of metabolism where pathways converge, and where intermediates are maintained near to equilibrium with each other by reversible enzyme reactions, can be viewed as “pools” of metabolic intermediates (Fig. 13.6). This concept allows the pathways to be simplified and their connections to be emphasized. Metabolites can be added to or withdrawn from these pools to serve the needs of various biochemical and metabolic pathways.

The direction of flow through a pool depends on the requirements and activities of the cell. For example, in photosynthetic tissues, carbon fluxes through pathways are largely governed by whether cells are in light or darkness. Thus, the directions of flux through a given pool might be reversed between day and night. Metabolite pools can also occur in different subcellular compartments (e.g., the plastid stroma and the cytosol). Equilibration between these pools depends on whether they are linked by the activities of **metabolite transport** proteins (Fig. 13.7). One important metabolite pool in plants is composed of **hexose phosphates** (see Section 13.2), and another is composed of **pentose phosphate pathway** intermediates and the **triose phosphates** glyceraldehyde 3-phosphate and dihydroxyacetone phosphate (see Section 13.8) (Fig. 13.7; see also Fig. 13.1).

FIGURE 13.6 A metabolic pool with four metabolites close to equilibrium. Flow through this pool is dictated by the addition of specific metabolites (A), or withdrawal of intermediates (B and C). In many cases, the metabolic status of the cell determines whether a particular compound (D) enters or leaves the pool.

13.2 The hexose phosphate pool: a major crossroads in plant metabolism

13.2.1 Three interconvertible hexose phosphates make up the hexose phosphate pool

The **hexose phosphate pool** consists of three metabolic intermediates: **glucose 6-phosphate**, **glucose 1-phosphate**, and **fructose 6-phosphate** (Fig. 13.8). These three metabolites are kept in equilibrium through the action of phosphoglucosmutase (Reaction 13.1) and **glucose-6-phosphate isomerase**

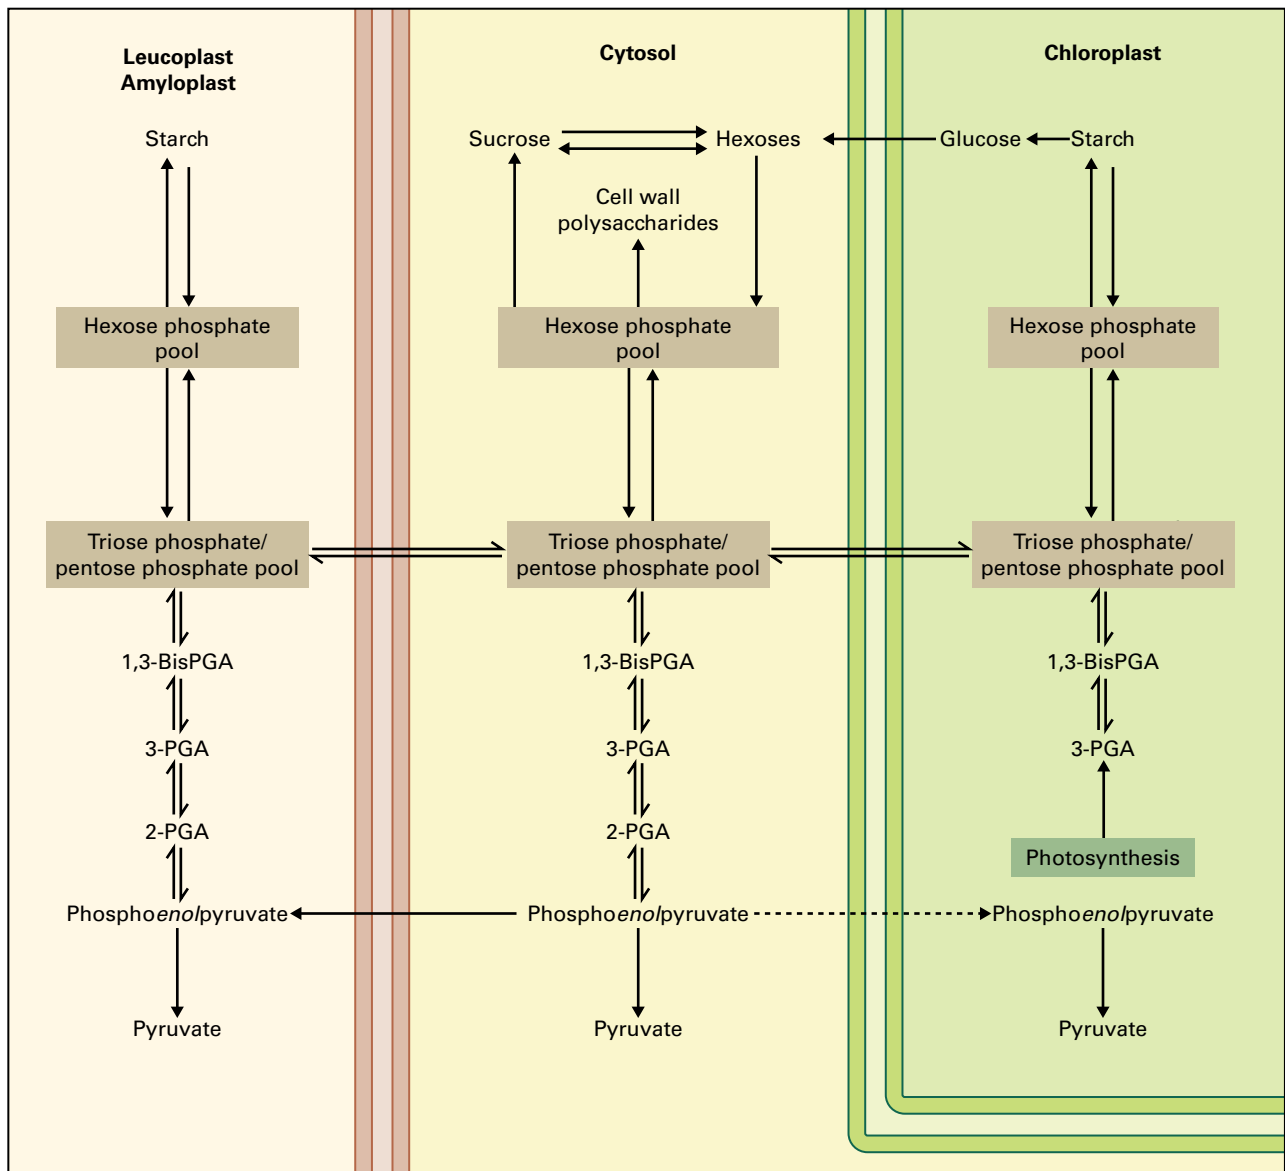

FIGURE 13.7 Duplication of metabolic pathways between the plant cell cytosol and the stroma of photosynthetic chloroplasts and nonphotosynthetic plastids. Pathways are shown in a simplified form.

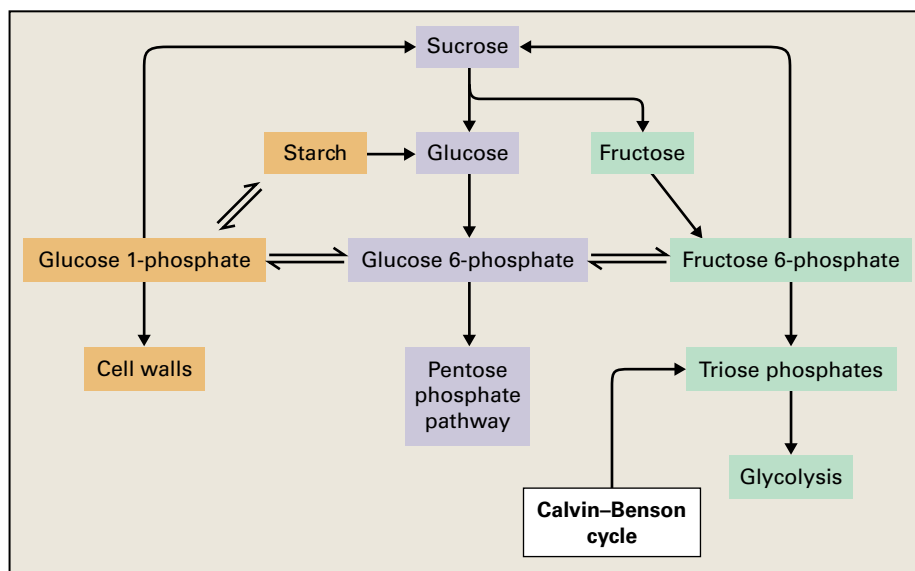

FIGURE 13.8 Intermediates of the hexose phosphate pool are interconverted by two enzymes, phosphoglucomutase and glucose-6-phosphate isomerase.

FIGURE 13.9 The hexose phosphate pool contributes intermediates to glycolysis and the oxidative pentose phosphate pathway as well as to many biosynthetic processes.

(**phosphoglucose isomerase**; Reaction 13.2). Both reactions are readily reversible and remain close to equilibrium *in vivo*.

Reaction 13.1: Phosphoglucomutase

Reaction 13.2: Glucose-6-phosphate isomerase

Fructose 1,6-bisphosphate, another hexose phosphate present in plant cells, is not considered part of the hexose phosphate pool, because most organisms interconvert **fructose 1,6-bisphosphate** and **fructose 6-phosphate** by means of regulated, irreversible reactions catalyzed by ATP-dependent **phosphofruktokinase** (PFK) and fructose 1,6-bisphosphatase. In plants, however, these metabolites can also be interconverted by a reversible reaction catalyzed by **pyrophosphate-dependent phosphofruktokinase** (PPF),

an enigmatic enzyme whose role in metabolism is not fully understood (see Section 13.6.1).

Carbon can enter and leave the hexose phosphate pool in a number of different ways (Fig. 13.9). It can enter the pool during photosynthesis, when the triose phosphates produced are converted to hexose phosphates, and it can leave the pool for starch and sucrose synthesis and cell wall formation. An additional pathway for the production of hexose phosphates observed in germinated oilseeds is **gluconeogenesis**, by which storage lipids are converted to sugars (see Chapters 1 and 14). At night, when no photosynthesis occurs, or in heterotrophic tissues, carbon can enter the hexose phosphate pool through the phosphorylation of free hexoses derived from the degradation of sucrose (see Section 13.4), or from storage carbohydrates, such as starch (see Section 13.7). Other major drains on the hexose phosphate pool in the absence of photosynthesis are the respiratory pathways of **glycolysis** and the oxidative reactions of the pentose phosphate pathway, which provide energy and reducing power for the cell, respectively (Fig. 13.9).

13.2.2 Hexose phosphate pools exist in both the cytosol and the plastid stroma

The plant cytosol and plastids both contain hexose phosphate pools; depending on the plastid type, however, the capacity for the transport of hexose phosphates across the envelopes differs.

Most leaf chloroplasts have a low capacity for hexose phosphate transport, and their hexose phosphate pools are used in metabolic pathways distinct from those in the cytosol. Instead, carbohydrate exchange between these compartments is primarily by transport of the three-carbon intermediates **dihydroxyacetone phosphate**, **3-phosphoglycerate**, and **phosphoenolpyruvate**, and the five carbon intermediate **xylulose 5-phosphate**. Phosphorylated intermediates are exchanged for **inorganic phosphate** via **antiporters** (see Chapter 3) that belong to the same family of integral membrane proteins. The counter-exchange mechanism is strictly coupled, and there is little transport of phosphate in the absence of an exchangeable substrate. Indeed, the major protein in the chloroplast inner membrane is the triose phosphate translocator (TPT; see Fig. 13.4), which is responsible for the export of the products of the Calvin–Benson cycle (see Chapter 12). The nonphosphorylated sugars derived from starch breakdown (see Section 13.7), glucose and maltose, can also cross the chloroplast envelope, but without exchange for phosphate (see Fig. 13.4).

Other plastid types, including colored **chromoplasts** and colorless, starch-storing **amyloplasts**, possess another antiporter, the **glucose-6-phosphate/phosphate translocator** (GPT). This protein can transport glucose 6-phosphate across the plastid envelope, as well as triose phosphates and xylulose 5-phosphate, in exchange for inorganic phosphate (P_i). The presence of the GPT implies a direct interaction between the cytosolic and plastid hexose phosphate pools. Chloroplasts in some cells or tissues (e.g., in guard cells, in the cells adjacent to the leaf vasculature, or in developing fruit) also possess the GPT. These chloroplasts likely perform specialized functions, and their metabolism differs from that of chloroplasts performing photosynthetic carbon assimilation. Under exceptional circumstances, such as drought or artificial feeding of leaves with high concentrations of sucrose, expression of a chloroplast hexose phosphate translocator can also be induced, and this is associated with major changes in metabolic fluxes within the leaf mesophyll cells.

13.3 Sucrose biosynthesis

Sucrose is a major product of photosynthesis in green leaves and accounts for much of the CO_2 fixed during photosynthesis. It also serves as the principal long-distance transport compound in most plants and as a storage compound in some [including sugar beet (*Beta vulgaris*), sugar cane (*Saccharum* sp.), and carrot (*Daucus carota*)]. Sucrose is suited to its transport role: By joining the carbonyl carbons of

glucose and fructose in a stable glycosidic bond, sucrose formation prevents these groups from becoming oxidized through nonenzymatic reactions with other cellular components. For this reason, sucrose is described as a nonreducing sugar (Fig. 13.10).

Sucrose synthesis occurs exclusively in the cytosolic compartment of plant cells using carbon from the hexose phosphate pool. During the day, carbon enters this pool via the gluconeogenic flux from triose phosphates, which are exported from the chloroplast. This flux is regulated at the step of **fructose-1,6-bisphosphatase** (FBPase; see Section 13.6). During the night, hexose phosphates for sucrose synthesis are derived from other sources, such as by catabolism of transitory starch stored in the chloroplast. In this case, carbon exported from the chloroplast as free glucose or maltose is metabolized to hexose phosphates in the cytosol (see Section 13.7).

13.3.1 Glucose 1-phosphate can be reversibly converted to UDP-glucose

Uridine diphosphate-glucose (**UDP-glucose**; Fig. 13.11) is one of the two substrates required for sucrose synthesis (the other is fructose-6-phosphate; see Section 13.3.2). UDP-glucose is also a substrate for other anabolic reactions, including cell wall synthesis (see Chapter 2). The enzyme **UDP-glucose pyrophosphorylase** generates UDP-glucose and **pyrophosphate** (PP_i) from glucose 1-phosphate and UTP (Reaction 13.3).

Reaction 13.3: UDP-glucose pyrophosphorylase

The reaction catalyzed by UDP-glucose pyrophosphorylase is readily reversible, and whether carbon enters or leaves the hexose phosphate pool depends on the concentrations of the respective metabolites. During sucrose synthesis, the flux through this step is driven by the consumption of UDP-glucose. Interestingly, cytosolic concentrations of pyrophosphate remain relatively constant in plants. In this way, plant metabolism differs from that of animals. The cytosol of animal cells contains a **pyrophosphatase** that rapidly hydrolyzes any PP_i produced during biosynthetic reactions; the metabolism of PP_i in the plant cell cytosol, however, is coupled with other metabolic processes (see Box 13.1).

13.3.2 Sucrose is synthesized from UDP-glucose and fructose 6-phosphate

The principal route of sucrose synthesis involves the reactions catalyzed by two enzymes, **sucrose-phosphate synthase** and **sucrose-phosphate phosphatase** (Fig. 13.12).

FIGURE 13.10 Some sugars can act as reductants. (A) Glucose undergoes a conversion at the anomeric carbon (C-1) that yields an aldehyde (D-glucose) and two hemiacetal isomers (α -D-glucopyranose and β -D-glucopyranose). The aldehyde group can react with (reduce) organic and inorganic substrates and is, therefore, described as the reducing end of the molecule. (B) During sucrose synthesis, the anomeric carbon of fructose (C-2) is joined to the anomeric carbon of glucose (C-1) by a glycosidic bond. This bond protects the reducing ends of both monomers, and defines sucrose as a nonreducing sugar. (C) In the disaccharide maltose, one of the anomeric carbons of glucose remains unbound and reactive. For this reason, maltose is a reducing sugar. In trehalose, also a disaccharide of glucose, the two anomeric carbons are bound, rendering it a nonreducing sugar (not shown).

FIGURE 13.11 Structure of uridine diphosphate-glucose (UDP-glucose).

Reaction 13.4: Sucrose-phosphate synthase

Reaction 13.5: Sucrose-phosphate phosphatase

Sucrose-phosphate synthase transfers the glucosyl moiety of UDP-glucose to fructose 6-phosphate, yielding sucrose 6-phosphate, and the subsequent hydrolysis of sucrose 6-phosphate by sucrose-phosphate phosphatase yields sucrose and phosphate. Overall, the formation of sucrose by this route has a large negative free energy change ($\Delta G^{\circ} = -25 \text{ kJ mol}^{-1}$), which renders this sequence of reactions essentially irreversible in vivo. This is primarily due to the large negative free energy change ($\Delta G^{\circ} = -16.5 \text{ kJ mol}^{-1}$) associated with the dephosphorylation of sucrose; the preceding steps (the formation of UDP-glucose and of sucrose 6-phosphate) have relatively small negative free energy changes (ΔG° of $-2.88 \text{ kJ mol}^{-1}$ and -5.7 kJ mol^{-1} , respectively).

BOX 13.1

Pyrophosphate is a mysterious player in plant metabolism

Pyrophosphate (PP_i) is generated in many biosynthetic reactions (e.g., the synthesis of nucleotide sugars, such as UDP-glucose and ADP-glucose, the activation of amino acids for protein synthesis, and the polymerization of nucleic acids). In animals and many microorganisms, hydrolysis by pyrophosphatase removes the pyrophosphate produced in these reactions, and the large change in free energy (ΔG° of $-33.4 \text{ kJ mol}^{-1}$) drives otherwise energetically unfavorable reactions in the direction of synthesis.

The stroma of plastids, the site of many biosynthetic reactions in plants, also contains a pyrophosphatase, but the plant cytosol, where sucrose and cell wall biosynthesis take place, can accumulate a substantial concentration of PP_i (up to 0.3 mM). This cytosolic PP_i pool is important; overexpression of a cytosol-localized bacterial pyrophosphatase in transgenic tobacco (*Nicotiana tabacum*) significantly inhibits growth. However, the way in which PP_i metabolism is linked to other cellular processes is not fully understood.

The discovery of this cytosolic PP_i pool followed the discovery of one of the enzymes that can metabolize it: the PP_i -dependent phosphofructokinase (PFP; see Section 13.6). PFP can remove or produce PP_i while interconverting fructose 1,6-bisphosphate and fructose 6-phosphate in a reversible reaction. Its presence is an enigma because it acts alongside two other cytosolic enzymes catalyzing similar, yet irreversible reactions. The conversion of fructose 6-phosphate to fructose 1,6-

bisphosphate is a principal regulatory step in glycolysis in other organisms. However, regulation differs in plants due to their autotrophic nature, and it has been proposed that PFP serves other functions, including:

- maintenance of a stable pyrophosphate concentration in the cell
- generation of pyrophosphate required for the breakdown of sucrose by way of the sucrose synthase pathway (see Section 13.4)
- bypass of PFK during times of phosphate starvation, when the amounts of ATP may be insufficient for the PFK reaction (see Box 13.5)
- stimulation of carbon flow in glycolysis during anaerobic conditions
- equilibration of the hexose and pentose phosphate/triose phosphate pools during increased biosynthetic activity.

PFP has been repressed or mutated in a range of species. In general, such plants appear normal, but examination of the metabolite levels and fluxes reveals differences in each case, including minor reductions in starch content of potato (*Solanum tuberosum*) tubers, increases in the sucrose content of sugar cane (*Saccharum* sp.) stems, slight inhibition of glycolysis, and changes in the balance of hexose phosphates to triose phosphates. These studies suggest PFP influences fluxes between the hexose phosphate and triose

phosphate pools, but it is not an essential enzyme. Thus, its function remains unresolved. It may be that, under normal laboratory or greenhouse conditions, the enzyme enhances growth and fitness by a margin that is too small to measure, but large enough to ensure conservation of the enzyme during evolution. Alternatively, the enzyme may be important only under certain conditions not tested in the laboratory.

Another player in PP_i metabolism is the proton-pumping pyrophosphatase located in the tonoplast (see Chapter 3). Energy released by pyrophosphate hydrolysis drives the pump, acidifying the vacuole and generating an

electrochemical gradient used to power transmembrane transport. This H^+ -pyrophosphatase may participate in removing cytosolic pyrophosphate produced during biosynthesis. Analysis of *Arabidopsis* mutants deficient in this pump supports this idea: *Arabidopsis* seedlings convert storage lipids in their cotyledons into sucrose via gluconeogenesis, and pump-deficient mutants have reduced sucrose content and stunted growth due to accumulation of inhibitory levels of PP_i .

Despite these discoveries, we still do not fully understand how or why plant cells maintain a stable pool of cytosolic PP_i .

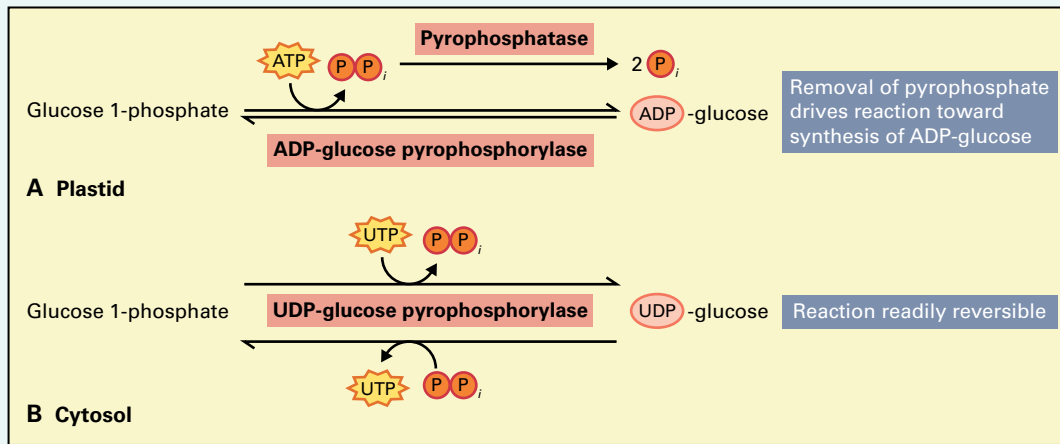

FIGURE 13.12 Sucrose synthesis by sucrose-phosphate synthase (SPS) and sucrose-phosphate phosphatase.

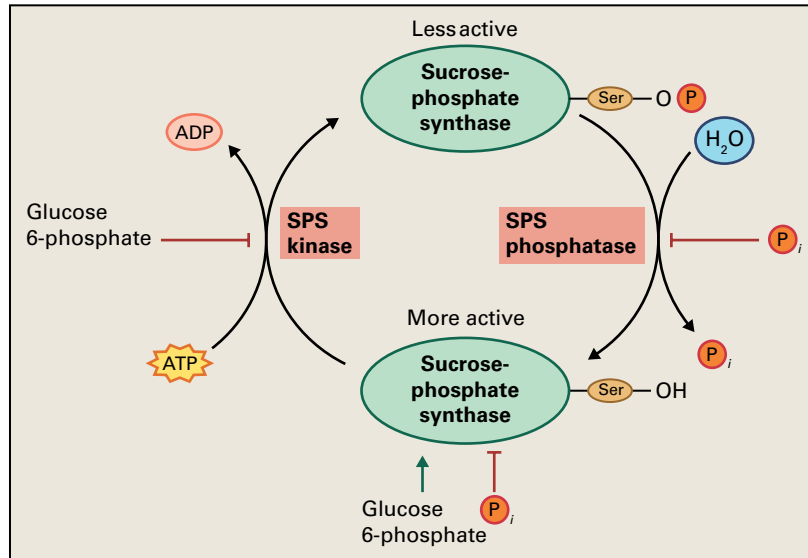

FIGURE 13.13 Regulation of sucrose-phosphate synthase (SPS). SPS is regulated by both allosteric effectors and phosphorylation/ dephosphorylation of a serine residue in the enzyme. The active enzyme is dephosphorylated and can be activated further, allosterically, by glucose 6-phosphate. SPS is inhibited by inorganic phosphate and possibly by sucrose. In addition, glucose 6-phosphate inhibits the SPS-kinase, and inorganic phosphate inhibits the SPS-phosphatase. As a result, a high ratio of glucose 6-phosphate to inorganic phosphate maintains the enzyme in its active form, whereas a low ratio inhibits the enzyme and promotes its conversion to the inactive form.

There is evidence, mainly from work on spinach (*Spinacia oleracea*) in the 1990s, that sucrose synthesis is regulated by mechanisms that coordinate the activity of sucrose-phosphate synthase with the status of the hexose phosphate pool (Fig. 13.13). First, sucrose-phosphate synthase is subject to **allosteric modulation** by glucose 6-phosphate, which activates the enzyme, and by P_i , which inhibits it. When hexose phosphates are abundant, the enzyme is activated. Furthermore, a decrease in free P_i , which generally accompanies high concentrations of hexose phosphates, lifts inhibition. Second, sucrose-phosphate synthase is regulated by multisite, reversible protein phosphorylation. One kinase that phosphorylates Ser¹⁵⁸ and downregulates sucrose-phosphate synthase activity is itself inhibited by glucose 6-phosphate. The phosphatase that upregulates the activity of sucrose-phosphate synthase is inhibited by high concentrations of P_i . Sucrose-phosphate synthase is also phosphorylated at other sites. Phosphorylation at Ser²²⁹ allows interaction with 14-3-3 proteins, which also inhibits its activity. By contrast, phosphorylation at Ser⁴²⁴, which can occur during osmotic stress, can activate the enzyme. The effects of allosteric and post-translational modifications combine to provide sensitive control of sucrose synthesis. There is also evidence that sucrose levels can feed back on sucrose-phosphate synthase activity, preventing overproduction; the mechanism of this feedback, however, is not understood.

While such biochemical findings have laid the foundation for understanding the control of sucrose synthesis, the situation is likely more complex. Multiple conserved genes encode various isoforms of both sucrose-phosphate synthase and sucrose-phosphate phosphatase, and the properties of each of these isoforms have not been rigorously investigated (see Box 13.2). This may complicate the interpretation of some biochemical

studies in which a uniformity of enzyme activity or activation state is assumed. For instance, one class of sucrose-phosphate synthase isoforms found in wheat (*Triticum aestivum*) and other monocotyledonous Poaceae lack the phosphorylation sites associated with 14-3-3 protein binding and osmotic stress activation, and their regulatory features are unknown.

13.4 Sucrose metabolism

After its production in source tissues, sucrose is transported within the plant via the phloem to sink tissues, where it can enter destination cells by two routes. In most cells, it moves by **symplasmic transport**, diffusing through the **plasmodesmata**. In this case, the sucrose is broken down in the cytosol or sequestered in the vacuole to maintain passive import. In some tissues, however, sucrose is unloaded from the phloem into the **apoplast** and must cross the plasma membrane to enter the destination cell, often against a concentration gradient. This **apoplastic pathway** is particularly important to developing embryos, which have no direct cytoplasmic connections to the tissues of the maternal plant. The sucrose can be either transported into these cells directly, or is first hydrolyzed to glucose and fructose in the apoplast. The potential significance of the various means of sucrose transport and degradation is receiving more attention, given that carbohydrates, in addition to being intermediates in metabolism, play a role in regulating the expression of many genes. Thus, the form of carbohydrate taken up may influence the activity of the cell (see Chapters 8 and 16).

Sucrose can be degraded by either **sucrose synthase** (Fig. 13.14) or **invertase** (Fig. 13.15):

BOX
13.2

Why plants have multiple genes that encode the same enzyme is not fully understood

Genome sequencing has revealed that multiple conserved genes frequently encode particular metabolic enzymes. In some cases, this is because the enzyme is required in different cellular compartments. For example, some enzymes of glycolysis are present in both the plastid and the cytosol, and each protein is encoded by a separate gene. This subfunctionalization offers advantages over mechanisms for dual-targeting of the same gene product to multiple compartments, as each enzyme can evolve different kinetic and regulatory properties that confer advantages to the plant.

In some cases, however, targeting to different cellular compartments cannot explain these gene duplications. For example, sucrose-phosphate synthase and sucrose-phosphate phosphatase are cytosolic enzymes, each encoded by small gene families. Here, the significance of the multiple isoforms is unknown, but different patterns of expression could mean that each isoform is responsible for synthesizing sucrose in a different tissue. In some

cases, there is even greater gene replication: The *Arabidopsis* genome encodes 17 putative invertase genes, with multiple isoforms targeted to each of four cellular (and extracellular!) compartments.

Such revelations from genome sequencing define one of the challenges for molecular geneticists and biochemists today, who must work to explain the functions of these different genes. The answers may often be surprising. Studies of the β -amylase gene family in *Arabidopsis*, which has nine members, have confirmed the enzymes' supposed role in starch catabolism in chloroplasts (see Section 13.7). They have also revealed the existence of apparently noncatalytic isoforms acting in an undefined role alongside them. Furthermore, two members of the protein family are targeted to the nucleus, where they act as transcriptional regulators. Such neofunctionalization allows proteins that originate from metabolic enzymes to take on new roles, such as metabolic sensors.

FIGURE 13.14 Sucrose synthase catalyzes a reversible reaction that can synthesize or degrade sucrose. In plant cells, this enzyme is associated primarily with sucrose degradation.

FIGURE 13.15 Degradation of sucrose by invertase.

Reaction 13.6: Sucrose synthase**Reaction 13.7: Invertase**

The name sucrose synthase can be confusing. The enzyme is capable of catalyzing both sucrose synthesis and degradation; however, the activity of sucrose-phosphate synthase (see Reaction 13.4) is high in tissues that synthesize sucrose, indicating that it is the dominant enzyme for sucrose biosynthesis. In contrast, sucrose synthase is present in higher activities in sucrose-utilizing tissues (e.g., developing seeds) than in sucrose-exporting tissues (e.g., photosynthetic leaves and germinated oil seeds). Thus, the principal role of sucrose synthase is thought to be sucrose catabolism. The reaction catalyzed by invertase is irreversible and so leads only to sucrose degradation.

A difference between these two sucrose-degrading enzymes lies in the energy status of the products in relation to the cytosolic hexose phosphate pool. Invertase produces free hexoses that must be phosphorylated at the expense of ATP. By contrast, sucrose synthase generates UDP-glucose, which can react with pyrophosphate to produce glucose 1-phosphate and uridine triphosphate (UTP). Thus, sucrose synthase, combined with UDP-glucose pyrophosphorylase (see Reaction 13.3), can provide an ATP-independent pathway for hexose phosphorylation (Fig. 13.16).

The precise roles of invertase and sucrose synthase in sucrose breakdown are not well understood. Both enzymes often appear in the same tissues. In addition, both sucrose synthase and invertase occur as multiple isoenzymes, each of which probably functions in a specific tissue or cellular compartment (e.g., in *Arabidopsis* six genes encode sucrose synthase, and 17 encode different invertase isoforms; see Box 13.2).

In potato (*Solanum tuberosum*) tubers, invertase activity is too low to account for the required rate of sucrose

breakdown, implicating sucrose synthase in that role. In addition, repressing the major sucrose synthase gene expressed in tubers decreases starch content and tuber growth. Comparable findings have been made in pea (*Pisum sativum*) and maize (*Zea mays*), where mutation of sucrose synthase genes results in decreased starch synthesis in developing embryos and endosperm, respectively. Studies like these have led to the concept that sucrose synthase activity tends to be associated with the utilization of sucrose for the biosynthesis of nonstructural carbohydrate polymers like starch, and of structural carbohydrate polymers like cellulose and callose. Models have been proposed that suggest direct interaction between sucrose synthase with the cellulose synthase complex, which could allow direct channeling of the UDP-glucose produced by sucrose synthase to the active site of cellulose synthase.

Invertases are often defined as either acid invertases (acidic pH optima) or alkaline invertases (neutral or alkaline pH optima). These forms operate in different cellular compartments: Acid invertases are present in both the vacuole and the apoplast, whereas alkaline invertases are present in the cytosol and plastid. Vacuolar invertase probably hydrolyzes sucrose stored in the vacuole, with the subsequent transport of the free hexoses to the cytosol for metabolism. High levels of vacuolar invertases are observed in tissues accumulating hexoses, such as developing fruits, and in rapidly growing tissues, such as the elongation zones of roots and hypocotyls. The apoplastic form of invertase is bound firmly to the cell wall matrix and hydrolyzes apoplastic sucrose delivered to sink tissues. This is particularly important in plant reproductive tissues. Repression of cell wall invertases interferes with pollen development, causing male sterility and decreased seed size in important crops like maize (*Zea mays*) and rice (*Oryza sativa*). Cytosolic invertases are also important for plant growth, particularly roots, as demonstrated through the analysis of mutants of *Arabidopsis*, *Lotus japonicus*, and rice.

Plants also possess proteinaceous invertase inhibitors that interact with the acid invertases of the apoplast and the vacuole. These inhibitors likely repress invertase activity, although

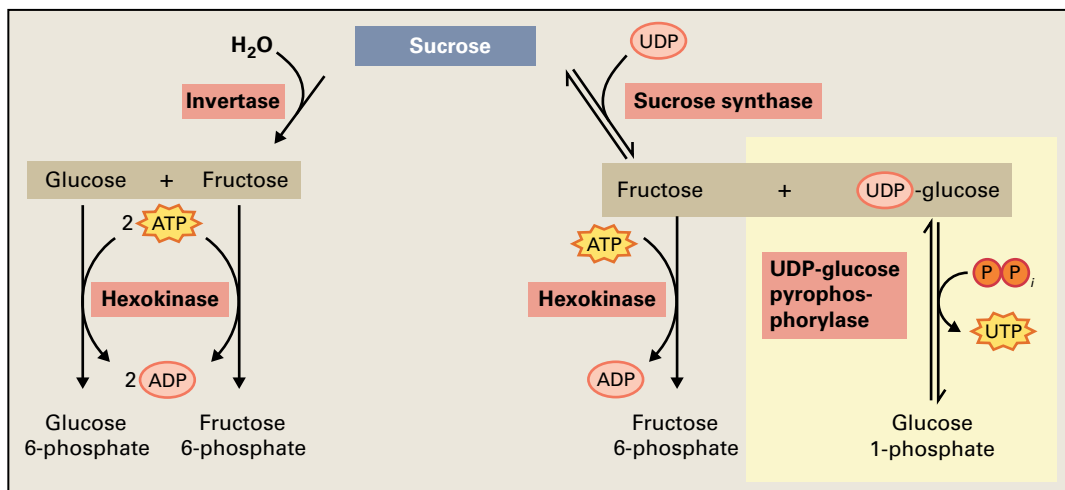

FIGURE 13.16 Hexokinase uses ATP to phosphorylate glucose and fructose, the products of invertase. Sucrose synthase and UDP-glucose pyrophosphorylase act together to generate hexose phosphate by an ATP-independent pathway, highlighted here in yellow.

FIGURE 13.17 Schematic diagram of invertase-mediated or sucrose synthase-mediated sucrose degradation in heterotrophic tissues. Phloem unloading of sucrose (Suc) in sinks may occur apoplastically into the cell wall matrix or symplasmically through plasmodesmata (PD). In the former case, unloaded sucrose can be hydrolyzed by cell wall bound invertase (CW-INV) into glucose (Glc) and fructose (Fru) before being taken up by membrane hexose transporters (light-blue circles). Symplasmically imported sucrose, or that taken up by membrane bound sucrose transporters (dark-blue circles), can be hydrolyzed by cytoplasmic invertase (C-INV). In some tissues, cytosolic sucrose enters the vacuole or the plastid, where it is hydrolyzed by vacuolar invertase (V-INV) or plastid invertases (P-INV) (latter not shown). Both CW-INV and V-INV are subject to posttranslational inhibition by proteinaceous inhibitors (not shown). The intracellular Glc and Fru may be respired, stored in the vacuole, or used for biosynthesis of sugar polymers (e.g., starch and cellulose). Sucrose can also be metabolized by sucrose synthase (SUS) in the cytosol.

little is known about their precise roles. Their existence adds an additional layer of complexity onto an already complex process (Fig. 13.17). However, this is not surprising, considering the central role sucrose plays in plant metabolic biology.

13.5 Starch biosynthesis

Not all the carbohydrate assimilated in leaves is immediately used for sucrose biosynthesis and growth; some is stored for later use, when photosynthesis is not possible (see Fig. 13.3). Carbohydrate can be stored in several forms, including vacuolar sucrose or **fructans**, but the most common storage form is **starch**. In leaves, starch is synthesized during the day in chloroplasts and stored temporarily until the night, when it is degraded

again. In storage tissues, such as tubers or seeds, it is synthesized in amyloplasts and stored for much longer periods.

Starch is an important plant product, accounting for half of humankind's caloric intake. Consequently, much research has been focused on its metabolism, both in crops and model species. The analogous storage compound to starch in other organisms is glycogen. In animals and fungi, glycogen is synthesized in the cytosol from UDP-glucose, while in bacteria it is synthesized from ADP-glucose. Starch and glycogen share some structural similarities (both are composed of polymers of glucose), but glycogen has a more branched structure. The biosynthesis of starch is more complex than that of glycogen.

Starch is a remarkable substance that takes the form of massive, insoluble semicrystalline granules (Fig. 13.18). By linking thousands of glucose monomers into a small number of molecules that then partially crystallize, starch represents a compact, stable, osmotically inert form of carbohydrate storage. If a comparable number of hexose units accumulated in the plastid as sucrose, the stromal solution would contain too many solute particles, and water from the cytosol would flood in by osmosis, causing the plastid to swell and burst.

13.5.1 Starch synthesis in plants begins with ADP-glucose

In the chloroplast, the Calvin-Benson cycle can feed carbon directly into the stromal hexose phosphate pool and then the starch biosynthetic pathway (Fig. 13.19). Thus, starch biosynthesis is supplied by a different pool than sucrose synthesis.

Fructose 6-phosphate can be converted to glucose 1-phosphate by the sequential action of the plastid isoforms of phosphoglucomutase and glucose-6-phosphate isomerase (see Reactions 13.1 and 13.2). The first committed step in the starch biosynthetic pathway is the production of **ADP-glucose** by **ADP-glucose pyrophosphorylase** (Reaction 13.8). Genetic studies in *Arabidopsis* and other species have demonstrated that this is the major pathway of starch synthesis in leaves, as mutants deficient in each of these three enzymes have greatly reduced starch content.

Reaction 13.8: ADP-glucose pyrophosphorylase

In amyloplasts, carbon for starch synthesis is derived from the metabolism of sucrose translocated from source tissues (see Chapter 15 and Section 13.4). Substrates for ADP-glucose production must be imported from the cytosol, usually in the form of glucose 6-phosphate (Fig. 13.19). This is illustrated by the *rugosus3* mutant of pea (*Pisum sativum*), which lacks the plastid phosphoglucomutase. It cannot convert glucose 6-phosphate into glucose 1-phosphate in the amyloplasts of its embryos and so cannot synthesize starch (see Box 13.3). In the **endosperm** of maize (*Zea mays*) and other cereal seeds, however, a second form of ADP-glucose pyrophosphorylase

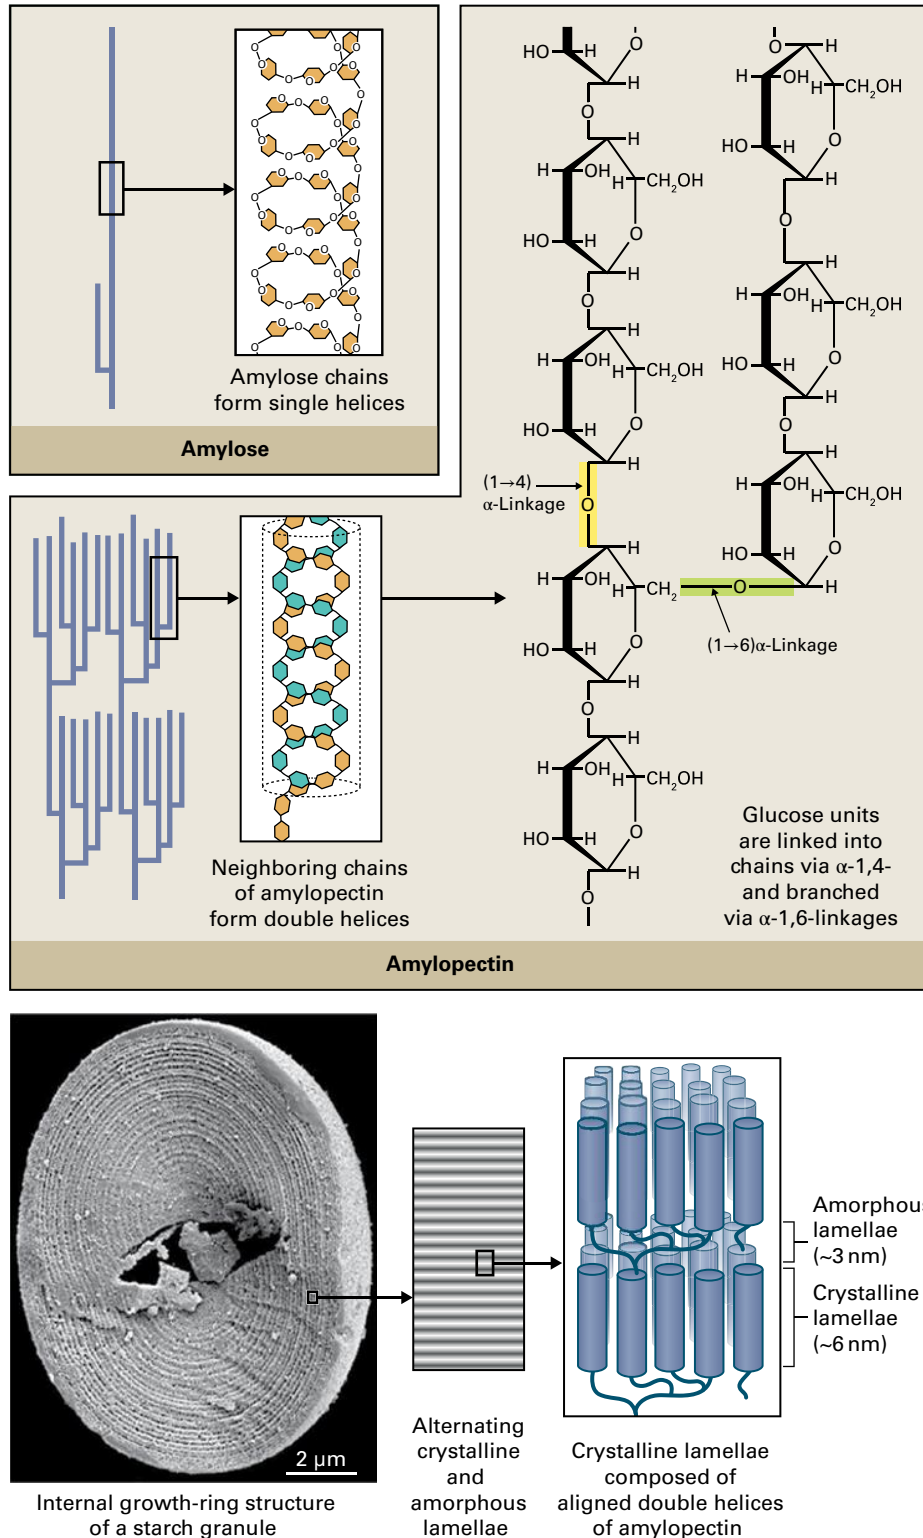

FIGURE 13.18 Starch is a remarkable substance. Although composed almost exclusively of the two glucose polymers, amylose and amylopectin, it takes the form of massive, insoluble, semi-crystalline granules. Amylopectin is the major polymer responsible for the granule structure. It has a nonrandom branching pattern resulting in clusters of unbranched chain segments. Left-handed double helices with six glucose units per turn form between these linear segments (middle). Amylose is linear or only slightly branched. It forms single helical structures (top left). The double helices of amylopectin arrange into ordered crystalline lamellae. Crystalline lamellae alternate with amorphous lamellae (containing the branch points) with 9 nm periodicity (bottom right). A higher-order structure, with a periodicity of hundreds of nanometers is visible with light or scanning electron microscopy (bottom left). These are often referred to as growth rings, owing to the similarity in appearance to the growth rings of a tree. However, starch granule growth rings are probably a structural feature rather than representing periodic phases of growth.

FIGURE 13.19 Schematic representation of the pathway of starch biosynthesis and its subcellular compartmentalization in leaves (A) and heterotrophic tissues (B). Energy and substrates for starch synthesis in leaves are derived from photosynthesis, while in heterotrophic tissues they are derived from the metabolism of imported sucrose. Cereal crops have the capacity to generate ADP-glucose in the cytosol and translocate it into the amyloplast (highlighted in blue), as well as the plastid-localized pathway. This ability appears to be restricted to members of the Poaceae.

exists in the cytosol in addition to the one in the amyloplast. A transporter specific to these monocotyledonous plants can import ADP-glucose directly into the amyloplasts in exchange for ADP (Fig. 13.19). This cytosolic route, rather than the plastid one, appears to be the major source of ADP-glucose in the cereal endosperm. Mutations affecting the cytosolic isoform of ADP-glucose pyrophosphorylase or the ADP-glucose transporter reduce starch accumulation by about 75%.

13.5.2 ADP-glucose pyrophosphorylase is a multisubunit, highly regulated enzyme

Almost all ADP-glucose produced in the plastid is directed to starch synthesis, and ADP-glucose pyrophosphorylase (Reaction 13.8) is regarded as the major regulated enzyme of the pathway. This contrasts with cytosolic **UDP-glucose pyrophosphorylase**, which provides **UDP-glucose** for multiple biosynthetic pathways (e.g., sucrose synthesis and cellulose synthesis) and so is poorly suited as a regulatory step. Another key difference is the presence of an active pyrophosphatase in the plastid stroma, but not in the cytosol. The hydrolysis of pyrophosphate renders the production of ADP-glucose in the plastid essentially irreversible.

ADP-glucose pyrophosphorylase is a heterotetramer of two large and two small subunits (Fig. 13.20), which have a common ancestry. The small subunits are catalytically active, while the large subunits have little or no activity. However, the large subunits influence the activity and regulatory properties

of the small subunits in the native enzyme. Multiple isoenzymes of both subunits exist, which may be expressed on a tissue-specific basis or under different environmental conditions. The large subunit, in particular, is present in multiple copies that have diverged more in sequence over time than the small subunits. Although the function of these isoenzymes is not fully understood, different combinations of large and small subunits may yield enzymes with distinct kinetic and regulatory properties in different tissue or cell types.

In photosynthetic tissues, ADP-glucose pyrophosphorylase is activated by 3-phosphoglycerate and inhibited by P_i in a regulatory mechanism that links enzyme activity with the supply of photosynthate (Fig. 13.20). Increasing levels of the Calvin-Benson cycle intermediate 3-phosphoglycerate indicate an abundance of fixed carbon. P_i levels decrease as phosphorylated intermediates of metabolism accumulate (e.g., in the light). Consequently, the levels of the activator and inhibitor are linked and change in a reciprocal manner (Fig. 13.21). Thus, relatively small changes in the P_i :3-phosphoglycerate ratio have a large impact on ADP-glucose pyrophosphorylase activity. When photophosphorylation slows or ceases altogether (e.g., in the dark), the P_i concentration in the chloroplast rises, and starch synthesis is repressed.

In leaves, starch synthesis occurs concurrently with sucrose synthesis, with the fine allosteric control of the pathways influencing each other (see Section 13.6.2). ADP-glucose pyrophosphorylase is also regulated by reversible redox activation (see Fig 13.20). The formation of a covalent intermolecular disulfide bridge between two cysteine residues on each of the small subunits deactivates the enzyme.

BOX
13.3

Mendel's round and wrinkled peas reflect different alleles of a starch-branching enzyme

A century before the structure of DNA was discovered, an Austrian monk named **Gregor Mendel** bred peas in the monastery garden in the town of Brno. Mendel crossed round peas with wrinkled peas and followed these traits through a series of generations. He concluded that a pair of factors (now called genes), passed from parent to offspring, governed the appearance of the seeds. Mendel published his observations in 1865, initiating the discipline of classical genetics.

In 1990, modern molecular biology revealed the molecular basis of the round and wrinkled pea phenotypes. The mutation Mendel followed was due to a transposon-like insertion into the gene encoding one of two isoforms

of starch-branching enzyme. In these mutants, this loss of function is not fully compensated by the presence of the second isoform, and starch production falls by $\approx 30\%$. Carbon that would have been stored as starch instead accumulates as sucrose, lowering the osmotic potential of the developing seed and causing it to swell with fluid. On drying, the loss of the additional water results in the seed having a wrinkled appearance. The subsequent study of other wrinkled-seeded (or *rugosus*) peas helped establish other critical steps in the starch biosynthetic pathway.

This bridge can be broken by reduction, whereupon the enzyme becomes active. In illuminated chloroplasts, reduction is mediated by **thioredoxin** (Trx), using electrons derived from the photosynthetic electron transport chain (see Chapter 12). This provides an additional link between the light reactions of photosynthesis and starch synthesis. At night, ADP-glucose pyrophosphorylase is primarily in the oxidized, inactive form, minimizing starch biosynthesis. However, the enzyme can also be activated in the dark by NTRC (see below) to an extent that depends on the level of NADPH, reflecting available sucrose. ADP-glucose pyrophosphorylase can thus link both light and sugar availability to the synthesis of starch.

In amyloplasts and other nonphotosynthetic plastids, the mechanism and importance of ADP-glucose pyrophosphorylase regulation are less clear. The potato (*Solanum tuberosum*) tuber enzyme is also redox-regulated and sensitive to the same allosteric regulation as the leaf enzyme. Redox activation is still possible, with the electrons from sucrose-derived

NADPH, either via the sequential actions of **ferredoxin-NADP reductase** and **ferredoxin-thioredoxin reductase**, or via the plastid-localized protein **NADP-thioredoxin reductase C** (NTRC, which contains a Trx-like domain) (see Fig. 13.20). The latter enzyme has been implicated in the light-independent, sucrose-dependent reductive activation of ADP-glucose pyrophosphorylase in *Arabidopsis* chloroplasts, as well as in the activation of the amyloplast enzyme in roots. The inhibition of ADP-glucose pyrophosphorylase by phosphate is also understandable, because nonphotosynthetic plastids synthesize starch from glucose phosphate, which is imported into the plastid by a hexose phosphate/ P_i antiporter. High concentrations of P_i , therefore, indicate that hexose phosphate supply from the cytosol is limiting (see Fig. 13.19). Activation of this enzyme by 3-phosphoglycerate in amyloplasts is more difficult to comprehend, though it may signal a sufficient carbohydrate supply. Interestingly, not all amyloplast-localized forms of ADP-glucose pyrophosphorylase display this regulatory characteristic.

The importance of ADP-glucose pyrophosphorylase in the regulation of starch biosynthesis has been demonstrated by the expression of an unregulated bacterial ADP-glucose pyrophosphorylase in different plant tissues. The presence of this enzyme boosts the amount of starch by up to 60%, suggesting

FIGURE 13.20 Structure and regulation of plastid ADP-glucose pyrophosphorylase. Multiple mechanisms of regulation allow starch synthesis to respond to physiological and environmental stimuli. The enzyme is a heterotetramer of two large (L) and two small (S) subunits. Allosteric regulation by 3-phosphoglycerate (3-PGA) and inorganic phosphate (P_i) can rapidly adjust the rate of starch synthesis to the availability of substrates. Redox regulation via reversible disulfide bond formation between the small subunits occurs in response to light and sugar signals. Redox regulation involves thioredoxin (Trx) and a special type of NADP-dependent thioredoxin reductase (NTRC) and its associated thioredoxin found in plastids. The enzyme is more active in the reduced state (thiol groups) and less active in the oxidized state (black sulfur atoms). Transcriptional regulation in response to changes in carbon and nutrient supply allows more gradual changes in AGPase activity, which may require some days to develop. Red indicates inhibition, blue indicates activation.

FIGURE 13.21 Regulation of starch synthesis in chloroplasts. When 3-phosphoglycerate is abundant, signifying the availability of photoassimilates, ADP-glucose pyrophosphorylase is activated. Inorganic phosphate, which generally changes in a reciprocal manner to phosphorylated intermediates, inhibits the enzyme. Redox regulation in response to light or sugar signals increases the enzyme's sensitivity to 3-phosphoglycerate and decreases its sensitivity to phosphate.

that in wild-type plants, the amount of this enzyme, or its regulation, limits starch formation. In tissues that already contained high starch, however, this increased flux of carbon into starch is matched by the induction of starch degradation enzymes, and starch levels do not increase. This reveals a remarkable sensitivity of the plant to its own metabolic status.

Other factors may also be important in controlling the rate of starch synthesis, particularly membrane transport steps. For example, transgenic potato (*Solanum tuberosum*) plants with an increased capacity for ATP transport across the plastid envelope accumulate more starch in their tubers. Likewise, in cereal endosperm, the activity of the amyloplast ADP-glucose transporter might limit starch production.

13.5.3 Starch granules contain two distinct glucose polymers, amylose and amylopectin

Starch consists of two molecules, **amylose** and **amylopectin** (see Fig. 13.18), both of which are homopolymers of α -1,4-linked glucose. Amylopectin molecules typically contain over 100,000 glucose residues and account for 70% or more of the starch. It is a branched molecule, with 4–5% of the linkages being α -1,6-bonds (branch points). The branching pattern of amylopectin is not random; the combination of branch frequency, branching pattern, and α -1,4-linked chain lengths underlie the semi-crystalline nature of starch (see Fig. 13.18). Extensive hydrogen bonding between the hydroxyl groups of the glucose residues in adjacent chains promotes the formation of double helices. These pack together into ordered crystalline layers that alternate with amorphous layers containing the branch points. Amylose is smaller than amylopectin. It typically contains around 1,000 glucose residues and accounts for 30% or less of the starch. In contrast to amylopectin, amylose has very few branch points. The proportions of amylose to amylopectin, together with the size and structure of starch granules, determine the properties of extracted starch that are

Starch has properties that make it useful both in cooking and in industry

Starch is the major nutritive component of our staple crops (e.g., cereals, tubers, roots, seeds). Its unique properties affect the texture of the food we eat and make it useful for other, nonfood applications.

When heated in water (e.g., during cooking), starch suspensions thicken. The granules absorb water and swell, disrupting the semi-crystalline structure and separating amylose from amylopectin. On cooling, a gel is produced as hydrogen bonds reform between amylose and amylopectin molecules, trapping water in the network. These thickened suspensions and coagulated starch gels form the basis of many a fine recipe (sauces, puddings).

When such starchy foods are frozen or cooled for long periods, however, the amylose molecules associate more closely, forming dense crystals, a process called **retrogradation**. The resulting watery, unappetizing mess can be rescued to some extent by re-heating. Similar changes occur in old bread, which loses its texture and becomes stale, not necessarily because it loses moisture, but because the amylose molecules, which disperse when the bread is baked, crystallize. Stale bread can be revived by dampening and heating to disperse the amylose (perhaps why some restaurants serve bread warm).

Food manufacturers use starches with different structures or composition. A commonly used starch comes from the waxy mutant of maize (see Chapter 7), which lacks granule-bound starch synthase and so produces only amylopectin. The kernels of this mutant have a waxy appearance, hence the name. With no amylose to crystallize out of the gel, foods produced from waxy starch can be frozen and thawed with minimal loss of texture. Mutations affecting granule-bound starch synthase and resulting in waxy-type starches are known for several crops. In the laboratory, transgenic approaches have been used to modulate multiple starch biosynthetic enzymes simultaneously, creating plants that synthesize starches with unique properties.

Many nonfood industries also use starch as a raw material. Starch finds its way into biodegradable plastics and packaging materials, into paints as a thickener, into building materials as an adhesive, into paper and textiles as a coating and sizing agent, and into pharmaceuticals and cosmetics as an inert carrying agent, to name but a few. In many cases, the native starches are chemically modified after extraction to optimize their properties for each application. Starch is also used extensively for the production of bioethanol, particularly in the United States, where over a third of the maize (*Zea mays*) crop is used for this.

important in both food and nonfood industries. These characteristics vary depending on the species and the organ used for starch storage, but can also be influenced using biotechnology by producing plants with altered amounts of the starch biosynthetic enzymes (see Box 13.4).

Starch granules range in size, from less than 1 μm in diameter to more than 100 μm and, in some cases, have distinctive morphologies. In fact, archaeologists have been able to determine the crops used by ancient civilizations through examination of the residual starch grains stuck to their cooking utensils. The transitory starch granules in leaves tend to be smaller than those in storage organs like tubers and seeds, reflecting the fact that they are synthesized over a much shorter time (a single day) and subsequently degraded at night.

13.5.4 Starch synthesis involves chain elongation, branching, and debranching reactions

Three enzymes are responsible for the synthesis of starch from ADP-glucose: **starch synthases** (Reaction 13.9), **starch branching enzymes** (Reaction 13.10) and, surprisingly, **starch debranching enzymes** (Reaction 13.11).

Reaction 13.9: Starch synthase

Reaction 13.10: Starch branching enzyme

Reaction 13.11: Starch debranching enzyme

Starch synthase forms new $\alpha\text{-1,4}$ -bonds by adding individual glucose molecules from ADP-glucose to the nonreducing ends of an amylose or amylopectin chain (because the glucose residues are not symmetrical, the glucans in starch have both reducing and nonreducing ends; see Fig. 13.10). Five distinct isoforms of starch synthase are present in plants, each with a distinct biochemical function. The first to be characterized was **granule-bound starch synthase** (GBSS), which differs from the others as it is exclusively bound to starch and becomes buried within the granule as it grows. GBSS is responsible for amylose synthesis, and mutants lacking it produce amylose-free starch

(such as the waxy mutant of maize; Box 13.4). GBSS synthesizes long chains by acting in a processive way on the same substrate, using ADP-glucose that diffuses into the starch granule matrix. The embedding of GBSS may be a prerequisite for amylose production, as its product is protected from the activity of branching enzymes present in the plastid stroma.

The remaining four starch synthase isoforms are soluble in plastid stroma and partially bound to the starch granule. They contribute to the formation of amylopectin, each preferentially elongating chains of different lengths. Single isoform mutants can still synthesize starch, but usually with an altered amylopectin structure (Fig. 13.22).

Starch branching enzyme produces the α -1,6 branches in starch (see Fig. 13.18). This **glucanotransferase** cleaves an α -1,4 linkage, then joins the reducing end of the severed fragment to the side of the same or an adjacent chain, thereby forming an α -1,6 linkage. Most plants contain two isoforms of branching enzyme (class I and II), which differ in specificity. The two forms have different substrate preferences, and class I enzymes transfer longer **glucan chains** than class II enzymes. Partial loss of branching enzyme can lead to an inhibition of

starch synthesis and an increase in the proportion of amylose in starch, such as in the *rugosus* mutant of pea (*Pisum sativum*; see Box 13.3). A total loss of branching enzyme (achieved using reverse-genetic methods in *Arabidopsis*) abolishes leaf starch synthesis altogether; the plant can only synthesize linear glucan chains that are rapidly degraded into fragments, such as the disaccharide **maltose**.

Although starch synthases and branching enzymes are probably sufficient for amylopectin biosynthesis, the process normally involves a degree of debranching as well. Mutants in several species that are deficient in a specific class of debranching enzyme (isoamylase 1) accumulate a highly branched soluble polymer more akin to glycogen than amylopectin (thus called phytoglycogen; Fig. 13.23). Debranching may promote crystallization by removing misplaced branches that interfere with the formation of higher-order structures within amylopectin molecules. This represents an interesting evolutionary innovation, where an enzyme associated with degradation has, through gene duplication and functional specialization, been recruited to a biosynthetic role. Other classes of debranching enzymes in plants mediate branch point hydrolysis during starch breakdown (see Section 13.7.2).

FIGURE 13.22 Starch synthesis in the plastid stroma involves the production of branched amylopectin through the concerted actions of four isoenzymes of soluble starch synthases, two of branching enzymes, and a specialized debranching enzyme, all acting at the granule surface. The resulting amylopectin forms a semi-crystalline matrix, entrapping granule bound starch synthase, which synthesizes amylose using ADP-glucose, which diffuses into the amylopectin matrix.

FIGURE 13.23 Evidence that debranching enzymes participate in starch biosynthesis. Mutants of *Arabidopsis* lacking a specific class of debranching enzyme (B) synthesize less insoluble starch (S) than wild-type plants (A) and instead produce a soluble branched glucan called phytoglycogen (pg) in their chloroplasts. Each panel shows a single chloroplast approximately 5 μ m in length.

13.6 Partitioning of photoassimilates between sucrose and starch

In the leaves of most plants, sucrose and starch represent the major products of photosynthesis, and the **partitioning** between these two products depends on the species and environmental conditions. There is increasing evidence that these biosynthetic pathways are influenced by several cellular signaling processes, including light perception, the circadian clock, and metabolic signals. These inputs are integrated to optimize the allocation of assimilates into growth or storage. Not all of these regulatory mechanisms are understood, but some enzymes in the biosynthetic pathways have been identified as important control points.

13.6.1 The interconversion of fructose 6-phosphate and fructose 1,6-bisphosphate in the cytosol involves three enzymes

A critical step in central metabolism is the interconversion of fructose 6-phosphate and fructose 1,6-bisphosphate in the cytosol. This step has been studied for many years, yet numerous questions remain. This is partly because three enzymes are involved (PFK, PFP, and fructose-1,6-bisphosphatase; Fig. 13.24), each with a different mechanism of regulation. Furthermore, isoforms of PFK and fructose-1,6-bisphosphatase also occur in the plastid, which has complicated

experiments designed to investigate the cytosolic step. Nevertheless, during photosynthesis, control at this point operates in conjunction with that applied to other steps discussed above (namely sucrose phosphate synthase in the cytosol and ADP-glucose pyrophosphorylase in the chloroplast). Together, these control mechanisms help to determine the distribution of photosynthate into the different biosynthetic pathways. Metabolites play an important part in this regulation by acting as allosteric effectors, while the **triose phosphate translocator** communicates changes in metabolite levels between the cytosol and the chloroplast stroma.
