## OVERVIEW

### Lost Worlds

**E**arly Antarctic explorers encountered one of Earth's harshest, most barren environments, a land of extreme cold and almost no liquid water.

Antarctic life is sparse and small—the largest fully terrestrial animal is a fly 5 mm long. But even as they struggled to survive, some of these explorers made an astonishing discovery: fossil evidence that life once thrived where it now barely exists. Fossils reveal that 500 million years ago, the ocean around Antarctica was warm and teeming with tropical invertebrates. Later, the continent was covered in forests for hundreds of millions of years. At various times, diverse animals stalked through these forests, including 3-m-tall predatory “terror birds” and giant dinosaurs, such as the voracious *Cryolophosaurus* (**Figure 23.1**), a relative of *Tyrannosaurus rex*.

Fossils discovered in other parts of the world tell a similar, if not quite as surprising, story: Past organisms were very different from those presently living. The sweeping changes in life on Earth as revealed by fossils illustrate **macroevolution**, the broad pattern of evolution above the species level. Examples of macroevolutionary change include the emergence of terrestrial vertebrates through a series of speciation events, the impact of mass extinctions on the diversity of life, and the origin of key adaptations, such as flight in birds.

Taken together, such changes provide a grand view of the evolutionary history of life. In this chapter, we'll examine how fossils form and the evidence they provide about the pattern of life's evolution, focusing on factors that have helped shape the rise and fall of different groups of organisms over time. The next unit (Chapters 24–27) will explore major steps in the history of life.

## CONCEPT 23.1

### The fossil record documents life's history

Starting with the earliest traces of life, the fossil record opens a window into the world of long ago and provides glimpses of the evolution of life over billions of years (**Figure 23.2**). In this section, we'll examine fossils as a form of scientific evidence: how fossils form, how scientists date and interpret them, and what they can and cannot tell us about changes in the history of life.

▼ **Figure 23.2 Documenting the history of life.** These fossils illustrate representative organisms from different points in time. Although prokaryotes and unicellular eukaryotes are shown only at the base of the diagram, these organisms continue to thrive today. In fact, most organisms on Earth are unicellular.

▼ *Dimetrodon*, the largest known carnivore of its day, was more closely related to mammals than to reptiles. The spectacular “sail” on its back may have functioned in temperature regulation.

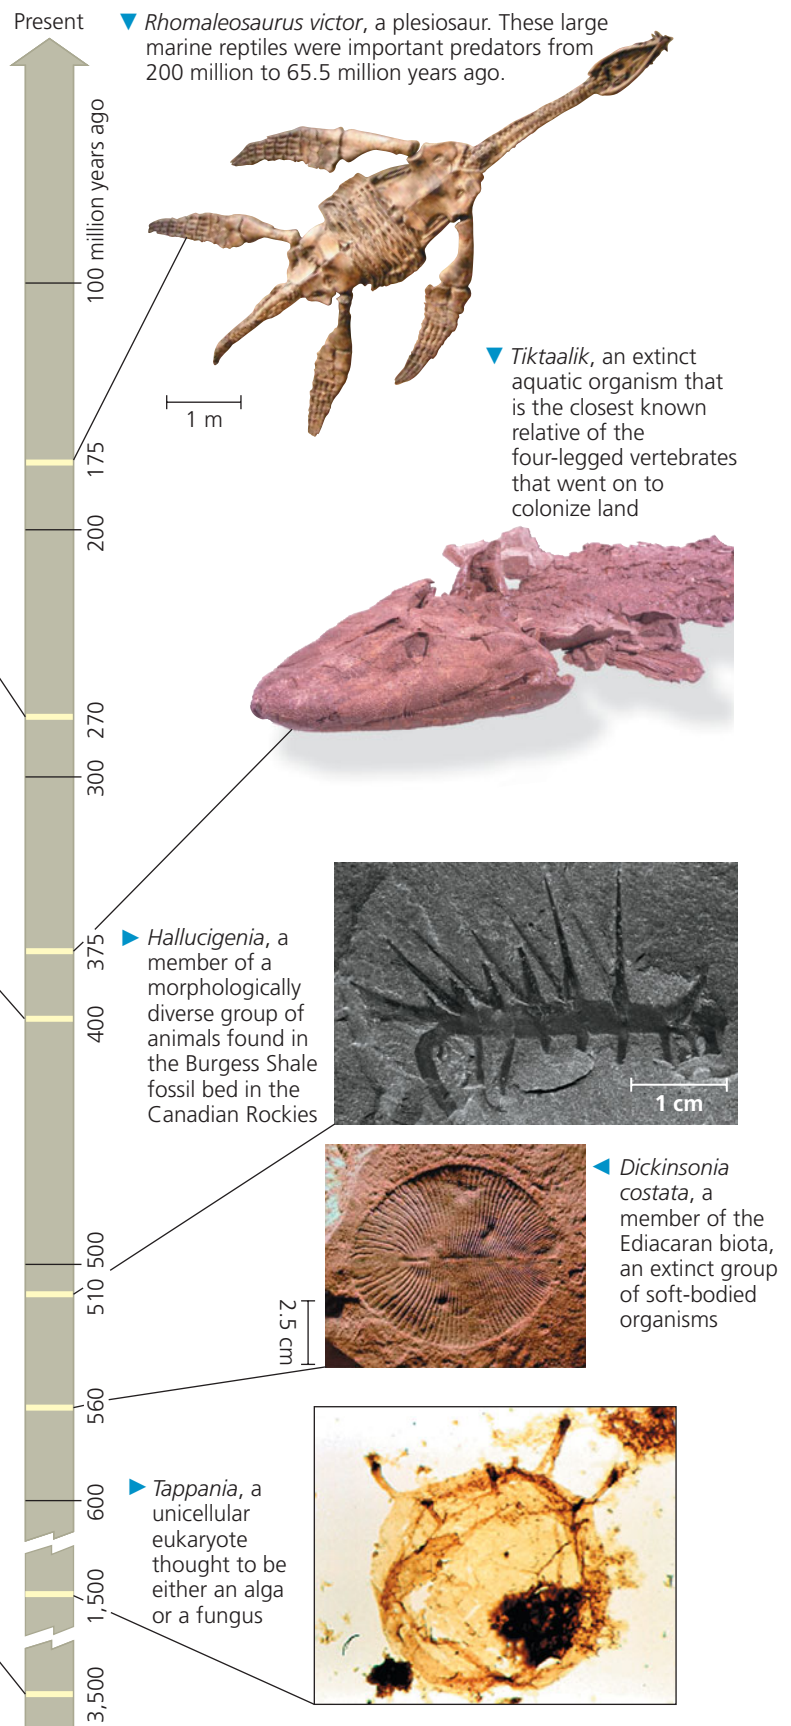

▲ *Coccosteus cuspidatus*, a placoderm (fishlike vertebrate) that had a bony shield covering its head and front end

▲ Some prokaryotes bind thin films of sediments together, producing layered rocks called stromatolites, such as these in Shark Bay, Australia.

▲ A section through a fossilized stromatolite

## The Fossil Record

Sedimentary rocks are the richest source of fossils. As a result, the fossil record is based primarily on the sequence in which fossils have accumulated in sedimentary rock layers, called *strata* (see Figure 19.3). Useful information is also provided by other types of fossils, such as insects preserved in amber (fossilized tree sap) and mammals frozen in ice.

The fossil record shows that there have been great changes in the kinds of organisms on Earth at different points in time (Figure 23.2). Many past organisms were unlike organisms living today, and many organisms that once were common are now extinct. As we'll see later in this section, fossils also document how new groups of organisms arose from previously existing ones.

As substantial and significant as the fossil record is, keep in mind that it is an incomplete chronicle of evolutionary change. Many of Earth's organisms did not die in the right place at the right time to be preserved as fossils. Of those fossils that were formed, many were destroyed by later geologic processes, and only a fraction of the others have been discovered. As a result, the known fossil record is biased in favor of species that existed for a long time, were abundant and widespread in certain kinds of environments, and had hard shells, skeletons, or other parts that facilitated their fossilization. Even with its limitations, however, the fossil record is a remarkably detailed account of biological change over the vast scale of geologic time. Furthermore, as shown by the recently unearthed fossils of whale ancestors with hind limbs (see Figures 19.18 and 19.19), gaps in the fossil record continue to be filled by new discoveries. Although some of these discoveries are fortuitous, others illustrate the predictive nature of paleontology (see Figure 27.22).

## How Rocks and Fossils Are Dated

Fossils are valuable data for reconstructing the history of life, but only if we can determine where they fit in that unfolding story. While the order of fossils in rock strata tells us the sequence in which the fossils were laid down—their relative ages—it does not tell us their actual (absolute) ages. Examining the relative positions of fossils is like peeling off layers of wallpaper in an old house. You can infer the sequence in which the layers were applied, but not the year each layer was added.

How can we determine the absolute age of a fossil? (Note that “absolute” dating does not mean errorless dating, but only that an age is given in years rather than relative terms such as *before* and *after*.) One of the most common techniques is **radiometric dating**, which is based on the decay of radioactive isotopes (see Chapter 2). In this process, a radioactive “parent” isotope decays to a “daughter” isotope at a characteristic rate. The rate of decay is expressed by the **half-life**, the time required for 50% of the parent isotope to decay (Figure 23.3). Each type of radioactive isotope has a characteristic half-life, which is not affected by temperature, pressure, or other environmental variables. For example, carbon-14 decays relatively

© 1976 Pearson Education, Inc.

▲ **Figure 23.3 Radiometric dating.** In this diagram, each division of the clock face represents a half-life.

quickly; it has a half-life of 5,730 years. Uranium-238 decays slowly; its half-life is 4.5 billion years.

Fossils contain isotopes of elements that accumulated in the organisms when they were alive. For example, a living organism contains the most common carbon isotope, carbon-12, as well as a radioactive isotope, carbon-14. When the organism dies, it stops accumulating carbon, and the amount of carbon-12 in its tissues does not change over time. However, the carbon-14 that it contains at the time of death slowly decays into another element, nitrogen-14. Thus, by measuring the ratio of carbon-14 to carbon-12 in a fossil, we can determine the fossil's age. This method works for fossils up to about 75,000 years old; fossils older than that contain too little carbon-14 to be detected with current techniques. Radioactive isotopes with longer half-lives are used to date older fossils.

Determining the age of these older fossils in sedimentary rocks is challenging. Organisms do not use radioisotopes with long half-lives, such as uranium-238, to build their bones or shells. In addition, the sedimentary rocks themselves tend to consist of sediments of differing ages. So while we may not be able to date these older fossils directly, an indirect method can be used to infer the age of fossils that are sandwiched between two layers of volcanic rock. As lava cools into volcanic rock, radioisotopes from the surrounding environment become trapped in the newly formed rock. Some of the trapped radioisotopes have long half-lives, allowing geologists to estimate the ages of ancient volcanic rocks. If two volcanic layers surrounding fossils are determined to be 525 million and 535 million years old, for example, then the fossils are roughly 530 million years old.

## The Geologic Record

The study of fossils has helped geologists establish a **geologic record**, a standard time scale that divides Earth's history into four eons and further subdivisions (Table 23.1). The first three

**Table 23.1 The Geologic Record**

Relative Duration of Eons	Era	Period	Epoch	Age (Millions of Years Ago)	Some Important Events in the History of Life		
Phan-erozoic	Cenozoic	Quaternary	Holocene		Historical time		
			Pleistocene	0.01	Ice ages; origin of genus <i>Homo</i>		
		Neogene	Pliocene	2.6	Appearance of bipedal human ancestors		
			Miocene	5.3	Continued radiation of mammals and angiosperms; earliest direct human ancestors		
		Paleogene	Oligocene	23	Origins of many primate groups		
			Eocene	33.9	Angiosperm dominance increases; continued radiation of most present-day mammalian orders		
			Paleocene	55.8	Major radiation of mammals, birds, and pollinating insects		
			Mesozoic	Cretaceous	65.5	Flowering plants (angiosperms) appear and diversify; many groups of organisms, including most dinosaurs, become extinct at end of period	
				Jurassic	145.5	Gymnosperms continue as dominant plants; dinosaurs abundant and diverse	
		Triassic		199.6	Cone-bearing plants (gymnosperms) dominate landscape; dinosaurs evolve and radiate; origin of mammals		
Proter-ozoic	Paleozoic	Permian	251	Radiation of reptiles; origin of most present-day groups of insects; extinction of many marine and terrestrial organisms at end of period			
		Carboniferous	299	Extensive forests of vascular plants form; first seed plants appear; origin of reptiles; amphibians dominant			
		Devonian	359	Diversification of bony fishes; first tetrapods and insects appear			
		Silurian	416	Diversification of early vascular plants			
		Ordovician	444	Marine algae abundant; colonization of land by diverse fungi, plants, and animals			
		Cambrian	488	Sudden increase in diversity of many animal phyla (Cambrian explosion)			
		Ediacaran	542	Diverse algae and soft-bodied invertebrate animals appear			
	Archaean			635			
				1,800	Oldest fossils of eukaryotic cells appear		
				2,500			
			2,700	Concentration of atmospheric oxygen begins to increase			
			3,500	Oldest fossils of cells (prokaryotes) appear			
Hadean			3,850	Oldest known rocks on Earth's surface			
			Approx. 4,600	Origin of Earth			

eons—the Hadean, Archaean, and Proterozoic—together lasted about 4 billion years. The Phanerozoic eon, roughly the last half billion years, encompasses most of the time that animals have existed on Earth. It is divided into three eras: the Paleozoic, Mesozoic, and Cenozoic. Each era represents a distinct age in the history of Earth and its life. For example, the Mesozoic era is sometimes called the “age of reptiles” because of its abundance of reptilian fossils, including those of dinosaurs. The boundaries between the eras correspond to major extinction events seen in the fossil record, when many forms of life disappeared and were replaced by forms that evolved from the survivors.

The earliest direct evidence of life comes from the Archaean eon, based on 3.5 billion-year-old fossils of stromatolites (see Figure 23.2). **Stromatolites** are layered rocks that form when certain prokaryotes bind thin films of sediment together. These and other early prokaryotes were Earth’s sole inhabitants for more than 1.5 billion years. Early prokaryotes transformed life on our planet by releasing oxygen to the atmosphere during the water-splitting step of photosynthesis (see Chapter 24).

The ensuing increase in atmospheric oxygen—a process that began about 2.4 billion years ago—led to the extinction of some organisms and the proliferation of others. One group that flourished was the eukaryotes, which originated about 1.8 billion years ago (see Chapter 25). The rise of the eukaryotes was associated with a series of other key events in the history of life, including the origin of multicellular organisms and the colonization of land. Fossil evidence and molecular clock estimates based on DNA sequence data suggest that simple multicellular organisms emerged about 1.5 billion years ago. Later, more complex multicellular organisms arose independently in several groups of eukaryotes, including those that eventually moved onto land: plants, fungi, and animals (see Chapters 26 and 27).

## The Origin of New Groups of Organisms

Some fossils provide a detailed look at the origin of new groups of organisms. Such fossils are central to our understanding of evolution; they illustrate how new features arise and how long it takes for such changes to occur. We’ll examine one such case here: the origin of mammals.

Along with amphibians and reptiles, mammals belong to the group of animals called *tetrapods* (from the Greek *tetra*, four, and *pod*, foot), named for having four limbs. Mammals have a number of unique anatomical features that fossilize readily, allowing scientists to trace their origin. For example, the lower jaw is composed of one bone (the dentary) in mammals but several bones in other tetrapods. In addition, the lower and upper jaws hinge between a different set of bones in mammals than in other tetrapods. Mammals also have a unique set of three bones that transmit sound in the middle ear (the hammer, anvil, and stirrup), whereas other tetrapods have only one such bone (the stirrup). Finally, the teeth of mammals are differentiated into incisors (for tearing), canines (for piercing), and the multi-pointed premolars and molars (for crushing and grinding). In

contrast, the teeth of other tetrapods usually consist of a row of undifferentiated, single-pointed teeth.

As detailed in **Figure 23.4**, the fossil record shows that the unique features of mammalian jaws and teeth evolved gradually over time, in a series of steps. As you study Figure 23.4, bear in mind that it includes just a few examples of the fossil skulls that document the origin of mammals. If all the known fossils in the sequence were arranged by shape and placed side by side, their features would blend smoothly from one group to the next. Some of these fossils would reflect how the features of a group that dominates life today, the mammals, gradually arose in a previously existing group, the cynodonts. Others would reveal side branches on the tree of life—groups of organisms that thrived for millions of years but ultimately left no descendants that survive today.

### CONCEPT CHECK 23.1

1. Your measurements indicate that a fossilized skull you unearthed has a carbon-14/carbon-12 ratio about 1/16 that of the skulls of present-day animals. What is the approximate age of the fossilized skull?
2. Describe an example from the fossil record that shows how life has changed over time.
3. **DRAW IT** Relabel the x-axis of the graph in Figure 23.3 with time measurements in years to illustrate the radioactive decay of uranium-238 (half-life = 4.5 billion years).
4. **WHAT IF?** What would a fossil record of life today look like?
5. **WHAT IF?** Suppose researchers discover a fossil of an organism that lived 300 million years ago but had mammalian teeth and a mammalian jaw hinge. What inferences might you draw from this fossil about the origin of mammals and the evolution of novel skeletal structures? Explain.

For suggested answers, see Appendix A.

## CONCEPT 23.2

### The rise and fall of groups of organisms reflect differences in speciation and extinction rates

From its beginnings, life on Earth has been marked by the rise and fall of groups of organisms. Anaerobic prokaryotes originated, flourished, and then declined as the oxygen content of the atmosphere rose. Billions of years later, the first tetrapods emerged from the sea, giving rise to several major new groups of organisms. One of these, the amphibians, went on to dominate life on land for 100 million years, until other tetrapods (including dinosaurs and, later, mammals) replaced them as the dominant terrestrial vertebrates.

The rise and fall of these and other major groups of organisms have shaped the history of life. Narrowing our focus, we can also see that the rise or fall of any particular group of organisms is related to the speciation and extinction rates of

Over the course of 120 million years, mammals originated gradually from a group of tetrapods called synapsids. Shown here are a few of the many fossil organisms whose morphological features represent intermediate steps between living mammals and their early synapsid ancestors. The evolutionary context of the origin of mammals is shown in the tree diagram at right (the dagger symbol † indicates extinct lineages).

#### Key to skull bones

- |                                                                                                                                 |                                                                                                                                   |

| <span style="display:inline-block; width:15px; height:15px; background-color:green; border:1px solid black;"></span> Quadrate   | <span style="display:inline-block; width:15px; height:15px; background-color:purple; border:1px solid black;"></span> Squamosal   |

### Synapsid (300 mya)

Early synapsids had multiple bones in the lower jaw and single-pointed teeth. The jaw hinge was formed by the articular and quadrate bones. Early synapsids also had an opening called the *temporal fenestra* behind the eye socket. Powerful cheek muscles for closing the jaws probably passed through the temporal fenestra. Over time, this opening enlarged and moved in front of the hinge between the lower and upper jaws, thereby increasing the power and precision with which the jaws could be closed (much as moving a doorknob away from the hinge makes a door easier to close).

### Therapsid (280 mya)

Later, a group of synapsids called therapsids appeared. Therapsids had large dentary bones, long faces, and the first examples of specialized teeth, large canines. These trends continued in a group of therapsids called cynodonts.

### Early cynodont (260 mya)

In early cynodont therapsids, the dentary was the largest bone in the lower jaw, the temporal fenestra was large and positioned forward of the jaw hinge, and teeth with several cusps first appeared (not visible in the diagram). As in earlier synapsids, the jaw had an articular-quadrate hinge.

### Later cynodont (220 mya)

Later cynodonts had teeth with complex cusp patterns and their lower and upper jaws hinged in two locations: They retained the original articular-quadrate hinge and formed a new, second hinge between the dentary and squamosal bones. (The temporal fenestra is not visible in this or the below cynodont skull at the angles shown.)

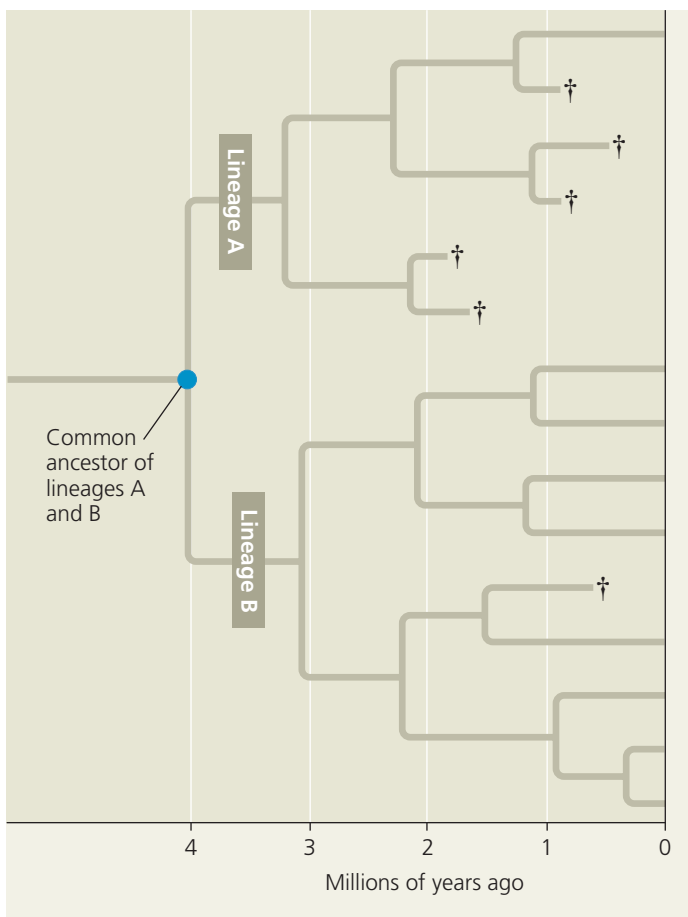

### Very late cynodont (195 mya)

In some very late (non-mammalian) cynodonts and early mammals, the original articular-quadrate hinge was lost, leaving the dentary-squamosal hinge as the only hinge between the lower and upper jaws, as in living mammals. The articular and quadrate bones migrated into the ear region (not shown), where they functioned in transmitting sound. In the mammal lineage, these two bones later evolved into the familiar hammer (malleus) and anvil (incus) bones of the ear.

▲ **Figure 23.5** How speciation and extinction affect diversity.

The species diversity of a particular evolutionary lineage will increase when more new member species originate than are lost to extinction. In the hypothetical example shown here, by 2 million years ago both lineage A and lineage B have given rise to four species, and no species have become extinct (denoted by a dagger symbol †). Over the next 2 million years, however, lineage A experiences higher extinction rates than lineage B. As a result, after 4 million years (that is, by time 0), lineage A contains only one species while lineage B contains eight species.

**?** Consider the period between 2 million and 1 million years ago. For each lineage, count the number of speciation and extinction events that occur during that time.

its member species (**Figure 23.5**). Just as a population grows when there are more births than deaths, a group of organisms grows (rises) when more new species appear than are lost to extinction. The reverse occurs when a group is in decline. In the **Scientific Skills Exercise**, you will interpret data from the fossil record about changes in a group of snail species in the early Paleogene period. Such changes in the fates of groups of organisms have been influenced by large-scale processes such as plate tectonics, mass extinctions, and adaptive radiations.

## Plate Tectonics

If photographs of Earth were taken from space every 10,000 years and spliced together to make a movie, it would show something many of us find hard to imagine: The seemingly “rock solid” continents we live on move over time. Since the

► **Figure 23.6** Cutaway view of Earth. The thickness of the crust is exaggerated here.

origin of multicellular eukaryotes roughly 1.5 billion years ago, there have been three occasions (1.1 billion, 600 million, and 250 million years ago) when most of the landmasses of Earth came together to form a supercontinent, then later broke apart. Each time, this breakup yielded a different configuration of continents. Looking into the future, some geologists have estimated that the continents will come together again and form a new supercontinent roughly 250 million years from now.

According to the theory of **plate tectonics**, the continents are part of great plates of Earth’s crust that essentially float on the hot, underlying portion of the mantle (**Figure 23.6**). Movements in the mantle cause the plates to move over time in a process called *continental drift*. Geologists can measure the rate at which the plates are moving now, usually only a few centimeters per year. They can also infer the past locations of the continents using the magnetic signal recorded in rocks at the time of their formation. This method works because as a continent shifts its position over time, the direction of magnetic north recorded in its newly formed rocks also changes.

Earth’s major tectonic plates are shown in **Figure 23.7**. Many important geologic processes, including the formation of mountains and islands, occur at plate boundaries. In some cases, two plates are moving away from each other, as are the North American and Eurasian plates, which are currently drifting apart at a rate of about 2 cm per year. In other cases, two plates slide past each other, forming regions where earthquakes are common. California’s infamous San Andreas Fault is part of a border where two plates slide past each other. In still other cases, two plates collide, producing violent upheavals and forming new mountains along the plate boundaries. One spectacular example of this occurred 45 million years ago, when the Indian plate crashed into the Eurasian plate, starting the formation of the Himalayan mountains.

## Consequences of Continental Drift

Plate movements rearrange geography slowly, but their cumulative effects are dramatic. In addition to reshaping the physical features of our planet, continental drift also has a major impact on life on Earth.

► **Figure 23.7 Earth's major tectonic plates.** The arrows indicate direction of movement. The reddish orange dots represent zones of violent tectonic activity.

## Scientific Skills Exercise

### *Estimating Quantitative Data from a Graph and Developing Hypotheses*

**Do Ecological Factors Affect Evolutionary Rates?** Researchers studied the fossil record to investigate whether differing modes of dispersal could explain differences in the longevity of species within one taxon of marine snails, the family Volutidae. Some volute snails had planktonic larvae that could disperse over great distances on ocean currents. Other volute snails had nonplanktonic larvae, which developed directly into adults without a swimming stage. The dispersal of snails with nonplanktonic larvae was limited by the distance they can crawl as adults.

**How the Research Was Done** The researchers studied the distribution of volute snail fossils in outcrops of sedimentary rocks located along North America's Gulf Coast. These rocks, which formed during the early Paleogene period, between 65 and 37 million years ago, contain many well-preserved snail fossils. Based on features of

the snail's shell, the researchers classified each fossil species as having planktonic or nonplanktonic larvae. Each bar in the graph shows how long one snail species persisted in the fossil record.

#### Interpret the Data

1. Here's a method for estimating quantitative data (fairly precisely) from a graph:

- (a) The first step is to measure along an axis that has a scale to obtain a conversion factor. In this case, 25 million years (my; from 40 to 65 million years ago (mya) on the x-axis) is represented by a distance of 7.0 cm.

This yields a conversion factor (a ratio) of

$$25 \text{ my} / 7.0 \text{ cm} = 3.6 \text{ my/cm}$$

- (b) Each horizontal bar represents the timespan during which a given snail species appears in the fossil record—the species' persistence time. To estimate the time period represented by a horizontal bar on this graph, measure the length of that bar in cm and multiply that measurement by the conversion factor, 3.6 my/cm. For example, the top (planktonic) bar on the graph has a length of about 1.1 cm; thus, that bar represents  $1.1 \text{ cm} \times 3.6 \text{ my/cm} = 4.0$  million years persistence time.

2. Calculate the mean persistence times for species with planktonic larvae and species with nonplanktonic larvae.
3. Count the number of new species that form in each group beginning at 60 mya (the first three species in each group were present around 64 mya, the first time period sampled, so we don't know when those species first appear in the fossil record).
4. Propose a hypothesis to explain the difference in mean longevity of snail species with planktonic and nonplanktonic larvae.

**Data from** T. Hansen, Larval dispersal and species longevity in Lower Tertiary gastropods, *Science* 199:885–887 (1978).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

▲ **Figure 23.8** The history of continental drift during the Phanerozoic eon.

**?** Is the Australian plate's current direction of movement (see Figure 23.7) similar to the direction it traveled over the past 65 million years?

One reason for its great impact on life is that continental drift alters the habitats in which organisms live. Consider the changes shown in **Figure 23.8**. About 250 million years ago, plate movements brought all the previously separated landmasses together into a supercontinent named **Pangaea**. Ocean basins became deeper, which lowered sea level and drained shallow coastal seas. At that time, as now, most marine species inhabited shallow waters, and the formation of Pangaea destroyed a considerable amount of that habitat. The interior of the vast continent was cold and dry, probably an even more severe environment than that of central Asia today. Overall, the formation of Pangaea had a tremendous impact on the physical environment and climate, which drove some species to extinction and provided new opportunities for groups of organisms that survived the crisis.

Another aspect of continental drift that affects organisms is the climate change that results when a continent shifts its location. The southern tip of Labrador, Canada, for example,

© 2001 AAAS

▲ **Figure 23.9** Speciation in frogs as a result of continental drift. When present-day Madagascar began to separate from India **1**, the frog subfamilies Mantellinae and Rhacophorinae started to diverge, ultimately forming hundreds of new species in each location. The maps show the movement of Madagascar (red) and India (blue) over time.

once was located in the tropics but has moved 40° to the north over the last 200 million years. When faced with the changes in climate that such shifts in position entail, organisms adapt, move to a new location, or become extinct (this last outcome occurred for many organisms stranded on Antarctica).

Continental drift also promotes allopatric speciation on a grand scale. When supercontinents break apart, regions that once were connected become geographically isolated. As the continents drifted apart over the last 200 million years, each became a separate evolutionary arena, with lineages of plants and animals that diverged from those on other continents. For example, genetic and geologic evidence indicates that two present-day groups of frog species, the subfamilies Mantellinae and Rhacophorinae, began to diverge when Madagascar separated from India (**Figure 23.9**). Finally, continental drift can help explain puzzles about the geographic distribution of extinct organisms, such as why fossils of the same species of Permian freshwater reptiles have been discovered in both Brazil and the West African nation of Ghana. These two parts of the world, now separated by 3,000 km of ocean, were joined together when these reptiles were living.

## Mass Extinctions

The fossil record shows that the overwhelming majority of species that ever lived are now extinct. A species may become extinct for many reasons. Its habitat may have been destroyed, or its environment may have changed in a manner unfavorable to the species. For example, if ocean temperatures fall by even a few degrees, species that are otherwise well adapted may perish. Even if physical factors in the environment remain

► **Figure 23.10 Mass extinction and the diversity of life.** The five generally recognized mass extinction events, indicated by red arrows, represent peaks in the extinction rate of marine animal families (red line and left vertical axis). These mass extinctions interrupted the overall increase in the number of marine animal families over time (blue line and right vertical axis).

? 96% of marine animal species became extinct in the Permian mass extinction. Explain why the blue curve shows only a 50% drop at that time.

stable, biological factors may change—the origin of one species can spell doom for another.

Although extinction occurs on a regular basis, at certain times disruptive changes to the global environment have caused the rate of extinction to increase dramatically. When this occurs, a **mass extinction** results, in which large numbers of species become extinct worldwide.

### The “Big Five” Mass Extinction Events

Patterns of the disappearance of species from the fossil record reveal that five mass extinctions have occurred during the past 500 million years (Figure 23.10). These events are particularly well documented for the decimation of hard-bodied animals that lived in shallow seas, the organisms for which the fossil record is most complete. In each mass extinction, 50% or more of Earth’s marine species became extinct.

Two mass extinctions—the Permian and the Cretaceous—have received the most attention. The Permian mass extinction, which defines the boundary between the Paleozoic and Mesozoic eras (251 million years ago), claimed about 96% of marine animal species and drastically altered life in the ocean. Terrestrial life was also affected. For example, 8 out of 27 known orders of insects were wiped out. This mass extinction occurred in less than 500,000 years, possibly in just a few thousand years—an instant in the context of geologic time.

The Permian mass extinction occurred at a time of enormous volcanic eruptions in what is now Siberia. This period was the most extreme episode of volcanism to have occurred during the past half billion years. Geologic data indicate that an area of 1.6 million km<sup>2</sup> (roughly half the size of western Europe) was covered with a layer of lava hundreds to thousands

of meters thick. Besides spewing enormous amounts of lava and ash, the eruptions may have produced enough carbon dioxide to warm the global climate by an estimated 6°C. If this hypothesis is correct, reduced temperature differences between the equator and the poles could have slowed the mixing of ocean water, which in turn could have led to a widespread drop in oxygen concentrations. The resulting low-oxygen condition, called *ocean anoxia*, would have suffocated oxygen-breathers and promoted the growth of anaerobic bacteria that emit a poisonous metabolic by-product, hydrogen sulfide (H<sub>2</sub>S) gas. As this gas bubbled into the atmosphere, it could have caused further extinctions by directly killing land plants and animals and by initiating chemical reactions that destroy the ozone layer, a “shield” that ordinarily protects organisms from life-threatening levels of UV radiation.

The Cretaceous mass extinction occurred about 65.5 million years ago and marks the boundary between the Mesozoic and Cenozoic eras. This event extinguished more than half of all marine species and eliminated many families of terrestrial plants and animals, including all dinosaurs (except birds, which are members of the same group; see Chapter 27). One clue to a possible cause of the Cretaceous mass extinction is a thin layer of clay enriched in iridium that separates sediments from the Mesozoic and Cenozoic eras. Iridium is an element that is very rare on Earth but common in many of the meteorites and other extraterrestrial objects that occasionally fall to Earth. This suggests that the high-iridium clay may be fallout from a huge cloud of debris that billowed into the atmosphere when an asteroid or large comet collided with Earth. This cloud would have blocked sunlight and severely disturbed the global climate for several months.

**▲ Figure 23.12 Fossil extinctions and temperature.** Extinction rates increased when global temperatures were high. Temperatures were estimated using ratios of oxygen isotopes and converted to an index in which 0 is the overall average temperature.

dramatic actions are taken, a sixth, human-caused mass extinction is likely to occur within the next few centuries or millennia.

### Consequences of Mass Extinctions

Mass extinctions have significant and long-term effects. By eliminating large numbers of species, a mass extinction can reduce a thriving and complex ecological community to a pale shadow of its former self. And once an evolutionary lineage disappears, it cannot reappear; the course of evolution is changed forever. Consider what would have happened if the early primates living 66 million years ago had died out in the

**▲ Figure 23.11 Trauma for Earth and its Cretaceous life.** Beneath the Caribbean Sea, the 65-million-year-old Chicxulub impact crater measures 180 km across. The horseshoe shape of the crater and the pattern of debris in sedimentary rocks indicate that an asteroid or comet struck at a low angle from the southeast. This artist's interpretation represents the impact and its immediate effect: a cloud of hot vapor and debris that could have killed many of the plants and animals in North America within hours.

Is there evidence of such an asteroid or comet? Research has focused on the Chicxulub crater, a 65-million-year-old scar beneath sediments off the Yucatán coast of Mexico (**Figure 23.11**). The crater is the right size to have been caused by an object with a diameter of 10 km. Critical evaluation of this and other hypotheses for mass extinctions continues.

### Is a Sixth Mass Extinction Under Way?

As you will read further in Chapter 43, human actions, such as habitat destruction, are modifying the global environment to such an extent that many species are threatened with extinction. More than a thousand species have become extinct in the last 400 years. Scientists estimate that this rate is 100 to 1,000 times the typical background rate seen in the fossil record. Is a sixth mass extinction now in progress?

This question is difficult to answer, in part because it is hard to document the number of extinctions occurring today. Tropical rain forests, for example, harbor many undiscovered species; destroying tropical forest may drive species to extinction before we even learn of their existence. Such uncertainties make it hard to assess the extent of the current extinction crisis. Even so, it is clear that losses have not reached those of the “big five” mass extinctions, in which large percentages of Earth’s species became extinct. This does not discount the seriousness of today’s situation. Monitoring programs show that many species are declining at an alarming rate due to habitat loss, introduced species, overharvesting, and other factors. Ongoing climate change may hasten some of these declines. Indeed, the fossil record indicates that over the last 500 million years, extinction rates have tended to increase when global temperatures were high (**Figure 23.12**). Overall, evidence suggests that unless

► **Figure 23.13 Mass extinctions and ecology.** The Permian and Cretaceous mass extinctions (indicated by red arrows) altered the ecology of the oceans by increasing the percentage of marine genera that were predators.

Cretaceous mass extinction. Humans would not exist, and life on Earth would differ greatly from what it is today.

The fossil record shows that 5–10 million years typically pass after a mass extinction before the diversity of life recovers to previous levels. In some cases, it has taken much longer: It took about 100 million years for the number of marine families to recover after the Permian mass extinction (see Figure 23.10). These data have sobering implications. If a sixth mass extinction occurs, it will take millions of years for life on Earth to recover its diversity.

Mass extinctions can also alter ecological communities by changing the types of organisms residing there. For example, after the Permian and Cretaceous mass extinctions, the percentage of marine organisms that were predators grew substantially (Figure 23.13). An increase in predators can increase both the pressures faced by prey and the competition among predators for food. In addition, mass extinctions can curtail lineages with novel and advantageous features. For example, in the late Triassic, a group of gastropods (snails and their relatives) arose that could drill through the shells of bivalves (such as clams) and feed on the animals inside. Although shell drilling provided access to a new and abundant source of food, this newly formed group was wiped out during the Triassic mass extinction (about 200 million years ago). Another 120 million years passed before another group of gastropods (the oyster drills) exhibited this drilling ability. As their predecessors might have done if they had not originated at an unfortunate time, oyster drills have since diversified into many new species. Finally, by eliminating so many species, mass extinctions can pave the way for adaptive radiations, in which new groups of organisms proliferate.

## Adaptive Radiations

The fossil record indicates that the diversity of life has increased over the past 250 million years (see blue line in Figure 23.10). This increase has been fueled by **adaptive radiations**, periods of evolutionary change in which groups of organisms form many new species whose adaptations allow them to fill different ecological roles, or niches, in their communities. Large-scale adaptive radiations occurred after each of the big five mass extinctions, when survivors became adapted to the many vacant ecological niches. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations, such as seeds or armored body coverings, or that colonized regions in which they faced little competition from other species.

## Worldwide Adaptive Radiations

Fossil evidence indicates that mammals underwent a dramatic adaptive radiation after the extinction of terrestrial dinosaurs 65.5 million years ago (Figure 23.14). Although mammals originated about 180 million years ago, the mammal fossils

▲ **Figure 23.14 Adaptive radiation of mammals.**

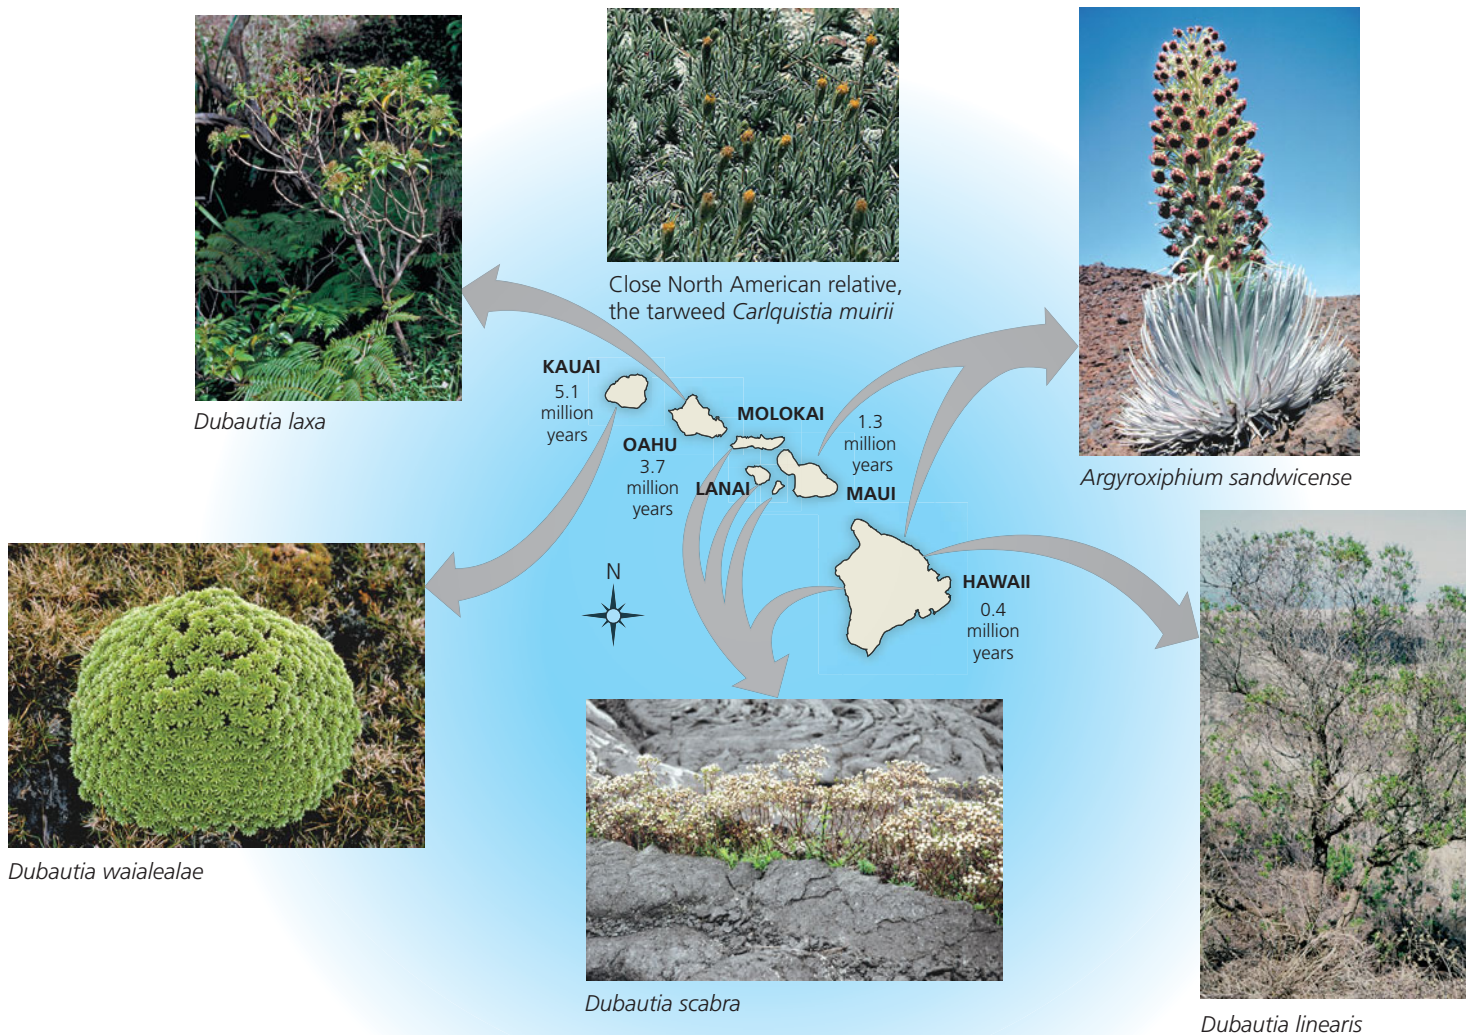

older than 65.5 million years are mostly small and not morphologically diverse. Many species appear to have been nocturnal based on their large eye sockets, similar to those in living nocturnal mammals. A few early mammals were intermediate in size, such as *Repenomamus giganticus*, a 1-m-long predator that lived 130 million years ago—but none approached the size of many dinosaurs. Early mammals may have been restricted in size and diversity because they were eaten or outcompeted by the larger and more diverse dinosaurs. With the disappearance of the dinosaurs (except for birds), mammals expanded greatly in both diversity and size, filling the ecological roles once occupied by terrestrial dinosaurs.

The history of life has also been greatly altered by radiations in which groups of organisms increased in diversity as they came to play entirely new ecological roles in their communities. Examples include the rise of photosynthetic prokaryotes, the evolution of large predators in the early Cambrian, and the radiations following the colonization of land by plants, insects,

and tetrapods. Each of these last three radiations was associated with major evolutionary innovations that facilitated life on land. The radiation of land plants, for example, was associated with key adaptations, such as stems that support plants against gravity and a waxy coat that protects leaves from water loss. Finally, organisms that arise in an adaptive radiation can serve as a new source of food for still other organisms. In fact, the diversification of land plants stimulated a series of adaptive radiations in insects that ate or pollinated plants, one reason that insects are the most diverse group of animals on Earth today.

### Regional Adaptive Radiations

Striking adaptive radiations have also occurred over more limited geographic areas. Such radiations can be initiated when a few organisms make their way to a new, often distant location in which they face relatively little competition from other organisms. The Hawaiian archipelago is one of the world's great showcases of this type of adaptive radiation (**Figure 23.15**).

**▲ Figure 23.15 Adaptive radiation on the Hawaiian Islands.** Molecular analysis indicates that these remarkably varied Hawaiian plants, known collectively as the “silversword alliance,” are all descended from an ancestral tarweed that arrived on the islands about 5 million years ago from North America. Members of the silversword alliance have since spread into different habitats and formed new species with strikingly different adaptations.

Located about 3,500 km from the nearest continent, the volcanic islands are progressively older as one follows the chain toward the northwest; the youngest island, Hawaii, is less than a million years old and still has active volcanoes. Each island was born “naked” and was gradually populated by stray organisms that rode the ocean currents and winds either from far-distant land areas or from older islands of the archipelago itself. The physical diversity of each island, including immense variation in elevation and rainfall, provides many opportunities for evolutionary divergence by natural selection. Multiple invasions followed by speciation events have ignited an explosion of adaptive radiation in Hawaii. As a result, most of the thousands of species that inhabit the islands are found nowhere else on Earth. Besides the silverswords in Figure 23.15, organisms unique to Hawaii include a large group of colorful birds called Hawaiian honeycreepers and hundreds of fruit fly species.

### CONCEPT CHECK 23.2

1. Explain the evolutionary consequences of continental drift for life on Earth.
2. Summarize how mass extinctions affect the evolutionary history of life.
3. What factors promote adaptive radiations?
4. **WHAT IF?** Suppose that an invertebrate species was lost in a mass extinction caused by a sudden catastrophic event. Would the last appearance of this species in the fossil record necessarily be close to when the extinction actually occurred? Would the answer to this question differ depending on whether the species was common (abundant and widespread) or rare? Explain.

For suggested answers, see Appendix A.

## CONCEPT 23.3

### Major changes in body form can result from changes in the sequences and regulation of developmental genes

The fossil record tells us what the great changes in the history of life have been and when they occurred. Moreover, an understanding of plate tectonics, mass extinction, and adaptive radiation provides a picture of how those changes came about. But we can also seek to understand the intrinsic biological mechanisms that underlie changes seen in the fossil record. For this, we turn to genetic mechanisms of change, paying particular attention to genes that influence development.

### Effects of Developmental Genes

As you read in Chapter 15, evo-devo—research at the interface between evolutionary biology and developmental biology—is

illuminating how slight genetic differences can produce major morphological differences between species. Genes that control development influence the rate, timing, and spatial pattern of change in an organism’s form as it develops from a zygote into an adult.

### Changes in Rate and Timing

Many striking evolutionary transformations are the result of **heterochrony** (from the Greek *hetero*, different, and *chronos*, time), an evolutionary change in the rate or timing of developmental events. For example, an organism’s shape depends in part on the relative growth rates of different body parts during development. Changes to these rates can alter the adult form substantially, as seen in the contrasting shapes of human and chimpanzee skulls (**Figure 23.16**).

Other examples of the dramatic evolutionary effects of heterochrony include how increased growth rates of finger bones yielded the skeletal structure of wings in bats

Chimpanzee infant

Chimpanzee adult

Chimpanzee fetus

Chimpanzee adult

Human fetus

Human adult

▲ **Figure 23.16 Relative skull growth rates.** In the human evolutionary lineage, mutations slowed the growth of the jaw relative to other parts of the skull. As a result, in humans the skull of an adult is more similar to the skull of an infant than is the case for chimpanzees.

▲ **Figure 23.17 Elongated hand and finger bones in a bat wing.** Heterochrony is responsible for the increased total length of hand and finger bones in a bat compared to that of other mammals.

**MAKE CONNECTIONS** Locate the bat's wrist and elbow joints (see Figure 19.16). Calculate the ratio of the length of the bat's longest set of hand and finger bones to the length of its radius. Compare this ratio to the ratio of the bones in your own hand and arm.

(Figure 23.17) and how slowed growth of leg and pelvic bones led to the reduction and eventual loss of hind limbs in whales (see Figure 19.19).

Heterochrony can also alter the timing of reproductive development relative to the development of nonreproductive organs. If reproductive organ development accelerates compared with other organs, the sexually mature stage of a species may retain body features that were juvenile structures in an ancestral species, a condition called **paedomorphosis** (from the Greek *paedos*, of a child, and *morphosis*, formation). For example, most salamander species have aquatic larvae that undergo metamorphosis in becoming adults. But some species grow to adult size and become sexually mature while retaining gills and other larval features (Figure 23.18). Such an evolutionary alteration of developmental timing can produce animals that appear very different from their ancestors, even though the overall genetic change may be small. Indeed, recent evidence indicates that a change at a single locus was probably sufficient to bring about paedomorphosis in the axolotl salamander, although other genes may have contributed as well.

### Changes in Spatial Pattern

Substantial evolutionary changes can also result from alterations in genes that control the placement and spatial organization of body parts. For example, master regulatory genes called **homeotic genes** (described in Chapters 16 and 18) determine such basic features as where a pair of wings and a pair of legs will develop on a bird or how a plant's flower parts are arranged.

The products of one class of homeotic genes, the *Hox* genes, provide positional information in an animal embryo. This

▲ **Figure 23.18 Paedomorphosis.** The adults of some species retain features that were juvenile in ancestors. This salamander is an axolotl, an aquatic species that grows to full size, becomes sexually mature, and reproduces while retaining certain larval (tadpole) characteristics, including gills.

information prompts cells to develop into structures appropriate for a particular location. Changes in *Hox* genes or in how they are expressed can have a profound impact on morphology. For example, among crustaceans, a change in the location where two *Hox* genes (*Ubx* and *Scr*) are expressed correlates with the conversion of a swimming appendage to a feeding appendage. Large effects are also seen in snakes, where changes in how two *Hox* genes (*HoxC6* and *HoxC8*) are expressed suppress limb formation. Similarly, when comparing plant species, changes to the expression of homeotic genes known as *MADS-box* genes can produce flowers that differ dramatically in form (see Chapter 28).

## The Evolution of Development

Large members of most animal phyla appear suddenly in fossils formed 535–525 million years ago. This rapid diversification of animals is referred to as the *Cambrian explosion* (see Concept 27.2). Yet the discovery of 560-million-year-old fossils of Ediacaran animals (see Figure 23.2) suggests that a set of genes sufficient to produce complex animals existed at least 25 million years before that time. If such genes have existed for so long, how can we explain the astonishing increases in diversity seen during and since the Cambrian explosion?

Adaptive evolution by natural selection provides one answer to this question. As we've seen throughout this unit, by sorting among differences in the sequences of protein-encoding genes, selection can improve adaptations rapidly. In addition, new genes (created by gene duplication events) can take on a wide range of new metabolic and structural functions. Thus, adaptive evolution of both new and existing genes may have played a key role in shaping the great diversity of life.

Examples in the previous section suggest that developmental genes may be particularly important. Next we'll examine

how new morphological forms arise from changes in the nucleotide sequences or regulation of developmental genes.

## Changes in Gene Sequence

New developmental genes arising after gene duplication events very likely facilitated the origin of novel morphological forms. But since other genetic changes also may have occurred at such times, it can be difficult to establish causal links between genetic and morphological changes that occurred in the past.

This difficulty was sidestepped in a recent study of developmental changes associated with the divergence of six-legged insects from crustacean-like ancestors that had more than six legs. In insects, such as *Drosophila*, the *Ubx* gene is expressed in the abdomen, while in crustaceans, such as *Artemia*, it is expressed in the main trunk of the body (**Figure 23.19**). When expressed, the *Ubx* gene suppresses leg formation in insects but not in crustaceans. To examine the workings of this gene, researchers cloned the *Ubx* gene from *Drosophila* and *Artemia*. Next, they genetically engineered fruit fly embryos to express either the *Drosophila Ubx* gene or the *Artemia Ubx* gene throughout their bodies. The *Drosophila* gene suppressed 100% of the limbs in the embryos, as expected, whereas the *Artemia* gene suppressed only 15%.

The researchers then sought to uncover key steps involved in the evolutionary transition from a crustacean *Ubx* gene to an insect *Ubx* gene. Their approach was to identify mutations that would cause the *Artemia Ubx* gene to suppress leg formation, thus making the crustacean gene act more like an insect *Ubx* gene. To do this, they constructed a series of “hybrid” *Ubx* genes, each of which contained known segments of the *Drosophila Ubx* gene and known segments of the *Artemia Ubx* gene. By inserting these hybrid genes into fruit fly embryos (one hybrid gene per embryo) and observing their effects on

© 2002 Macmillan Publishers, Ltd.

**▲ Figure 23.19 Origin of the insect body plan.** Expression of the *Hox* gene *Ubx* suppresses the formation of legs in fruit flies (*Drosophila*) but not in brine shrimp (*Artemia*), thus helping to build the insect body plan. Fruit fly and brine shrimp *Hox* genes have evolved independently for 400 million years. The green triangles indicate the relative amounts of *Ubx* expression in different body regions.

leg development, the researchers were able to pinpoint the exact amino acid changes responsible for the suppression of additional limbs in insects. In so doing, this study provided evidence linking a particular change in the nucleotide sequence of a developmental gene to a major evolutionary change: the origin of the six-legged insect body plan.

## Changes in Gene Regulation

Changes in the nucleotide sequence or regulation of developmental genes can result in morphological changes that harm the organism (see Chapter 16). However, a change in the nucleotide sequence of a gene may affect its function wherever the gene is expressed, while changes in the regulation of gene expression can be limited to a single cell type. Thus, a change in the regulation of a developmental gene may have fewer harmful side effects than a change to the sequence of the gene. This line of reasoning has prompted researchers to suggest that changes in the form of organisms may often be caused by mutations that affect the regulation of developmental genes—not their sequences.

This idea is supported by studies of a variety of species, including threespine stickleback fish. These fish live in the open ocean and in shallow, coastal waters. In western Canada, they also live in lakes formed when the coastline receded during the past 12,000 years. Marine stickleback fish have a pair of spines on their ventral (lower) surface, which deter some predators. These spines are often reduced or absent in stickleback fish living in lakes that lack predatory fishes and that are also low in calcium. Spines may have been lost in such lakes because they are not advantageous in the absence of predators, and the limited calcium is needed for purposes other than constructing spines.

**▲ Threespine stickleback (*Gasterosteus aculeatus*)**

At the genetic level, the developmental gene *Pitx1* was known to influence whether stickleback fish have ventral spines. Was the reduction of spines in some lake populations due to changes in the sequence of the *Pitx1* gene or to changes in how the gene is expressed? **Figure 23.20**, on the next page, describes an experiment designed to study this question. The researchers’ results indicate that the regulation of gene expression has changed, not the DNA sequence of the gene. Furthermore, lake stickleback fish do express the *Pitx1* gene in tissues not related to the production of spines (for example, the mouth), illustrating how morphological change can be caused by altering the expression of a developmental gene in some parts of the body but not others.

## ▼ Figure 23.20 Inquiry

### What caused the loss of spines in lake stickleback fish?

**Experiment** Marine populations of the threespine stickleback fish have a set of protective spines on their lower (ventral) surface; however, these spines have been lost or reduced in some lake populations of this fish. Researchers performed genetic crosses and found that most of the reduction in spine size resulted from the effects of a single developmental gene, *Pitx1*. The researchers then tested two hypotheses about how *Pitx1* causes this morphological change.

**Hypothesis A:** A change in the DNA sequence of *Pitx1* caused spine reduction in lake populations. To test this idea, the team used DNA sequencing to compare the coding sequence of the *Pitx1* gene between marine and lake stickleback populations.

**Hypothesis B:** A change in the regulation of the expression of *Pitx1* caused spine reduction. To test this idea, the researchers monitored where in the developing embryo the *Pitx1* gene was expressed. They conducted whole-body *in situ* hybridization experiments (see Concept 15.4) using *Pitx1* DNA as a probe to detect *Pitx1* mRNA in the fish.

#### Results

**Test of Hypothesis A:** Are there differences in the coding sequence of the *Pitx1* gene in marine and lake stickleback fish?

**Result:**  
No

The 283 amino acids of the *Pitx1* protein are identical in marine and lake stickleback populations.

**Test of Hypothesis B:** Are there any differences in the regulation of expression of *Pitx1*?

**Result:**  
Yes

Red arrows (→) indicate regions of *Pitx1* gene expression in the photographs below. *Pitx1* is expressed in the ventral spine and mouth regions of developing marine stickleback fish but only in the mouth region of developing lake stickleback fish.

**Marine stickleback embryo**

**Lake stickleback embryo**

**Conclusion** The loss or reduction of ventral spines in lake populations of threespine stickleback fish appears to have resulted primarily from a change in the regulation of *Pitx1* gene expression, not from a change in the gene's sequence.

**Source** M. D. Shapiro et al., Genetic and developmental basis of evolutionary pelvic reduction in three-spine sticklebacks, *Nature* 428:717–723 (2004).

**WHAT IF?** What results would have led researchers to conclude that a change in the coding sequence of *Pitx1* was more important than a change in regulation of gene expression?

#### CONCEPT CHECK 23.3

1. How can heterochrony cause evolution of novel body forms?
2. Why is it likely that *Hox* genes have played a major role in the evolution of novel morphological forms?
3. **MAKE CONNECTIONS** Given that changes in morphology are often caused by changes in the regulation of gene expression, predict whether noncoding DNA is likely to be affected by natural selection. (Review Concept 15.3.)

For suggested answers, see Appendix A.

## CONCEPT 23.4

### Evolution is not goal oriented

What does our study of macroevolution tell us about how evolution works? One lesson is that throughout the history of life, the origin of new species has been affected by both small-scale factors (described in Chapter 21), such as natural selection operating in populations, and the large-scale factors described

in this chapter, such as continental drift promoting bursts of speciation throughout the globe. Moreover, to paraphrase the Nobel Prize–winning geneticist François Jacob, evolution is like tinkering—a process in which new forms arise by the slight modification of existing forms. Even large changes, like the ones that produced the first mammals or the six-legged body plan of insects, can result from the modification of existing structures or existing developmental genes. Over time, such tinkering has led to three key features of the natural world (see Chapter 19): the striking ways in which organisms are suited for life in their environments; the many shared characteristics of life; and the rich diversity of life.

## Evolutionary Novelties

François Jacob’s view of evolution harkens back to Darwin’s concept of descent with modification. As new species form, novel and complex structures can arise as gradual modifications of ancestral structures. In many cases, complex structures have evolved in increments from simpler versions that performed the same basic function. For example, consider the human eye, an intricate organ constructed from numerous parts that work together in forming an image and transmitting it to the brain. How could the human eye have evolved in gradual increments? Some argue that if the eye needs all of its components to function, a partial eye could not have been of use to our ancestors.

The flaw in this argument, as Darwin himself noted, lies in the assumption that only complicated eyes are useful. In fact, many animals depend on eyes that are far less complex than our own (**Figure 23.21**). The simplest eyes that we know of are patches of light-sensitive photoreceptor cells. These simple eyes appear to have had a single evolutionary origin and are now found in a variety of animals, including small molluscs called limpets. Such eyes have no equipment for focusing images, but they do enable the animal to distinguish light from dark. Limpets cling more tightly to their rock when a shadow falls on them, a behavioral adaptation that reduces the risk of being eaten. Because limpets have had a long evolutionary history, we can conclude that their “simple” eyes are quite adequate to support their survival and reproduction.

In the animal kingdom, complex eyes have evolved independently from such basic structures many times. Some molluscs, such as squids and octopuses, have eyes as complex as those of humans and other vertebrates (see Figure 23.21). Although complex mollusc eyes evolved independently of vertebrate eyes, both evolved from a simple cluster of photoreceptor cells present in a common ancestor. In each case, the complex eye evolved through a series of incremental modifications that benefited the eyes’ owners at every stage. Evidence of their independent evolution may also be found in their structure: Vertebrate eyes detect light at the back layer of the retina and conduct nerve impulses toward the front, while complex mollusc eyes do the reverse.

▼ **Figure 23.21** A range of eye complexity in molluscs.

### (a) Patch of pigmented cells

The limpet *Patella* has a simple patch of photoreceptors.

### (b) Eyecup

The slit shell mollusc *Pleurotomaria* has an eyecup.

### (c) Pinhole camera-type eye

The *Nautilus* eye functions like a pinhole camera (an early type of camera lacking a lens).

### (d) Eye with primitive lens

The marine snail *Murex* has a primitive lens consisting of a mass of crystal-like cells. The cornea is a transparent region of tissue that protects the eye and helps focus light.

### (e) Complex camera lens-type eye

The squid *Loligo* has a complex eye with features (cornea, lens, and retina) similar to those of vertebrate eyes. However, the squid eye evolved independently from vertebrate eyes.

Throughout their evolutionary history, eyes retained their basic function of vision. But evolutionary novelties can also arise when structures that originally played one role gradually acquire a different one. For example, as cynodonts gave rise to early mammals, bones that formerly comprised the jaw hinge (the articular and quadrate; see Figure 23.4) were incorporated into the ear region of mammals, where they eventually took on a new function: the transmission of sound. Structures that evolve in one context but become co-opted for another function are sometimes called *exaptations* to distinguish them from the adaptive origin of the original structure. Note that the concept of exaptation does not imply that a structure somehow evolves in anticipation of future use. Natural selection cannot predict the future; it can only improve a structure in the context of its *current* utility. Novel features, such as the new jaw hinge and ear bones of early mammals, can arise gradually via a series of intermediate stages, each of which has some function in the organism’s current context.

## Evolutionary Trends

What else can we learn from patterns of macroevolution? Consider evolutionary “trends” observed in the fossil record. For instance, some evolutionary lineages exhibit a trend toward larger or smaller body size. An example is the evolution of the present-day horse (genus *Equus*), a descendant of the 55-million-year-old *Hyracotherium* (Figure 23.22). About the size of a large dog, *Hyracotherium* had four toes on its front feet, three toes on its hind feet, and teeth adapted for browsing on bushes and trees. In comparison, present-day horses are larger, have only one toe on each foot, and possess teeth modified for grazing on grasses.

Extracting a single evolutionary progression from the fossil record can be misleading, however; it is like describing a bush as growing toward a single point by tracing only the branches that lead to that twig. For example, by selecting certain species from the available fossils, it is possible to arrange a succession of animals intermediate between *Hyracotherium* and living horses that shows a trend toward large, single-toed species (follow the yellow highlighting in Figure 23.22). However, if we consider *all* fossil horses known today, this apparent trend vanishes. The genus *Equus* did not evolve in a straight line; it is the only surviving twig of an evolutionary tree that is so branched that it is more like a bush. *Equus* actually descended

through a series of speciation episodes that included several adaptive radiations, not all of which led to large, one-toed, grazing horses. In fact, phylogenetic analyses suggest that all lineages that include grazers are closely related to *Parahippus*; the many other horse lineages, all of which are now extinct, remained multi-toed browsers for 35 million years.

Branching evolution *can* result in a real evolutionary trend even if some species counter the trend. One model of long-term trends views species as analogous to individuals: Speciation is their birth, extinction is their death, and new species that diverge from them are their offspring. In this model, just as populations of individual organisms undergo natural selection, species undergo *species selection*. The species that endure the longest and generate the most new offspring species determine the direction of major evolutionary trends. The species selection model suggests that “differential speciation success” plays a role in macroevolution similar to the role of differential reproductive success in microevolution. Evolutionary trends can also result directly from natural selection. For example, when horse ancestors invaded the grasslands that spread during the mid-Cenozoic, there was strong selection for grazers that could escape

predators by running faster. This trend would not have occurred without open grasslands.

Whatever its cause, an evolutionary trend does not imply that there is some intrinsic drive toward a particular phenotype. Evolution is the result of the interactions between organisms and their current environments; if environmental conditions change, an evolutionary trend may cease or even reverse itself. The cumulative effect of these ongoing interactions between organisms and their environments is enormous: It is through them that the staggering diversity of life—Darwin’s “endless forms most beautiful”—has arisen.

#### CONCEPT CHECK 23.4

1. How can the Darwinian concept of descent with modification explain the evolution of such complex structures as the vertebrate eye?
2. **WHAT IF?** The myxoma virus kills up to 99.8% of infected European rabbits in populations with no previous exposure to the virus. The virus is transmitted by mosquitoes, which only bite living rabbits. Describe an evolutionary trend (in either the rabbit or virus) that might occur after a rabbit population first encounters the virus.

For suggested answers, see Appendix A.

## 23 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 23.1

##### The fossil record documents life’s history (pp. 436–440)

- The **fossil record**, based largely on fossils found in sedimentary rocks, documents the rise and fall of different groups of organisms over time. Sedimentary strata reveal the relative ages of **fossils**. The absolute ages of fossils can be estimated by radiometric dating and other methods.
- The study of fossils has helped geologists establish a **geologic record** of Earth’s history.
- The fossil record shows how new groups of organisms can arise via the gradual modification of preexisting organisms.

**?** *What are the challenges of estimating the absolute ages of old fossils? Explain how these challenges may be overcome in some circumstances.*

#### CONCEPT 23.2

##### The rise and fall of groups of organisms reflect differences in speciation and extinction rates (pp. 440–449)

- In **plate tectonics**, continental plates move gradually over time, altering the physical geography and climate of Earth. These changes lead to extinctions in some groups of organisms and bursts of speciation in others.
- Evolutionary history has been punctuated by five **mass extinctions** that radically altered the history of life. Some of these extinctions may have been caused by changes in

continent positions, volcanic activity, or impacts from meteorites or comets.

- Large increases in the diversity of life have resulted from **adaptive radiations** that followed mass extinctions. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations or that colonized new regions in which there was little competition from other organisms.

**?** *Explain how the broad evolutionary changes seen in the fossil record are the cumulative result of speciation and extinction events.*

#### CONCEPT 23.3

##### Major changes in body form can result from changes in the sequences and regulation of developmental genes (pp. 449–452)

- Developmental genes affect morphological differences between species by influencing the rate, timing, and spatial patterns of change in an organism’s form as it develops into an adult.
- The evolution of new forms can be caused by changes in the nucleotide sequences or regulation of developmental genes.

**?** *How could changes in a single gene or DNA region ultimately lead to the origin of a new group of organisms?*

#### CONCEPT 23.4

##### Evolution is not goal oriented (pp. 452–455)

- Novel and complex biological structures can evolve through a series of incremental modifications, each of which benefits the organism that possesses it.

- Evolutionary trends can be caused by factors such as natural selection in a changing environment or species selection. Like all aspects of evolution, evolutionary trends result from interactions between organisms and their current environments.

**?** Explain the reasoning behind the statement “Evolution is not goal oriented.”

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. Which factor most likely caused animals and plants in India to differ greatly from species in nearby Southeast Asia?
  - a. The species became separated by convergent evolution.
  - b. The climates of the two regions are similar.
  - c. India is in the process of separating from the rest of Asia.
  - d. Life in India was wiped out by ancient volcanic eruptions.
  - e. India was a separate continent until 45 million years ago.
2. Adaptive radiations can be a direct consequence of four of the following five factors. Select the exception.
  - a. vacant ecological niches
  - b. genetic drift
  - c. colonization of an isolated region that contains suitable habitat and few competitor species
  - d. evolutionary innovation
  - e. an adaptive radiation in a group of organisms (such as plants) that another group uses as food
3. A researcher discovers a fossil of what appears to be one of the oldest-known multicellular organisms. The researcher could estimate the age of this fossil based on
  - a. the amount of carbon-14 in the fossil.
  - b. the amount of uranium-238 in the fossil.
  - c. the amount of carbon-14 in the sedimentary rocks in which the fossil was found.
  - d. the amount of uranium-238 in volcanic layers surrounding the fossil.
  - e. the amount of uranium-238 in the sedimentary rocks in which the fossil was found.

### Level 2: Application/Analysis

4. A genetic change that caused a certain *Hox* gene to be expressed along the tip of a vertebrate limb bud instead of farther back helped make possible the evolution of the tetrapod limb. This type of change is illustrative of
  - a. the influence of environment on development.
  - b. paedomorphosis.
  - c. a change in a developmental gene or in its regulation that altered the spatial organization of body parts.
  - d. heterochrony.
  - e. gene duplication.
5. A swim bladder is a gas-filled sac that helps fish maintain buoyancy. The evolution of the swim bladder from the air-breathing organ (a simple lung) of an ancestral fish is an example of
  - a. an evolutionary trend.
  - b. exaptation.
  - c. changes in *Hox* gene expression.
  - d. paedomorphosis.
  - e. adaptive radiation.
6. **MAKE CONNECTIONS** Review Figure 20.10. Based on the phylogeny shown in Figure 23.4, identify the most inclusive clade to which both *Dimetrodon* and mammals belong. Explain.

### Level 3: Synthesis/Evaluation

#### 7. SCIENTIFIC INQUIRY

Herbivory (plant eating) has evolved repeatedly in insects, typically from meat-eating or detritus-feeding ancestors (detritus is dead organic matter). Moths and butterflies, for example, eat plants, whereas their “sister group” (the insect group to which they are most closely related), the caddisflies, feed on animals, fungi, or detritus. As illustrated in the phylogenetic tree below, the combined moth/butterfly and caddisfly group shares a common ancestor with flies and fleas. Like caddisflies, flies and fleas are thought to have evolved from ancestors that did not eat plants.

There are 140,000 species of moths and butterflies and 7,000 species of caddisflies. State a hypothesis about the impact of herbivory on adaptive radiations in insects. How could this hypothesis be tested?

#### 8. SCIENCE, TECHNOLOGY, AND SOCIETY

Experts estimate that human activities cause the extinction of hundreds of species every year. In contrast, the natural rate of extinction is thought to average only a few species per year. If human actions continue to alter the global environment, especially by destroying tropical rain forests and changing Earth's climate, the likely result will be a wave of extinctions that could rival those at the end of the Cretaceous period. Considering that life has endured five mass extinctions, should we be concerned that we may cause a sixth mass extinction? How would such an extinction differ from previous extinctions? What might be some of the consequences?

#### 9. FOCUS ON EVOLUTION

Describe how gene flow, genetic drift, and natural selection all can influence macroevolution.

#### 10. FOCUS ON ORGANIZATION

You have seen many examples of how form fits function at all levels of the biological hierarchy. However, we can imagine forms that would function better than some forms actually found in nature. For example, if the wings of a bird were not formed from its forelimbs, such a hypothetical bird could fly yet also hold objects with its forelimbs. In a short essay (100–150 words), use the concept of “evolution as tinkering” to explain why there are limits to the functionality of forms in nature.

For selected answers, see Appendix A.

# Unit 4 The Evolutionary History of Life

## 24 Early Life and the Diversification of Prokaryotes

Life on Earth began 3.5 billion years ago with the origin of single-celled **prokaryotes**. Over this long history, a wide range of metabolic adaptations have evolved in prokaryotes, enabling them to thrive throughout the biosphere.

## 25 The Origin and Diversification of Eukaryotes

Following the metabolic diversification of prokaryotes, the origin of **eukaryotes** 1.8 billion years ago led to the evolution of a vast array of structurally complex organisms—the protists, plants, fungi, and animals that fill our world today.

## 26 The Colonization of Land by Plants and Fungi

The **colonization of land** by plants and fungi 500 million years ago transformed terrestrial environments from a “green slime” consisting of bacteria and single-celled eukaryotes to lush forests and other plant communities.

## 27 The Rise of Animal Diversity

The earliest animals were microscopic and lived in marine environments. By 530 million years ago, the origin of larger, mobile animals with complex nervous and digestive systems led to an explosive **radiation of animals**, transforming the microbe-only world to a world filled with predators, prey, and other large eukaryotes.

# Early Life and the Diversification of Prokaryotes

▼ **Figure 24.1** What organisms lived on early Earth?

## KEY CONCEPTS

- 24.1** Conditions on early Earth made the origin of life possible
- 24.2** Diverse structural and metabolic adaptations have evolved in prokaryotes
- 24.3** Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes
- 24.4** Prokaryotes have radiated into a diverse set of lineages
- 24.5** Prokaryotes play crucial roles in the biosphere

## OVERVIEW

### The First Cells

Our planet formed 4.6 billion years ago, condensing from a vast cloud of dust and rocks that surrounded the young sun. For its first few hundred million years, Earth was bombarded by huge chunks of rock and ice left over from the birth of the solar system. The collisions generated so much heat that all of the available water was vaporized, preventing the formation of seas and lakes. As a result, life probably could not have originated or survived during this time.

This massive bombardment ended about 4 billion years ago, setting the stage for the origin of life on our young planet. While chemical signatures of life date back to 3.8 billion years ago, the earliest direct evidence comes from fossils that are 3.5 billion years old. These fossils are of **prokaryotes**, an informal term for single-celled organisms in domains Bacteria and Archaea (see Figure 20.20). Some of the earliest prokaryotic cells lived in dense mats similar to those that resemble stepping stones in **Figure 24.1**; others lived as free-floating, individual cells. These early prokaryotes were Earth's first organisms, and their descendants had the planet to themselves for about 1.5 billion years—until eukaryotes first appeared about 1.8 billion years ago (see Concept 25.1).

Over their long evolutionary history, descendants of Earth's first cells have given rise to the vast diversity of prokaryotes living today. This diversity includes “extreme” species such as *Deinococcus radiodurans*, which can survive 3 million rads of radiation (3,000 times the dose fatal to humans). Other prokaryotes live in environments that are too cold or hot or salty for most other organisms, and some have even been found living in rocks 3.2 km (2 miles) below Earth's surface.

But prokaryotic species also thrive in more “normal” habitats—the lands and waters in which most other species are found. And within these lands and waters, prokaryotes have colonized the bodies of other organisms that live there, including humans (**Figure 24.2**). Their ability to live in a broad range of habitats helps explain why prokaryotes are the most abundant organisms on Earth—indeed, the number of prokaryotes in a handful of fertile soil is greater than the number of people who have ever lived. In this chapter, we'll examine the origin, adaptations, diversity, and enormous ecological impact of these remarkable organisms.

► **Figure 24.2**  
**Bacteria that inhabit the human body.** Touching an agar gel led to the handprint-shaped growth of *Staphylococcus epidermidis*, just one of more than 1,000 species of bacteria that live on or in the human body.

## CONCEPT 24.1

### Conditions on early Earth made the origin of life possible

The earliest fossils are of prokaryotes that lived 3.5 billion years ago. But how did the first living cells appear? Observations and experiments in chemistry, geology, and physics have led scientists to propose one scenario that we'll examine here. They hypothesize that chemical and physical processes could have produced simple cells through a sequence of four main stages:

1. The abiotic (nonliving) synthesis of small organic molecules, such as amino acids and nitrogenous bases
2. The joining of these small molecules into macromolecules, such as proteins and nucleic acids
3. The packaging of these molecules into **protocells**, droplets with membranes that maintained an internal chemistry different from that of their surroundings
4. The origin of self-replicating molecules that eventually made inheritance possible

Though speculative, this scenario leads to predictions that can be tested in the laboratory. In this section, we'll examine some of the evidence for each stage.

### Synthesis of Organic Compounds on Early Earth

As the bombardment of early Earth ended, the first atmosphere had little oxygen and was probably thick with water vapor, along with compounds released by volcanic eruptions, including nitrogen and its oxides, carbon dioxide, methane, ammonia, and hydrogen. As Earth cooled, the water vapor condensed into oceans, and much of the hydrogen escaped into space.

During the 1920s, Russian chemist A. I. Oparin and British scientist J. B. S. Haldane independently hypothesized that Earth's early atmosphere was a reducing (electron-adding) environment, in which organic compounds could have formed

from simpler molecules. The energy for this organic synthesis could have come from lightning and intense UV radiation. Haldane suggested that the early oceans were a solution of organic molecules, a "primitive soup" from which life arose.

In 1953, Stanley Miller, working under the guidance of Harold Urey at the University of Chicago, tested the Oparin-Haldane hypothesis by creating laboratory conditions comparable to those that scientists at the time thought existed on early Earth. His apparatus yielded a variety of amino acids found in organisms today, along with other organic compounds. Many laboratories have since repeated Miller's classic experiment using different recipes for the atmosphere, some of which also produced organic compounds.

However, some evidence suggests that the early atmosphere was made up primarily of nitrogen and carbon dioxide and was neither reducing nor oxidizing (electron removing). Recent Miller-Urey-type experiments using such "neutral" atmospheres have also produced organic molecules. In addition, small pockets of the early atmosphere—such as those near the openings of volcanoes—may have been reducing. Perhaps the first organic compounds formed near volcanoes or deep-sea vents, where hot water and minerals gush into the ocean from Earth's interior. In a 2008 test of the volcanic-atmosphere hypothesis, researchers used modern equipment to reanalyze molecules that Miller had saved from one of his experiments. The study found that numerous amino acids had formed under conditions that simulated a volcanic eruption (**Figure 24.3**).

▲ **Figure 24.3** **Amino acid synthesis in a simulated volcanic eruption.** In addition to his classic 1953 study, Miller also conducted an experiment simulating a volcanic eruption. In a 2008 reanalysis of those results, researchers found that far more amino acids were produced under simulated volcanic conditions than were produced in the conditions of the original 1953 experiment.

**MAKE CONNECTIONS** After reviewing Concept 3.5, explain how more than 20 amino acids could have been produced in the 2008 experiment.

Miller-Urey-type experiments show that the abiotic synthesis of organic molecules is possible under various assumptions about the composition of the early atmosphere. A second source of organic molecules may have been meteorites. For example, fragments of the Murchison meteorite, a 4.5-billion-year-old rock that fell to Australia in 1969, contain more than 80 amino acids, some in large amounts. These amino acids cannot be contaminants from Earth because they include an equal mix of two different structural forms—only one of which is typically produced or used by organisms on our planet. Recent studies have shown that the Murchison meteorite also contained other key organic molecules, including lipids, simple sugars, and nitrogenous bases such as uracil.

## Abiotic Synthesis of Macromolecules

The presence of small organic molecules, such as amino acids and nitrogenous bases, is not sufficient for the emergence of life as we know it. Every cell has a vast assortment of macromolecules, including enzymes and other proteins and the nucleic acids that are essential for self-replication. Could such macromolecules have formed on early Earth? A 2009 study demonstrated that one key step, the abiotic synthesis of RNA monomers, can occur spontaneously from simple precursor molecules. In addition, by dripping solutions of amino acids or RNA nucleotides onto hot sand, clay, or rock, researchers have produced polymers of these molecules. The polymers formed spontaneously, without the help of enzymes or ribosomes. Unlike proteins, the amino acid polymers are a complex mix of linked and cross-linked amino acids. Nevertheless, it is possible that such polymers may have acted as weak catalysts for a variety of chemical reactions on early Earth.

## Protocells

All organisms must be able to carry out reproduction and energy processing (metabolism). Life cannot persist without both of these functions. DNA molecules carry genetic information, including the instructions needed to replicate themselves accurately during reproduction. But the replication of DNA requires elaborate enzymatic machinery, along with an abundant supply of nucleotide building blocks that are provided by the cell's metabolism (see Chapter 13). This suggests that self-replicating molecules and a metabolism-like source of the building blocks may have appeared together in early protocells. How did that happen?

The necessary conditions may have been met in *vesicles*, fluid-filled compartments enclosed by a membrane-like structure. Recent experiments show that abiotically produced vesicles can exhibit certain properties of life, including simple reproduction and metabolism, as well as the maintenance of an internal chemical environment different from that of their surroundings.

For example, vesicles can form spontaneously when lipids or other organic molecules are added to water. When this

**(a) Self-assembly.** The presence of montmorillonite clay greatly increases the rate of vesicle self-assembly.

**(b) Reproduction.** Vesicles can divide on their own, as in this vesicle “giving birth” to smaller vesicles (LM).

© 2003 AAAS

**(c) Absorption of RNA.** This vesicle has incorporated montmorillonite clay particles coated with RNA (orange).

### ▲ Figure 24.4 Features of abiotically produced vesicles.

occurs, the hydrophobic molecules in the mixture organize into a bilayer similar to the lipid bilayer of a plasma membrane. Adding substances such as *montmorillonite*, a soft mineral clay produced by the weathering of volcanic ash, greatly increases the rate of vesicle self-assembly (**Figure 24.4a**). This clay, which is thought to have been common on early Earth, provides surfaces on which organic molecules become concentrated, increasing the likelihood that the molecules will react with each other and form vesicles. Abiotically produced vesicles can “reproduce” on their own (**Figure 24.4b**), and they can increase in size (“grow”) without dilution of their contents. Vesicles also can absorb montmorillonite particles, including those on which RNA and other organic molecules have become attached (**Figure 24.4c**). Finally, experiments have shown that some vesicles have a selectively permeable bilayer and can perform metabolic reactions using an external source of reagents—another important prerequisite for life.

## Self-Replicating RNA

The first genetic material was most likely RNA, not DNA. RNA plays a central role in protein synthesis, but it can also perform many enzyme-like catalytic functions (see Chapter 14). Such RNA catalysts are called **ribozymes**.

Some ribozymes can make complementary copies of short pieces of RNA, if they are supplied with nucleotide building blocks.

Natural selection on the molecular level has produced ribozymes capable of self-replication in the laboratory. How does this occur? Unlike double-stranded DNA, which takes the form of a uniform helix, single-stranded RNA molecules assume a variety of specific three-dimensional shapes mandated by their nucleotide sequences. In a particular environment, RNA molecules with certain nucleotide sequences replicate faster and with fewer errors than other sequences. The RNA molecule whose sequence is best suited to the surrounding environment and has the greatest ability to replicate itself will leave the most descendant molecules. Occasionally, a copying error will result in a molecule that folds into a shape that is more adept at self-replication than the ancestral sequence. Similar selection events may have occurred on early Earth. Thus, life as we know it may have been preceded by an “RNA world,” in which small RNA molecules could replicate and store genetic information about the vesicles that carried them.

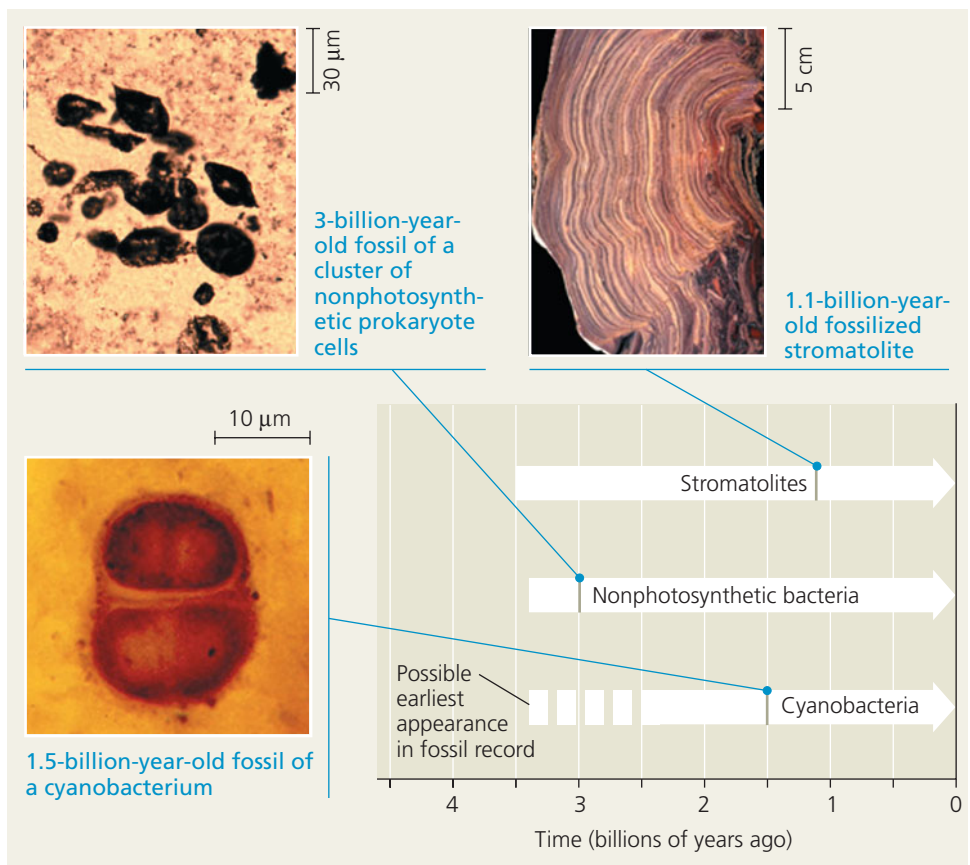

A vesicle with self-replicating, catalytic RNA would differ from its many neighbors that lacked such molecules. If that vesicle could grow, split, and pass its RNA molecules to its daughters, the daughters would be protocells that had some of the properties of their parent. Although the first such protocells likely carried only limited amounts of genetic information, specifying only a few properties, their inherited characteristics could have been acted on by natural selection. The most successful of the early protocells would have increased in number because they could exploit their resources effectively and pass their abilities on to subsequent generations.

Once RNA sequences that carried genetic information appeared in protocells, many additional changes would have been possible. For example, RNA could have provided the template on which DNA nucleotides were assembled. Double-stranded DNA is a more chemically stable repository for genetic information than is the more fragile RNA. DNA also can be replicated more accurately. Accurate replication was advantageous as genomes grew larger through gene duplication and other processes and as more properties of the protocells became coded in genetic information. Once DNA appeared, the stage was set for a blossoming of new forms of life—a change we see documented in the fossil record.

## Fossil Evidence of Early Life

Many of the oldest known fossils are of *stromatolites*, layered rocks that form from the activities of certain prokaryotes (**Figure 24.5**). The earliest stromatolites date to 3.5 billion years ago. For several hundred million years, all such fossils were similar in overall structure and all were from shallow marine bays; stromatolites are still found in such bays today (see Figure 23.2). By 3.1 billion years ago, stromatolites with two distinctly different morphologies had appeared, and by 2.8 billion years ago, stromatolites occurred in salty lakes as well as marine environments. Thus, early fossil stromatolites show signs of ecological and evolutionary change over time.

Ancient fossils of individual prokaryotic cells have also been discovered that are nearly as old as the oldest stromatolites. For example, a 2011 study found fossilized prokaryotic cells in 3.4-billion-year-old rocks from Australia (see Figure 24.5). In South Africa, other researchers have found 3.4-billion-year-old fossils of prokaryotes that resemble cyanobacteria, a group of photosynthetic bacteria living today. Some scientists question whether the South African fossils really were cyanobacteria, but by 2.5 billion years ago, diverse communities of cyanobacteria lived in the oceans. Cyanobacteria remained the main photosynthetic organisms for over a billion years, and they continue to be one of the most important groups of photosynthetic organisms alive today.

▲ **Figure 24.5** Appearance in the fossil record of early prokaryote groups.

Early cyanobacteria began what is arguably the greatest impact organisms have ever had on our planet: the release of oxygen to Earth's atmosphere during the water-splitting step of photosynthesis. In certain of its chemical forms, oxygen attacks chemical bonds and can inhibit enzymes and damage cells. As a result, the rising concentration of atmospheric O<sub>2</sub> probably doomed many prokaryotic groups. Some species survived in habitats that remained anaerobic, where we find their descendants living today. As we'll see, among other survivors, diverse adaptations to the changing atmosphere evolved, including cellular respiration, which uses O<sub>2</sub> in the process of harvesting the energy stored in organic molecules.

#### CONCEPT CHECK 24.1

1. What hypothesis did Miller test in his classic experiment?
2. How would the appearance of protocells have represented a key step in the origin of life?
3. Summarize fossil evidence of early prokaryotes. Describe how these organisms altered Earth's atmosphere.
4. **MAKE CONNECTIONS** In changing from an "RNA world" to today's "DNA world," genetic information must have flowed from RNA to DNA. After reviewing Figures 14.4 and 17.7, suggest how this could have occurred. Is such a flow a common occurrence today?

For suggested answers, see Appendix A.

(a) Spherical

(b) Rod-shaped

(c) Spiral

#### ▲ Figure 24.6 The most common shapes of prokaryotes.

(a) Cocci (singular, *coccus*) are spherical prokaryotes. They occur singly, in pairs (diplococci), in chains of many cells (streptococci), and in clusters resembling bunches of grapes (staphylococci). (b) Bacilli (singular, *bacillus*) are rod-shaped prokaryotes. They are usually solitary, but in some forms the rods are arranged in chains (streptobacilli). (c) Spiral prokaryotes include spirilla, which range from comma-like shapes to loose coils, and spirochetes (shown here), which are corkscrew-shaped (colorized SEMs).

organized, achieving all of an organism's life functions within a single cell.

### Cell-Surface Structures

A key feature of nearly all prokaryotic cells is the cell wall, which maintains cell shape, protects the cell, and prevents it from bursting in a hypotonic environment (see Concept 5.3). In a hypertonic environment, most prokaryotes lose water and shrink away from their wall (plasmolyze). Such water losses can inhibit cell reproduction. Thus, salt can be used to preserve foods because it causes food-spoiling prokaryotes to lose water, preventing them from rapidly multiplying.

The cell walls of prokaryotes differ in structure from those of eukaryotes. In eukaryotes that have cell walls, such as plants and fungi, the walls are usually made of cellulose or chitin (see Concept 3.3). In contrast, most bacterial cell walls contain **peptidoglycan**, a polymer composed of modified sugars cross-linked by short polypeptides. This molecular fabric encloses the entire bacterium and anchors other molecules that extend from its surface. Archaeal cell walls contain a variety of polysaccharides and proteins but lack peptidoglycan.

Using a staining technique developed by the Dutch scientist Hans Christian Gram, biologists can categorize many bacterial species according to cell wall composition (**Figure 24.7**). **Gram-positive** bacteria have simpler walls with a relatively large amount of peptidoglycan. **Gram-negative** bacteria have less peptidoglycan and are structurally more complex, with an outer membrane that contains lipopolysaccharides

## CONCEPT 24.2

### Diverse structural and metabolic adaptations have evolved in prokaryotes

Throughout their long history, prokaryotic populations have been (and continue to be) subjected to natural selection in all kinds of environments, resulting in their enormous diversity today. As described in Concept 24.1, fossils of early prokaryotes document some of the major steps in their evolutionary history, including the appearance of the first photosynthetic organisms. However, prokaryotic populations have also evolved in ways that cannot be seen in the fossil record, including changes in the type and efficiency of their enzymes. Although we cannot trace the time course of such changes in the fossil record, we can examine their end results—the adaptations found in prokaryotes today. We'll survey those adaptations here, beginning with a description of prokaryotic cells.

Most prokaryotes are unicellular, although the cells of some species remain attached to each other after cell division. Prokaryotic cells typically have diameters of 0.5–5 µm, much smaller than the 10–100 µm diameter of many eukaryotic cells. (One notable exception, *Thiomargarita namibiensis*, can be as large as 750 µm in diameter—bigger than the dot on this i.) Prokaryotic cells have a variety of shapes (**Figure 24.6**). Finally, although they are unicellular and small, prokaryotes are well

▼ **Figure 24.7 Gram staining.**

(carbohydrates bonded to lipids). These differences in cell wall composition have medical implications. The lipid portions of the lipopolysaccharides in the walls of many gram-negative bacteria are toxic, causing fever or shock. Furthermore, the outer membrane of a gram-negative bacterium helps protect it from the body's defenses. Gram-negative bacteria also tend to be more resistant than gram-positive species to antibiotics because the outer membrane impedes entry of the drugs.

The cell wall of many prokaryotes is surrounded by a sticky layer of polysaccharide or protein. This layer is called a **capsule** if it is dense and well defined (**Figure 24.8**) or a *slime layer* if it is not as well organized. Both kinds of sticky outer layers enable prokaryotes to adhere to their substrate or to other individuals in a colony. Some capsules and slime layers protect against dehydration, and some shield pathogenic prokaryotes from attacks by their host's immune system.

▲ **Figure 24.8 Capsule.** The polysaccharide capsule around this *Streptococcus* bacterium enables the prokaryote to attach to cells in the respiratory tract—in this colored TEM, a tonsil cell.

Other bacteria develop resistant cells called **endospores** when they lack an essential nutrient. The original cell produces a copy of its chromosome and surrounds that copy with a tough multilayered structure, forming the endospore. Water is removed from the endospore, halting its metabolism, and the original cell then lyses, releasing the endospore. Most endospores are so durable that they can survive in boiling water; killing them requires heating lab equipment to 121°C under high pressure. In less hostile environments, endospores can remain dormant but viable for centuries, able to rehydrate and resume metabolism when their environment improves.

Finally, some prokaryotes stick to their substrate or to one another by means of hairlike appendages called **fimbriae** (singular, *fimbria*) (**Figure 24.9**). For example, the bacterium that causes gonorrhea, *Neisseria gonorrhoeae*, uses fimbriae to fasten itself to the mucous membranes of its host. Fimbriae are usually

▲ **Figure 24.9 Fimbriae.** These numerous protein-containing appendages enable some prokaryotes to attach to surfaces or to other cells (colored TEM).

shorter and more numerous than **pili** (singular, *pilus*), appendages that pull two cells together prior to DNA transfer from one cell to the other (see Figure 24.16); pili are sometimes referred to as *sex pili*.

## Motility

About half of all prokaryotes are capable of **taxis**, a directed movement toward or away from a stimulus (from the Greek *taxis*, to arrange). For example, prokaryotes that exhibit *chemotaxis* change their movement pattern in response to chemicals. They may move *toward* nutrients or oxygen (positive chemotaxis) or *away from* a toxic substance (negative chemotaxis). Some species can move at velocities exceeding 50  $\mu\text{m}/\text{sec}$ —up to 50 times their body length per second. For perspective, consider that a person 1.7 m tall moving that fast would be running 306 km (190 miles) per hour!

Of the various structures that enable prokaryotes to move, the most common are flagella (**Figure 24.10**). Flagella (singular, *flagellum*) may be scattered over the entire surface of the cell or concentrated at one or both ends. Prokaryotic flagella differ greatly from eukaryotic flagella: They are one-tenth the width and typically are not covered by an extension of the plasma membrane (see Figure 4.23). The flagella of prokaryotes and eukaryotes also differ in their molecular composition and their mechanism of propulsion. Among prokaryotes, bacterial and archaeal flagella are similar in size and propulsion mechanism, but they are composed of entirely different and unrelated proteins. Overall, these structural and molecular comparisons indicate that the flagella of bacteria, archaea, and eukaryotes arose independently. Since current evidence shows that the flagella of organisms in the three domains perform similar functions but are not related by common descent, they are described as analogous, not homologous, structures.

### Evolutionary Origins of Bacterial Flagella

The bacterial flagellum shown in Figure 24.10 has three main parts (the motor, hook, and filament) that are themselves composed of 42 different kinds of proteins. How could such a complex structure evolve? In fact, much evidence indicates that bacterial flagella originated as simpler structures that were modified in a stepwise fashion over time. As in the case of the human eye (see Concept 23.4), biologists asked whether a less complex version of the flagellum could still benefit its owner. Analyses of hundreds of bacterial genomes indicate that only half of the flagellum's protein components appear to be necessary for it to function; the others are inessential or not encoded in the genomes of some species. Of the 21 proteins required by

**▲ Figure 24.10 A prokaryotic flagellum.** The motor of a prokaryotic flagellum consists of a system of rings embedded in the cell wall and plasma membrane (TEM). ATP-driven pumps in the membrane transport protons out of the cell. The diffusion of protons back into the cell provides the force that turns a curved hook and thereby causes the attached filament to rotate and propel the cell. (This diagram shows flagellar structures characteristic of gram-negative bacteria.)

all species studied to date, 19 are modified versions of proteins that perform other tasks in bacteria. For example, a set of 10 proteins in the motor are homologous to 10 similar proteins in a secretory system found in bacteria. (A secretory system is a protein complex that enables a cell to secrete certain macromolecules.) Two other proteins in the motor are homologous to proteins that function in ion transport. The proteins that comprise the rod, hook, and filament are all related to each other and are descended from an ancestral protein that formed a pilus-like tube. These findings suggest that the bacterial flagellum evolved as other proteins were added to an ancestral secretory system. This is an example of *exaptation*, the process in which existing structures take on new functions through descent with modification.

### Internal Organization and DNA

The cells of prokaryotes are simpler than those of eukaryotes in both their internal structure and the physical arrangement of their DNA (see Figure 4.4). Prokaryotic cells lack the complex compartmentalization associated with the membrane-enclosed organelles found in eukaryotic cells. However, some prokaryotic cells do have specialized membranes that perform metabolic functions (**Figure 24.11**). These membranes are usually infoldings of the plasma membrane. Recent discoveries also indicate that some prokaryotes can store metabolic by-products in simple compartments that are made out of proteins (and that do not have a membrane).

The genome of a prokaryote is structurally different from a eukaryotic genome and in most cases has considerably less

(a) Aerobic prokaryote

(b) Photosynthetic prokaryote

### ▲ Figure 24.11 Specialized membranes of prokaryotes.

(a) Infoldings of the plasma membrane, reminiscent of the cristae of mitochondria, function in cellular respiration in some aerobic prokaryotes (TEM). (b) Photosynthetic prokaryotes called cyanobacteria have thylakoid membranes, much like those in chloroplasts (TEM).

DNA. Prokaryotes generally have circular chromosomes (Figure 24.12), whereas eukaryotes have linear chromosomes. In addition, in prokaryotes the chromosome is associated with many fewer proteins than are the chromosomes of eukaryotes. Also unlike eukaryotes, prokaryotes lack a nucleus; their chromosome is located in the **nucleoid**, a region of cytoplasm that is not enclosed by a membrane. In addition to its single chromosome, a typical prokaryotic cell may also have much smaller rings of independently replicating DNA molecules called **plasmids** (see Figure 24.12), most carrying only a few genes.

Although DNA replication, transcription, and translation are fundamentally similar processes in prokaryotes and eukaryotes, some of the details differ between the two groups (see Chapters 13 and 14). For example, prokaryotic ribosomes are slightly smaller than eukaryotic ribosomes and differ in their protein and RNA content. These differences allow certain antibiotics, such as erythromycin and tetracycline, to bind to ribosomes and block protein synthesis in prokaryotes but not in eukaryotes. As a result, people can use these antibiotics to kill or inhibit the growth of bacteria without harming themselves.

## Nutritional and Metabolic Adaptations

Like all organisms, prokaryotes can be categorized by how they obtain energy and the carbon used in building organic molecules. Every type of nutrition observed in eukaryotes is represented among prokaryotes, along with some nutritional modes unique to prokaryotes. In fact, prokaryotes have an astounding range of metabolic adaptations, much broader than that found in eukaryotes.

▲ Figure 24.12 A prokaryotic chromosome and plasmids. The thin, tangled loops surrounding this ruptured *E. coli* cell are parts of the cell's large, circular chromosome (colorized TEM). Three of the cell's plasmids, the much smaller rings of DNA, are also shown.

Organisms that obtain energy from light are called *phototrophs*, and those that obtain energy from chemicals are called *chemotrophs*. Organisms that need only  $\text{CO}_2$  or related compounds as a carbon source are called *autotrophs*. In contrast, *heterotrophs* require at least one organic nutrient, such as glucose, to make other organic compounds. Combining possible energy sources and carbon sources results in four major modes of nutrition, summarized in Table 24.1.

### The Role of Oxygen in Metabolism

Prokaryotic metabolism also varies with respect to oxygen ( $\text{O}_2$ ). *Obligate aerobes* must use  $\text{O}_2$  for cellular respiration (see Chapter 7) and cannot grow without it. *Obligate anaerobes*, on the other hand, are poisoned by  $\text{O}_2$ . Some obligate anaerobes live exclusively by fermentation; others extract chemical energy by **anaerobic respiration**, in which substances other than  $\text{O}_2$ , such

Table 24.1 Major Nutritional Modes

Mode	Energy Source	Carbon Source	Types of Organisms
<b>AUTOTROPH</b>			
<b>Photoautotroph</b>	Light	$\text{CO}_2$ , $\text{HCO}_3^-$ , or related compound	Photosynthetic prokaryotes (for example, cyanobacteria); plants; certain protists (for example, algae)
<b>Chemoautotroph</b>	Inorganic chemicals (such as $\text{H}_2\text{S}$ , $\text{NH}_3$ , or $\text{Fe}^{2+}$ )	$\text{CO}_2$ , $\text{HCO}_3^-$ , or related compound	Unique to certain prokaryotes (for example, <i>Sulfolobus</i> )
<b>HETEROTROPH</b>			
<b>Photoheterotroph</b>	Light	Organic compounds	Unique to certain aquatic and salt-loving prokaryotes (for example, <i>Rhodobacter</i> , <i>Chloroflexus</i> )
<b>Chemoheterotroph</b>	Organic compounds	Organic compounds	Many prokaryotes (for example, <i>Clostridium</i> ) and protists; fungi; animals; some plants

as nitrate ions ( $\text{NO}_3^-$ ) or sulfate ions ( $\text{SO}_4^{2-}$ ), accept electrons at the “downhill” end of electron transport chains. *Facultative anaerobes* use  $\text{O}_2$  if it is present but can also carry out fermentation or anaerobic respiration in an anaerobic environment.

### Nitrogen Metabolism

Nitrogen is essential for the production of amino acids and nucleic acids in all organisms. Whereas eukaryotes can obtain nitrogen from only a limited group of nitrogen compounds, prokaryotes can metabolize nitrogen in a wide variety of forms. For example, some cyanobacteria and some methanogens (a group of archaea) convert atmospheric nitrogen ( $\text{N}_2$ ) to ammonia ( $\text{NH}_3$ ), a process called **nitrogen fixation**. The cells can then incorporate this “fixed” nitrogen into amino acids and other organic molecules. In terms of their nutrition, nitrogen-fixing cyanobacteria are some of the most self-sufficient organisms, since they need only light,  $\text{CO}_2$ ,  $\text{N}_2$ , water, and some minerals to grow.

Nitrogen fixation by prokaryotes has a large impact on other organisms. For example, it can increase the nitrogen available to plants, which cannot use atmospheric nitrogen but can use the nitrogen compounds that the prokaryotes produce from ammonia. Chapter 42 discusses this and other essential roles of prokaryotes in the nitrogen cycles of ecosystems.

### Metabolic Cooperation

Cooperation between prokaryotic cells allows them to use environmental resources they could not use as individual cells. In some cases, this cooperation takes place between specialized cells of a filament. For instance, the cyanobacterium *Anabaena* has genes that encode proteins for photosynthesis and for nitrogen fixation, but a single cell cannot carry out both processes at the same time. The reason is that photosynthesis produces  $\text{O}_2$ , which inactivates the enzymes involved in nitrogen fixation. Instead of living as isolated cells, *Anabaena* forms filamentous chains (Figure 24.13). Most cells in a filament carry out only photosynthesis, while a few specialized cells called **heterocysts** (sometimes called *heterocytes*) carry out only nitrogen fixation. Each heterocyst is surrounded by a thickened cell wall that restricts entry of  $\text{O}_2$  produced by neighboring photosynthetic cells. Intercellular connections allow heterocysts to transport fixed nitrogen to neighboring cells and to receive carbohydrates.

Metabolic cooperation between different prokaryotic species often occurs in surface-coating colonies known as **biofilms**. Cells in a biofilm secrete signaling molecules that recruit nearby cells, causing the colonies to grow. The cells also produce polysaccharides and proteins that stick the cells to the substrate and to one another. Channels in the biofilm allow nutrients to reach cells in the interior and wastes to be expelled. Biofilms are common in nature, but they can cause problems by contaminating industrial products and medical equipment and contributing to tooth decay and more serious health problems. Altogether, damage caused by biofilms costs billions of dollars annually.

▲ **Figure 24.13 Metabolic cooperation in a prokaryote.** In the filamentous cyanobacterium *Anabaena*, cells called heterocysts fix nitrogen, while the other cells carry out photosynthesis (LM). *Anabaena* is found in many freshwater lakes.

### Reproduction

Many prokaryotes can reproduce quickly in favorable environments. By *binary fission* (see Figure 9.12), a single prokaryotic cell divides into 2 cells, which then divide into 4, 8, 16, and so on. Under optimal conditions, many prokaryotes can divide every 1–3 hours; some species can produce a new generation in only 20 minutes. At this rate, a single prokaryotic cell could give rise to a colony outweighing Earth in only two days!

In reality, of course, this does not occur. The cells eventually exhaust their nutrient supply, poison themselves with metabolic wastes, face competition from other microorganisms, or are consumed by other organisms. Still, the fact that many prokaryotic species can divide after short periods of time draws attention to three key features of their biology: *They are small, they reproduce by binary fission, and they often have short generation times.* As a result, prokaryotic populations can consist of many trillions of individuals—far more than populations of multicellular eukaryotes, such as plants or animals.

### Adaptations of Prokaryotes: A Summary

Let’s step back and examine the big picture of the adaptations that have arisen in prokaryotic populations. We’ve described some of their key structural features, such as cell walls, endospores, fimbriae, and flagella. But prokaryotic cells are much simpler structurally than are eukaryotic cells—they do not vary as much in shape or size, and they lack the complex compartmentalization associated with the membrane-enclosed organelles of eukaryotic cells. Indeed, the ongoing success of prokaryotes is not primarily a story of structural diversification; rather, their success is an extraordinary example of physiological and metabolic diversification. As we’ve seen, prokaryotes thrive under a wide variety of physical and chemical conditions, and they have an astonishing range of metabolic adaptations that allow them to obtain energy and carbon in these environments.

Overall, the metabolic diversification of prokaryotes can be viewed as a first great wave of adaptive radiation in the evolutionary history of life. Bearing that broad perspective in mind, we turn now to the genetic diversity that has enabled the adaptations found in prokaryotic populations.

## CONCEPT CHECK 24.2

1. Contrast the cellular and DNA structures of prokaryotes and eukaryotes.
2. Distinguish between the four major modes of nutrition, noting which are unique to prokaryotes.
3. **MAKE CONNECTIONS** Suggest a hypothesis to explain why the thylakoid membranes of chloroplasts resemble those of cyanobacteria. Refer to Figures 4.16 and 20.20.
4. **WHAT IF?** Describe what you might eat for a typical meal if humans, like cyanobacteria, could fix nitrogen.

For suggested answers, see Appendix A.

## CONCEPT 24.3

### Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes

As we saw in Unit Three, evolution cannot occur without genetic variation. The evolutionary changes seen in the prokaryotic fossil record and the diverse adaptations found in prokaryotes living today suggest that their populations must have considerable genetic variation—and they do. In this section, we'll examine three factors that give rise to high levels of genetic diversity in prokaryotes: rapid reproduction, mutation, and genetic recombination.

#### Rapid Reproduction and Mutation

The generation of a novel allele by a new mutation is rare for any particular gene. Moreover, since prokaryotes do not reproduce sexually, at first glance their extensive genetic variation may seem puzzling. But in many species, this variation can result from rapid reproduction and mutation.

Consider the bacterium *Escherichia coli* as it reproduces by binary fission in a human intestine, one of its natural environments. After repeated rounds of division, most of the offspring cells are genetically identical to the original parent cell. However, if errors occur during DNA replication, some of the offspring cells may differ genetically. The probability of such a mutation occurring in a given *E. coli* gene is about one in 10 million ( $1 \times 10^{-7}$ ) per cell division. But among the  $2 \times 10^{10}$  new *E. coli* cells that arise each day in a person's intestine, there will be approximately  $(2 \times 10^{10}) \times (1 \times 10^{-7}) = 2,000$  bacteria that have a mutation in that gene. Thus, the total number of mutations when all 4,300 *E. coli* genes are considered is about  $4,300 \times 2,000 = 9$  million per day per human host.

The key point is that new mutations, though rare on a per gene basis, can increase genetic diversity quickly in species with short generation times and large populations. This diversity, in turn, can lead to rapid evolution: Individuals that are

## ▼ Figure 24.14 Inquiry

### Can prokaryotes evolve rapidly in response to environmental change?

**Experiment** Vaughn Cooper and Richard Lenski tested the ability of *E. coli* populations to adapt to a new environment. They established 12 populations, each founded by a single cell from an *E. coli* strain, and followed these populations for 20,000 generations (3,000 days). To maintain a continual supply of resources, each day the researchers performed a *serial transfer*: They transferred 0.1 mL of each population to a new tube containing 9.9 mL of fresh growth medium. The growth medium used throughout the experiment provided a challenging environment that contained only low levels of glucose and other resources needed for growth.

Samples were periodically removed from the 12 populations and grown in competition with the common ancestral strain in the experimental (low-glucose) environment.

**Results** The fitness of the experimental populations, as measured by the growth rate of each population, increased rapidly for the first 5,000 generations (2 years) and more slowly for the next 15,000 generations. The graph shows the averages for the 12 populations.

© 2000 Macmillan Publishers, Ltd.

**Conclusion** Populations of *E. coli* continued to accumulate beneficial mutations for 20,000 generations in their new environment, resulting in the rapid evolution of increased population growth rates.

**Source** V. S. Cooper and R. E. Lenski, The population genetics of ecological specialization in evolving *Escherichia coli* populations, *Nature* 407:736–739 (2000).

**WHAT IF?** Suggest possible functions of the genes whose sequence or expression was altered as the experimental populations evolved in the low-glucose environment.

genetically better equipped for their environment tend to survive and reproduce at higher rates than other individuals (**Figure 24.14**). The ability of prokaryotes to adapt rapidly to

new conditions highlights the point that although the structure of their cells is simpler than that of eukaryotic cells, prokaryotes are not “primitive” or “inferior” in an evolutionary sense. They are, in fact, highly evolved: For over 3.5 billion years, prokaryotic populations have responded successfully to many different types of environmental challenges.

## Genetic Recombination

Although new mutations are a major source of variation in prokaryotic populations, additional diversity arises from *genetic recombination*, the combining of DNA from two sources. In eukaryotes, the sexual processes of meiosis and fertilization combine DNA from two individuals in a single zygote. But meiosis and fertilization do not occur in prokaryotes. Instead, three other mechanisms—transformation, transduction, and conjugation—can bring together prokaryotic DNA from different individuals (that is, different cells). When the individuals are members of different species, this movement of genes from one organism to another is called *horizontal gene transfer*. Although scientists have found evidence that each of these mechanisms can transfer DNA within and between species in both domain Bacteria and domain Archaea, to date most of our knowledge comes from research on bacteria.

### Transformation and Transduction

In **transformation**, the genotype and possibly phenotype of a prokaryotic cell are altered by the uptake of foreign DNA from its surroundings. For example, a harmless strain of *Streptococcus pneumoniae* can be transformed into pneumonia-causing cells if the cells are exposed to DNA from a pathogenic strain (see Concept 13.1). This transformation occurs when a nonpathogenic cell takes up a piece of DNA carrying the allele for pathogenicity and replaces its own allele with the foreign allele, an exchange of homologous DNA segments. The cell is now a recombinant: Its chromosome contains DNA derived from two different cells.

For many years after transformation was discovered in laboratory cultures, most biologists thought the process to be too rare and haphazard to play an important role in natural bacterial populations. But researchers have since learned that many bacteria have cell-surface proteins that recognize DNA from closely related species and transport it into the cell. Once inside the cell, the foreign DNA can be incorporated into the genome by homologous DNA exchange.

In **transduction**, phages (from “bacteriophages,” the viruses that infect bacteria) carry prokaryotic genes from one host cell to another. In most cases, transduction results from accidents that occur during the phage replicative cycle (**Figure 24.15**). A virus that carries prokaryotic DNA may not be able to replicate because it lacks some or all of its own genetic material. However, the virus can attach to another prokaryotic cell (a recipient) and inject prokaryotic DNA acquired from the first cell (the donor). If some of this DNA is then incorporated into the recipient cell’s chromosome by crossing over, a recombinant cell is formed.

▲ **Figure 24.15 Transduction.** Phages may carry pieces of a bacterial chromosome from one cell (the donor) to another (the recipient). If crossing over occurs after the transfer, genes from the donor may be incorporated into the recipient’s genome.

**?** Under what circumstances would a transduction event result in horizontal gene transfer?

### Conjugation and Plasmids

In a process called **conjugation**, DNA is transferred between two prokaryotic cells (usually of the same species) that are temporarily joined. In bacteria, the DNA transfer is always one-way: One cell donates the DNA, and the other receives it. The best-understood mechanism is that used by *E. coli*, and we’ll focus on this organism for the rest of this section.

In *E. coli*, a pilus of the donor cell attaches to the recipient (**Figure 24.16**). The pilus then retracts, pulling the two cells together, much like a grappling hook. The next step is thought to be the formation of a temporary “mating bridge” between the two cells, through which the donor may transfer DNA to the recipient. However, the mechanism by which this transfer oc-

▲ **Figure 24.16 Bacterial conjugation.** The *E. coli* donor cell (left) extends a pilus that attaches to a recipient cell, a key first step in the transfer of DNA. The pilus is a flexible tube of protein subunits (TEM).

curs is an unsettled issue; indeed, recent evidence suggests that DNA may pass directly through the pilus, which is hollow.

**The F Factor** However the transfer of DNA takes place, the ability to form pili and donate DNA during conjugation results from the presence of a particular piece of DNA called the **F factor** (F for fertility). The F factor of *E. coli* consists of about 25 genes, most required for the production of pili. The F factor can exist either as a plasmid or as a segment of DNA within the bacterial chromosome.

The F factor in its plasmid form is called the **F plasmid**. Cells containing the F plasmid, designated  $F^+$  cells, function as DNA donors during conjugation. Cells lacking the F factor, designated  $F^-$ , function as DNA recipients during conjugation. The  $F^+$  condition is transferable in the sense that an  $F^+$  cell converts an  $F^-$  cell to  $F^+$  if a copy of the entire F plasmid is transferred (**Figure 24.17**). In any case, as long as some of

the F plasmid's DNA is transferred successfully to the recipient cell, that cell is now a recombinant cell.

A donor cell's F factor can also be integrated into the chromosome. In this case, chromosomal genes can be transferred to a recipient cell during conjugation. When this occurs, homologous regions of the donor and recipient chromosomes may align, allowing segments of their DNA to be exchanged. As a result, the recipient cell becomes a recombinant bacterium that has genes derived from the circular chromosomes of two different cells—a new genetic variant on which evolution can act.

**R Plasmids and Antibiotic Resistance** During the 1950s in Japan, physicians started noticing that some hospital patients with bacterial dysentery, which produces severe diarrhea, did not respond to antibiotics that had been effective in the past. Apparently, resistance to these antibiotics had evolved in some strains of *Shigella*, the bacterium that causes the disease.

Eventually, researchers began to identify the specific genes that confer antibiotic resistance in *Shigella* and other pathogenic bacteria. Sometimes, mutation in a chromosomal gene of the pathogen can confer resistance. For example, a mutation in one gene may make it less likely that the pathogen will transport a particular antibiotic into its cell. Mutation in a different gene may alter the intracellular target protein for an antibiotic molecule, reducing its inhibitory effect. In other cases, bacteria have “resistance genes,” which code for enzymes that specifically destroy or otherwise hinder the effectiveness of certain antibiotics, such as tetracycline or ampicillin. Such resistance genes are often carried by plasmids known as **R plasmids** (R for resistance).

Exposing a bacterial population to a specific antibiotic will kill antibiotic-sensitive bacteria but not those that happen to have R plasmids with genes that counter the antibiotic. Under these circumstances, we would predict that natural selection would cause the fraction of the bacterial population carrying

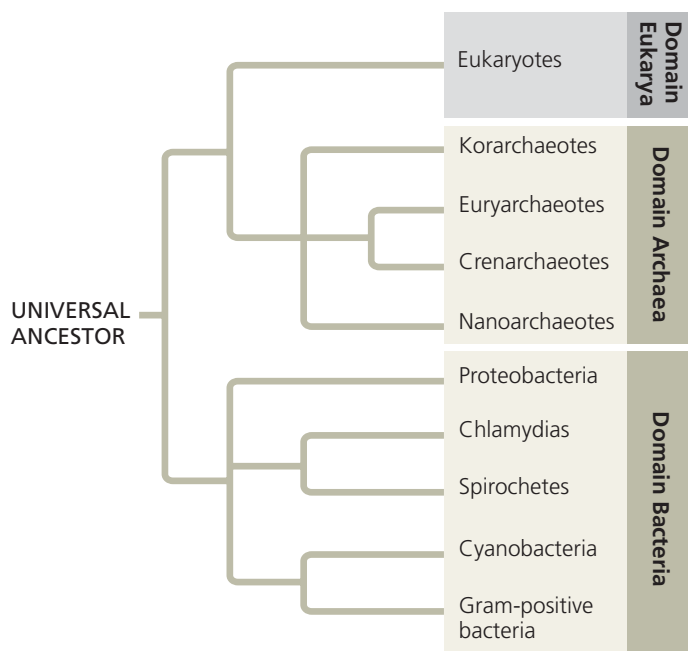

▲ **Figure 24.17 Conjugation and transfer of an F plasmid, resulting in recombination.** The DNA replication that accompanies the transfer of an F plasmid is called *rolling circle replication*. In effect, the intact circular DNA strand from the donor cell's F plasmid “rolls” as its other strand peels off and a new complementary strand is synthesized.

genes for antibiotic resistance to increase, and that is exactly what happens. The medical consequences are also predictable: Resistant strains of pathogens are becoming more common, making the treatment of certain bacterial infections more difficult. The problem is compounded by the fact that many R plasmids, like F plasmids, have genes that encode pili and enable DNA transfer from one bacterial cell to another by conjugation. Making the problem still worse, some R plasmids carry as many as ten genes for resistance to that many antibiotics.

### CONCEPT CHECK 24.3

1. Although rare on a per gene basis, new mutations can add considerable genetic variation to prokaryotic populations in each generation. Explain how this occurs.
2. Distinguish between the three mechanisms of transferring DNA from one bacterial cell to another.
3. In a rapidly changing environment, which bacterial population would likely be more successful, one that includes individuals capable of conjugation or one that does not? Explain.
4. **WHAT IF?** If a nonpathogenic bacterium were to acquire resistance to antibiotics, could this strain pose a health risk to people? Explain. In general, how does DNA transfer among bacteria affect the spread of resistance genes?

For suggested answers, see Appendix A.

**▲ Figure 24.18 A simplified phylogeny of prokaryotes.**

This phylogenetic tree based on molecular data shows one of several debated hypotheses of the relationships between the major prokaryotic groups discussed in this chapter. Within Archaea, the placement of the korarchaeotes and nanoarchaeotes remains unclear.

**?** Which domain is the sister group of Archaea?

One lesson from studying prokaryotic phylogeny is that the genetic diversity of prokaryotes is immense. When researchers began to sequence the genes of prokaryotes, they could investigate only the small fraction of species that could be cultured in the laboratory. In the 1980s, researchers began using the polymerase chain reaction (PCR; see Figure 13.25) to analyze the genes of prokaryotes collected from the environment (such as from soil or water samples). Such “genetic prospecting” is now widely used; in fact, today entire prokaryotic genomes can be obtained from environmental samples using *metagenomics* (see Concept 18.1). Each year, these techniques add new branches to the tree of life. While only about 9,800 prokaryotic species have been assigned scientific names, a single handful of soil could contain 10,000 prokaryotic species by some estimates. Taking full stock of this diversity will require many years of research.

Another important lesson from molecular systematics is that horizontal gene transfer has played a major role in the evolution of prokaryotes. Over hundreds of millions of years, prokaryotes have acquired genes from even distantly related species, and they continue to do so today. As a result, significant portions of the genomes of many prokaryotes are actually mosaics of genes imported from other species. For example, a 2011 study of 329 sequenced bacterial genomes found that an average of 75% of the genes in each genome had been transferred horizontally at some point in their evolutionary history. As discussed in Chapter 20, such gene transfers can make it difficult to determine phylogenetic relationships. Still, it is clear that for billions of

## CONCEPT 24.4

### Prokaryotes have radiated into a diverse set of lineages

Since their origin 3.5 billion years ago, prokaryotic populations have radiated extensively as they acquired diverse structural and metabolic adaptations. Collectively, these adaptations have enabled prokaryotes to inhabit every environment known to support life; if there are organisms in a particular place, some of those organisms are prokaryotes. Yet despite their obvious success, it is only in recent decades that we have begun to uncover the full extent of prokaryotic diversity.

#### An Overview of Prokaryotic Diversity

Microbiologists began comparing the sequences of prokaryotic genes in the 1970s. For example, using small-subunit ribosomal RNA as a marker for evolutionary relationships, researchers concluded that many prokaryotes once classified as bacteria are actually more closely related to eukaryotes and belong in a domain of their own: Archaea. Microbiologists have since analyzed larger amounts of genetic data—including more than 1,700 entire genomes—and have concluded that a few traditional taxonomic groups, such as cyanobacteria, are monophyletic. However, other traditional groups, such as gram-negative bacteria, are scattered throughout several lineages. **Figure 24.18** shows one phylogenetic hypothesis for some of the major taxa of prokaryotes based on molecular systematics.

years, the prokaryotes have evolved in two separate lineages, the bacteria and the archaea (see Figure 24.18).

Bacteria

Bacteria include the vast majority of prokaryotic species familiar to most people, from the pathogenic species that cause strep throat and tuberculosis to the beneficial species used to make Swiss cheese and yogurt. Every major mode of nutrition and metabolism is represented among bacteria, and even a small taxonomic group of bacteria may contain species exhibiting many different nutritional modes. As we'll see, the diverse nutritional and metabolic capabilities of bacteria—and archaea—are behind the great impact these organisms have on Earth and its life. **Figure 24.19**, on the next two pages, provides a closer look at several major groups of bacteria.

Archaea

Archaea share certain traits with bacteria and other traits with eukaryotes (**Table 24.2**). However, archaea also have many unique characteristics, as we would expect in a taxon that has followed a separate evolutionary path for so long.

The first prokaryotes assigned to domain Archaea live in environments so extreme that few other organisms can survive

there. Such organisms are called **extremophiles**, meaning “lovers” of extreme conditions (from the Greek *philos*, lover), and include extreme halophiles and extreme thermophiles.

**Extreme halophiles** (from the Greek *halo*, salt) live in highly saline environments, such as the Great Salt Lake and the Dead Sea. Some species merely tolerate salinity, while others require an environment that is several times saltier than seawater (which has a salinity of 3.5%). For example, the proteins and cell walls of archaea in the genus *Halobacterium* have unusual features that improve function in extremely salty environments but render these organisms incapable of survival if the salinity drops below 9%.

**Extreme thermophiles** (from the Greek *thermos*, hot) thrive in very hot environments (**Figure 24.20**). For example, archaea in the genus *Sulfolobus* live in sulfur-rich volcanic springs as hot as 90°C. At temperatures this high, the cells of most organisms die because their DNA does not remain in a double helix and many of their proteins denature. *Sulfolobus* and other extreme thermophiles avoid this fate because they have structural and biochemical adaptations that make their DNA and proteins stable at high temperatures. One extreme thermophile that lives near deep-sea hot springs called *hydrothermal vents* is informally known as “strain 121,” since it can reproduce even at 121°C. Another extreme thermophile, *Pyrococcus furiosus*, is used in biotechnology as a source of DNA polymerase for the PCR technique.

Many other archaea live in more moderate environments. Consider the **methanogens**, archaea that release methane as

**MAKE CONNECTIONS** Review the discussion of enzymes in Concept 6.4. How might the enzymes of thermophiles differ from those of other organisms?

## Proteobacteria

This large and diverse clade of gram-negative bacteria includes photoautotrophs, chemoautotrophs, and heterotrophs. Some proteobacteria are anaerobic, while others are aerobic. Molecular systematists currently recognize five subgroups of proteobacteria; the phylogenetic tree at right shows their relationships based on molecular data.

### Subgroup: Alpha Proteobacteria

Many of the species in this subgroup are closely associated with eukaryotic hosts. For example, *Rhizobium* species live in nodules within the roots of legumes (plants of the pea/bean family), where the bacteria convert atmospheric  $N_2$  to compounds the host plant can use to make proteins. Species in the genus *Agrobacterium* produce tumors in plants; genetic engineers use these bacteria to carry foreign DNA into the genomes of crop plants. Scientists hypothesize that mitochondria evolved from aerobic alpha proteobacteria through endosymbiosis.

*Rhizobium* (arrows)  
inside a root cell of a  
legume (TEM)

2.5  $\mu m$

### Subgroup: Beta Proteobacteria

This nutritionally diverse subgroup includes *Nitrosomonas*, a genus of soil bacteria that play an important role in nitrogen recycling by oxidizing ammonium ( $NH_4^+$ ), producing nitrite ( $NO_2^-$ ) as a waste product.

*Nitrosomonas*  
(colorized TEM)

1  $\mu m$

### Subgroup: Gamma Proteobacteria

This subgroup's autotrophic members include sulfur bacteria, such as *Thiomargarita namibiensis*, which obtain energy by oxidizing  $H_2S$ , producing sulfur as a waste product (the small globules in the photograph at right). Some heterotrophic gamma proteobacteria are pathogens; for example, *Legionella* causes Legionnaires' disease, *Salmonella* is responsible for some cases of food poisoning, and *Vibrio cholerae* causes cholera. *Escherichia coli*, a common resident of the intestines of humans and other mammals, normally is not pathogenic.

*Thiomargarita*  
*namibiensis* containing  
sulfur wastes (LM)

200  $\mu m$

### Subgroup: Delta Proteobacteria

This subgroup includes the slime-secreting myxobacteria. When the soil dries out or food is scarce, the cells congregate into a fruiting body that releases resistant "myxospores." These cells found new colonies in favorable environments. Another group of delta proteobacteria, the bdellovibrios, attack other bacteria, charging at up to 100  $\mu m/sec$  (comparable to a human running 240 km/hr). The attack begins when a bdellovibrio attaches to specific molecules found on the outer covering of some bacterial species. The bdellovibrio then drills into its prey by using digestive enzymes and spinning at 100 revolutions per second.

Fruiting bodies of  
*Chondromyces crocatus*,  
a myxobacterium (SEM)

300  $\mu m$

### Subgroup: Epsilon Proteobacteria

Most species in this subgroup are pathogenic to humans or other animals. Epsilon proteobacteria include *Campylobacter*, which causes blood poisoning and intestinal inflammation, and *Helicobacter pylori*, which causes stomach ulcers.

*Helicobacter pylori*  
(colorized TEM)

2  $\mu m$

## Chlamydias

These parasites can survive only within animal cells, depending on their hosts for resources as basic as ATP. The gram-negative walls of chlamydias are unusual in that they lack peptidoglycan. One species, *Chlamydia trachomatis*, is the most common cause of blindness in the world and also causes nongonococcal urethritis, the most common sexually transmitted disease in the United States.

*Chlamydia* (arrows) inside an animal cell (colorized TEM)

2.5  $\mu\text{m}$

## Spirochetes

These helical gram-negative heterotrophs spiral through their environment by means of rotating, internal, flagellum-like filaments. Many spirochetes are free-living, but others are notorious pathogenic parasites: *Treponema pallidum* causes syphilis, and *Borrelia burgdorferi* causes Lyme disease.

*Leptospira*, a spirochete (colorized TEM)

5  $\mu\text{m}$

## Cyanobacteria

These gram-negative photoautotrophs are the only prokaryotes with plantlike, oxygen-generating photosynthesis. (In fact, chloroplasts likely evolved from an endosymbiotic cyanobacterium.) Both solitary and filamentous cyanobacteria are abundant components of freshwater and marine *phytoplankton*, the collection of photosynthetic organisms that drift near the water's surface. Some filaments have cells specialized for nitrogen fixation, the process that incorporates atmospheric  $\text{N}_2$  into inorganic compounds that can be used in the synthesis of amino acids and other organic molecules.

*Oscillatoria*, a filamentous cyanobacterium

40  $\mu\text{m}$

## Gram-Positive Bacteria

Gram-positive bacteria rival the proteobacteria in diversity. Species in one subgroup, the actinomycetes (from the Greek *mykes*, fungus, for which these bacteria were once mistaken), form colonies containing branched chains of cells. Two species of actinomycetes cause tuberculosis and leprosy. However, most actinomycetes are free-living species that help decompose the organic matter in soil; their secretions are partly responsible for the “earthy” odor of rich soil. Soil-dwelling species in the genus *Streptomyces* (top) are cultured by pharmaceutical companies as a source of many antibiotics, including streptomycin.

Gram-positive bacteria include many solitary species, such as *Bacillus anthracis*, which causes anthrax, and *Clostridium botulinum*, which causes botulism. The various species of *Staphylococcus* and *Streptococcus* are also gram-positive bacteria.

Mycoplasmas (bottom) are the only bacteria known to lack cell walls. They are also the tiniest known cells, with diameters as small as 0.1  $\mu\text{m}$ , only about five times as large as a ribosome. Mycoplasmas have small genomes—*Mycoplasma genitalium* has only 517 genes, for example. Many mycoplasmas are free-living soil bacteria, but others are pathogens.

*Streptomyces*, the source of many antibiotics (SEM)

2  $\mu\text{m}$

▲ **Figure 24.21 A highly thermophilic methanogen.** The archaean *Methanopyrus kandleri* (inset) lives in the extreme heat of “black smoker” hydrothermal vents on the ocean floor.

a by-product of their unique ways of obtaining energy. Many methanogens use  $\text{CO}_2$  to oxidize  $\text{H}_2$ , a process that produces both energy and methane waste. Among the strictest of anaerobes, methanogens are poisoned by  $\text{O}_2$ . Although some methanogens live in extreme environments, such as around deep-sea hydrothermal vents (**Figure 24.21**), others live in swamps where other microorganisms have consumed all the  $\text{O}_2$ . The “marsh gas” found in such environments is the methane released by these archaea. Other species of methanogens inhabit the anaerobic environment within the guts of cattle, termites, and other herbivores, playing an essential role in the nutrition of these animals. Methanogens also have an important application as decomposers in sewage treatment facilities.

Many extreme halophiles and all known methanogens are archaea in the clade Euryarchaeota (from the Greek *eury*, broad, a reference to the habitat range of these prokaryotes). The euryarchaeotes also include some extreme thermophiles, though most thermophilic species belong to a second clade, Crenarchaeota (*cren* means “spring,” such as a hydrothermal spring). Recent metagenomic studies have identified many species of euryarchaeotes and crenarchaeotes that are not extremophiles. These archaea exist in habitats ranging from farm soils to lake sediments to the surface waters of the open ocean.

New findings continue to update the picture of archaeal phylogeny. In 1996, researchers sampling a hot spring in Yellowstone National Park discovered archaea that do not appear to belong to either Euryarchaeota or Crenarchaeota. They placed these archaea in a new clade, Korarchaeota (from the Greek *koron*, young man). In 2002, researchers exploring hydrothermal vents off the coast of Iceland discovered archaeal cells only  $0.4\ \mu\text{m}$  in diameter attached to a much larger crenarchaeote. The genome of the smaller archaeon is one of the smallest known of any organism, containing only 500,000 base pairs. Genetic analysis indicates that this prokaryote belongs to a fourth archaeal clade, Nanoarchaeota (from the Greek *nanos*, dwarf). Within a year after this clade was named, three other DNA sequences from nanoarchaeote species were isolated: one from Yellowstone’s hot springs, one from hot springs in

Siberia, and one from a hydrothermal vent in the Pacific. As metagenomic prospecting continues, the tree in Figure 24.18 may well undergo further changes.

#### CONCEPT CHECK 24.4

1. Explain how molecular systematics has contributed to our understanding of the phylogeny and evolution of prokaryotes.
2. How has metagenomics contributed to our understanding of prokaryotic diversity and phylogeny?
3. **WHAT IF?** What would the discovery of a bacterial species that is a methanogen imply about the evolution of the methane-producing pathway?

For suggested answers, see Appendix A.

## CONCEPT 24.5

### Prokaryotes play crucial roles in the biosphere

If people were to disappear from the planet tomorrow, life on Earth would change for many species, but few would be driven to extinction. In contrast, prokaryotes are so important to the biosphere that if they were to disappear, the prospects of survival for many other species would be dim.

#### Chemical Recycling

The atoms that make up the organic molecules in all living things were at one time part of inorganic substances in the soil, air, and water. Sooner or later, those atoms will return there. Ecosystems depend on the continual recycling of chemical elements between the living and nonliving components of the environment, and prokaryotes play a major role in this process. For example, chemoheterotrophic prokaryotes function as **decomposers**, breaking down dead organisms as well as waste products and thereby unlocking supplies of carbon, nitrogen, and other elements. Without the actions of prokaryotes and other decomposers such as fungi, life as we know it would cease. (See Chapter 42 for a detailed discussion of chemical cycles.)

Prokaryotes also convert some molecules to forms that can be taken up by other organisms. Cyanobacteria and other autotrophic prokaryotes use  $\text{CO}_2$  to make organic compounds such as sugars, which are then passed up through food chains. Cyanobacteria also produce atmospheric  $\text{O}_2$ , and a variety of prokaryotes fix atmospheric nitrogen ( $\text{N}_2$ ) into forms that other organisms can use to make the building blocks of proteins and nucleic acids. Under some conditions, prokaryotes can increase the availability of nutrients that plants require for growth, such as nitrogen, phosphorus, and potassium (**Figure 24.22**). Prokaryotes can also *decrease* the availability of key plant nutrients; this occurs when prokaryotes “immobilize” nutrients by using them to synthesize molecules that remain within their cells. Thus, prokaryotes can have complex effects on soil nutrient

► **Figure 24.22 Impact of bacteria on soil nutrient availability.** Pine seedlings grown in sterile soils to which one of three strains of the bacterium *Burkholderia glathei* had been added absorbed more potassium ( $K^+$ ) than did seedlings grown in soil without any bacteria. Other results (not shown) demonstrated that strain 3 increased the amount of  $K^+$  released from mineral crystals to the soil.

**WHAT IF?** Estimate the average uptake of  $K^+$  for seedlings in soils with bacteria. What would you expect this average to be if bacteria had no effect on nutrient availability?

concentrations. In marine environments, a recent study found that an archaean from the clade Crenarchaeota can perform nitrification, a key step in the nitrogen cycle (see Figure 42.13). Crenarchaeotes dominate the oceans by numbers, comprising an estimated  $10^{28}$  cells. Their abundance suggests that these organisms may have a large impact on the global nitrogen cycle; scientists are investigating this possibility.

## Ecological Interactions

Prokaryotes play a central role in many ecological interactions. Consider **symbiosis** (from a Greek word meaning “living together”), an ecological relationship in which two species live in close contact with each other. Prokaryotes often form symbiotic associations with much larger organisms. In general, the larger organism in a symbiotic relationship is known as the **host**, and the smaller is known as the **symbiont**. There are many cases in which a prokaryote and its host participate in **mutualism**, an ecological interaction between two species in which both benefit (Figure 24.23). Other interactions take the form of **commensalism**, an interaction in which one species benefits while the other is not harmed or helped in any significant way. For example, more than 150 bacterial species live on the surface of your body, covering portions of your skin with up to 10 million cells per

▲ **Figure 24.23 Mutualism: bacterial “headlights.”** The glowing oval below the eye of the flashlight fish (*Photoblepharon palpebratus*) is an organ harboring bioluminescent bacteria. The fish uses the light to attract prey and to signal potential mates. The bacteria receive nutrients from the fish.

square centimeter. Some of these species are commensalists: You provide them with food, such as the oils that exude from your pores, and a place to live, while they neither harm nor benefit you. Finally, some prokaryotes engage in **parasitism**, an interaction in which a **parasite** eats the cell contents, tissues, or body fluids of its host. As a group, parasites harm but usually do not kill their host, at least not immediately (unlike a predator). Parasites that cause disease are known as **pathogens**, many of which are prokaryotic. (Chapter 41 discusses mutualism, commensalism, and parasitism in more detail.)

The very existence of an ecosystem can depend on prokaryotes. For example, consider the diverse ecological communities found at hydrothermal vents. These communities are densely populated by many different kinds of animals, including worms, clams, crabs, and fishes. But since sunlight does not penetrate to the deep ocean floor, the community does not include photosynthetic organisms. Instead, the energy that supports the community is derived from the metabolic activities of chemoautotrophic bacteria. These bacteria harvest chemical energy from compounds such as hydrogen sulfide ( $H_2S$ ) that are released from the vent. An active hydrothermal vent may support hundreds of eukaryotic species, but when the vent stops releasing chemicals, the chemoautotrophic bacteria cannot survive. As a result, the entire vent community collapses.

## Impact on Humans

Though the best-known prokaryotes tend to be the bacteria that cause human illness, these pathogens represent only a small fraction of prokaryotic species. Many other prokaryotes have positive interactions with people, and some play essential roles in agriculture and industry.

### Mutualistic Bacteria

As is true for many other eukaryotes, human well-being can depend on mutualistic prokaryotes. For example, our intestines are home to an estimated 500–1,000 species of bacteria; their cells outnumber all human cells in the body by a factor of ten. Different species live in different portions of the intestines, and they vary in their ability to process different foods. Many of

these species are mutualists, digesting food that our own intestines cannot break down. In 2003, scientists published the first complete genome of one of these gut mutualists, *Bacteroides thetaiotaomicron*. The genome includes a large array of genes involved in synthesizing carbohydrates, vitamins, and other nutrients needed by humans. Signals from the bacterium activate human genes that build the network of intestinal blood vessels necessary to absorb nutrient molecules. Other signals induce human cells to produce antimicrobial compounds to which *B. thetaiotaomicron* is not susceptible. This action may reduce the population sizes of other, competing species, thus potentially benefiting both *B. thetaiotaomicron* and its human host.

### Pathogenic Bacteria

All the pathogenic prokaryotes known to date are bacteria, and they deserve their negative reputation. Bacteria cause about half of all human diseases. For example, about 2 million people die each year of the lung disease tuberculosis, caused by *Mycobacterium tuberculosis*. And another 2 million people die each year from diarrheal diseases caused by various bacteria.

Some bacterial diseases are transmitted by other species, such as fleas or ticks. In the United States, the most widespread pest-carried disease is Lyme disease, which infects 15,000 to 20,000 people each year (Figure 24.24). Caused by a bacterium carried by ticks that live on deer and field mice, Lyme disease can result in debilitating arthritis, heart disease, nervous disorders, and death if untreated.

Pathogenic prokaryotes usually cause illness by producing poisons, which are classified as exotoxins or endotoxins.

**Exotoxins** are proteins secreted by certain bacteria and other organisms. Cholera, a dangerous diarrheal disease, is caused by an exotoxin secreted by the proteobacterium *Vibrio cholerae*. The exotoxin stimulates intestinal cells to release chloride ions into the gut, and water follows by osmosis. In another example, the potentially fatal disease botulism is caused by botulinum toxin, an exotoxin secreted

by the gram-positive bacterium *Clostridium botulinum* as it ferments various foods, including improperly canned meat, seafood, and vegetables. Like other exotoxins, the botulinum toxin can produce disease even if the bacteria that manufacture it are not present. In one such case, eight people contracted botulism after eating salted fish that did not contain any *C. botulinum* bacteria, but did contain the botulinum toxin. Even though the bacterium was no longer present, at some point in the fish preparation process the bacterium must have been able to grow and secrete the toxin.

**Endotoxins** are lipopolysaccharide components of the outer membrane of gram-negative bacteria. In contrast to exotoxins, endotoxins are released only when the bacteria die and their cell walls break down. Endotoxin-producing bacteria include species in the genus *Salmonella*, such as *Salmonella typhi*, which causes typhoid fever. You might have heard of food poisoning caused by other *Salmonella* species that can be found in poultry and some fruits and vegetables.

Since the 19th century, improved sanitation systems in the industrialized world have greatly reduced the threat of pathogenic bacteria. Antibiotics have saved a great many lives and reduced the incidence of disease. However, resistance to antibiotics is currently evolving in many bacterial strains. As you read earlier, the rapid reproduction of bacteria enables cells carrying resistance genes to quickly give rise to large populations as a result of natural selection, and these genes can also spread to other species by horizontal gene transfer.

Horizontal gene transfer can also spread genes associated with virulence, turning normally harmless bacteria into potent pathogens. *E. coli*, for instance, is ordinarily a harmless symbiont in the human intestines, but pathogenic strains that cause bloody diarrhea have emerged. One of the most dangerous strains, O157:H7, is a global threat; in the United States alone, there are 75,000 cases of O157:H7 infection per year, often from contaminated beef or produce. In 2001, scientists sequenced the genome of O157:H7 and compared it with the genome of a harmless strain of *E. coli* called K-12. They discovered that 1,387 out of the 5,416 genes in O157:H7 have no counterpart in K-12. Many of these 1,387 genes are found in chromosomal regions that include phage DNA. This suggests that at least some of the 1,387 genes were incorporated into the genome of O157:H7 through phage-mediated horizontal gene transfer (transduction). Some of the genes found only in O157:H7 are associated with virulence, including genes that code for adhesive fimbriae that enable O157:H7 to attach itself to the intestinal wall and extract nutrients.

### Prokaryotes in Research and Technology

On a positive note, we reap many benefits from the metabolic capabilities of both bacteria and archaea. For example, people have long used bacteria to convert milk to cheese and yogurt. In recent years, our greater understanding of prokaryotes has led

▲ **Figure 24.24 Lyme disease.** Ticks in the genus *Ixodes* spread the disease by transmitting the spirochete *Borrelia burgdorferi* (colorized SEM). A rash may develop at the site of the tick's bite; the rash may be large and ring-shaped (as shown) or much less distinctive.

# Making a Bar Graph and Interpreting Data

**Do Soil Microorganisms Protect Against Crop Disease?** The soil layer surrounding plant roots, called the *rhizosphere*, is a complex community in which archaea, bacteria, fungi, and plants interact with one another. When crop plants are attacked by fungal or bacterial pathogens, in some cases soil from the rhizosphere protects plants from future attacks. Such protective soil is called disease-suppressive soil. Plants grown in disease-suppressive soils appear to be less vulnerable to pathogen attack. In this exercise, you'll interpret data from an experiment studying whether microorganisms were responsible for the protective effects of disease-suppressive soils.

**How the Experiment Was Done** The researchers obtained disease-suppressive soil from 25 random sites in an agricultural field in the Netherlands in which sugar beet crops had previously been attacked by *Rhizoctonia solani*, a fungal pathogen that also afflicts potatoes and rice. The researchers collected other soil samples from the grassy margins of the field where sugar beets had not been grown. The researchers predicted that these soil samples from the margins would not offer protection against pathogens.

The researchers then planted and raised sugar beets in greenhouses, using 5 different soil treatments. Each soil treatment was applied to 4 pots, and each pot contained 8 plants. The pots were inoculated with *Rhizoctonia solani*. After 20 days, researchers determined the percentage of infected sugar beet seedlings for each soil treatment.

## Data from the Experiment

Soil Treatment	Percentage of Seedlings with Fungal Disease
Disease-suppressive soil	3.0
Soil from margin of field	62
Soil from margin of field + 10% disease-suppressive soil	39
Disease-suppressive soil heated to 50°C for 1 hour	31
Disease-suppressive soil heated to 80°C for 1 hour	70

## Interpret the Data

1. What hypothesis were the researchers testing in this study? What is the independent variable in this study? What is the dependent variable?
2. What is the total number of pots used in this experiment, and how many plants received each soil treatment? Explain why multiple pots and plants were used for each treatment.
3. Use the data in the table to create a bar graph. Then in words, describe and compare the results for the five soil treatments.
4. The researchers stated, "Collectively, these results indicated that disease suppressiveness [of soil] toward *Rhizoctonia solani* was microbiological in nature." Is this statement supported by the results shown in the graph? Explain.

**Data from** R. Mendes, et al. Deciphering the rhizosphere for disease-suppressive bacteria, *Science* 332: 1097–1100 (2011).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

to an explosion of new applications in biotechnology; two examples are the use of *E. coli* in gene cloning (see Figure 13.22) and the use of *Agrobacterium tumefaciens* in producing transgenic plants. Naturally occurring soil bacteria may have potential for combating diseases that affect crop plants; in the **Scientific Skills Exercise**, you can interpret data from an experiment studying the effect of these bacteria.

Bacteria may soon figure prominently in another major industry: plastics. Globally, each year about 350 billion pounds of plastic are produced from petroleum and used to make toys, storage containers, soft drink bottles, and many other items. These products degrade slowly, creating environmental problems. Bacteria can now be used to make natural plastics (**Figure 24.25a**). For example, some bacteria synthesize a type of polymer known as PHA (polyhydroxyalkanoate), which they use to store chemical energy. The PHA they produce can be extracted, formed into pellets, and used to make durable, yet biodegradable plastics. Through genetic engineering, we can now modify bacteria to produce vitamins, antibiotics, hormones, and other products (see Concept 13.4). Researchers are seeking to reduce fossil fuel use by engineering bacteria that can produce ethanol from various forms of biomass, including agricultural waste, switchgrass, municipal waste (such as paper products that are not recycled), and corn (**Figure 24.25b**).

Another way to harness prokaryotes is in **bioremediation**, the use of organisms to remove pollutants from soil, air, or water. For example, anaerobic bacteria and archaea decompose the organic matter in sewage, converting it to material that can be used as landfill or fertilizer after chemical sterilization. Other bioremediation applications include cleaning up oil

**▲ Figure 24.25 Products from prokaryotes.** (a) These bacteria synthesize and store PHA, which can be extracted and used to make biodegradable plastic products. (b) Current research seeks to develop bacteria that produce ethanol (E-85) fuel efficiently from renewable plant products.

▲ **Figure 24.26 Bioremediation of an oil spill.** Spraying fertilizers on an oil-soaked area stimulates growth of native bacteria that metabolize the oil. This can speed up the natural breakdown process by a factor of five.

spills (**Figure 24.26**) and precipitating radioactive material (such as uranium) out of groundwater.

The usefulness of prokaryotes largely derives from their diverse forms of nutrition and metabolism. All this metabolic versatility evolved prior to the appearance of the structural novelties that heralded the evolution of eukaryotic organisms, to which we devote the remainder of this unit.

#### CONCEPT CHECK 24.5

1. Explain how prokaryotes, though small, can be considered giants in their collective impact on Earth and its life.
2. A pathogenic bacterium's toxin causes symptoms that increase the bacterium's chance of spreading from host to host. Does this information indicate whether the poison is an exotoxin or endotoxin? Explain.
3. **MAKE CONNECTIONS** Review photosynthesis in Figure 8.5. Then summarize the main steps by which cyanobacteria produce  $O_2$  and use  $CO_2$  to make organic compounds.
4. **WHAT IF?** How might a sudden and dramatic change in your diet affect the diversity of prokaryotic species that live in your digestive tract?

For suggested answers, see Appendix A.

## 24 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 24.1

##### Conditions on early Earth made the origin of life possible (pp. 459–462)

- Experiments simulating possible early atmospheres have produced organic molecules from inorganic precursors. Amino acids, lipids, sugars, and nitrogenous bases have also been found in meteorites.
- Amino acids and RNA nucleotides polymerize when dripped onto hot sand, clay, or rock. Organic compounds can spontaneously assemble into **protocells**, membrane-enclosed droplets that have some properties of cells.
- The first genetic material may have been short pieces of RNA capable of guiding polypeptide synthesis and self-replication. Early protocells containing such RNA would have increased through natural selection.
- Fossil evidence of early prokaryotes dates to 3.5 billion years ago. By 2.8 billion years ago, prokaryotes included stromatolites that differed in morphology and habitat. Early prokaryotes also included cyanobacteria that released oxygen as a by-product of photosynthesis, thereby changing Earth's atmosphere and altering the course of evolution.

**?** Describe the roles that montmorillonite clay and vesicles may have played in the origin of life.

#### CONCEPT 24.2

##### Diverse structural and metabolic adaptations have evolved in prokaryotes (pp. 462–467)

- Nutritional diversity is much greater in prokaryotes than in eukaryotes. As a group, prokaryotes perform all four modes of nutrition: photoautotrophy, chemoautotrophy, photoheterotrophy, and chemoheterotrophy.
- Among prokaryotes, obligate aerobes require  $O_2$ , obligate anaerobes are poisoned by  $O_2$ , and facultative anaerobes can survive with or without  $O_2$ .
- Unlike eukaryotes, prokaryotes can metabolize nitrogen in many different forms. Some can convert atmospheric nitrogen to ammonia, a process called **nitrogen fixation**.
- Prokaryotic cells and even species may cooperate metabolically. In *Anabaena*, photosynthetic cells and nitrogen-fixing cells exchange metabolic products. Metabolic cooperation also occurs in surface-coating **biofilms** that include different species.
- Prokaryotes can reproduce quickly by binary fission.

**?** Describe features of prokaryotes that enable them to thrive in a wide range of different environments.

## CONCEPT 24.3

### Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes (pp. 467–470)

- Because prokaryotes can often proliferate rapidly, mutations can quickly increase a population's genetic variation. As a result, prokaryotic populations often can evolve in short periods of time in response to changing conditions.
- Genetic diversity in prokaryotes also can arise by recombination of the DNA from two different cells (via **transformation**, **transduction**, or **conjugation**). By transferring advantageous alleles, such as ones for antibiotic resistance, genetic recombination can promote adaptive evolution in prokaryotic populations.

**?** Although prokaryotes reproduce asexually, their populations can have high genetic diversity. Explain how this can occur.

## CONCEPT 24.4

### Prokaryotes have radiated into a diverse set of lineages (pp. 470–474)

- Molecular systematics is leading to a phylogenetic classification of prokaryotes, allowing systematists to identify major new clades.
- Some archaea, such as **extreme thermophiles** and **extreme halophiles**, live in extreme environments. Other archaea live in moderate environments, such as soils and lakes.
- Diverse nutritional types are scattered among the major groups of bacteria. The two largest groups are the proteobacteria and gram-positive bacteria.

**?** What impact have molecular data had on constructing prokaryotic phylogeny?

## CONCEPT 24.5

### Prokaryotes play crucial roles in the biosphere (pp. 474–478)

- Decomposition by heterotrophic prokaryotes and the synthetic activities of autotrophic and nitrogen-fixing prokaryotes contribute to the recycling of elements in ecosystems.
- Many prokaryotes have a symbiotic relationship with a host; the relationships between prokaryotes and their hosts range from mutualism to commensalism to parasitism.

- People depend on mutualistic prokaryotes, including hundreds of species that live in our intestines and help digest food.
- Pathogenic bacteria typically cause disease by releasing **exotoxins** or **endotoxins**. Horizontal gene transfer can spread genes associated with virulence to previously harmless species or strains.
- Experiments with bacteria such as *E. coli* have led to important advances in DNA technology. Prokaryotes can be used in bioremediation and in the synthesis of vitamins, antibiotics, and other products.

**?** In what ways are prokaryotes key to the survival of many species?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- Which of the following steps has *not* yet been accomplished by scientists studying the origin of life?
  - synthesis of small RNA polymers by ribozymes
  - abiotic synthesis of polypeptides
  - formation of molecular aggregates with selectively permeable membranes
  - formation of protocells that use DNA to direct the polymerization of amino acids
  - abiotic synthesis of organic molecules
- Fossilized stromatolites
  - more than 2.8 billion years old have not been discovered.
  - formed around deep-sea vents.
  - resemble structures formed by bacterial communities that are found today in some shallow marine bays.
  - provide evidence that plants moved onto land in the company of fungi around 500 million years ago.
  - contain the first undisputed fossils of eukaryotes and date from 1.8 billion years ago.
- Genetic variation in bacterial populations cannot result from
  - transduction.
  - transformation.
  - conjugation.
  - mutation.
  - meiosis.
- Photoautotrophs use
  - light as an energy source and methane as a carbon source.
  - light as an energy source and  $CO_2$  as a carbon source.
  - $N_2$  as an energy source and  $CO_2$  as a carbon source.
  - $CO_2$  as both an energy source and a carbon source.
  - $H_2S$  as an energy source and  $CO_2$  as a carbon source.
- Which of the following statements is *not* true?
  - Archaea and bacteria have different membrane lipids.
  - Both archaea and bacteria generally lack membrane-enclosed organelles.
  - The cell walls of archaea lack peptidoglycan.
  - Only bacteria have histones associated with DNA.
  - Only some archaea use  $CO_2$  to oxidize  $H_2$ , releasing methane.
- Bacteria perform the following ecological roles. Which role typically does *not* involve symbiosis?
  - skin commensalist
  - pathogen
  - bioluminescent bacteria in fish
  - gut mutualist
  - decomposer

7. Plantlike photosynthesis that releases  $O_2$  occurs in
- cyanobacteria.
  - chlamydias.
  - archaea.
  - actinomycetes.
  - chemoautotrophic bacteria.

## Level 2: Application/Analysis

### 8. SCIENTIFIC INQUIRY

**DRAW IT** The nitrogen-fixing bacterium *Rhizobium* infects the roots of some plant species, forming a mutualism in which the bacterium provides nitrogen and the plant provides carbohydrates. Scientists measured the 12-week growth of one such plant species (*Acacia irrorata*) when infected by six different *Rhizobium* strains. (a) Graph the data. (b) Interpret your graph.

<i>Rhizobium</i> strain	1	2	3	4	5	6
Plant mass (g)	0.91	0.06	1.56	1.72	0.14	1.03

**Source** J. J. Burdon et al., Variation in the effectiveness of symbiotic associations between native rhizobia and temperate Australian *Acacia*: Within-species interactions, *Journal of Applied Ecology* 36:398–408 (1999).

**Note:** Without *Rhizobium*, after 12 weeks, *Acacia* plants have a mass of about 0.1 g.

## Level 3: Synthesis/Evaluation

### 9. FOCUS ON EVOLUTION

In patients infected with nonresistant strains of the tuberculosis bacterium, antibiotics can relieve symptoms in a few weeks. However, it takes much longer to halt the infection, and patients may discontinue treatment while bacteria are still present. How might this result in the evolution of drug-resistant pathogens?

### 10. FOCUS ON ENERGY AND MATTER

In a short essay (about 100–150 words), discuss how prokaryotes and other members of hydrothermal vent communities transfer and transform energy.

For selected answers, see Appendix A.

# The Origin and Diversification of Eukaryotes

▼ **Figure 25.1** What enables the cell on the left to engulf its prey?

## KEY CONCEPTS

**25.1** Eukaryotes arose by endosymbiosis more than 1.8 billion years ago

**25.2** Multicellularity has originated several times in eukaryotes

**25.3** Four “supergroups” of eukaryotes have been proposed based on morphological and molecular data

**25.4** Single-celled eukaryotes play key roles in ecological communities and affect human health

## OVERVIEW

### Shape Changers

**T**he organisms in **Figure 25.1** are ciliates, a diverse group of single-celled eukaryotes named after the small appendages—cilia—that cover much of their bodies and enable them to move. The ciliate on the left, *Didinium*, has begun a seemingly impossible task: it will completely engulf the *Paramecium* (right), even though the *Paramecium* is as large as it is.

Reflect for a moment on the magnitude of this feat. If we humans could do this, in a single swallow we could ingest more food than we would typically eat in a month. Like us, even the prokaryotes discussed in Chapter 24 cannot engulf food items their own size—although prokaryotes can metabolize an astonishing range of compounds, they can only absorb small particles of food. What enables *Didinium* to tackle food items that could easily evade a hungry prokaryote?

One key to *Didinium*'s success lies within its cells—it has a complex set of cytoskeletal proteins that enable the cell to change in shape dramatically as it feeds. *Didinium* also has small structures similar to miniature harpoons that it can eject to help ensnare its prey. These two features illustrate the structural complexity that characterizes the cells of *Didinium* and the other diverse, mostly unicellular groups of eukaryotes informally known as **protists**.

As we'll see, some protists change their form as they creep along using blob-like appendages, others are shaped like tiny trumpets, and still others resemble miniature jewelry. In this chapter, we'll explore how

these shape-changing, structurally complex eukaryotic cells arose from their morphologically simpler prokaryotic ancestors. We'll also examine another major step in the evolutionary history of life: the origin of multicellular eukaryotes such as plants, fungi, and animals. Finally, we'll consider how single-celled eukaryotes affect ecosystems and human health.

## CONCEPT 25.1

### Eukaryotes arose by endosymbiosis more than 1.8 billion years ago

As we discussed in Chapter 24, all organisms were unicellular early in the history of life. The evolution of eukaryotes did not immediately change this, but it did involve fundamental changes in the structure of these individual cells. For

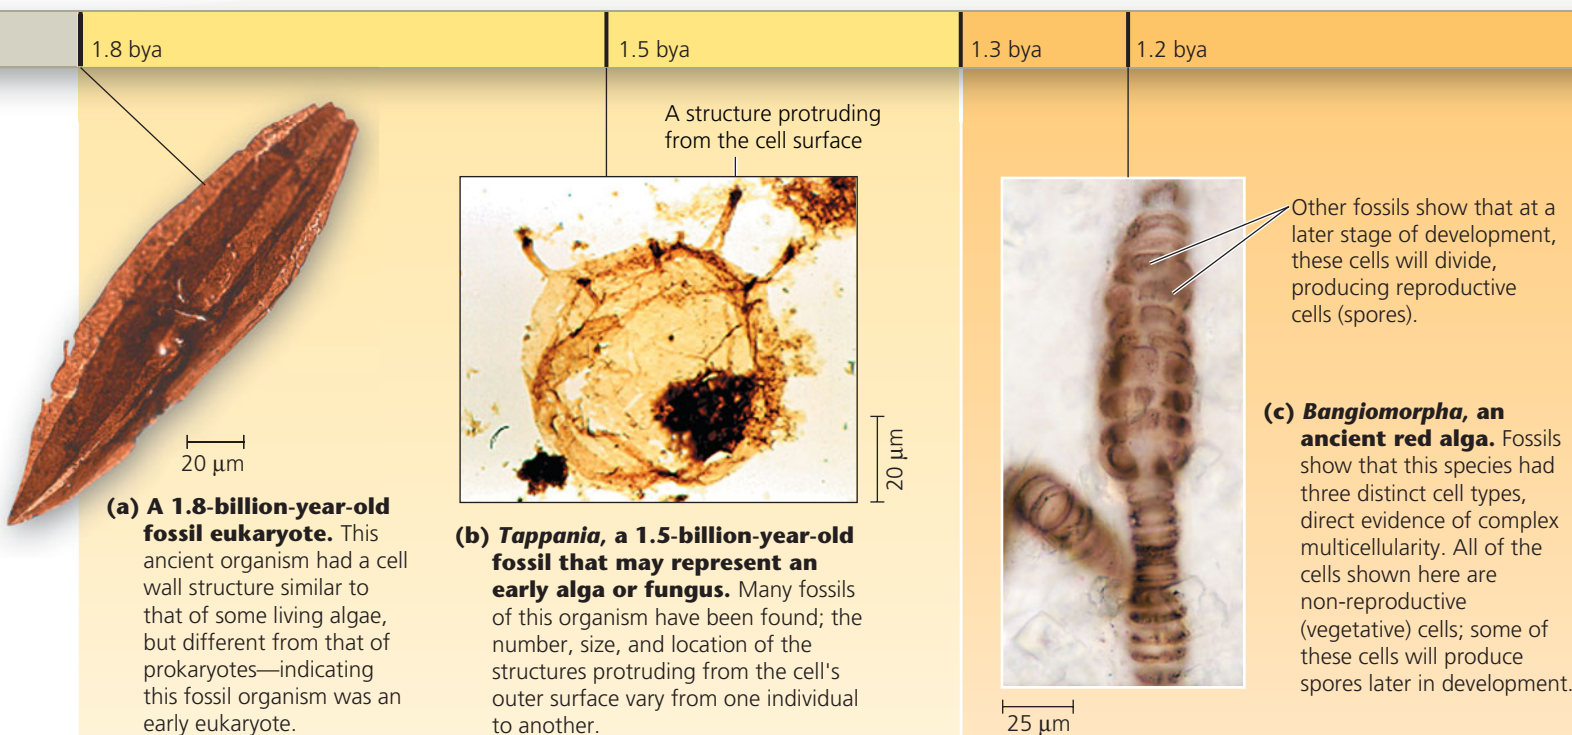

example, unlike the cells of prokaryotes, the cells of all eukaryotes have a nucleus and other membrane-enclosed organelles, such as mitochondria and the Golgi apparatus. Such organelles provide specific locations where particular cellular functions are accomplished, making the structure and organization of eukaryotic cells more complex than that of prokaryotic cells.

Another key eukaryote characteristic is a well-developed cytoskeleton that extends throughout the cell (see Figure 4.20). The cytoskeleton provides structural support that enables

eukaryotic cells to have asymmetric (irregular) forms, as well as to change shape as they feed, move, or grow. Although some prokaryotes have proteins related to eukaryotic cytoskeletal proteins, their rigid cell walls and lack of a well-developed cytoskeleton limit the extent to which their cells can maintain asymmetric forms or change shape over time.

The fossil record indicates that prokaryotes were inhabiting Earth at least 3.5 billion years ago (see Chapter 24). At what

## ▼ Figure 25.2 Exploring the Early Evolution of Eukaryotes

### Initial Diversification

The fossil record shows that a moderate diversity of single-celled eukaryotes was already present 1.8 billion years ago, including the fossil specimen in (a). Researchers have discovered other fossil eukaryotes of the same age that vary in size and had shapes ranging from spherical to elliptical (some that are spindle-shaped, or tapering at each end). This variety suggests that the eukaryotes may have originated much earlier in time.

Early members of domain Eukarya had a nucleus, a flexible membrane, and a cytoskeleton capable of supporting an irregular cell shape, like that seen in (b). Other fossils from this time period include several different types of simple filaments thought to be of small, multicellular eukaryotes. Although fossil eukaryotes from this time range are moderately diverse, none of these organisms can be assigned with confidence to an extant group of eukaryotes.

(Time line not to scale.)

### Appearance of Novel Features

The oldest known eukaryotic fossils that can be resolved taxonomically are of small red algae that lived 1.2 billion years ago (c); note that **algae** is a general term that includes all groups of photosynthetic protists. Other fossils from this period include green algae (d) and certain types of amoebas that lived within vase-shaped structures (e), as well as a variety of colonial and multicellular protists of unknown taxonomic affinity.

The taxonomic diversification seen in these fossils was accompanied by a suite of novel biological features, including the origins of complex multicellularity (a term that applies to multicellular organisms with differentiated cell types), sexual life cycles, and eukaryotic photosynthesis. Some of these features can be

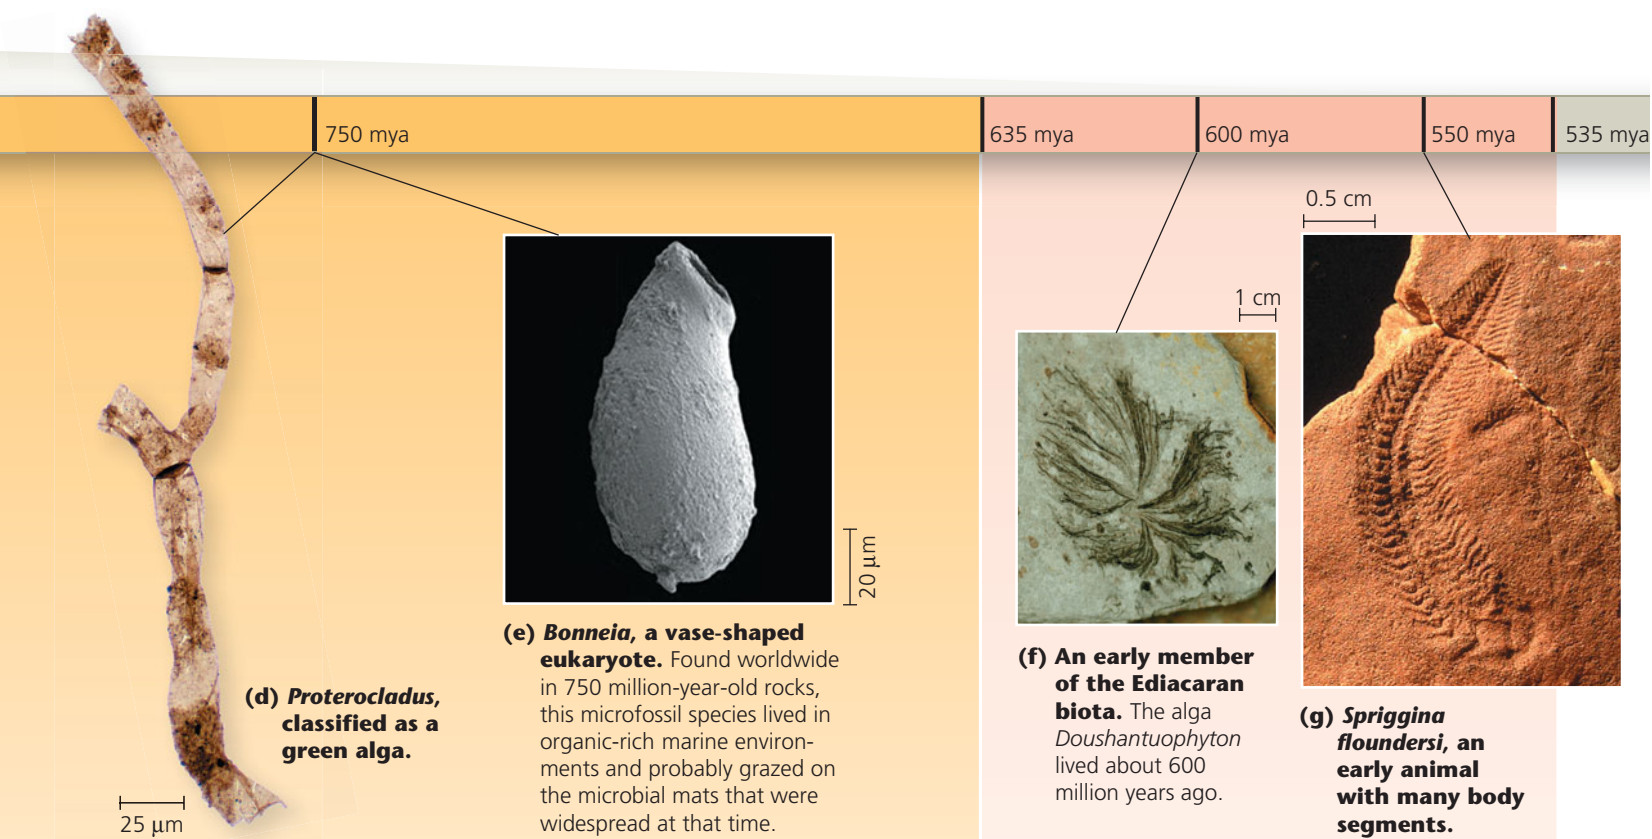

point did irregular forms and other novel features of eukaryotes appear, signifying the origin of the group? Fossils and molecular data provide clues to when and how eukaryotes may have arisen from their prokaryotic ancestors.

## The Fossil Record of Early Eukaryotes

Complex lipids that are synthesized by eukaryotes (but not by prokaryotes) have been found in rocks dated to 2.7 billion years ago. Although such chemical evidence is consistent with

eukaryotes having lived at that time, the oldest widely accepted fossils of eukaryotic organisms are 1.8 billion years old. Over time, the descendants of these organisms gave rise to the rich diversity of protists and other eukaryotes alive today.

**Figure 25.2** surveys how that diversity arose, focusing on three stages documented by the fossil record: an initial diversification (1.8–1.3 billion years ago), the origin of multicellularity and other novel features (1.3 billion–635 million years ago), and the emergence of large eukaryotes (635–535 million years ago).

observed directly, while others are inferred from living members of the group to which a fossil belongs. For example, *Bangiomorpha* (c) had "holdfasts" similar to those that anchor living red algae to their substrate; it also had a pattern of cell division that is only known to occur in a particular group of extant red algae. Hence, *Bangiomorpha* is classified as a member of this group of red algae. Living members of this group have sexual life cycles and are photosynthetic, so it is likely that *Bangiomorpha* also had these features.

A range of other fossils show that by 800–750 million years ago, increasingly complex communities of eukaryotes had emerged, with algae at the bottom of the food chain and species that ate algae (or each other) above. These organisms remained small, however, and the entire community began to decline with the onset of a series of severe ice ages and other environmental changes.

**(f) An early member of the Ediacaran biota.** The alga *Doushantuophyton* lived about 600 million years ago.

**(g) *Spriggina floundersi*, an early animal with many body segments.**

## Rise of Large Eukaryotes

For nearly 3 billion years, life on Earth was a world of microscopic forms. Larger multicellular eukaryotes do not appear in the fossil record until the Ediacaran period, 635–542 million years ago (**f, g**). These fossils, referred to as the **Ediacaran biota**, were of soft-bodied organisms, some over 1 m long.

More generally, the fossil record from 635–535 million years ago documents changes in the history of life: maximum body size, taxonomic diversity, and the extent of morphological differences all increased dramatically. In addition, the average time that species persisted in the fossil record dropped considerably. Indeed, the entire Ediacaran biota declined 535 million years ago with the onset of another great wave of evolutionary diversification—the so-called “Cambrian explosion.”

As discussed in Figure 25.2, large, multicellular eukaryotes did not appear until about 600 million years ago. Prior to that time, Earth was a microbial world: Its only inhabitants were single-celled prokaryotes and eukaryotes, along with an assortment of microscopic, multicellular eukaryotes. We'll return to the rise of large, multicellular eukaryotes in Chapters 26 and 27.

### Endosymbiosis in Eukaryotic Evolution

The fossil record documents when early eukaryotes lived and when key eukaryotic traits, such as a well-developed cytoskeleton and sexual life cycles, first appeared. Additional insights into the origin of eukaryotes have come from molecular studies. In particular, DNA sequence data suggest that eukaryotes are “combination” organisms, with some of their genes and cellular characteristics being derived from archaea, and others from bacteria (**Table 25.1**).

How did eukaryotes come to have both archaeal and bacterial features? This mixture of features may be a consequence of **endosymbiosis**, a symbiotic relationship in which one organism lives inside the body or cell of another organism. According to this hypothesis, the defining moment in the origin of eukaryotes occurred when an archaeal cell (or a cell with archaeal ancestors) engulfed a bacterium that would later become an organelle found in all eukaryotes—the mitochondrion.

#### Origin of Mitochondria and Plastids

The idea that eukaryotes are “combination” organisms is related to the **endosymbiont theory**, which holds that mitochondria and plastids (a general term for chloroplasts and related organelles) were formerly small prokaryotes that began living within larger cells (**Figure 25.3**). The term *endosymbiont* refers to a cell that lives within another cell, called the *host cell*. The prokaryotic ancestors of mitochondria and plastids probably gained entry to the host cell as undigested prey or internal parasites. Though such a process may seem unlikely, scientists have directly observed cases in which endosymbionts that began as prey or parasites came to have a mutually beneficial relationship with the host in as little as five years.

By whatever means the relationship began, we can hypothesize how the symbiosis could have become mutually beneficial.

Table 25.1 Inferred Origins of Key Eukaryotic Features	
Feature	Original Source
DNA replication enzymes	Archaeal
Transcription enzymes	Archaeal
Translation enzymes	Mostly archaeal
Cell division apparatus	Mostly archaeal
Endoplasmic reticulum	Archaeal and bacterial
Mitochondrion	Bacterial
Metabolic genes	Mostly bacterial

For example, in a world that was gradually becoming more aerobic, a host that was itself an anaerobe would have benefited from endosymbionts that could make use of the oxygen. Over time, the host and endosymbionts would have become a single organism, its parts inseparable. Although all eukaryotes have mitochondria or remnants of these organelles, they do not all have plastids. Thus, the **serial endosymbiosis** hypothesis

▲ **Figure 25.3 A hypothesis for the origin of eukaryotes through endosymbiosis.** The proposed host was an archaean or a cell descended from archaeal ancestors. The proposed ancestors of mitochondria were aerobic, heterotrophic prokaryotes, whereas those of plastids were photosynthetic prokaryotes. In this figure, the arrows represent change over evolutionary time.

supposes that mitochondria evolved before plastids through a sequence of endosymbiotic events (see Figure 25.3).

A great deal of evidence supports the endosymbiotic origin of mitochondria and plastids:

- The inner membranes of both organelles have enzymes and transport systems that are homologous to those found in the plasma membranes of living prokaryotes.
- Mitochondria and plastids replicate by a splitting process that is similar to that of certain prokaryotes. Mitochondria and plastids both contain circular DNA molecules that, like the chromosomes of bacteria, are not associated with histones or large amounts of other proteins.
- As might be expected of organelles descended from free-living organisms, mitochondria and plastids also have the cellular machinery (including ribosomes) needed to transcribe and translate their DNA into proteins.

- Finally, in terms of size, RNA sequences, and sensitivity to certain antibiotics, the ribosomes of mitochondria and plastids are more similar to prokaryotic ribosomes than they are to the cytoplasmic ribosomes of eukaryotic cells.

Which prokaryotic lineages gave rise to mitochondria? To answer this question, researchers have compared the DNA sequences of mitochondrial genes (mtDNA) with those found in major clades of bacteria and archaea. In the **Scientific Skills Exercise**, you will interpret one such set of DNA sequence comparisons. Collectively, such studies indicate that mitochondria arose from an alpha proteobacterium (see Figure 24.19). Researchers have also compared genome sequences of various alpha proteobacteria with the entire mtDNA sequences of animals, plants, fungi, and protists. Such studies indicate that eukaryotic mitochondria descended from a single common ancestor, suggesting that mitochondria arose only

## Scientific Skills Exercise

### Interpreting Comparisons of Genetic Sequences

#### Which Prokaryotes Are Most Closely Related to Mitochondria?

The first eukaryotes acquired mitochondria by endosymbiosis: A host cell engulfed an aerobic prokaryote that persisted within the cytoplasm to the mutual benefit of both cells. In studying which living prokaryotes might be most closely related to mitochondria, researchers compared ribosomal RNA (rRNA) sequences. Because most cells contain thousands of ribosomes, rRNA is the most abundant form of RNA in living cells and is suitable for comparing even distantly related species. In this exercise, you'll interpret some of their results to draw conclusions about the phylogeny of mitochondria.

**How the Research Was Done** Researchers isolated and cloned nucleotide sequences from the gene that codes for the small-subunit rRNA molecule for six organisms: wheat (a plant) and five bacterial species.

- Wheat, used as the source of mitochondrial rRNA genes
- *Agrobacterium tumefaciens*, an alpha proteobacterium that lives within plant tissue and produces tumors in the host
- *Comamonas testosteroni*, a beta proteobacterium
- *Escherichia coli*, a well-studied gamma proteobacterium that inhabits human intestines
- *Mycoplasma capricolum*, a gram-positive mycoplasma, which is the only group of bacteria lacking cell walls
- *Anacystis nidulans*, a cyanobacterium

**Data from the Research** Cloned rRNA gene sequences for the six organisms were aligned and compared. The data table below, called a

comparison matrix, summarizes the comparison of 617 nucleotide positions from the gene sequences. Each value in the table is the percentage of the 617 nucleotide positions for which the pair of organisms have the same composition. Any positions that were identical across the rRNA genes of all six organisms were omitted from this comparison matrix.

#### Interpret the Data

1. First, make sure you understand how to read the comparison matrix. Find the cell that represents the comparison of *C. testosteroni* and *E. coli*. What value is given in this cell? What does that value signify about the comparable rRNA gene sequences in those two organisms? Explain why some cells have a dash rather than a value. Why are some cells shaded gray, with no value?
2. Why did the researchers choose one plant mitochondrion and five bacterial species to include in the comparison matrix?
3. Which species of bacterium has an rRNA gene that is most similar to that of the wheat mitochondrion? What is the significance of this similarity?

**Data from** D. Yang, et al., Mitochondrial origins, *Proceedings of the National Academy of Sciences USA* 82:4443–4447 (1985).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

once over the course of evolution. Similar analyses indicate that plastids arose once from an engulfed cyanobacterium.

While the lineages that gave rise to mitochondria and plastids have been identified, questions remain about the identity of the host cell that engulfed an alpha proteobacterium. According to recent genomic studies, the host came from an archaeal lineage, but which lineage remains undetermined. Alternatively, the host could have been a member of a lineage that was related to, but had diverged from, its archaeal ancestors. In this case, the host may have been a “protoeukaryote” in which certain features of eukaryotic cells had evolved, such as an endomembrane system and a cytoskeleton that enabled it to change shape (and thereby engulf the alpha proteobacterium).

### Plastid Evolution: A Closer Look

As you’ve seen, current evidence indicates that mitochondria are descended from a bacterium that was engulfed by a cell from an archaeal lineage. This event gave rise to the eukaryotes. There is also much evidence that later in eukaryotic history, a lineage of heterotrophic eukaryotes acquired an additional endosymbiont—a photosynthetic cyanobacterium—that then evolved into plastids. According to the hypothesis illustrated in **Figure 25.4**, this plastid-bearing lineage gave rise to two lineages of photosynthetic protists, red algae and green algae.

Let’s examine some of the steps shown in Figure 25.4 in more detail. First, recall that cyanobacteria are gram-negative and that gram-negative bacteria have two cell membranes, an inner plasma membrane and an outer membrane that is part of the cell wall (see Figure 24.7). Plastids in red algae and green algae are also surrounded by two membranes. Transport proteins in these membranes are homologous to proteins in the inner and outer membranes of cyanobacteria, providing further support for the hypothesis that plastids originated from a cyanobacterial endosymbiont.

On several occasions during eukaryotic evolution, red algae and green algae underwent **secondary endosymbiosis**: They were ingested in the food vacuoles of heterotrophic eukaryotes and became endosymbionts themselves. For example, as shown in Figure 25.4, protists known as chlorarachniophytes likely evolved when a heterotrophic eukaryote engulfed a green alga. Evidence for this process can be found within the engulfed cell, which contains a tiny vestigial nucleus, called a *nucleomorph*. Genes from the nucleomorph are still transcribed, and their DNA sequences indicate that the engulfed cell was a green alga. Also consistent with the hypothesis that chlorarachniophytes evolved from a eukaryote that engulfed another eukaryote, their plastids are surrounded by *four* membranes. The two inner membranes originated as the inner and

▼ **Figure 25.4 Diversity of plastids produced by endosymbiosis.** Studies of plastid-bearing eukaryotes suggest that plastids evolved from a cyanobacterium that was engulfed by an ancestral heterotrophic eukaryote (primary endosymbiosis). That ancestor then diversified into red algae and green algae, some of which were subsequently engulfed by other eukaryotes (secondary endosymbiosis).

**MAKE CONNECTIONS** How many distinct genomes does a chlorarachniophyte cell contain? Explain. (See Figure 4.16.)

outer membranes of the ancient cyanobacterium; the third membrane is derived from the engulfed alga's plasma membrane; and the outermost membrane is derived from the heterotrophic eukaryote's food vacuole.

### CONCEPT CHECK 25.1

1. Describe major events in the evolution of early eukaryotes that are documented in the fossil record.
2. Explain why eukaryotes are said to be “combination” organisms, and summarize the role of endosymbiosis in eukaryotic evolution.
3. **WHAT IF?** Suppose the photosynthetic organelle of a protist is discovered to be most closely related to a different cyanobacterium than the one that gave rise to plastids. What would this result suggest about the origin of eukaryotic photosynthesis?

For suggested answers, see Appendix A.

## CONCEPT 25.2

### Multicellularity has originated several times in eukaryotes

An orchestra can play a greater variety of musical compositions than a violin soloist can; the increased complexity of the orchestra makes more variations possible. Likewise, the origin of structurally complex eukaryotic cells sparked the evolution of greater morphological diversity than was possible for the simpler prokaryotic cells. This burst of evolutionary change resulted in the immense variety of unicellular protists that continue to flourish today. Another wave of diversification also occurred: Some single-celled eukaryotes gave rise to multicellular forms, whose descendants include a variety of algae, plants, fungi, and animals.

#### Multicellular Colonies

The first multicellular forms were *colonies*, collections of cells that are connected to one another but show little or no cellular differentiation. Multicellular colonies consisting of simple filaments, balls, or cell sheets occur early and often in the eukaryotic fossil record, and they remain common today (**Figure 25.5**).

Such simple colonies are often found in eukaryotic lineages whose members have rigid cell walls. In such organisms, a colony may take shape as the cells divide and remain attached to one another by their shared cell walls. Simple colonies are also found in eukaryotes that lack rigid cell walls, but in this

▲ **Figure 25.5 Pediastrum.** This photosynthetic eukaryote forms flat colonies (LM).

case a colony may form when dividing cells are held together by proteins that physically connect adjacent cells to one another.

Some simple colonies have features that are intermediate between those of single-celled eukaryotes and those of more complex multicellular forms, such as plants, fungi, and animals. As you'll see in the following sections, such differences between unicellular, colonial, and multicellular eukaryotes can reveal clues to the origin of multicellularity.

### Independent Origins of Complex Multicellularity

Although they occur in fewer lineages than do simple colonies, multicellular organisms with differentiated cells originated multiple times over the course of eukaryotic evolution. Examples include lineages of red, green, and brown algae, as well as plants, fungi, and animals. Genetic and morphological data indicate that these different lineages of complex multicellular eukaryotes arose independently of one another. For example, although both fungi and animals arose from single-celled ancestors, they arose from *different* single-celled ancestors.

The fact that complex multicellularity has originated multiple times allows us to examine the similarities and differences in how these independent groups arose. We'll begin with *Volvox*, a multicellular green alga with two types of differentiated cells (**Figure 25.6**). (It is because of these differentiated cells that most researchers refer to *Volvox* as “multicellular,” as opposed to “colonial.”) DNA evidence indicates that this

▲ **Figure 25.6 Morphological change in the Volvox lineage.** *Chlamydomonas* cell wall has both an outer wall (gray) and an inner wall (yellow). *Gonium* cells resemble a *Chlamydomonas* cell, and the structures that attach *Gonium* cells to one another contain proteins homologous to those in the *Chlamydomonas* cell wall. In *Pandorina* and *Volvox*, the cells are embedded in an extracellular matrix containing proteins homologous to those found in the *Chlamydomonas* inner wall.

species forms a monophyletic group with a single-celled alga (*Chlamydomonas*) and several colonial species. *Volvox* cells are embedded in an extracellular matrix composed of proteins homologous to those in the *Chlamydomonas* cell wall; the same is true for the colonial species that branch between *Chlamydomonas* and *Volvox*. This suggests that multicellularity in *Volvox* may have originated as descendants of a single-celled common ancestor gave rise to a series of larger and more complex colonial forms.

A 2010 comparison of the *Chlamydomonas* and *Volvox* genomes yielded a further surprising result: *Volvox* has few novel genes that could account for the differences in morphology seen between these species. This suggests that the transition to multicellularity may not require the origin of many new genes. Instead, this transition may result from changes in how existing genes are used—a conclusion that is also supported by recent studies on the origin of multicellularity in animals.

## Steps in the Origin of Multicellular Animals

Although the origin of animals was a pivotal moment in the history of life, until recently little was known about the genetic toolkit that facilitated the emergence of multicellular animals from their single-celled ancestors. One way to gather information about this toolkit is to identify protist groups that are closely related to animals. As shown in **Figure 25.7**, a combination of morphological and molecular evidence points to choanoflagellates as the closest living relatives of animals. Based on such evidence, researchers have hypothesized that the common ancestor of

choanoflagellates and living animals may have been a unicellular suspension feeder that resembled present-day choanoflagellates.

Note that the origin of multicellularity in animals required the evolution of new ways for cells to adhere (attach) and signal (communicate) to each other. In an effort to learn more about such mechanisms, a recent study compared the genome of the unicellular choanoflagellate *Monosiga brevicollis* with those of representative animals.

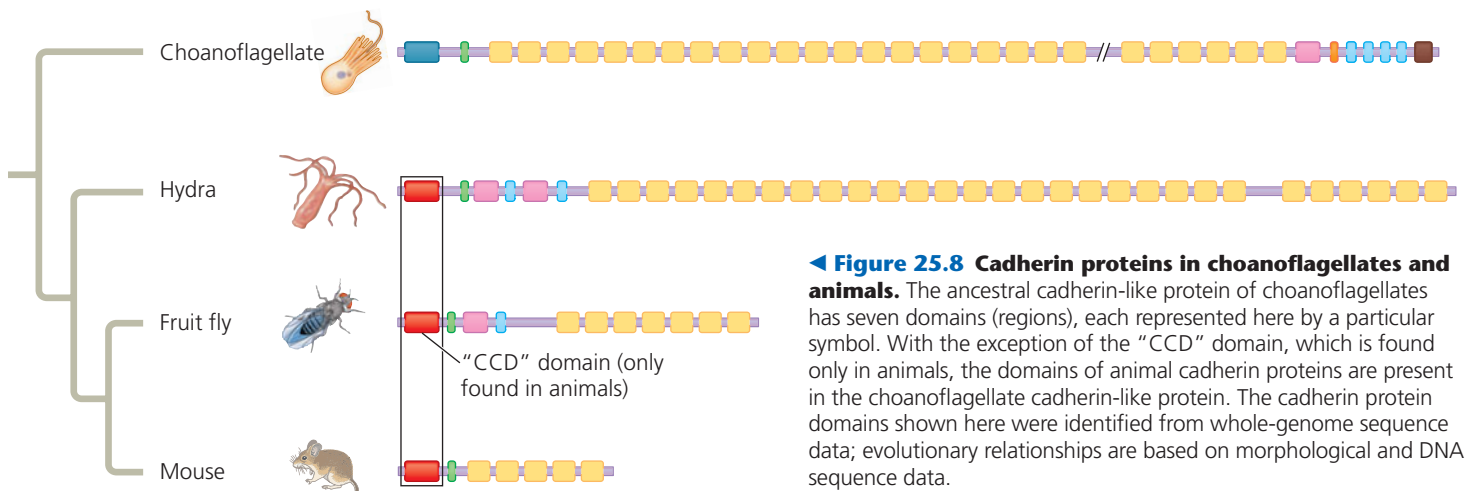

This analysis uncovered 78 protein domains in *M. brevicollis* that were otherwise only known to occur in animals. (A *domain* is a key structural or functional region of a protein.) In animals, many of these shared protein domains function in cell adherence or cell signaling. To give just two examples, *M. brevicollis* has genes that encode domains of certain proteins (known as cadherins) that play key roles in how animal cells attach to one another, as well as genes that encode protein domains that animals (and only animals) use in cell-signaling pathways.

New research has also enabled us to take a closer look at specific proteins that played important roles in the origin of multicellularity in animals. Were these proteins composed mostly of domains found in ancestral choanoflagellate proteins? Or did they have a more novel structure? Consider the cadherin attachment proteins mentioned earlier. DNA sequence analyses show that animal cadherin proteins are composed primarily of domains that are also found in a cadherin-like protein of choanoflagellates (**Figure 25.8**). However, animal cadherin proteins that attach cells to one another also contain a highly conserved region not found in

▼ **Figure 25.7 Three lines of evidence that choanoflagellates are closely related to animals.**

**?** Are the data described in observation 3 consistent with predictions that could be made from the evidence in observations 1 and 2? Explain.

the choanoflagellate protein (the “CCD” domain shown in Figure 25.8). These results suggest that the origin of the cadherin attachment protein occurred by the rearrangement of protein domains found in choanoflagellates—along with the incorporation of a novel domain, the conserved CCD region.

Overall, comparisons of choanoflagellate and animal genome sequences tell us that key steps in the transition to multicellularity in animals involved new ways of using proteins or parts of proteins that were encoded by genes found in choanoflagellates. Thus, as we also saw for the origin of multicellularity in *Volvox*, the origin of multicellularity in animals may have resulted mostly from the co-opting of genes used for other purposes in choanoflagellates—not from the evolution of a genetic toolkit composed of many novel genes.

#### CONCEPT CHECK 25.2

1. Summarize the evidence that choanoflagellates are the sister group of animals.
2. **MAKE CONNECTIONS** Describe how the origin of multicellularity in animals illustrates Darwin’s concept of descent with modification (see Concept 19.2).
3. **WHAT IF?** Cells in *Volvox*, plants, and fungi are similar in being bounded by a cell wall. Predict whether the cell-to-cell attachments of these organisms form using similar or different molecules. Explain.

For suggested answers, see Appendix A.

## CONCEPT 25.3

### Four “supergroups” of eukaryotes have been proposed based on morphological and molecular data

How have events described so far in this chapter influenced the diversity of eukaryotes living today? First, by their very nature, eukaryotes are “combination” organisms. Having originated

by endosymbiosis, they had archaeal and bacterial genes and they possessed endosymbionts with novel metabolic capabilities. These features promoted the diversification of unicellular protists seen in the fossil record and still evident today in a drop of pond water. The independent origins of complex multicellularity in several eukaryotic lineages also had a major influence. Each of these independent groups evolved different solutions to the various challenges that all organisms face, thus contributing to the rich diversity of eukaryotes alive today. We’ll survey that diversity here, beginning with an overview of the big picture: the four eukaryotic “supergroups.”

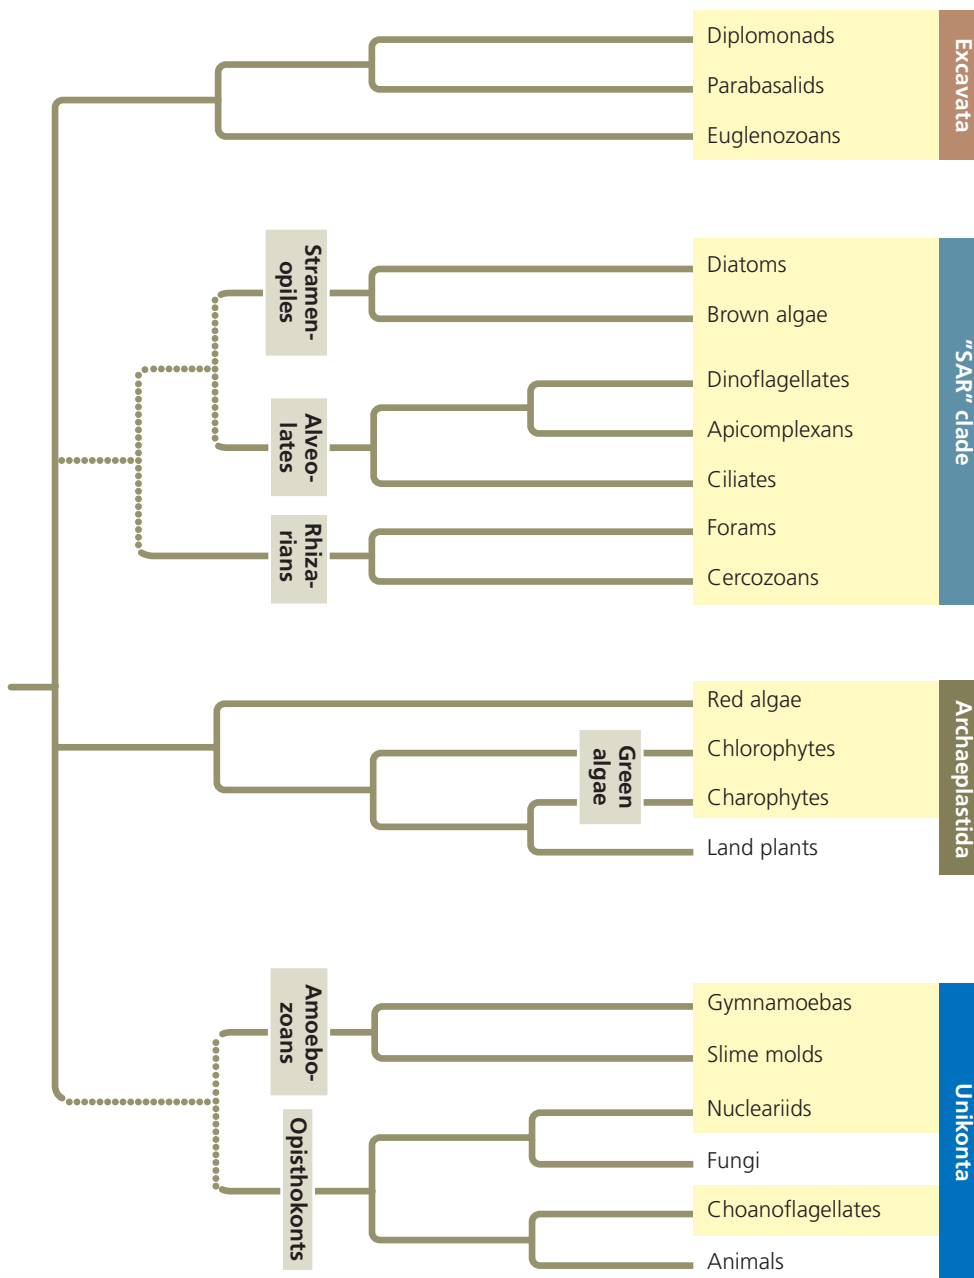

### Four Supergroups of Eukaryotes

Our understanding of the evolutionary history of eukaryotes has been in a state of flux in recent years. Genetic and morphological studies have shown that some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom in which all protists once were classified, Protista, has been abandoned, and various lineages of protists are now recognized as kingdoms in their own right. Other hypotheses have been discarded as well. For example, in the early 1990s, many biologists thought that the oldest lineage of living eukaryotes consisted of the *amitochondriate* protists, organisms without conventional mitochondria. But recent structural and DNA data have undermined this hypothesis. Many of the so-called amitochondriate protists have been shown to have mitochondria—though reduced ones—and some of these organisms are now classified in distantly related groups.

The ongoing changes in our understanding of the phylogeny of eukaryotes pose challenges to students and instructors alike. Hypotheses about these relationships are a focus of scientific activity, changing rapidly as new data cause previous ideas to be modified or discarded. We’ll focus here on one current hypothesis: the four supergroups of eukaryotes shown in **Figure 25.9**. Because the root of the eukaryotic tree is not

The tree below represents a phylogenetic hypothesis for the relationships among eukaryotes on Earth today. The eukaryotic groups at the branch tips are related in larger “supergroups,” labeled vertically at the far right of the tree. Groups that were formerly classified in the kingdom Protista are highlighted in yellow. Dotted lines indicate evolutionary relationships that are uncertain and proposed clades that are under active debate. For clarity, this tree only includes representative clades from each supergroup. In addition, the recent discoveries of many new groups of eukaryotes indicate that eukaryotic diversity is actually much greater than shown here.

## Excavata

Some members of this supergroup have an “excavated” groove on one side of the cell body. Two major clades (the parabasalids and diplomonads) have modified mitochondria; members of a third clade (the euglenozoans) have flagella that differ in structure from those of other organisms. Excavates include parasites such as *Giardia*, as well as many predatory and photosynthetic species.

***Giardia intestinalis*, a diplomonad parasite.** This diplomonad (colorized SEM), which lacks the characteristic surface groove of the Excavata, inhabits the intestines of mammals. It can infect people when they drink water contaminated with feces containing *Giardia* cysts. Drinking such water—even from a seemingly pristine stream—can cause severe diarrhea. Boiling the water kills the parasite.

Based on the fossil record of early eukaryotes and the tree shown here, by what date had the supergroups begun to diverge from one another? Explain.

## ■ “SAR” Clade

This supergroup contains (and is named after) three large and very diverse clades: Stramenopila, Alveolata, and Rhizaria. Stramenopiles include some of the most important photosynthetic organisms on Earth, such as the diatoms shown here. Alveolates also include photosynthetic species, as well as important pathogens, such as *Plasmodium*, which causes malaria. Many of the key groups of photosynthetic stramenopiles and alveolates are thought to have arisen by secondary endosymbiosis.

**Diatom diversity.** These beautiful single-celled protists are important photosynthetic organisms in aquatic communities (LM).

The rhizarian subgroup of the SAR clade includes many species of amoebas, most of which have pseudopodia that are threadlike in shape. Pseudopodia are extensions that can bulge from any portion of the cell; they are used in movement and in the capture of prey.

**Globigerina, a rhizarian in the SAR supergroup.** This species is a foraminifer, a group whose members have threadlike pseudopodia that extend through pores in the shell, or test (LM). The inset shows a foraminiferan test, which is hardened by calcium carbonate.

## ■ Archaeplastida

This supergroup of eukaryotes includes red algae and green algae, along with land plants. Red algae and green algae include unicellular species, colonial species, and multicellular species (including the green alga *Volvox*). Many of the large algae known informally as “seaweeds” are multicellular red or green algae. Protists in Archaeplastida include key photosynthetic species that form the base of the food web in many aquatic communities.

**Volvox, a multicellular freshwater green alga.** This alga resembles a hollow ball whose wall is composed of hundreds of biflagellated cells (see inset LM) embedded in a gelatinous matrix. The cells in the wall are usually connected by cytoplasmic strands; if isolated, these cells cannot reproduce. However, the alga also contains cells that are specialized for either sexual or asexual reproduction. The large algae shown here will eventually release the small “daughter” algae that can be seen within them (LM).

## ■ Unikonta

This supergroup of eukaryotes includes amoebas that have lobe- or tube-shaped pseudopodia, as well as animals, fungi, and non-amoeba protists that are closely related to animals or fungi. According to one current hypothesis, the unikonts may have been the first group of eukaryotes to diverge from other eukaryotes; however, this hypothesis has yet to be widely accepted.

**A unikont amoeba.** This amoeba, the gymnamoeba *Amoeba proteus*, is using its pseudopodia to move.

known, all four supergroups are shown as diverging simultaneously from a common ancestor. We know that this is not correct, but we do not know which organisms were the first to diverge from the others. In addition, while some of the groups in Figure 25.9 are well supported by morphological and DNA data, others are more controversial.

We'll now examine some representative members of the four supergroups. As you read about these groups, it may be helpful to focus less on the specific names of their members and more on why these organisms are important and how ongoing research is elucidating their evolutionary relationships.

## Excavates

The clade **Excavata** (the excavates) was originally proposed based on morphological studies of the cytoskeleton. The name derives from

the fact that some members of this diverse group feature an “excavated” feeding groove on one side of the cell body. The excavates include the diplomonads, the parabasalids, and the euglenozoans. Molecular data indicate that each of these three groups is monophyletic, and recent genomic studies have supported the monophyly of the excavate supergroup.

### Diplomonads and Parabasalids

The protists in these two groups lack plastids and have highly modified mitochondria (until recently, they were thought to lack mitochondria altogether). Most diplomonads and parabasalids are found in anaerobic environments.

**Diplomonads** have reduced mitochondria called *mitosomes*. These organelles lack functional electron transport chains and hence cannot use oxygen to help extract energy from carbohydrates and other organic molecules. Instead, diplomonads get the energy they need from anaerobic biochemical pathways. Many diplomonads are parasites, including the infamous *Giardia intestinalis* (see Figure 25.9). These parasites propel themselves within a host using multiple flagella.

**Parabasalids** also have reduced mitochondria; called *hydrogenosomes*, these organelles generate some energy anaerobically, releasing hydrogen gas as a by-product. The best-known parabasalid is *Trichomonas vaginalis*, a sexually transmitted parasite that infects some 5 million people each year. *T. vaginalis* travels along the mucus-coated lining of the human reproductive and urinary tracts by moving its flagella and by undulating part of its plasma membrane (**Figure 25.10**).

### Euglenozoans

Protists called **euglenozoans** belong to a diverse clade that includes predatory heterotrophs, photosynthetic autotrophs, and parasites. The main morphological feature that

▲ **Figure 25.10** The parabasalid parasite, *Trichomonas vaginalis* (colorized SEM).

▲ **Figure 25.11** Euglenozoan flagellum. Most euglenozoans have a crystalline rod inside one of their flagella (the TEM is a flagellum shown in cross section).

distinguishes protists in this clade is the presence of a rod with either a spiral or a crystalline structure inside each of their flagella (**Figure 25.11**). The two best-studied groups of euglenozoans are the euglenids and the kinetoplastids.

A *euglenid* has a pocket at one end of the cell from which one or two flagella emerge (see the drawing in Figure 25.11). Some euglenids perform photosynthesis when sunlight is available; when sunlight is not available, they can become heterotrophic, absorbing organic nutrients from their environment. Many other euglenids engulf prey by phagocytosis.

A *kinetoplastid* has a single, large mitochondrion that contains an organized mass of DNA called a kinetoplast. These protists include species that feed on prokaryotes in aquatic ecosystems, as well as species that parasitize animals, plants, and other protists. For example, kinetoplastids in the genus *Trypanosoma* infect humans and cause sleeping sickness, a neurological disease that is invariably fatal if not treated (**Figure 25.12**).

▲ **Figure 25.12** *Trypanosoma*, the kinetoplastid that causes sleeping sickness. The purple, ribbon-shaped cells among these red blood cells are the trypanosomes (colorized SEM).

◀ **Figure 25.13** The diatom *Triceratium morlandii* (colorized SEM).

## The “SAR” Clade

Recent genomic studies have led researchers to propose that three major clades of protists—the stramenopiles, alveolates, and rhizarians—form a monophyletic supergroup referred to as the “**SAR**” **clade**, after the first letters of its member clades.

### Stramenopiles

One major subgroup of the SAR clade, the **stramenopiles**, arose by secondary endosymbiosis (see Figure 25.4) and include some of the most important photosynthetic organisms on the planet. Here we’ll focus on two clades of stramenopiles: diatoms and brown algae.

**Diatoms** A key group of photosynthetic protists, **diatoms** are unicellular algae that have a unique glass-like wall made of silicon dioxide embedded in an organic matrix (**Figure 25.13**). The wall consists of two parts that overlap like a shoe box and its lid. These walls provide effective protection from the crushing jaws of predators: Live diatoms can withstand pressures as great as 1.4 million kg/m<sup>2</sup>, equal to the pressure under each leg of a table supporting an elephant!

With an estimated 100,000 living species, diatoms are a highly diverse group of protists. They are among the most abundant photosynthetic organisms both in the ocean and in lakes: One bucket of water scooped from the surface of the sea may contain millions of these microscopic algae. As we’ll

discuss later in the chapter, the photosynthetic activity of these widespread and abundant algae can affect global carbon dioxide levels.

**Brown Algae** The largest and most complex algae are **brown algae**. All are multicellular, and most are marine. Brown algae are especially common along temperate coasts, where the water is cool. They owe their characteristic brown or olive color to the carotenoids in their plastids.

Many of the species commonly called “seaweeds” are brown algae. Some brown algal seaweeds have specialized tissues and organs that resemble those in plants, such as a rootlike **holdfast**, which anchors the alga, and a stemlike **stipe**, which supports the leaflike **blades** (**Figure 25.14**). However, morphological and DNA evidence show that these

▲ **Figure 25.14** **Seaweeds: adapted to life at the ocean’s margins.** The sea palm (*Postelsia*) lives on rocks along the coast of the northwestern United States and western Canada. The body of this brown alga is well adapted to maintaining a firm foothold despite the crashing surf.

similarities evolved independently in the algal and plant lineages and are thus analogous, not homologous. In addition, while plants have adaptations (such as rigid stems) that provide support against gravity, brown algae have adaptations that enable their main photosynthetic surfaces (the leaflike blades) to be near the water surface. Some brown algae accomplish this task with gas-filled, bubble-shaped floats. Giant brown algae known as kelps that live in deep waters use a different means: Their blades are attached to stipes that can rise as much as 60 m from the seafloor, more than half the length of a football field.

## Alveolates

Members of the next subgroup of the SAR clade, the **alveolates**, have membrane-enclosed sacs (alveoli) just under the plasma membrane (**Figure 25.15**). Alveolates are abundant in many habitats and include a wide range of photosynthetic and heterotrophic protists. We'll discuss two alveolate clades here, a group of flagellates (the dinoflagellates) and a group of protists that move using cilia (the ciliates); we'll discuss a third clade (the apicomplexans) that parasitizes animals in Concept 25.4.

▲ **Figure 25.15 Alveoli.** These sacs under the plasma membrane are a characteristic that distinguishes alveolates from other eukaryotes (TEM).

**Dinoflagellates** The cells of many **dinoflagellates** are reinforced by cellulose plates. Two flagella located in grooves in this “armor” make dinoflagellates (from the Greek *dinos*, whirling) spin as they move through the waters of their marine and freshwater communities (**Figure 25.16**). Although the group originated by secondary endosymbiosis (see Figure 25.4), roughly half of all dinoflagellates are now purely heterotrophic. Others are important photosynthetic species, while still others are **mixotrophs**, organisms that combine photosynthesis and heterotrophic nutrition.

Episodes of explosive population growth, or *blooms*, in dinoflagellates sometimes cause a phenomenon called “red tide.” The blooms make coastal waters appear brownish red or pink because of the presence of carotenoids, the most common pigments in dinoflagellate plastids. Toxins produced by certain

▲ **Figure 25.16 Pfiesteria shumwayae, a dinoflagellate.** Beating of the spiral flagellum, which lies in a groove that encircles the cell, makes this alveolate spin (colorized SEM).

dinoflagellates have caused massive kills of invertebrates and fishes. Humans who eat molluscs that have accumulated the toxins are affected as well, sometimes fatally.

**Ciliates** The **ciliates** are a large and varied group of protists named for their use of cilia to move and feed (**Figure 25.17**). Most ciliates are predators, typically of bacteria or small protists (see Figure 25.1). The cilia may completely cover the cell surface or may be clustered in a few rows or tufts. In certain species, rows of tightly packed cilia function collectively in locomotion. Other ciliates scurry about on leg-like structures constructed from many cilia bonded together.

## Rhizarians

Our next subgroup of the SAR clade is the **rhizarians**. Many species in this group are **amoebas**, protists that move and feed by means of **pseudopodia**, extensions that may bulge from almost anywhere on the cell surface. An amoeba moves by extending a pseudopodium and anchoring the tip; more cytoplasm then streams into the pseudopodium. Amoebas do not constitute a monophyletic group; instead, they are dispersed across many distantly related eukaryotic taxa. Most amoebas that are rhizarians differ morphologically from other amoebas by having threadlike pseudopodia. Rhizarians also include flagellated (non-amoeboid) protists that feed using threadlike pseudopodia.

We'll examine two groups of rhizarians here: forams and cercozoans.

**Forams** The protists called **foraminiferans** (from the Latin *foramen*, little hole, and *ferre*, to bear), or **forams**, are named for their porous shells, called **tests** (see Figure 25.9). Forams tests consist of a single piece of organic material that is hardened with calcium carbonate in most species. The pseudopodia that extend through the pores function in swimming, test formation, and feeding. Many forams also derive nourishment from the photosynthesis of symbiotic algae that live within

▲ **Figure 25.17** Structure and function in the ciliate *Paramecium caudatum*.

the tests. Found in both lakes and oceans, most forams live in sand or attach themselves to rocks or algae, but some drift in currents near the water's surface. The largest forams, though single-celled, have tests with a diameter of several centimeters.

**Cercozoans** First identified in molecular phylogenies, the **cercozoans** are a large group of amoeboid and flagellated protists that feed with threadlike pseudopodia. Common in marine, freshwater, and soil ecosystems, many cercozoans are parasites of plants, animals, or other protists; many others are predators that feed on bacteria, fungi, and other protists. One small group of cercozoans, the chlorarachniophytes (mentioned earlier in the discussion of secondary endosymbiosis), are mixotrophic: These organisms ingest smaller protists and bacteria as well as perform photosynthesis. At least one other cercozoan, *Paulinella chromatophora*, is an autotroph, deriving its energy from light and its carbon from carbon dioxide. As described in **Figure 25.18**,

▲ **Figure 25.18** A second case of primary endosymbiosis?

The cercozoan *Paulinella* conducts photosynthesis in a unique sausage-shaped structure called a chromatophore (LM). Chromatophores are surrounded by a membrane with a peptidoglycan layer, suggesting that they are derived from a bacterium. DNA evidence indicates that chromatophores are derived from a different cyanobacterium than that from which other plastids are derived.

*Paulinella* appears to represent an intriguing additional evolutionary example of a eukaryotic lineage that obtained its photosynthetic apparatus directly from a cyanobacterium.

## Archaeplastids

As described earlier, morphological and molecular evidence indicates that plastids arose when a heterotrophic protist acquired a cyanobacterial endosymbiont. Later, photosynthetic descendants of this ancient protist evolved into red algae and green algae (see Figure 25.4), and the lineage that produced green algae then gave rise to land plants. Together, red algae, green algae, and land plants make up our third eukaryotic supergroup, which is called **Archaeplastida**. We will examine plants and the colonization of land in Chapter 26; here we will look at the diversity of their closest algal relatives, red algae and green algae.

### Red Algae

Many of the 6,000 known species of **red algae** (rhodophytes, from the Greek *rhodos*, red) are reddish, owing to a photosynthetic pigment called phycoerythrin, which masks the green of chlorophyll. However, other species (those adapted to more shallow water) have less phycoerythrin. As a result, red algal species may be greenish red in very shallow water, bright red at moderate depths, and almost black in deep water. Some species lack pigmentation altogether and function heterotrophically as parasites on other red algae.

► **Bonnemaisonia hamifera**. This red alga has a filamentous form.

▼ **Nori**. The red alga *Porphyra* has a leafy form and is the source of a traditional Japanese food.

The seaweed is grown on nets in shallow coastal waters.

After being dried, the paper-thin, glossy sheets of nori make a mineral-rich wrap for rice, seafood, and vegetables in sushi.

▲ **Figure 25.19** Red algae.

Red algae are the most abundant large algae in the warm coastal waters of tropical oceans. Some of their photosynthetic pigments, including phycoerythrin, allow them to absorb blue and green light, which penetrate relatively far into the water—one species of red alga has been discovered near the Bahamas at a depth of more than 260 m. Most red algae are multicellular, and they grow in a variety of forms (**Figure 25.19**). Although none are as big as the giant brown kelps, the largest multicellular red algae are included in the informal designation “seaweeds.” You may have eaten one of these multicellular red algae, *Porphyra* (Japanese “nori”), as crispy sheets or as a wrap for sushi. Red algae reproduce sexually. However, unlike other algae, red algae do not have flagellated gametes, so they depend on water currents to bring gametes together for fertilization.

## Green Algae

The grass-green chloroplasts of **green algae** have a structure and pigment composition much like the chloroplasts of land plants. Molecular systematics and cellular morphology leave little doubt that green algae and land plants are closely related. In fact, some systematists now advocate including green algae in an expanded “plant” kingdom, Viridiplantae (from the Latin *viridis*, green). Phylogenetically, this change makes sense, since otherwise the green algae are a paraphyletic group.

(a) ***Ulva*, or sea lettuce**. This edible chlorophyte has leaflike blades and a holdfast that anchors the alga.

(b) ***Caulerpa*, an intertidal chlorophyte**. The filaments lack cross-walls and thus are multinucleate. In effect, the algal body is one huge “supercell.”

▲ **Figure 25.20** Multicellular chlorophytes.

Green algae are divided into two main groups, the charophytes and the chlorophytes. The charophytes are the algae most closely related to land plants, and we will discuss them along with plants in Chapter 26.

The second group, the chlorophytes (from the Greek *chloros*, green), includes more than 7,000 species. Most live in fresh water, but there are also many marine and some terrestrial species. Nearly all species of chlorophytes reproduce sexually by means of biflagellated gametes that have cup-shaped chloroplasts. The simplest chlorophytes are unicellular species such as *Chlamydomonas* (see Figure 25.6), which resemble gametes of more complex chlorophytes. Some unicellular chlorophytes live independently in aquatic habitats while others live symbiotically within other eukaryotes, contributing part of their photosynthetic output to the food supply of their hosts. Larger size and greater complexity are found in various multicellular chlorophytes, including *Volvox* (see Figure 25.9) and *Ulva* (**Figure 25.20**).

## Unikonts

The fourth supergroup, **Unikonta**, is an extremely diverse group that includes animals, fungi, and some protists. There are two major clades of unikonts, the amoebozoans (gymnamoebas and

slime molds) and the opisthokonts (animals, fungi, and closely related protist groups). Each of these two major clades is strongly supported by molecular systematics. The close relationship between amoebozoans and opisthokonts is more controversial. Support for this close relationship is provided by comparisons of myosin proteins and by some (but not all) studies based on hundreds of genes or whole genomes.

Another controversy involving the unikonts concerns the root of the eukaryotic tree. Recall that the root of a phylogenetic tree anchors the tree in time: Branch points close to the root are the oldest. At present, the root of the eukaryotic tree is uncertain; hence, we do not know which group of eukaryotes was the first to diverge from other eukaryotes. Some hypotheses, such as the amitochondriate hypothesis described earlier, have been abandoned, but researchers have yet to agree on an alternative. If the root of the eukaryotic tree were known, scientists could infer characteristics of the common ancestor of all eukaryotes.

In trying to determine the root of the eukaryotic tree, researchers have based their phylogenies on different sets of genes, some of which have produced conflicting results. Researchers have also tried a different approach based on tracing the occurrence of a rare evolutionary event (**Figure 25.21**). Results from this “rare event” approach suggest that the unikonts were the first eukaryotes to diverge from other eukaryotes. If this hypothesis is correct, animals and fungi belong to an early-diverging group of eukaryotes, while protists that lack typical mitochondria (such as the diplomonads and parabasalids) diverged much later in the history of life. This idea remains controversial and will require more supporting evidence to be widely accepted.

### Amoebozoans

The **amoebozoan** clade includes many species of amoebas that have lobe- or tube-shaped pseudopodia, rather than the thread-like pseudopodia found in rhizarians. Although some amoebozoans are parasites, most are free-living. The gymnamoebas, for example, are a group of free-living, unicellular predators and scavengers that are ubiquitous in soil and in aquatic environments (see Figure 25.9). Free-living amoebozoans also include the slime molds, a group of multicellular amoebozoans.

Slime molds were once thought to be fungi because, like fungi, they produce fruiting bodies that aid in spore dispersal. However, the resemblance between slime molds and fungi appears to be another case of evolutionary convergence. DNA sequence analyses indicate that slime molds descended from unicellular amoebozoan ancestors, making them another example of the independent evolution of multicellularity in eukaryotes (see Concept 25.2).

The life cycle of some slime molds can prompt us to question what it means to be an individual organism. Consider the cellular slime mold *Dictyostelium*. The feeding stage of this organism consists of solitary cells that function individually; but when food is depleted, the cells form an aggregate

## ▼ Figure 25.21 Inquiry

### Where is the root of the eukaryotic tree?

**Experiment** Responding to the difficulty in determining the root of the eukaryotic phylogenetic tree, Alexandra Stechmann and Thomas Cavalier-Smith proposed a new approach. They studied two genes, one coding for the enzyme dihydrofolate reductase (DHFR), the other for the enzyme thymidylate synthase (TS). Their approach took advantage of a rare evolutionary event: In some organisms, the genes for DHFR and TS have fused, leading to the production of a single protein with both enzyme activities. Stechmann and Cavalier-Smith amplified (using PCR; see Figure 13.25) and sequenced the genes for DHFR and TS in nine species (one choanoflagellate; two amoebozoans; one euglenozoan; one stramenopile; one alveolate; and three rhizarians). They combined their data with previously published data for species of bacteria, animals, plants, and fungi.

**Results** The bacteria studied all have separate genes coding for DHFR and TS, suggesting that this is the ancestral condition (red dot on the tree below). Other taxa with separate genes are denoted by red type. Fused genes are a derived character, found in certain members (blue type) of the supergroups Excavata, the SAR clade, and Archaeplastida:

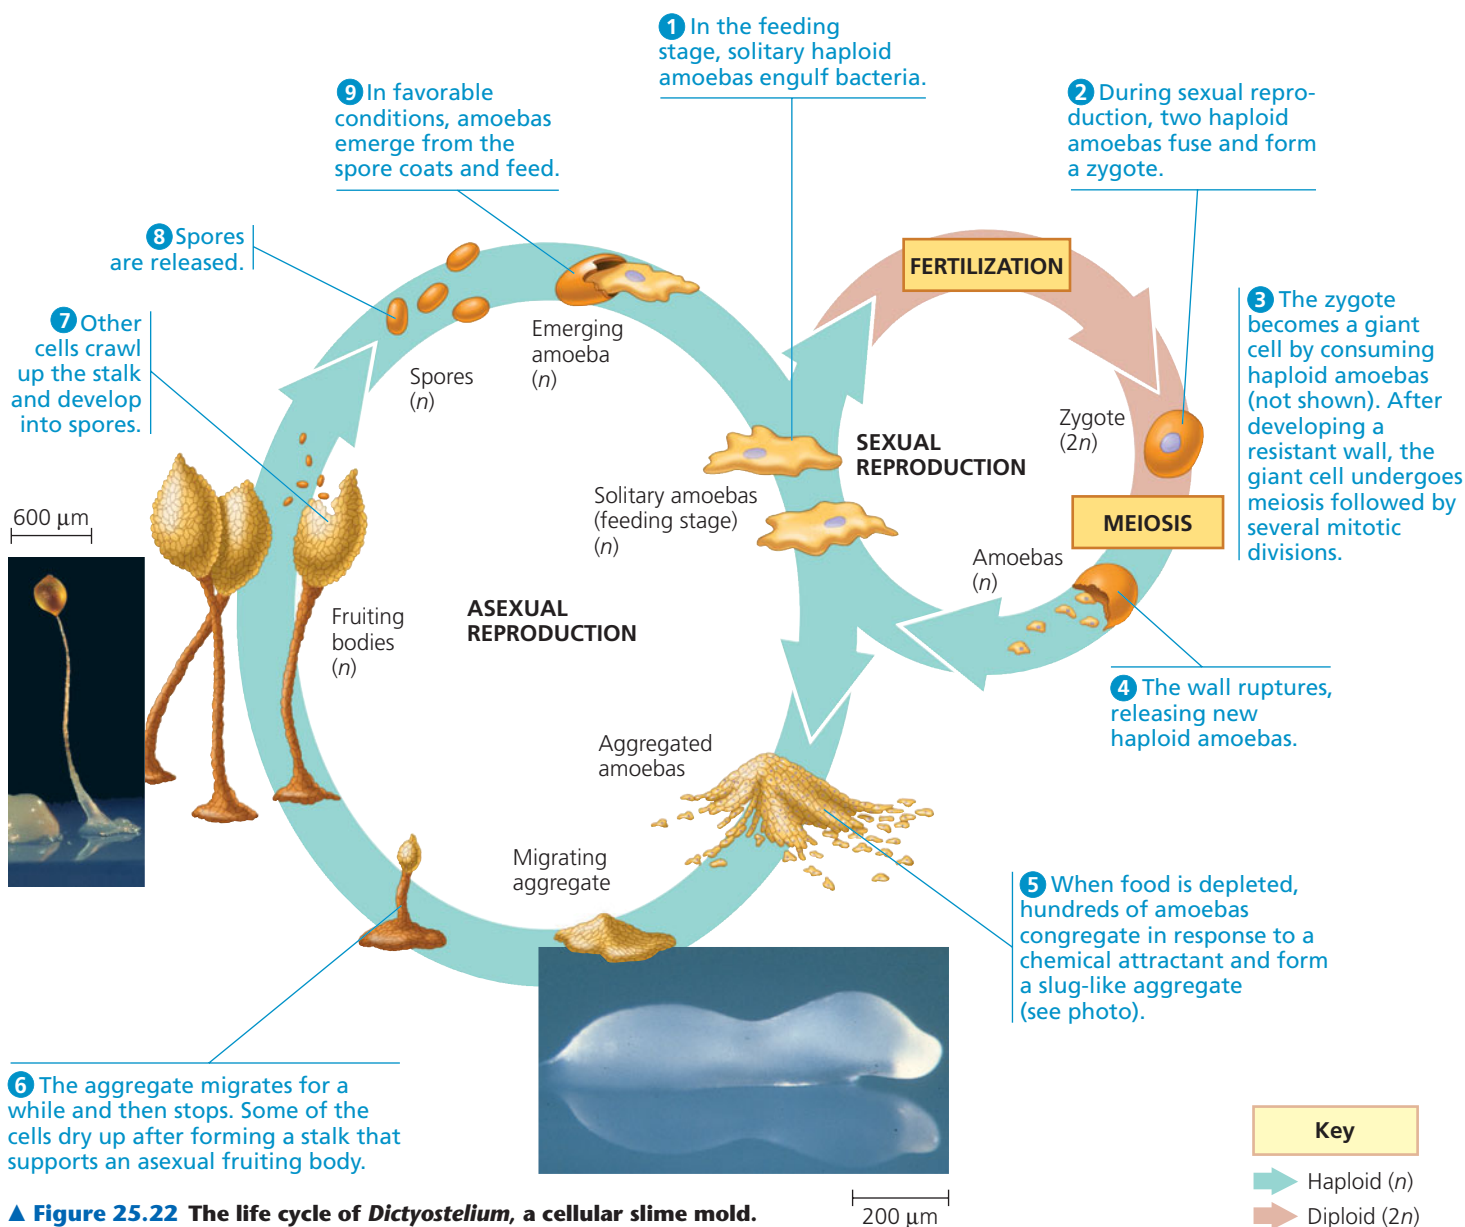

**Conclusion** These results support the hypothesis that the root of the tree is located between the unikonts and all other eukaryotes, suggesting that the unikonts were the first group of eukaryotes to diverge. Because support for this hypothesis is based on only one trait—the fusion of the genes for DHFR and TS—more data are needed to evaluate its validity.

**Source** A. Stechmann and T. Cavalier-Smith, Rooting the eukaryote tree by using a derived gene fusion, *Science* 297:89–91 (2002).

**WHAT IF?** Stechmann and Cavalier-Smith wrote that their conclusions are “valid only if the genes fused just once and were never secondarily split.” Why is this assumption critical to their approach?

that functions as a unit (Figure 25.22). These aggregated cells eventually form the slime mold's fruiting body stage. During this stage, the cells that form the stalk die as they dry out, while the spore cells at the top survive and have the potential to disperse and later reproduce.

### Opisthokonts

**Opisthokonts** are an extremely diverse group of eukaryotes that includes animals, fungi, and several groups of protists. We will discuss the colonization of land and the evolutionary history of fungi and animals in Chapters 26 and 27. Of the opisthokont protists, we will discuss the nucleariids in Chapter 26 because they are more closely related to fungi than they are to other protists. And as we discussed earlier in this chapter, the choanoflagellates are more closely related to animals than they are to other protists. The nucleariids and choanoflagellates illustrate why scientists have abandoned the former kingdom

Protista: A monophyletic group that includes these single-celled eukaryotes would also have to include the multicellular animals and fungi that are closely related to them.

### CONCEPT CHECK 25.3

- Briefly describe the organisms found in each of the four eukaryotic supergroups.
- MAKE CONNECTIONS** Review Figures 7.2 and 8.5. Summarize how  $\text{CO}_2$  and  $\text{O}_2$  are both used and produced by aerobic algae.
- WHAT IF?** DNA sequence data for a diplomonad, a euglenozoan, a plant, and an unidentified protist suggest that the unidentified species is most closely related to the diplomonad. Further studies reveal that the unknown species has fully functional mitochondria. Based on these data, at what point on the phylogenetic tree in Figure 25.9 did the mystery protist's lineage probably diverge from other eukaryotic lineages? Explain.

For suggested answers, see Appendix A.

## Single-celled eukaryotes play key roles in ecological communities and affect human health

As our survey of the four eukaryotic supergroups suggests, the large, multicellular organisms that we know best—the plants, animals, and fungi—are the tips of just a few branches on the eukaryotic tree of life. All the other branches are lineages of protists, and these protists exhibit an impressive range of structural and functional diversity, as we'll discuss. We'll then examine the effects of protists on ecological communities and human societies. (We focus on protists here, but we'll address similar topics for plants, fungi, and animals in Chapters 26 and 27.)

### Structural and Functional Diversity in Protists

Most protists are unicellular, although there are some colonial and multicellular species. Single-celled protists are justifiably considered the simplest eukaryotes, but at the cellular level, many protists are very complex—the most elaborate of all cells. In multicellular organisms, essential biological functions are carried out by organs. Unicellular protists carry out the same functions, but they do so using subcellular organelles, not multicellular organs: the nucleus, endoplasmic reticulum, Golgi apparatus, and lysosomes.

Most protists are aquatic, and they are found almost anywhere there is water, including moist terrestrial habitats such as damp soil and leaf litter. In oceans and lakes, many protists attach to the bottom or creep through the sand and silt, while others float near the water's surface. The protists living in these varied habitats also show a wide range of nutritional diversity. As we've seen, many protists are photoautotrophs and contain chloroplasts. Many others are heterotrophs, absorbing organic molecules or ingesting larger food particles; such heterotrophic protists include important mutualistic and parasitic species. Still other protists are mixotrophs that combine photosynthesis *and* heterotrophic nutrition. Photoautotrophy, heterotrophy, and mixotrophy have all arisen independently in many different protist lineages. In part as a result of this nutritional and taxonomic diversity, protist producers and symbionts are abundant in natural communities and have large ecological effects.

### Photosynthetic Protists

Many protists are important **producers**, organisms that use energy from light (or inorganic chemicals) to convert carbon dioxide to organic compounds. Producers form the base of ecological food webs. In aquatic communities, the main producers are photosynthetic protists and prokaryotes. All other organisms in the community depend on them for food, either directly (by eating them) or indirectly (by eating an organism that ate a producer; **Figure 25.23**). Scientists estimate that roughly 30% of the world's photosynthesis is performed by

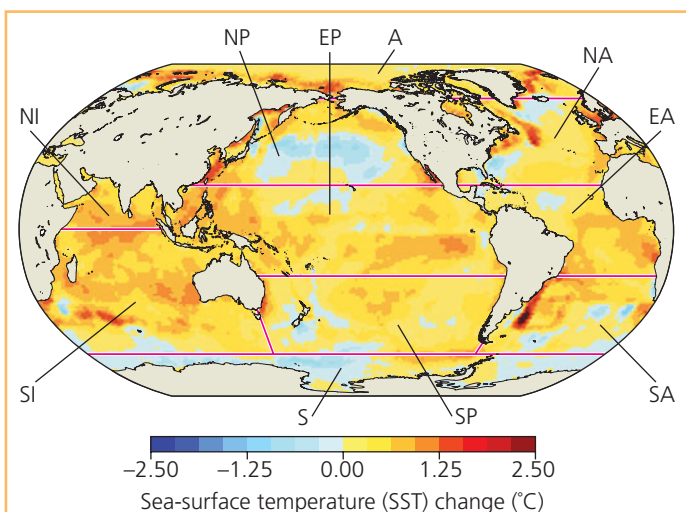

▲ **Figure 25.23 Protists: key producers in aquatic communities.** Arrows in this simplified food web lead from food sources to the organisms that eat them.

diatoms, dinoflagellates, multicellular algae, and other aquatic protists. Photosynthetic prokaryotes contribute another 20%, and land plants are responsible for the remaining 50%.

Because producers form the foundation of food webs, factors that affect producers can affect their entire community. In aquatic environments, photosynthetic protists are often held in check by low concentrations of nitrogen, phosphorus, or iron. Various human actions can increase the concentrations of these elements in aquatic communities. For example, some of the fertilizer applied to a field may be washed by rain into a river that drains into a lake or ocean. When people add nutrients to aquatic communities in this or other ways, the abundance of photosynthetic protists can increase spectacularly.

Such increases can have major ecological consequences. For example, earlier in the chapter we mentioned that diatoms can affect global carbon dioxide levels. This effect can result from a chain of events that occurs when ample nutrients produce a rapid increase (a bloom) in diatom abundance. Typically, diatoms are eaten by a variety of protists and invertebrates, but during a bloom, many escape this fate. When these uneaten diatoms die, their bodies sink to the ocean floor. Diatoms that sink to the ocean floor are not very likely to be broken down by bacteria and other decomposers. Hence, the carbon in their bodies remains there, rather than being released as carbon dioxide as the decomposers respire. The overall effect of these events is that carbon dioxide absorbed by diatoms during photosynthesis is transported, or “pumped,” to the ocean floor. With an eye toward reducing global warming by lowering atmospheric carbon dioxide levels, some scientists advocate promoting diatom blooms by fertilizing the ocean with essential nutrients such as iron. Other scientists question this strategy, noting that small-scale tests of this idea have yielded mixed results and that it is difficult to predict the effects of large-scale manipulations of ecological communities.

(a) Researchers studied 10 ocean regions, identified with letters on the map (see (b) for the corresponding names). SSTs have increased since 1950 in most areas of these regions.

(b) The concentration of chlorophyll, an index for the biomass and growth of marine producers, has decreased over the same time period in most ocean regions.

#### ▲ Figure 25.24 Effects of climate change on marine producers.

A related and pressing question is how global warming will affect photosynthetic protists and other producers. Satellite data and historical observations show that the growth of photosynthetic protists and prokaryotes has declined in many ocean regions as sea surface temperatures have increased (Figure 25.24). By what mechanism do rising sea surface temperatures reduce the growth of marine producers? One hypothesis relates to the rise, or upwelling, of cold, nutrient-rich waters from below. Many marine producers rely on nutrients brought to the surface in this way. However, rising sea surface temperatures can cause the formation of a layer of light, warm water that acts as a barrier to nutrient upwelling—thus reducing the growth of marine producers. If sustained, these changes would likely have far-reaching effects on marine ecosystems, fishery yields, and the global carbon cycle (see Chapter 42).

#### ► Figure 25.25

**A symbiotic protist.** This organism is a hypermastigote, a member of a group of parabasalids that live in the gut of termites and certain cockroaches and enable the hosts to digest wood (SEM).

### Symbiotic Protists

Many protists form symbiotic associations with other species. For example, photosynthetic dinoflagellates are food-providing symbiotic partners of the coral polyps that build coral reefs. Coral reefs are highly diverse ecological communities. That diversity ultimately depends on corals—and on the mutualistic protist symbionts that nourish them. Corals support reef diversity by providing food to some species and habitat to many others.

Another example is the wood-digesting protists that inhabit the gut of many termite species (Figure 25.25). Unaided, termites cannot digest wood, and they rely on protistan or prokaryotic symbionts to do so. Termites cause over \$3.5 billion in damage annually to wooden homes in the United States.

Symbiotic protists also include parasites that feed on the tissues of plants or animals. Among the species that parasitize plants, the stramenopile *Phytophthora ramorum* has emerged as a major new forest pathogen. This species causes sudden oak death (SOD), a disease that has killed millions of oaks and other trees in California and Oregon (see Chapter 41). A closely related species, *P. infestans*, causes potato late blight, which turns the stalk and stem of potato plants to black slime. Late blight contributed to the devastating Irish famine of the 19th century, in which a million people died and at least that many were forced to leave Ireland. The disease remains a major problem today, destroying as much as 70% of the crop in some areas.

We'll close the chapter by taking a closer look at the parasitic protists that cause disease in humans.

### Effects on Human Health

Our bodies are home to many symbiotic species, including some protists that can cause disease. While bacteria and viruses may be the pathogens that most readily come to mind, protists that cause infectious disease can pose major challenges, both to our immune systems and to public health.

Consider *Trypanosoma*, the excavate that causes sleeping sickness (see Figure 25.12). This disease is fatal if not treated.

Trypanosomes evade immune responses with an effective “bait-and-switch” defense. The surface of a trypanosome is coated with millions of copies of a single protein. However, before the host’s immune system can recognize the protein and mount an attack, new generations of the parasite switch to another surface protein with a different molecular structure. Frequent changes in the surface protein prevent the host from developing immunity. About a third of *Trypanosoma*’s genome is dedicated to producing these surface proteins.

A group of alveolates, the **apicomplexans**, includes protists that cause serious human diseases such as malaria. Nearly all apicomplexans are parasites of animals—and virtually all animal species examined so far are attacked by these parasites. Although apicomplexans are not photosynthetic, they retain a modified plastid (*apicoplast*), most likely of red algal origin

(see Figure 25.4). Apicomplexans typically have intricate life cycles with both sexual and asexual stages. Those life cycles often require two or more host species for completion. For example, *Plasmodium*, the parasite that causes malaria, lives in both mosquitoes and humans (**Figure 25.26**).

Historically, malaria has rivaled tuberculosis (which is caused by a bacterium) as the leading cause of human death by infectious disease. The incidence of malaria was diminished in the 1960s by insecticides that reduced carrier populations of *Anopheles* mosquitoes and by drugs that killed *Plasmodium* in humans. But the emergence of resistant varieties of both *Anopheles* and *Plasmodium* has led to a resurgence of malaria. About 250 million people in the tropics are currently infected, and 900,000 die each year. Efforts are under way to develop new methods of treatment, including drugs that target the

▼ **Figure 25.26 The two-host life cycle of *Plasmodium*, the apicomplexan that causes malaria.**

The parasite enters its human host as tiny infectious cells called sporozoites.

**?** In 2011, researchers discovered that the merozoite apicoplast has only one essential function: It synthesizes a chemical that the parasite requires for survival and cannot otherwise make. Explain why drugs that target the metabolic pathway by which this chemical is made would probably not harm humans.

**8** An oocyst develops from the zygote in the wall of the mosquito’s gut. The oocyst releases thousands of sporozoites, which migrate to the mosquito’s salivary gland.

**7** Fertilization occurs in the mosquito’s digestive tract, and a zygote forms.

**6** Gametes form from gametocytes; each male gametocyte produces several slender male gametes.

**1** An infected *Anopheles* mosquito bites a person, injecting *Plasmodium* sporozoites in its saliva.

**2** The sporozoites enter the person’s liver cells. After several days, the sporozoites undergo multiple divisions and become merozoites, which use their apical complex to penetrate red blood cells (see TEM below).

**3** The merozoites divide asexually inside the red blood cells. At intervals of 48 or 72 hours (depending on the species), large numbers of merozoites break out of the blood cells, causing periodic chills and fever. Some of the merozoites infect other red blood cells.

**4** Some merozoites form gametocytes.

**5** Another *Anopheles* mosquito bites the infected person and picks up *Plasmodium* gametocytes along with blood.

apicoplast. This approach may be effective because the apicoplast, derived by secondary endosymbiosis from a prokaryote, has metabolic pathways different from those in humans.

As we’ve seen in this chapter, the origin of eukaryotes had an enormous impact on the history of life, leading to a great increase in the structural diversity of cells and ultimately to the rise of large, multicellular organisms. These changes set the stage for the events we’ll describe in the next two chapters: the colonization of land by plants and fungi (Chapter 26) and the ecological and evolutionary effects resulting from the origin of animals (Chapter 27).

# 25 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 25.1

**Eukaryotes arose by endosymbiosis more than 1.8 billion years ago (pp. 481–487)**

- Domain Eukarya contains many groups of **protists**, along with plants, animals, and fungi. Eukaryotic cells have a nucleus and other membrane-enclosed organelles, unlike the cells of prokaryotes. These membrane-enclosed organelles make the cells of eukaryotes more complex than the cells of prokaryotes. Eukaryotic cells also have a well-developed cytoskeleton that enables them to have asymmetric forms and to change in shape as they move, feed, or grow.
- The oldest fossils of eukaryotes are of single-celled organisms that lived 1.8 billion years ago. By 1.5 billion years ago, some fossil eukaryotes had asymmetric forms, indicating a well-developed cytoskeleton. Other biological innovations, such as complex multicellularity and sexual life cycles, were in place by 1.2 billion years ago. Larger eukaryotes appeared in the fossil record about 600 million years ago.
- DNA sequence analyses indicate that eukaryotes contain a mixture of archaeal and bacterial genes and cellular characteristics. According to **endosymbiont theory**, this mixture of features likely resulted because eukaryotes originated when an archaeal host (or a host with archaeal ancestors) engulfed a bacterium that would later become an organelle found in all eukaryotes, the mitochondrion.
- In addition to mitochondria, plastids are also thought to be descendants of bacteria that were engulfed by an early eukaryote and became endosymbionts. The plastid-bearing lineage eventually evolved into **red algae** and **green algae**. Other groups of photosynthetic protists evolved from secondary endosymbiosis events in which red algae or green algae were themselves engulfed.

**?** *What evidence indicates that mitochondria arose before plastids in eukaryotic evolution?*

### CONCEPT 25.2

**Multicellularity has originated several times in eukaryotes (pp. 487–489)**

- The first multicellular eukaryotes were colonies, collections of cells that are connected to one another but show little or no cellular differentiation.
- Complex multicellular eukaryotes—those with differentiated cell types—arose independently in a variety of eukaryotic groups, including plants, fungi, animals, and several lineages of algae.

### CONCEPT CHECK 25.4

- Justify the claim that photosynthetic protists are among the biosphere’s most important organisms.
- Describe three symbioses that include protists.
- WHAT IF?** High water temperatures and pollution can cause corals to expel their dinoflagellate symbionts. Predict how such “coral bleaching” would affect corals and other species in the community.

For suggested answers, see Appendix A.

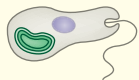

- Genomic analyses suggest that a transition to multicellularity from unicellular ancestors does not require the origin of large numbers of novel genes; instead, such transitions can result primarily from changes in how existing genes are used.

**?** *Describe an example that illustrates the role of co-opting genes in the origin of complex multicellular eukaryotes from their unicellular ancestors.*

### CONCEPT 25.3

**Four “supergroups” of eukaryotes have been proposed based on morphological and molecular data (pp. 489–498)**

- In one hypothesis, eukaryotes are grouped into four supergroups, each a monophyletic clade. Each eukaryotic supergroup contains a great diversity of organisms, most of which are unicellular.

Supergroup	Major Clades	Specific Example
Excavata	Diplomonads, parabasalids, euglenozoans	<i>Euglena</i> 
“SAR” clade	Stramenopiles, alveolates, rhizarians	<i>Plasmodium</i> 
Archaeplastida	Red algae, green algae, land plants	<i>Chlamydomonas</i> 
Unikonta	Amoebozoans, opisthokonts	<i>Amoeba</i> 

- The root of the eukaryotic tree is not known. An approach based on a tracing the occurrence of a rare evolutionary event suggests that the unikonts were the first eukaryotes to diverge from other eukaryotes. This hypothesis will require more supporting evidence before it is widely accepted.

**?** *Summarize recent changes in our understanding of the evolutionary history of eukaryotes, beginning with an explanation for why kingdom Protista has been abandoned.*

## CONCEPT 25.4

### Single-celled eukaryotes play key roles in ecological communities and affect human health (pp. 499–506)

- The most elaborate of all cells, unicellular protists use subcellular organelles to accomplish the essential biological functions that multicellular organisms perform with organs. Protists live in a wide range of habitats and include many different lineages of photoautotrophic, heterotrophic, and mixotrophic species.
- Photosynthetic protists are among the most important **producers** in aquatic communities. Because they are at the base of the food web, factors that affect photosynthetic protists affect many other species in the community.
- Protists form a wide range of mutualistic and parasitic relationships that affect their symbiotic partners and many other members of the community. Some protists, such as the malaria parasite *Plasmodium*, pose major challenges to human health.

**?** Describe several protists that are ecologically important.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. The oldest fossil eukaryote that can be resolved taxonomically is of
  - a. a red alga that lived 1.2 billion years ago.
  - b. a red alga that lived 635 million years ago.
  - c. a fungus that lived 2 billion years ago.
  - d. a fungus that lived 550 million years ago.
  - e. an Ediacaran that lived 550 million years ago.
2. The evolution of complex multicellularity in eukaryotes
  - a. occurred only once, in the common ancestor of all eukaryotes.
  - b. occurred only once, in the common ancestor of all multicellular eukaryotes.
  - c. occurred only once, in the animal lineage.
  - d. is not documented by the fossil record.
  - e. occurred independently in several different eukaryotic lineages.
3. Plastids that are surrounded by more than two membranes are evidence of
  - a. evolution from mitochondria.
  - b. fusion of plastids.
  - c. origin of the plastids from archaea.
  - d. secondary endosymbiosis.
  - e. budding of the plastids from the nuclear envelope.
4. Biologists think that endosymbiosis gave rise to mitochondria before plastids partly because
  - a. the products of photosynthesis could not be metabolized without mitochondrial enzymes.
  - b. all eukaryotes have mitochondria (or their remnants), whereas many eukaryotes do not have plastids.
  - c. mitochondrial DNA is less similar to prokaryotic DNA than is plastid DNA.
  - d. without mitochondrial CO<sub>2</sub> production, photosynthesis could not occur.
  - e. mitochondrial proteins are synthesized on cytosolic ribosomes, whereas plastids utilize their own ribosomes.
5. Which group is *incorrectly* paired with its description?
  - a. rhizarians—morphologically diverse group that includes amoebas with threadlike pseudopodia
  - b. diatoms—important producers in aquatic communities
  - c. red algae—acquired plastids by secondary endosymbiosis
  - d. apicomplexans—parasites with intricate life cycles
  - e. diplomonads—protists with modified mitochondria

### Level 2: Application/Analysis

6. Based on the phylogenetic tree in Figure 25.9, which of the following statements is correct?
  - a. The most recent common ancestor of Excavata is older than that of the SAR clade.
  - b. The most recent common ancestor of the SAR clade is older than that of Unikonta.
  - c. The most recent common ancestor of red algae and land plants is older than that of nucleariids and fungi.
  - d. The most basal (first to diverge) eukaryotic supergroup cannot be determined.
  - e. Excavata is the most basal eukaryotic supergroup.

### Level 3: Synthesis/Evaluation

7. **MAKE CONNECTIONS** The bacterium *Wolbachia* is a symbiont that lives in mosquito cells and spreads rapidly through mosquito populations. *Wolbachia* can make mosquitoes resistant to infection by *Plasmodium*; researchers are seeking a strain that confers resistance and does not harm mosquitoes. Compare evolutionary changes that could occur if malaria control is attempted using such a *Wolbachia* strain versus using insecticides to kill mosquitoes. (Review Figure 25.26 and Concept 21.3.)
8. **SCIENTIFIC INQUIRY** Applying the “If ... then” logic of science (see Chapter 1), what are a few of the predictions that arise from the hypothesis that plants evolved from green algae? Put another way, how could you test this hypothesis?
9. **FOCUS ON EVOLUTION**  
**DRAW IT** Medical researchers seek to develop drugs that can kill or restrict the growth of human pathogens yet have few harmful effects on patients. These drugs often work by disrupting the metabolism of the pathogen or by targeting its structural features.  
Draw and label a phylogenetic tree that includes an ancestral prokaryote and the following groups of organisms: Excavata, the SAR clade, Archaeplastida, Unikonta, and, within Unikonta, amoebozoans, animals, choanoflagellates, fungi, and nucleariids. Based on this tree, hypothesize whether it would be most difficult to develop drugs to combat human pathogens that are prokaryotes, protists, animals, or fungi. (You do not need to consider the evolution of drug resistance by the pathogen.)
10. **FOCUS ON INTERACTIONS** Organisms interact with each other and the physical environment. In a short essay (100–150 words), explain how the response of diatom populations to a drop in nutrient availability can affect both other organisms and aspects of the physical environment (such as carbon dioxide concentrations).

For selected answers, see Appendix A.

# The Colonization of Land by Plants and Fungi

▼ **Figure 26.1** How have plants and fungi changed the world?

## KEY CONCEPTS

- 26.1** Fossils show that plants colonized land more than 470 million years ago
- 26.2** Fungi played an essential role in the colonization of land
- 26.3** Early land plants radiated into a diverse set of lineages
- 26.4** Seeds and pollen grains are key adaptations for life on land
- 26.5** Land plants and fungi fundamentally changed chemical cycling and biotic interactions

## OVERVIEW

### The Greening of Earth

Looking at a lush landscape, such as the forest scene in **Figure 26.1**, it is difficult to imagine the terrestrial environment without plants\* or other organisms. Yet for more than 2 billion years of Earth's history, the land surface was largely lifeless. Geochemical and fossil evidence suggest that this

had changed by 1.2 billion years ago, by which time thin coatings of cyanobacteria and protists existed on land. But it was only within the last 500 million years that fungi as well as small plants and animals joined them ashore. Finally, by about 385 million years ago, some plants appeared that could grow much taller, leading to the formation of the first forests (though with a very different set of species than those in **Figure 26.1**).

In this chapter, we'll examine the colonization of land by plants and fungi; we'll turn to animals in Chapter 27. Although plants and fungi are not closely related (**Figure 26.2**), we discuss them together in this chapter in part because fossil evidence suggests that they both arrived on land before animals, which depend on them to survive. Plants supply oxygen and ultimately most of the food eaten by terrestrial animals. Also, plant roots create habitats for animals and other organisms by stabilizing the soil in many terrestrial environments. Fungi break down organic material and recycle nutrients, allowing other organisms to assimilate essential chemical elements.

Fossil evidence also suggests that plants colonized land in partnership with fungi. This partnership and the diversification of plants and fungi that occurred in terrestrial environments fundamentally changed biotic interactions and chemical cycling. We'll begin this story with the origin of plants, an event that occurred over millions of years as the algal ancestors of early plants adapted to life in a new environment—land.

\*Although a few plant species returned to aquatic habitats during their evolution, most present-day plants live on land. In this chapter, we often refer to all plants as *land* plants, even those that are now aquatic, to distinguish them from algae, which are photosynthetic protists.

▲ **Figure 26.2 Relationships among multicellular eukaryotes.** As shown in this phylogenetic tree, fungi and animals are more closely related than either group is to plants or charophytes (or other algae).

## CONCEPT 26.1

# Fossils show that plants colonized land more than 470 million years ago

Evidence in the form of fossils documents key steps in the origin of plants from their algal ancestors. As you read in Chapter 25, researchers have identified green algae called charophytes as the closest living relatives of land plants (see Figure 26.2). After discussing evidence for this relationship, we'll describe the terrestrial adaptations and fossil record of early land plants.

## Evidence of Algal Ancestry

Many key traits of land plants also appear in some algae. For example, plants are multicellular, eukaryotic, photosynthetic autotrophs, as are brown, red, and certain green algae. Plants have cell walls made of cellulose, and so do green algae, dinoflagellates, and brown algae. And chloroplasts with chlorophylls *a* and *b* are present in green algae, euglenids, and a few dinoflagellates, as well as in plants.

However, the charophytes are the only present-day algae that share certain distinctive traits with land plants, suggesting that they are the closest living relatives of plants. For example, the cells of both land plants and charophytes have distinctive circular rings of proteins in the plasma membrane (Figure 26.3); these protein rings synthesize the cellulose found in the cell wall. In contrast, noncharophyte algae have linear sets of proteins that synthesize cellulose. Likewise, in species of land plants that have flagellated sperm, the structure of the sperm closely resembles that of charophyte sperm.

Biochemical studies and analyses of nuclear and chloroplast genes from a wide range of plants and algae also indicate that charophytes—particularly *Chara* and *Coleochaete*—are the closest living relatives of land plants (Figure 26.4). Note that this does not mean that plants are descended from these living algae; however, present-day charophytes may tell us something about what the algal ancestors of plants were like.

## Adaptations Enabling the Move to Land

Many species of charophyte algae inhabit shallow waters around the edges of ponds and lakes, where they are subject to occasional drying. In such environments, natural selection favors individual algae that can survive periods when they are

► **Figure 26.3** Rings of cellulose-synthesizing proteins. These circular sets of proteins embedded in the plasma membrane are found only in land plants and charophyte algae (SEM).

30 nm

◀ *Chara vulgaris*, a pond organism

▼ *Coleochaete orbicularis*, a disk-shaped charophyte that also lives in ponds (LM)

▲ **Figure 26.4** Examples of charophytes, the closest algal relatives of land plants.

not submerged in water. In charophytes, a layer of a durable polymer called **sporopollenin** prevents exposed zygotes from drying out. A similar chemical adaptation is found in the tough sporopollenin walls that encase the spores of plants.

The accumulation of such traits by at least one population of charophyte ancestors probably enabled their descendants—the first land plants—to live permanently above the waterline. This ability opened a new frontier: a terrestrial habitat that offered enormous benefits. The bright sunlight was unfiltered by water and plankton; the atmosphere offered more plentiful carbon dioxide than did water; and the soil by the water's edge was rich in some mineral nutrients. But these benefits were accompanied by challenges: a relative scarcity of water and a lack of structural support against gravity. (To appreciate why such support is important, picture how the soft body of a jellyfish sags when taken out of water.) Land plants diversified as adaptations evolved that enabled plants to thrive despite these challenges.

Today, what adaptations are unique to plants? The answer depends on where you draw the boundary dividing plants from algae (Figure 26.5). Since the placement of this boundary is the

▲ **Figure 26.5** Three possible “plant” kingdoms.

Charophyte algae lack the key traits of land plants described in this figure: alternation of generations and the associated trait of multicellular, dependent embryos. As described on the facing page, charophyte algae also lack walled spores produced in sporangia and apical meristems. This suggests that these four traits were absent in the ancestor common to land plants and charophytes but instead evolved as derived traits of land plants.

## Alternation of Generations

The life cycles of all land plants alternate between two generations of distinct multicellular organisms: gametophytes and sporophytes. As shown in the diagram below (using a fern as an example), each generation gives rise to the other, a process that is called **alternation of generations**. This type of reproductive cycle evolved in various groups of algae but does not occur in the charophytes, the algae most closely related to land plants. Take care not to confuse the alternation of generations in plants with the haploid and diploid stages in the life cycles of other sexually reproducing organisms (see Figure 10.6). Alternation of generations is distinguished by the fact that the life cycle

**Alternation of generations: five generalized steps**

5 The spores develop into multicellular haploid gametophytes.

4 The sporophyte produces unicellular haploid spores by meiosis.

1 The gametophyte produces haploid gametes by mitosis.

2 Two gametes unite (fertilization) and form a diploid zygote.

3 The zygote develops into a multicellular diploid sporophyte.

includes both multicellular haploid organisms and multicellular diploid organisms. The multicellular haploid **gametophyte** ("gamete-producing plant") is named for its production by mitosis of haploid gametes—eggs and sperm—that fuse during fertilization, forming diploid zygotes. Mitotic division of the zygote produces a multicellular diploid **sporophyte** ("spore-producing plant"). Meiosis in a mature sporophyte produces haploid **spores**, reproductive cells that can develop into a new haploid organism without fusing with another cell. Mitotic division of the spore cell produces a new multicellular gametophyte, and the cycle begins again.

## Multicellular, Dependent Embryos

As part of a life cycle with alternation of generations, multicellular plant embryos develop from zygotes that are retained within the tissues of the female parent (a gametophyte). The parental tissues protect the developing embryo from harsh environmental conditions and provide nutrients such as sugars and amino acids. The embryo has specialized *placental transfer cells* that enhance the transfer of nutrients to the embryo through elaborate ingrowths of the wall surface (plasma membrane and cell wall). The multicellular, dependent embryo of land plants is such a significant derived trait that land plants are also known as **embryophytes**.

**Embryo (LM) and placental transfer cell (TEM) of *Marchantia* (a liverwort)**

**MAKE CONNECTIONS** Review sexual life cycles in Figure 10.6. Identify which type of sexual life cycle has alternation of generations, and summarize how it differs from other life cycles.

subject of ongoing debate, this text uses a traditional definition that equates the kingdom Plantae with embryophytes (plants with embryos). In this context, let's now examine the derived traits that separate land plants from their closest algal relatives.

## Derived Traits of Plants

A series of adaptations that facilitate survival and reproduction on dry land emerged after land plants diverged from their algal relatives. Examples of such traits that are found in land plants but not in the charophyte algae include the following:

- **Alternation of generations.** This type of life cycle, consisting of multicellular forms that give rise to each other in turn, is described in [Figure 26.6](#), on the preceding page.
- **Walled spores produced in sporangia.** The sporophyte stage of the plant life cycle has multicellular organs called **sporangia** (singular, *sporangium*) that produce spores ([Figure 26.7](#)). The polymer sporopollenin makes the walls of these spores resistant to harsh environments, enabling plant spores to be dispersed through dry air without harm.
- **Apical meristems.** Land plants also differ from their algal ancestors in having **apical meristems**, localized regions of cell division at the tips of roots and shoots (see [Figure 28.16](#)). Apical meristem cells can divide throughout the plant's life, enabling its roots and shoots to elongate, thus increasing the plant's exposure to environmental resources.

Additional derived traits that relate to terrestrial life have evolved in many plant species. For example, the epidermis in many species has a covering, the **cuticle**, that consists of wax and other polymers. Permanently exposed to the air, land plants run a far greater risk of desiccation (drying out) than their algal ancestors. The cuticle acts as waterproofing, helping prevent excessive water loss from the aboveground plant organs, while also providing some protection from microbial attack. Most plants also have specialized pores called

▲ **Figure 26.7 Sporophytes and sporangia of a moss (*Sphagnum*).** Each of the many spores produced by a sporangium is encased by a durable, sporopollenin-enriched wall.

**stomata** (singular, *stoma*), which support photosynthesis by allowing the exchange of CO<sub>2</sub> and O<sub>2</sub> between the outside air and the plant (see [Figure 8.3](#)). Stomata are also the main avenues by which water evaporates from the plant; in hot, dry conditions, the stomata close, minimizing water loss. As we describe in the next section, fossil evidence documents the appearance of stomata and other novel traits in early land plants.

## Early Land Plants

The algae from which land plants evolved include many unicellular and small, colonial species. Since their ancestors were small, the search for the earliest fossils of land plants has focused on the microscopic world. As mentioned earlier, microorganisms colonized land as early as 1.2 billion years ago. But the microscopic fossils documenting life on land changed dramatically 470 million years ago with the appearance of spores from early land plants.

What distinguishes these spores from those of algae or fungi? One clue comes from their chemical composition, which matches that found in plant spores but differs from that in the spores of other organisms. In addition, the structure of the walls of these ancient spores shows features found only in the spores of certain land plants (liverworts). And in rocks dating to 450 million years ago, researchers have discovered similar spores embedded in plant cuticle material that resembles spore-bearing tissue in living plants ([Figure 26.8](#)).

It is not surprising that spores provide the earliest fossil evidence of land plants. For one thing, plants produce large numbers of widely dispersed spores. In addition, recall that plant spores contain sporopollenin, a durable compound that allows the spores to be well represented in the fossil record. Larger plant structures, such as the spore-producing structure

### (a) Fossilized spores.

The chemical composition and physical structure of these 450 million-year-old spores match those found in land plants.

### (b) Fossilized sporophyte tissue.

The spores in (a) were embedded in tissue that appears to be from plants.

▲ **Figure 26.8 Ancient plant spores and tissue** (colorized SEMs).

► **Cooksonia** sporangium fossil (425 million years old).

(sporangium) from *Cooksonia* shown above, first appear in the fossil record dating to 425 million years ago. By 400 million years ago, a diverse assemblage of plants lived on land. Some of these early plants had key traits not found in their algal ancestors, including specialized tissues for water transport, stomata, and branched sporophytes (**Figure 26.9**). Although these early plants were less than 20 cm tall, their branching enabled their bodies to become more complex. As plant bodies became increasingly complex, competition for space and sunlight probably increased. That competition may have stimulated still more evolution in later plant lineages—eventually leading to the formation of the first forests.

Overall, the fossil record shows that by 400 million years ago, early land plants differed greatly from their algal ancestors. As they adapted to life on land, plants evolved a suite of novel features, including sporopollenin-containing spores, cuticles, stomata, transport systems, and branched sporophytes. In

▲ **Figure 26.9** *Aglaophyton major*, an early land plant. This reconstruction from 405-million-year-old fossils exhibits dichotomous (Y-shaped) branching with sporangia at the ends of the branches. *Aglaophyton* had rhizoids that anchored it to the ground. The inset shows a fossilized stoma of *A. major* (colorized LM).

addition, early land plants formed a key symbiotic association with the group we turn to next, the fungi.

#### CONCEPT CHECK 26.1

1. Why do researchers identify charophytes rather than another group as the closest relatives of land plants?
2. Identify three derived traits that distinguish plants from charophytes and facilitate life on land.
3. Describe fossil evidence of early land plants.
4. **WHAT IF?** What would the human life cycle be like if we had alternation of generations? Assume that the multicellular diploid stage would be similar in form to an adult human.

For suggested answers, see Appendix A.

## CONCEPT 26.2

### Fungi played an essential role in the colonization of land

The earliest land plants lacked true roots and leaves. Without roots, how did these plants absorb nutrients from the soil? Fossil evidence reveals an adaptation that may have aided their uptake of nutrients: They formed symbiotic associations with fungi. We'll describe these associations, called *mycorrhizae*, a little later in the chapter. For now, the main point is that mycorrhizal fungi form extensive networks of filaments through the soil and transfer nutrients to their symbiotic plant partners. This benefit may have helped plants without roots to colonize land.

Fungi may, in fact, have colonized land before plants. Once on land, fungi diversified into a wide range of living species. To help us interpret the role fungi played in the colonization of land, we'll begin by examining some of their key features, including how they feed and reproduce.

#### Fungal Nutrition

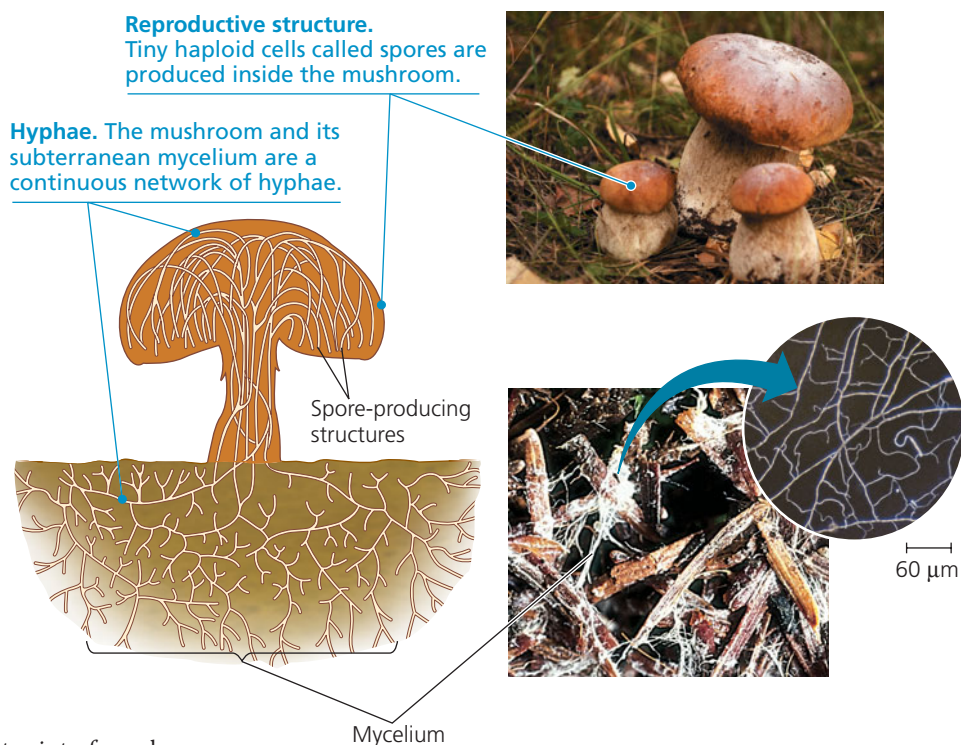

Like animals, fungi are heterotrophs: They cannot make their own food as plants and algae can. But unlike animals, fungi do not ingest (eat) their food. Instead, a fungus absorbs nutrients from the environment outside of its body; in brief, fungi are heterotrophs that feed by absorption. Many fungi accomplish this task by secreting hydrolytic enzymes into their surroundings. These enzymes break down complex molecules to smaller organic compounds that the fungi can absorb into their bodies and use. Collectively, fungi can digest compounds from a wide range of sources, living or dead.

#### Adaptations for Feeding by Absorption

What fungal traits facilitate feeding by absorption? One such trait is a cell wall strengthened by **chitin**, a strong but flexible nitrogen-containing polysaccharide. As fungi absorb nutrients from their environment, the concentration of those nutrients in their cells increases; that, in turn, causes water to move into

► **Figure 26.10 Structure of a multicellular fungus.** The top photograph shows the sexual structures, in this case called mushrooms, of the penny bun fungus (*Boletus edulis*). The bottom photograph shows a mycelium growing on fallen conifer needles. The inset SEM shows hyphae.

**?** Although the mushrooms in the top photograph appear to be different individuals, could their DNA be identical? Explain.

fungal cells by osmosis. The movement of water into fungal cells creates pressure that would cause their cells to burst if they were not surrounded by a rigid cell wall.

Many fungi also have a structure that increases the efficiency of nutrient absorption. The most common fungal body structures are multicellular filaments and single cells (**yeasts**). Many fungal species can grow as both filaments and yeasts, but even more grow only as filaments; relatively few species grow only as yeasts. Yeasts often inhabit moist environments, including plant sap and animal tissues, where there is a ready supply of soluble nutrients, such as sugars and amino acids.

The morphology of multicellular fungi enhances their ability to grow into and absorb nutrients from their surroundings (**Figure 26.10**). The bodies of these fungi typically form a network of tiny filaments called **hyphae** (singular, *hypha*). Hyphae consist of tubular (chitin-rich) cell walls surrounding the plasma membrane and cytoplasm of the cells. Fungal hyphae form an interwoven mass called a **mycelium** (plural, *mycelia*) that infiltrates the material on which the fungus feeds. The structure of a mycelium maximizes its surface-to-volume ratio, making feeding very efficient. Just 1 cm<sup>3</sup> of rich soil may contain as much as 1 km of hyphae with a total surface area of 300 cm<sup>2</sup> in contact with the soil.

### Specialized Hyphae in Mycorrhizal Fungi

Some fungi have specialized hyphae called **haustoria** (**Figure 26.11**), which the fungi use to extract nutrients from, or exchange nutrients with, their plant hosts. Mutually beneficial relationships between such fungi and plant roots are called **mycorrhizae** (the term means “fungus roots”).

Mycorrhizal fungi (fungi that form mycorrhizae) can improve delivery of phosphate ions and other minerals to plants

▲ **Figure 26.11 Haustoria of mycorrhizae.** Mutualistic mycorrhizal fungi grow specialized hyphae called haustoria that can exchange nutrients with living plant cells. Haustoria remain separated from a plant cell's cytoplasm by the plasma membrane of the plant cell (orange).

because the vast mycelial networks of the fungi are more efficient than the plants' roots at acquiring these minerals from the soil. In exchange, the plants supply the fungi with organic nutrients such as carbohydrates.

There are two main types of mycorrhizal fungi. **Ectomycorrhizal fungi** (from the Greek *ektos*, out) form sheaths of hyphae over the surface of a root and typically grow into the extracellular spaces of the root cortex (see Figure 29.13a). **Arbuscular mycorrhizal fungi** (from the Latin *arbor*, tree) extend branching hyphae through the root cell wall and into tubes formed by invagination (pushing inward) of the root cell plasma membrane (see Figure 29.13b). In the **Scientific Skills Exercise**, you'll interpret data from an experiment studying how mycorrhizae affect plants.

## Synthesizing Information from Multiple Data Sets

### Can Mycorrhizae Help Plants Cope with High-Temperature Soils?

The branching hyphae of arbuscular mycorrhizal (AM) fungi extend through the cell walls of host plants, bringing water and inorganic nutrients into the plant roots in exchange for sugars. Researchers wondered whether AM fungi also can help plants grow in high-temperature (thermal) soils. To study this question, they investigated the role of AM fungi in the growth of *Dichanthelium lanuginosum*, a grass species that grows only in thermal soils.

**How the Study Was Done** The researchers collected *D. lanuginosum* seeds from geothermally heated soils in Yellowstone National Park. After the seeds germinated, 27 seedlings were transferred to a greenhouse, where they were grown separately in heated pots. Temperatures in the pots ranged from 30°C at the soil surface to 50°C at the base of the pot, comparable to conditions in thermal soils.

Each pot received one of three treatments: nine pots were not inoculated with AM fungi, nine pots were inoculated with nonthermal AM fungi collected from grassland soil in a nongeothermal area, and nine pots were inoculated with thermal AM fungi collected from high-temperature geothermal areas of Yellowstone. All seedlings received the same amount of light and water. After 80 days, all plants were harvested.

### Data from the Study

	Total root length (cm)	Mean root diameter (mm)
No AM fungi	1,800	0.19
Nonthermal AM fungi	4,800	0.23
Thermal AM fungi	4,300	0.22

### Interpret the Data

- Compare the mean dry weight of shoots, total root length, and mean root diameter of *D. lanuginosum* grown in pots with and without inoculation by AM fungi. How do AM fungi appear to affect *D. lanuginosum* plants grown at high temperatures?
- Compare the mean dry weight of shoots, total root length, and mean root diameter of *D. lanuginosum* in pots inoculated with thermal and nonthermal AM fungi. Do *D. lanuginosum* plants grow equally well when the soil is inoculated with thermal and nonthermal AM fungi? What does this suggest about the thermal tolerances of AM fungi from geothermal and grassland soils?
- The researchers also measured the length of *D. lanuginosum* roots and the hyphal length of AM fungi in geothermal soils of different temperatures. The curves below, which were estimated from a statistical best fit to the data, show how the average root or hyphal length (per gram of soil) varies with soil temperature. Use these curves to estimate average root and hyphal lengths in soils of 25°C and soils of 35°C.

- What do the curves in the graph suggest about the relative heat tolerances of *D. lanuginosum* roots and fungal hyphae? How might these results explain the differences in growth of *D. lanuginosum* plants grown in soils with and without AM fungi?

**Data from** R. Bunn et al., Arbuscular mycorrhizal fungi ameliorate temperature stress in thermophilic plants, *Ecology* 90: 1378–1388 (2009).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

## Sexual and Asexual Reproduction

Most fungi propagate themselves by producing vast numbers of spores, either sexually or asexually. Spores can be carried long distances by wind or water. If they land in a moist place where there is food, they germinate, producing new mycelia. **Figure 26.12** generalizes the many different life cycles that can produce fungal spores.

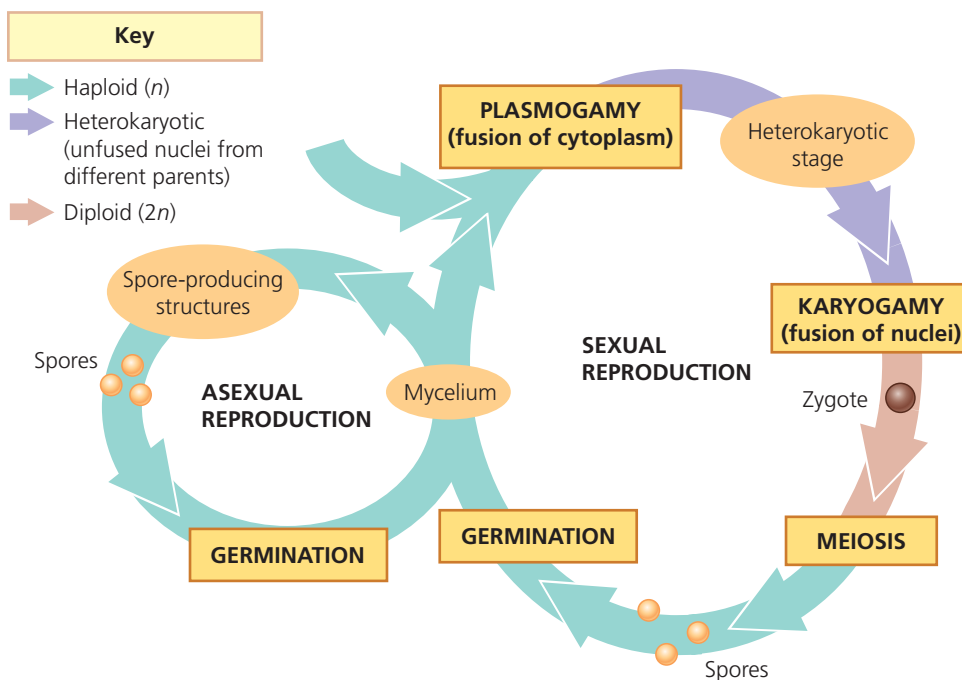

As shown in this figure, the sexual portion of a fungal life cycle typically occurs in two stages. First, the cytoplasm of two parent mycelia fuse, an event known as **plasmogamy**. Hours, days, or (in some fungi) even centuries may pass between plasmogamy and the next stage in the sexual cycle, **karyogamy**. During karyogamy, the haploid nuclei contributed by the two

parents fuse, producing diploid cells. Zygotes and other structures formed during karyogamy are the only diploid stage in most fungi. Meiosis then restores the haploid condition. Many fungi then reproduce asexually by growing as filamentous fungi that produce (haploid) spores by mitosis; such species are informally referred to as **molds** if they form visible mycelia. Other species reproduce asexually as single-celled yeasts that divide to produce genetically identical daughter cells.

## The Origin of Fungi

Although fungi were once thought to be closely related to plants, molecular data show that fungi and animals are more closely related to each other than either group is to plants

▲ **Figure 26.12 Generalized life cycle of fungi.** Many—but not all—fungi reproduce both sexually and asexually. Some reproduce only sexually, others only asexually.

or most other eukaryotes (see Figure 25.9). DNA sequence data also indicate that fungi are more closely related to several groups of single-celled protists than they are to animals, suggesting that the ancestor of fungi was unicellular. One such group of unicellular protists, the **nucleariids**, consists of amoebas that feed on algae and bacteria. As we discussed in Chapter 25, animals are more closely related to a *different* group of protists (the choanoflagellates) than they are to either fungi or nucleariids. Together, these results suggest that multicellularity must have evolved in animals and fungi independently, from different single-celled ancestors.

Based on molecular clock analyses (see Chapter 20), scientists have estimated that the ancestors of animals and fungi diverged into separate lineages 1–1.5 billion years ago. Fossils of certain unicellular, marine eukaryotes that lived as early as 1.5 billion years ago have been interpreted as fungi, but those claims remain controversial. Furthermore, although most biologists think that fungi originated in aquatic environments, the oldest fossils that are widely accepted as fungi are of terrestrial species that lived about 460 million years ago (**Figure 26.13**). Overall, additional fossil discoveries will be needed to clarify when fungi originated and what features were present in their earliest lineages.

▲ **Figure 26.13 Fossil fungal hyphae and spores from the Ordovician period (about 460 million years ago)** (LM).

## The Move to Land

As we mentioned earlier, fungi may have colonized land before plants. Indeed, some researchers have described life on land before the arrival of plants as a “green slime” that consisted of cyanobacteria, algae, and a variety of small, heterotrophic species, including fungi. With their rigid cell walls and extracellular digestion, fungi would have been well suited for feeding on other early terrestrial organisms (or their remains).

Once on land, some fungi formed symbiotic associations with early land plants. For example, 405-million-year-old fossils of the early land plant *Aglaophyton* (see Figure 26.9) contain evidence of mycorrhizal relationships between plants and fungi. This evidence includes fossils of hyphae that have penetrated within plant cells and formed structures that resemble the haustoria of arbuscular mycorrhizae (**Figure 26.14**). Similar structures have been found

in a variety of other early land plants, suggesting that plants probably existed in beneficial relationships with fungi from the earliest periods of colonization of land.

Support for the antiquity of mycorrhizal associations has also come from recent molecular studies. For a mycorrhizal fungus and its plant partner to establish a symbiotic relationship,

▲ **Figure 26.14 An ancient symbiosis.** This 405-million-year-old fossil stem (cross section) documents arbuscular mycorrhizae in the early land plant *Aglaophyton major*. The inset shows an enlarged view of a cell containing an arbuscule that has branched extensively; the fossil arbuscule resembles those seen today (see Figure 29.13b).

The phylogeny of fungi is currently the subject of much research. Most mycologists recognize five major groups of fungi, although the chytrids and zygomycetes are probably paraphyletic (as indicated by the parallel lines).

### Chytrids (1,000 species)

In chytrids such as *Chytridium*, the globular fruiting body forms multicellular, branched hyphae (LM); other species are single-celled. Ubiquitous in lakes and soil, chytrids have flagellated spores and are thought to include some of the earliest fungal groups to diverge from other fungi.

### Zygomycetes (1,000 species)

The hyphae of some zygomycetes, including this mold in the genus *Mucor* (LM), grow rapidly in foods such as fruits and bread. As such, the fungi may act as decomposers (if the food is not alive) or parasites; other species live as neutral (commensal) symbionts.

### Glomeromycetes (160 species)

The glomeromycetes form arbuscular mycorrhizae with plant roots, supplying minerals and other nutrients to the roots; about 80% of all plant species have such mutualistic partnerships with glomeromycetes. This SEM shows the branched hyphae—an arbuscule—of *Glomus mosseae* bulging into a plant root cell (the root has been treated to remove the cytoplasm).

### Ascomycetes (65,000 species)

Also called sac fungi, members of this diverse group are common to many marine, freshwater, and terrestrial habitats. The cup-shaped ascocarp (fruiting body) of the ascomycete shown here (*Aleuria aurantia*) gives this species its common name: orange peel fungus.

### Basidiomycetes (30,000 species)

Often important as decomposers and ectomycorrhizal fungi, basidiomycetes, or club fungi, are unusual in having a long-lived, heterokaryotic stage in which each cell has two nuclei (one from each parent). The fruiting bodies—commonly called mushrooms—of this fly agaric (*Amanita muscaria*) are a familiar sight in coniferous forests of the Northern Hemisphere.

certain genes must be expressed by the fungus and other genes must be expressed by the plant. Researchers focused on three plant genes (called *sym* genes) whose expression is required for the formation of mycorrhizae in flowering plants. They found that these genes were present in all major plant lineages, including basal lineages such as liverworts (see Figure 26.16). Furthermore, after they transferred a liverwort *sym* gene to a flowering plant mutant that could not form mycorrhizae, the mutant recovered its ability to form mycorrhizae. These results suggest that mycorrhizal *sym* genes were present in the land plant common ancestor—and that the function of these genes has been conserved for hundreds of millions of years as plants continued to adapt to life on land.

## Diversification of Fungi

In the past decade, molecular analyses have helped clarify the evolutionary relationships between fungal groups, although there are still areas of uncertainty. **Figure 26.15** presents a simplified version of one current hypothesis.

The groups shown in Figure 26.15 may represent only a small fraction of the diversity of extant fungi. While there are roughly 100,000 known species of fungi, there may actually be close to 1.5 million species. Two metagenomic studies published in 2011 support such higher estimates: Entirely new groups of unicellular fungi were discovered, and the genetic variation in some of these groups is as large as that across all of the groups in Figure 26.15.

As these phylogenetic data suggest, fungi diversified extensively after they colonized land. So, too, did the land plants that fungi helped ashore, as we'll discuss next.

### CONCEPT CHECK 26.2

1. Compare and contrast the nutritional mode of a fungus with your own nutritional mode.
2. Describe the importance of mycorrhizae, both today and in the colonization of land. What evidence supports the antiquity of mycorrhizal associations?
3. **MAKE CONNECTIONS** Review Figures 8.3 and 8.5. If a plant has mycorrhizae, where might carbon that enters the plant's stomata as CO<sub>2</sub> eventually be deposited: in the plant, in the mycorrhizal fungus, or in both? Explain.

For suggested answers, see Appendix A.

## CONCEPT 26.3

### Early land plants radiated into a diverse set of lineages

As early land plants adapted to terrestrial environments, they gave rise to the vast diversity of living plants. An overview of that diversity is provided by **Figure 26.16**, which summarizes the evolutionary history of extant plant groups. (Extant lineages are those that have surviving members.)

One way to distinguish plant groups is whether they have an extensive system of **vascular tissue**, cells joined into tubes that transport water and nutrients throughout the plant body. Most present-day plants have a complex vascular tissue system and are therefore called **vascular plants**. We'll return to

▼ **Figure 26.16 Highlights of plant evolution.** The phylogeny shown here illustrates a leading hypothesis about the relationships between plant groups.

(a) *Plagiochila deltoidea*, a liverwort. This group's name refers to the shape of its gametophytes. In medieval times, their shape was thought to be a sign that the plants could help treat liver diseases.

(b) *Polytrichum commune*, a moss. Moss gametophytes are less than 15 cm tall in most species but can reach up to 2 m. The familiar carpet of moss you observe consists mainly of gametophytes.

Capsule  
Seta  
Sporophyte (a sturdy plant that takes months to grow)  
Gametophyte

(c) *Anthoceros* sp., a hornwort. This group's name refers to the long, tapered shape of the sporophyte, which can grow to about 5 cm high.

Sporophyte  
Gametophyte

▲ **Figure 26.17 Bryophytes (nonvascular plants).** Molecular and morphological data indicate that bryophytes are paraphyletic; they do not form a single clade.

vascular plants later in this section, but first we'll discuss the nonvascular plants, or **bryophytes** (from the Greek *bryon*, moss, and *phyton*, plant), an informal name for plants that lack an extensive transport system.

## Bryophytes: A Collection of Early-Diverging Plant Lineages

The nonvascular plants (bryophytes) are represented today by three clades of small herbaceous

(nonwoody) plants: *liverworts*, *mosses*, and *hornworts* (Figure 26.17). Researchers think that these three clades were the earliest lineages to have diverged from the common ancestor of land plants (see Figure 26.16). Fossil evidence provides some support for this idea: The earliest spores of land plants (dating to 470–450 million years ago) have structural features found only in the spores of liverworts, and by 430 million years ago, spores similar to those of mosses and hornworts also occur in the fossil record.

As in some early land plants, the bryophytes of today are anchored to the ground by **rhizoids**, which lack specialized conducting cells and do not play a primary role in water and mineral absorption. Living bryophytes are typically found in moist habitats—as you might expect, since they have flagellated sperm that must swim through a film of water to fertilize an egg. Unlike most plants today, in bryophytes the haploid gametophytes are the dominant stage of the life cycle: The gametophytes are usually larger and longer-living than the sporophytes (see Figure 26.17). The gametophytes of mosses and other bryophytes typically form ground-hugging carpets, partly because their body parts are too thin to support a tall plant. A second constraint on the height of many bryophytes is the absence of vascular tissue, which would enable long-distance transport

of water and nutrients. These constraints were removed in the group we turn to next, the vascular plants.

## Seedless Vascular Plants: The First Plants to Grow Tall

During the first 100 million years of plant evolution, bryophytes were prominent members of the vegetation.

But it is vascular plants that dominate most landscapes today. The earliest fossils of vascular plants date to 425–420 million years ago. These plants lacked seeds but had well-developed vascular systems, an evolutionary novelty that set the stage for plants to grow tall.

The rise of vascular plants was accompanied by other evolutionary changes as well, resulting in life cycles with dominant sporophytes and the origin of well-developed roots and leaves. Our focus here will be on the two clades of vascular plants shown in Figure 26.18, the **lycophytes** (club mosses and their relatives) and the **monilophytes** (ferns and their relatives). The plants in these clades lack seeds, which is why collectively the two clades are often called **seedless vascular plants**. We'll discuss vascular plants that have seeds in Concept 26.4.

## Life Cycles with Dominant Sporophytes

As mentioned earlier, mosses and other bryophytes have life cycles dominated by gametophytes. Fossils suggest that a change began to occur in the ancestors of vascular plants, whose gametophytes and sporophytes were about equal in size. Further reductions in gametophyte size occurred among extant vascular plants; in these groups, the sporophyte generation is the larger and more complex plant form in the alternation of generations (Figure 26.19). In ferns, for example, the familiar leafy plants are

► **Figure 26.18 Lycophytes and monilophytes (seedless vascular plants).** Although lycophytes and monilophytes each form a monophyletic group, seedless vascular plants are paraphyletic.

	PLANT GROUP		
	Mosses and other nonvascular plants	Ferns and other seedless vascular plants	Seed plants (gymnosperms and angiosperms)
Gametophyte	Dominant	Reduced, independent (photosynthetic and free-living)	Reduced (usually microscopic), dependent on surrounding sporophyte tissue for nutrition
Sporophyte	Reduced, dependent on gametophyte for nutrition	Dominant	Dominant
Example	<p>Sporophyte (2n)</p> <p>Gametophyte (n)</p>	<p>Sporophyte (2n)</p> <p>Gametophyte (n)</p>	<div> <p><b>Gymnosperm</b></p> <p>Microscopic female gametophytes (n) inside ovulate cone</p> <p>Microscopic male gametophytes (n) inside pollen cone</p> <p>Sporophyte (2n)</p> </div> <div> <p><b>Angiosperm</b></p> <p>Microscopic female gametophytes (n) inside these parts of flowers</p> <p>Microscopic male gametophytes (n) inside these parts of flowers</p> <p>Sporophyte (2n)</p> </div>

▲ **Figure 26.19 Gametophyte-sporophyte relationships in different plant groups.**

the sporophytes. You would have to get down on your hands and knees and search the ground carefully to find fern gametophytes, which are tiny structures that often grow on or just below the soil surface. However, as in nonvascular plants, the sperm of ferns and all other seedless vascular plants are flagellated and must swim through a film of water to reach eggs.

### Transport in Xylem and Phloem

Vascular plants have two types of vascular tissue: xylem and phloem. **Xylem** conducts most of the water and minerals. The xylem of most vascular plants includes **tracheids**, tube-shaped cells that carry water and minerals up from the roots (see Figure 28.9). The water-conducting cells in vascular plants are *lignified*; that is, their cell walls are strengthened by the polymer **lignin**. The tissue called **phloem** has cells arranged into tubes that distribute sugars, amino acids, and other organic products (see Figure 28.9).

Lignified vascular tissue helped enable vascular plants to grow tall. Their stems became strong enough to provide support against gravity, and they could transport water and mineral nutrients high above the ground. Tall plants could also outcompete short plants for access to the sunlight needed for photosynthesis. In addition, the spores of tall plants could disperse farther than those of short plants, enabling tall species to colonize new environments rapidly. Overall, the ability to grow tall gave vascular plants a competitive edge over nonvascular plants, which rarely grow above 20 cm in height. Competition among vascular plants also increased, and taller growth forms were favored by natural selection—such as the trees that formed the first forests about 385 million years ago.

### Evolution of Roots and Leaves

Vascular tissue also provides benefits below ground. In contrast to the rhizoids of bryophytes, roots with vascular tissue evolved in the sporophytes of almost all vascular plants. **Roots** are organs that absorb water and nutrients from the soil; roots also anchor vascular plants.

**Leaves** increase the surface area of the plant body and serve as the primary photosynthetic organ of vascular plants. In terms of size and complexity, leaves can be classified as either microphylls or megaphylls. All of the lycophytes (the oldest lineage of extant vascular plants)—and only the lycophytes—have **microphylls**, small, usually spine-shaped leaves supported by a single strand of vascular tissue. Almost all other vascular plants have **megaphylls**, leaves with a highly branched vascular system; a few species have reduced leaves that appear to have evolved from megaphylls. Megaphylls are typically larger and support greater photosynthetic productivity than microphylls. Microphylls first appear in the fossil record 410 million years ago, but megaphylls do not emerge until about 370 million years ago.

Seedless vascular plants were abundant in the swampy forests and other moist ecosystems of the Carboniferous period (359–299 million years ago). Growing along with these seedless

plants were early seed plants. Though seed plants were not dominant at that time, they rose to prominence after the climate became drier at the end of the Carboniferous period. In Concept 26.4, we'll trace the origin and diversification of seed plants, continuing the story of adaptation to life on land.

#### CONCEPT CHECK 26.3

1. How do the main similarities and differences between seedless vascular plants and nonvascular plants influence function in these plants?
2. **MAKE CONNECTIONS** Figure 26.16 identifies lineages as land plants, nonvascular plants, vascular plants, seedless vascular plants, and seed plants. Which of these categories are monophyletic, and which are paraphyletic (see Figure 20.10)? Explain.
3. **MAKE CONNECTIONS** Monilophytes and seed plants both have megaphylls, as well as other traits not found in lycophytes. Explain this observation using Figure 26.16 and the concept of descent with modification (see Concept 19.2).

For suggested answers, see Appendix A.

## CONCEPT 26.4

### Seeds and pollen grains are key adaptations for life on land

Seed plants originated about 360 million years ago. As this new group of plants became established, they expanded

into a broad range of terrestrial environments, dramatically altering the course of plant evolution. This large impact was due in part to the innovation for which this group of plants is named: the seed. A **seed** consists of an embryo and its food supply, surrounded by a protective coat. When mature, seeds are dispersed from their parent by wind or other means.

Extant seed plants can be divided into two major clades, gymnosperms (pines and their relatives) and angiosperms (flowering plants). **Gymnosperms** (from the Greek *gymnos*, naked, and *sperm*, seed) are grouped together as “naked seed” plants because their seeds are not enclosed in chambers. In contrast, the seeds of **angiosperms** (from the Greek *angion*, container) develop inside chambers called ovaries. We'll begin our discussion of seed plants with an overview of their adaptations for life on land. Then we'll turn to their origin and evolutionary history.

### Terrestrial Adaptations in Seed Plants

In addition to seeds, all seed plants have reduced gametophytes, ovules, and pollen. These adaptations provided new ways for seed plants to cope with terrestrial conditions such as drought and exposure to the ultraviolet (UV) radiation in sunlight. These adaptations also freed seed plants from requiring water for fertilization, enabling reproduction to occur under a broader range of conditions than in seedless plants.

**(a) Unfertilized ovule.** In this longitudinal section through the ovule of a pine (a gymnosperm), a fleshy megasporangium is surrounded by a protective layer of tissue called an integument. The micropyle, the only opening through the integument, allows entry of a pollen grain.

**(b) Fertilized ovule.** A megaspore develops into a female gametophyte, which produces an egg. The pollen grain, which had entered through the micropyle, contains a male gametophyte. The male gametophyte develops a pollen tube that discharges sperm, thereby fertilizing the egg.

**(c) Gymnosperm seed.** Fertilization initiates the transformation of the ovule into a seed, which consists of a sporophyte embryo, a food supply, and a protective seed coat derived from the integument. The megasporangium dries out and collapses.

**▲ Figure 26.20 From ovule to seed in a gymnosperm.**

**?** A gymnosperm seed contains cells from how many different plant generations? Identify the cells and whether each is haploid or diploid.

## Reduced Gametophytes

Unlike mosses and other bryophytes, ferns and other seedless vascular plants have sporophyte-dominated life cycles. The evolutionary trend of gametophyte reduction continued further in the vascular plant lineage that led to seed plants. While the gametophytes of seedless vascular plants are visible to the naked eye, the gametophytes of most seed plants are microscopic (see Figure 26.19).

This miniaturization allowed for an important evolutionary innovation in seed plants: Their tiny gametophytes can develop from spores retained within the sporangia of the parental sporophyte. The moist reproductive tissues of the sporophyte shield the gametophytes from UV radiation and protect them from drying out. This relationship also enables the dependent gametophytes to obtain nutrients from the sporophyte. In contrast, the free-living gametophytes of seedless vascular plants must fend for themselves.

## Ovules and Pollen

Seed plants are unique in retaining the structures that develop into a female gametophyte within the parent sporophyte. Early in this process, a layer of sporophyte tissue called **integument** envelops and protects the tissues that will eventually give rise to the female gametophyte. The integument and the tissues it encloses together make up an **ovule** (Figure 26.20a). Inside each ovule, an egg-producing female gametophyte develops from a haploid spore. Spores that produce female gametophytes are called *megaspores* because they are larger than spores that produce male gametophytes (*microspores*).

A microspore develops into a **pollen grain** that consists of a male gametophyte enclosed within the pollen wall. The pollen wall, which contains sporopollenin, protects the gametophyte as it is transported from the parent plant by wind or by

hitchhiking on the body of an animal. The transfer of pollen to the part of a seed plant that contains the ovules is called **pollination**. If a pollen grain germinates (begins growing), it gives rise to a pollen tube that discharges sperm into the female gametophyte within the ovule, as shown in Figure 26.20b.

Recall that in nonvascular plants and seedless vascular plants such as ferns, free-living gametophytes release flagellated sperm that swim through a film of water to reach eggs; given this requirement, it is not surprising that many of these species are found in moist habitats. But in seed plants, a sperm-producing male gametophyte inside a pollen grain can be carried long distances by wind or animals, eliminating the dependence on water for sperm transport. The ability of seed plants to transfer sperm without water likely contributed to their successful colonization of dry habitats.

## The Evolutionary Advantage of Seeds

If a sperm fertilizes an egg of a seed plant, the zygote grows into a sporophyte embryo. As shown in Figure 26.20c, the whole ovule develops into a seed: the embryo, along with a food supply, packaged within a protective coat derived from the integument.

Until the advent of seeds, the spore was the only protective stage in any plant life cycle. What advantages do seeds provide over spores? Spores are usually single-celled, whereas seeds are multicellular, consisting of an embryo protected by a layer of tissue, the seed coat. A seed can remain dormant for days, months, or even years after being released from the parent plant, whereas most spores have shorter lifetimes. Also, unlike spores, seeds have a supply of stored food. Under favorable conditions, the seed can emerge from dormancy and germinate, with its stored food providing critical support for growth as the sporophyte embryo emerges as a seedling.

## Early Seed Plants and the Rise of Gymnosperms

Recall from Figure 26.16 that extant seed plants form two sister clades: gymnosperms and angiosperms. How did these two groups arise?

Fossils reveal that by the late Devonian period (about 380 million years ago), some plants had acquired features found in seed plants, such as the megaspores and microspores mentioned earlier. But these plants did not bear seeds and hence are not classified as seed plants. The first seed plants to appear in the fossil record date from around 360 million years ago, 55 million years before the first fossils of extant gymnosperms and more than 200 million years before the first angiosperm fossils. These early seed plants became extinct, and it remains uncertain which of these extinct lineages ultimately gave rise to the gymnosperms.

The earliest fossils of extant gymnosperms are about 305 million years old. These early gymnosperms lived in moist Carboniferous ecosystems still dominated by lycophytes, ferns, and other seedless vascular plants. As the Carboniferous period gave way to the Permian (299 million years ago), the climate became much drier. As a result, the lycophytes and ferns that dominated moist Carboniferous swamps were largely replaced by gymnosperms, which were better suited to the drier climate.

Gymnosperms thrived as the climate dried in part because they have the key terrestrial adaptations found in all seed plants, such as seeds and pollen. In addition, some gymnosperms were particularly well suited to arid conditions because of the thick cuticles and relatively small surface areas of their needle-shaped leaves. Today, gymnosperms remain an important part of Earth's flora (**Figure 26.21**). For example, vast regions in northern latitudes are covered by forests of cone-bearing gymnosperms called **conifers**, which include spruce, pine, fir, and redwood. Yet despite the ongoing importance of gymnosperms, most terrestrial ecosystems are now dominated by the group we turn to next, the angiosperms.

## The Origin and Diversification of Angiosperms

Commonly known as flowering plants, angiosperms are seed plants that produce the reproductive structures called flowers and fruits. Today, angiosperms are the most diverse and widespread of all plants, with more than 250,000 species (about 90% of all plant species). Before considering the evolution of angiosperms, we'll examine their two key adaptations—flowers and fruits.

### Flowers and Fruits

The **flower** is a unique angiosperm structure specialized for sexual reproduction. In many angiosperm species, insects or other animals transfer pollen from one flower to the sex organs on another flower, which makes pollination more directed than the wind-dependent pollination of most gymnosperms.

(a) **Sago palm (*Cycas revoluta*)**. This “palm” is actually a cycad, the next largest group of gymnosperms after the conifers (true palms are flowering plants). Cycads have large cones and palmlike leaves.

(b) **Douglas fir (*Pseudotsuga menziesii*)**. This conifer dominates large forested regions and provides more timber than any other North American tree species.

(c) **Creeping juniper (*Juniperus horizontalis*)**. The “berries” of this low-growing conifer are actually ovule-producing cones consisting of fleshy sporophylls.

▲ **Figure 26.21 Examples of gymnosperms.**

A flower is a specialized shoot that can have up to four types of modified leaves called floral organs: sepals, petals, stamens, and carpels (**Figure 26.22**). Starting at the base of the flower are the **sepals**, which are usually green and enclose the flower before it opens (think of a rosebud). Interior to the sepals are the **petals**, which are brightly colored in most flowers and aid

▲ **Figure 26.22** The structure of an idealized flower.

in attracting pollinators. Flowers that are wind-pollinated, however, generally lack brightly colored parts. In all angiosperms, the sepals and petals are sterile floral organs, meaning that they do not produce sperm or eggs. Within the petals are two whorls of fertile floral organs, the stamens and carpels. **Stamens** produce pollen grains containing male gametophytes. A stamen consists of a stalk called the filament and a terminal sac, the anther, where pollen is produced. **Carpels** make ovules, which, as in gymnosperms, contain female gametophytes. At the tip of the carpel is a sticky stigma that receives pollen. A style leads from the stigma to a structure at the base of the carpel, the **ovary**; the ovary contains one or more ovules. If fertilized, an ovule develops into a seed.

As seeds develop from ovules after fertilization, the ovary wall thickens and the ovary matures into a **fruit**. A pea pod is an example of a fruit, with seeds (mature ovules, the peas) encased in the ripened ovary (the pod). Fruits protect seeds and aid in their dispersal (see Figure 30.12). For example, the seeds of some flowering plants, such as dandelions and maples, are contained within fruits that function like parachutes or propellers, adaptations that enhance dispersal by wind. Many other angiosperms rely on animals to carry seeds. Some of these plants have fruits modified as burrs that cling to animal fur (or the clothes of humans). Other angiosperms produce edible fruits, which are usually nutritious, sweet tasting, and vividly colored, advertising their ripeness. When an animal eats the fruit, it digests the fruit's fleshy part, but the tough seeds usually pass unharmed through the

animal's digestive tract. When the animal defecates, it may deposit the seeds, along with a supply of natural fertilizer, many kilometers from where the fruit was eaten.

## Angiosperm Evolution

Charles Darwin once referred to the origin of angiosperms as an “abominable mystery.” He was particularly troubled by the relatively sudden and geographically widespread appearance of angiosperms in the fossil record. Fossil evidence and phylogenetic analyses have led to progress in solving Darwin's mystery, but we still do not fully understand how angiosperms arose from earlier seed plants.

**Fossil Evidence** Angiosperms are thought to have originated in the early Cretaceous period, about 140 million years ago. By the mid-Cretaceous (100 million years ago), angiosperms began to dominate some terrestrial ecosystems. Landscapes changed dramatically as conifers and other gymnosperms gave way to flowering plants in many parts of the world. The Cretaceous ended 65 million years ago with mass extinctions of dinosaurs and many other animal groups and with further increases in the diversity and importance of angiosperms.

What evidence suggests that angiosperms arose 140 million years ago? First, although pollen grains are common in rocks from the Jurassic period (200–145 million years ago), none of these pollen fossils have features diagnostic of angiosperms, suggesting that angiosperms may have originated after the Jurassic. Indeed, the earliest fossils with distinctive angiosperm features are 130-million-year-old pollen grains discovered in China, Israel, and England. Early fossils of larger flowering plant structures include those of *Archaeoфраctus* (Figure 26.23) and

(a) *Archaeoфраctus sinensis*, a 125-million-year-old fossil. This species may represent the sister group to all other angiosperms, or it may belong to the water lily group. Researchers are testing these two hypotheses with phylogenetic analyses.

(b) Artist's reconstruction of *Archaeoфраctus sinensis*

▲ **Figure 26.23** An early flowering plant.

*Leefructus*, both of which were discovered in China in rocks that are about 125 million years old. Overall, early angiosperm fossils indicate that the group arose and began to diversify over a 20- to 30-million-year period—a less sudden event than was suggested by the fossils known during Darwin’s lifetime.

Can we infer traits of the angiosperm common ancestor from traits found in early fossil angiosperms? *Archaeofructus*, for example, was herbaceous and had bulbous structures that may have served as floats, suggesting it was aquatic. But investigating whether the common ancestor of angiosperms was herbaceous and aquatic also requires examining fossils of other seed plants thought to have been closely related to angiosperms. All of those plants were woody, indicating that the common ancestor was probably woody. As we’ll see, this conclusion has been supported by recent phylogenetic analyses.

**Angiosperm Phylogeny** Molecular and morphological evidence suggests that living gymnosperm lineages diverged from the ancestors of angiosperms about 305 million years ago. Indeed, extant angiosperms may be more closely related to several extinct lineages of woody seed plants than they are to living gymnosperms. One such lineage is the Bennettitales, a group with flowerlike structures that may have been pollinated by insects (**Figure 26.24**).

© 1944 The Royal Society, and  
© 1985 Missouri Botanical Garden Press

▲ **Figure 26.24 A close relative of the angiosperms?** This reconstruction shows a longitudinal section through the flowerlike structures found in Bennettitales, an extinct group of seed plants hypothesized to be more closely related to extant angiosperms than to living gymnosperms.

**MAKE CONNECTIONS** Suppose the Bennettitales and extant angiosperms are sister taxa. Draw a phylogenetic tree that includes Bennettitales, angiosperms, gymnosperms, monilophytes, extant lycophytes. Identify the common ancestor and circle the basal taxon (see Figure 20.5).

Making sense of the origin of angiosperms also depends on working out the order in which angiosperm clades diverged from one another. Here, dramatic progress has been made in

## ▼ Figure 26.25 Exploring Angiosperm Phylogeny

The phylogenetic tree below represents one current hypothesis of angiosperm evolutionary relationships, based on morphological and molecular evidence.

■ **Amborella.** This small shrub (*Amborella trichopoda*), found only on the South Pacific island of New Caledonia, may be the sole survivor of a branch at the base of the angiosperm tree. *Amborella* lacks vessels, efficient water-conducting cells found in angiosperms in later-diverging lineages.

■ **Water lilies.** Species of water lilies (genus *Nymphaea*) are found in aquatic habitats throughout the world. Water lilies are living members of a clade that may be predated only by the *Amborella* lineage.

recent years. Molecular and morphological evidence suggests that a small South Pacific shrub called *Amborella trichopoda* and water lilies are living representatives of two of the most ancient angiosperm lineages (**Figure 26.25**). *Amborella* is woody, supporting the conclusion mentioned earlier that the angiosperm common ancestor was likely woody. Among the other lineages shown in Figure 26.25, the monocots and eudicots in particular have radiated extensively: There are now 70,000 species of monocots and 170,000 species of eudicots.

From their humble beginnings in the Cretaceous, angiosperms have diversified into more than 250,000 species, making them by far the largest group of living plants. This large group, along with fungi and nonflowering plants, has enormous ecological and evolutionary effects on other species.

#### CONCEPT CHECK 26.4

1. What features not present in seedless plants have contributed to the enormous success of seed plants on land?
2. Explain why Darwin called the origin of angiosperms an “abominable mystery,” and describe what has been learned from fossil evidence and phylogenetic analyses.
3. **MAKE CONNECTIONS** Does the hypothesis that living gymnosperms and angiosperms are sister clades imply that they originated at the same time (see Figure 20.5)?

For suggested answers, see Appendix A.

## CONCEPT 26.5

### Land plants and fungi fundamentally changed chemical cycling and biotic interactions

Throughout Unit Four, we are highlighting major steps in the evolutionary history of life. We have focused on great waves of adaptive radiation, such as the metabolic diversification of prokaryotes (Chapter 24) and the rise in structural diversity that followed the origin of eukaryotes (Chapter 25). In this chapter, we’ve examined another major step in the history of life: the colonization of land by plants and fungi. Let’s now explore how the colonization of land has altered the physical environment and the organisms that live there.

#### Physical Environment and Chemical Cycling

Fungi and plants have profound effects on the physical environment. Consider a **lichen**, a symbiotic association between a fungus and a photosynthetic microorganism. Lichens are important pioneers on cleared rock and soil surfaces, such as volcanic flows and burned forests. They break down the surface by physically penetrating and chemically altering it,

**Star anise.** Some of the shrubs and small trees in this genus (*Illicium*) are native to southeast Asia, others to the southeastern United States. Living species in the genus probably descended from ancestors whose populations were separated by continental drift.

**Magnoliids.** This clade consists of about 8,000 woody and herbaceous species, including such familiar and economically important plants as magnolias, laurels, avocado, cinnamon, and black pepper. The variety of southern magnolia shown here (*Magnolia grandiflora*, also called “Goliath”), has flowers that can measure up to about a foot across.

**Monocots.** Over 25% of extant angiosperms are monocots. This large clade includes the most important crop plants in the world today: grains such as maize, rice, and wheat. Other monocots are widely used as ornamental plants, such as the pygmy date palm (*Phoenix roebelenii*) shown at left. The monocots also include plants such as orchids, grasses, irises, and onions.

**Eudicots.** Nearly 70% of living flowering plants are eudicots. One example, zucchini, a subspecies of *Cucurbita pepo*, is an important crop, as are acorn squash, pumpkin, and other *C. pepo* subspecies. The eudicots also include sunflowers, roses, cacti, clovers, oaks, and a wide range of other species.

and they trap windblown soil. These processes affect the formation of soil and make it possible for plants to grow. **Figure 26.26** shows two examples of the diverse forms of lichens along with the structure of a lichen composed of a fungus and a green alga. Fossils show that lichens were on land 420 million years ago. These early lichens may have modified rocks and soil much as they do today, helping pave the way for plants.

The colonization of land by plants resulted in great changes to the physical environment. Like lichens, plants affect the formation of soil: Their roots hold the soil in place, and leaf litter and other decaying plant parts add nutrients to the soil. Plants also have altered the composition of Earth's atmosphere, perhaps most importantly by releasing oxygen to the air as a by-product of photosynthesis.

Plants and fungi also have profound effects on the cycling of chemicals in ecosystems (see Figure 1.9). This process begins when plants absorb nutrients from the physical environment. Next, those nutrients pass to organisms that eat plants. Decomposers then break down the bodies of dead organisms, thereby returning nutrients to the physical environment and completing the cycle. Fungi are well adapted as decomposers of organic material. In fact, almost any carbon-containing substrate—even jet fuel and house paint—can be consumed by at least some fungi. (The same is true of bacteria.) As a result, fungi and bacteria play a central role in keeping ecosystems stocked with the inorganic nutrients essential for plant growth. Without these decomposers, carbon, nitrogen, and other elements would remain tied up in organic matter; if that were to happen, life as we know it would cease.

Let's take a closer look at how plants affect carbon recycling. Carbon forms the basis of the organic compounds that are essential for life. During photosynthesis, plants remove large quantities of  $\text{CO}_2$  from the atmosphere—an action that can influence the global climate. A dramatic example occurred when seedless vascular plants first grew tall, forming the first forests about 385 million years ago (**Figure 26.27**). With the evolution of vascular tissue, roots, and leaves, these plants accelerated their rate of photosynthesis, greatly increasing the removal of  $\text{CO}_2$  from the atmosphere. Scientists estimate that  $\text{CO}_2$  levels dropped by up to a factor of five during the Carboniferous (359–299 million years ago), causing global cooling that resulted in widespread glacier formation. Today, plants continue to influence carbon cycling and thereby both the global climate and the extent of global climate change (see Chapters 42 and 43).

(a) Two common lichen growth forms

(b) Anatomy of a lichen involving an ascomycete fungus and an alga

▲ **Figure 26.26 Lichens.** Often found growing on rocks or rotting logs, lichens are a symbiotic association between a fungus and a photosynthetic microorganism (a green alga or a cyanobacterium).

▲ **Figure 26.27 Artist's conception of a Carboniferous forest based on fossil evidence.** In addition to plants, animals, including giant dragonflies like the one in the foreground, also thrived in Carboniferous forests.

## Biotic Interactions

The colonization of land by plants and fungi also had a dramatic effect on interactions between members of different species. Such biotic interactions include those in which both species benefit (mutualism) and those in which one species benefits while the other is harmed (as when a parasite feeds on its host).

Plants and fungi had such large effects on biotic interactions because their presence on land increased the availability of energy and nutrients for other organisms. For example, during photosynthesis, plants convert light energy to the chemical energy of food. That chemical energy supports all life on land, either directly (as when an insect eats a plant leaf) or indirectly (as when a bird eats an insect that ate a plant). Likewise, nitrogen and other nutrients are first absorbed by plants and then passed to organisms that eat plants; ultimately, these nutrients are returned to the environment by the actions of fungi and other decomposers. If plants and fungi had not colonized land, biotic interactions would still result in the transfer of energy and nutrients, but those transfers would likely occur on a much

### ▼ Figure 26.28 Inquiry

#### Do endophytes benefit a woody plant?

**Experiment** Endophytes are symbiotic fungi found within the bodies of all plants examined to date. Researchers tested whether endophytes benefit the cacao tree (*Theobroma cacao*). This tree, whose name means “food of the gods” in Greek, is the source of the beans used to make chocolate, and it is cultivated throughout the tropics. Endophytes were added to the leaves of some cacao seedlings, but not others. (In cacao, endophytes colonize leaves after the seedling germinates.) The seedlings were then inoculated with a virulent pathogen, the protist *Phytophthora*.

**Results** Fewer leaves were killed by the pathogen in seedlings with endophytes than in seedlings without endophytes. Among leaves that survived, pathogens damaged less of the leaf surface area in seedlings with endophytes than in seedlings without endophytes.

- Endophyte not present; pathogen present (E–P+)
- Both endophyte and pathogen present (E+P+)

**Conclusion** Endophytes appear to benefit cacao trees by reducing the leaf mortality and damage caused by *Phytophthora*.

**Source** A. E. Arnold et al., Fungal endophytes limit pathogen damage in a tropical tree, *Proceedings of the National Academy of Sciences* 100:15649–15654 (2003).

**WHAT IF?** The researchers also performed control treatments. Suggest two controls they might have used, and explain how each would be helpful in interpreting the results described here.

smaller scale, such as that of the “green slime” mentioned earlier in the chapter.

The previous paragraphs describe the big picture of how plants and fungi have affected biotic interactions. We’ll close the chapter with several specific examples.

### Fungi as Mutualists and Pathogens

The different enzymes found in various fungal species can digest compounds from a wide range of sources, living or dead. This diversity of food sources corresponds to the varied roles of fungi in ecological communities, with different species living as decomposers, mutualists, or parasites. Having already described the importance of fungi as decomposers, we’ll focus here on mutualism and parasitism.

Mutualistic fungi absorb nutrients from a host organism, but they reciprocate with actions that benefit the host—as we already saw for the enormously important mycorrhizal associations that fungi form with most vascular plants. In addition, all plant species studied to date appear to harbor symbiotic **endophytes**, fungi that live inside leaves or other plant parts without causing harm. Endophytes have been shown to benefit certain grasses by making toxins that deter herbivores or by increasing host plant tolerance of heat, drought, or heavy metals. Seeking to discover how endophytes affect a woody plant, researchers tested whether leaf endophytes benefit seedlings of the cacao tree, *Theobroma cacao* (Figure 26.28). Their findings show that the endophytes of woody flowering plants can play an important role in defending against pathogens.

Parasitic fungi also absorb nutrients from the cells of living hosts, but they provide no benefits in return (Figure 26.29).

▲ **Figure 26.29 Examples of fungal diseases of plants.** About 30% of the 100,000 known species of fungi make a living as parasites or pathogens, mostly of plants.

Some parasitic fungi are pathogenic, including many species that cause diseases in plants. For example, *Cryphonectria parasitica*, the ascomycete fungus that causes chestnut blight, dramatically changed the landscape of the northeastern United States. Accidentally introduced on trees imported from Asia in the early 1900s, spores of the fungus enter cracks in the bark of American chestnut trees and produce hyphae, killing the tree. The once-common chestnuts now survive mainly as sprouts from the stumps of former trees.

### Plant-Animal Interactions

Plants and animals have interacted for hundreds of millions of years, and those interactions have led to evolutionary change. For example, herbivores can reduce a plant's reproductive success by eating its roots, leaves, or seeds. As a result, if an effective defense against herbivores originates in a group of plants, those plants may be favored by natural selection—as will any herbivores that can overcome this new defense.

Interactions between plants and animals also may have affected the rates at which new species form. Consider the impact of flower shape, which can be symmetric in one direction only (*bilateral symmetry*) or symmetric in all directions (*radial symmetry*). On a flower with bilateral symmetry, an insect pollinator may only be able to enter the flower from a certain direction. This constraint can make it more likely that as an insect moves from flower to flower, pollen is placed on a part of the insect's body that will come into contact with the stigma of a flower of the same species.

Such specificity of pollen transfer tends to reduce gene flow between diverging populations and hence could lead to increased rates of plant speciation in plants with bilateral symmetry. This hypothesis can be tested using the approach illustrated in this diagram:

A key step is to identify cases in which a clade with bilaterally symmetric flowers shares an immediate common ancestor with a clade whose members have radially symmetric flowers. One recent study identified 19 such pairs of closely related “bilateral” and “radial” clades. On average, the clade with bilaterally symmetric flowers had nearly 2,400 more species than did its closely related clade with radially symmetric flowers. This result suggests that flower shape can affect the rate at which new species form—perhaps because of how flower shape affects the behavior of insect pollinators. Overall, the effects of plant-pollinator interactions are thought to have contributed

(a) A satellite image from 2000 shows clear-cut areas in Brazil (brown) surrounded by dense tropical forest (green).

(b) By 2009, much more of this same tropical forest had been cut down.

▲ **Figure 26.30 Clear-cutting of tropical forests.** Over the past several hundred years, nearly half of Earth's tropical forests have been cut down and converted to farmland and other uses.

to the diversification and increasing dominance of flowering plants in the Cretaceous period.

While angiosperms continue to dominate the communities of today, they and other plant groups are being threatened by the exploding human population and its demand for space and resources. The problem is especially severe in the tropics, where more than two-thirds of the human population live and where population growth is fastest. About 55,000 km<sup>2</sup> (14 million acres) of tropical rain forest are cleared each year (**Figure 26.30**), a rate that would completely eliminate the remaining 11 million km<sup>2</sup> of tropical forests in 200 years. As forests disappear, so do large numbers of plant species. Of course, once a species becomes extinct, it can never return.

The loss of plant species is often accompanied by the loss of insects and other rain forest animals. Scientists estimate that if current rates of loss in the tropics and elsewhere continue, 50% or more of Earth's species will become extinct within the next few centuries. Such losses would constitute a global mass extinction, rivaling the Permian and Cretaceous mass extinctions and changing the evolutionary history of life—including that of the animals, the group we'll turn to in Chapter 27.

### CONCEPT CHECK 26.5

1. Describe how terrestrial fungi and land plants have affected the physical environment.
2. Discuss the importance of fungi as mutualists and parasites.
3. **MAKE CONNECTIONS** Figure 1.9 illustrates the transfer of energy and matter in ecosystems. Draw a simple diagram of energy flow and chemical cycling in a terrestrial ecosystem; circle the steps that were affected by the colonization of land by plants and fungi.
4. **WHAT IF?** Explain why researchers testing whether flower shape (bilateral versus radial) affected speciation rates only analyzed cases in which a bilateral clade shared an immediate common ancestor with a radial clade.

For suggested answers, see Appendix A.

# 26 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 26.1

#### Fossils show that plants colonized land more than 470 million years ago (pp. 505–508)

- Morphological and biochemical traits, as well as similarities in nuclear and chloroplast gene sequences, indicate that land plants arose from charophyte green algae.
- A protective layer of **sporopollenin** and other traits allow charophytes to tolerate occasional drying along the edges of ponds and lakes. Such traits may have enabled the algal ancestors of plants to survive in terrestrial conditions, opening the way to the colonization of dry land.
- Derived traits that distinguish land plants from charophytes, their closest algal relatives, include **apical meristems**, **cuticles**, **stomata**, and the two shown here:

- Fossil evidence indicates that plants were inhabiting land by 470 million years ago. By 400 million years ago, a diverse assemblage of fossil plant species lived on land, some of which had specialized tissues for water transport, stomata, and branched sporophytes.

? The oldest fossil representing a large structure from a plant is 425 million years old, yet scientists think that plants colonized land 470 million years ago. What evidence supports this idea?

### CONCEPT 26.2

#### Fungi played an essential role in the colonization of land (pp. 508–513)

- All **fungi** are heterotrophs that acquire nutrients by absorption. Many fungi secrete enzymes that break down complex molecules to smaller molecules that can be absorbed.
- The cell walls of fungi are strengthened by **chitin**, a strong but flexible polysaccharide; these strong cell walls enable the cell to absorb nutrients and water without bursting.
- Most fungi grow as thin, multicellular filaments called **hyphae**; relatively few species grow only as single-celled **yeasts**. In their multicellular form, fungi consist of **mycelia**, networks of branched hyphae adapted for absorption. Mycorrhizal fungi have specialized hyphae that enable them to form a mutually beneficial relationship with plants.

- Fungi typically propagate themselves by producing **spores**, either sexually or asexually. Spores can be transported by wind or water; if they are deposited in a moist place that has food, they germinate, producing new mycelia.
- Although fungi likely colonized land before plants, the earliest fossils of fungi date to 460 million years ago. Once on land, some fungi formed mycorrhizal associations with early plants—a symbiosis that probably helped plants without roots to colonize land.
- Molecular data show that fungi arose from a single-celled protist and are more closely related to animals than to plants or most other eukaryotes. Since colonizing land, fungi have radiated into a diverse set of lineages.

? Explain how the morphology of multicellular fungi affects the efficiency of nutrient absorption and may have played a role in the colonization of land by plants.

### CONCEPT 26.3

#### Early land plants radiated into a diverse set of lineages (pp. 513–516)

- The three extant phyla of nonvascular plants, or **bryophytes**—liverworts, mosses, and hornworts—are the earliest-diverging plant lineages.
- In bryophytes, the dominant generation consists of haploid **gametophytes**, such as those that make up a carpet of moss. The flagellated sperm require a film of water to travel to the eggs.
- Fossils of the forerunners of today's vascular plants date back 425–420 million years and show that these small plants lacked seeds but had independent, branching sporophytes and a well-developed vascular system.
- Over time, other derived traits of living vascular plants arose, such as a life cycle with dominant sporophytes; lignified vascular tissue; and well-developed roots and leaves.
- Seedless vascular plants formed the first forests about 385 million years ago. Today, seedless vascular plants include the **lycophytes** (club mosses and their relatives) and the **monilophytes** (ferns and their relatives).

? What trait(s) allowed vascular plants to grow tall, and why might increased height have been advantageous?

### CONCEPT 26.4

#### Seeds and pollen grains are key adaptations for life on land (pp. 516–521)

- Derived traits of seed plants include **seeds** (which survive better than spores), highly reduced gametophytes (which are nourished and protected by the sporophyte), **ovules** (which house female gametophytes), and pollen (which eliminates dependency on water for fertilization).
- Seed plants originated 360 million years ago. Living seed plants can be divided into two monophyletic groups: **gymnosperms** and **angiosperms**. Gymnosperms appear early in the seed plant fossil record and dominated many terrestrial ecosystems until angiosperms (flowering plants) began to replace them 100 million years ago.
- **Flowers** typically have four whorls of modified leaves: **sepals**, **petals**, **stamens**, and **carpels**. Ovaries ripen into **fruits**, which often carry seeds by wind, water, or animals to new locations.

**Flower anatomy**

- Angiosperms arose and diversified greatly during the Cretaceous period. Fossils and phylogenetic analyses offer insights into the origin of flowering plants, which today are by far the largest group of extant land plants. The two most diverse angiosperm clades are monocots and eudicots.

**?** Summarize fossil and phylogenetic evidence that suggests that the angiosperm common ancestor was likely woody.

## CONCEPT 26.5

### Land plants and fungi fundamentally changed chemical cycling and biotic interactions (pp. 521–524)

- Lichens** and plants affect soil formation. Plants also alter the composition of Earth's atmosphere by releasing oxygen to the air as a by-product of photosynthesis.
- Plants play a central role in chemical cycling by absorbing nutrients from the physical environment; those nutrients then pass to organisms that eat plants. Fungal decomposers break down the bodies of dead organisms; this returns nutrients to the physical environment, completing the cycle.
- Since colonizing land, the activities of plants and fungi have altered biotic interactions by increasing the availability of energy and nutrients for other organisms.
- Fungi play key ecological roles as decomposers, mutualists (such as **endophytes** that help protect plants from herbivores and pathogens), and parasites.
- Interactions between plants and animals have led to natural selection in plant and animal populations and may have affected speciation rates. Destruction of habitat threatens the extinction of many plant species and the animal species they support.

**?** Summarize how plants and fungi have increased the availability of energy and nutrients for other organisms, and explain how this affects biotic interactions.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- All fungi are
  - symbiotic
  - heterotrophic
  - flagellated
  - pathogenic
  - decomposers

- Which of the following characteristics of plants is absent in their closest relatives, the charophyte algae?
  - chlorophyll *b*
  - cellulose in cell walls
  - multicellularity
  - sexual reproduction
  - alternation of generations
- Identify each of the following structures as haploid or diploid.
  - sporophyte
  - spore
  - gametophyte
  - zygote
  - sperm
- A fruit is usually
  - a mature ovary.
  - a thickened style.
  - an enlarged ovule.
  - a modified root.
  - a mature female gametophyte.
- Among the organisms listed here, which are thought to be the closest relatives of fungi?
  - slime molds
  - vascular plants
  - animals
  - brown algae
  - mosses

### Level 2: Application/Analysis

- The adaptive advantage associated with the filamentous nature of fungal mycelia is primarily related to
  - the ability to form haustoria and parasitize other organisms.
  - avoiding sexual reproduction until the environment changes.
  - the potential to inhabit almost all terrestrial habitats.
  - the increased probability of contact between different mating types.
  - an extensive surface area well suited for invasive growth and absorptive nutrition.
- DRAW IT** Use the letters a–d to label where on the phylogenetic tree each of the following derived characters appears.
  - flowers
  - embryos
  - seeds
  - vascular tissue

### 8. SCIENTIFIC INQUIRY

**DRAW IT** The grass *Dichanthelium languinosum* lives in hot soils and houses fungi of the genus *Curvularia* as endophytes. Researchers performed field experiments to test the impact of *Curvularia* on the heat tolerance of this grass. They grew plants without (E–) and with (E+) *Curvularia* endophytes in soils of different temperatures and measured plant mass and the number of new shoots the plants produced. Draw a bar graph of the results for plant mass versus temperature and interpret it.

Soil Temp.	<i>Curvularia</i> Presence	Plant Mass (g)	Number of New Shoots
30°C	E–	16.2	32
	E+	22.8	60
35°C	E–	21.7	43
	E+	28.4	60
40°C	E–	8.8	10
	E+	22.2	37
45°C	E–	0	0
	E+	15.1	24

**Source** R. S. Redman et al., *Science* 298:1581 (2002).

### Level 3: Synthesis/Evaluation

#### 9. FOCUS ON EVOLUTION

The history of life has been punctuated by several mass extinctions. For example, the impact of a meteorite may have wiped out most of the dinosaurs and many forms of marine life at the end of the Cretaceous period (see Chapter 23). Fossils indicate that plants were less severely affected by this mass extinction. What adaptations may have enabled plants to withstand this disaster better than animals?

#### 10. FOCUS ON INTERACTIONS

Giant lycophyte trees of Earth's early forests (see Figure 26.27) had microphylls, whereas ferns and seed plants have megaphylls. Write a short essay (100–150 words) describing how a forest of lycophyte trees may have differed from a forest of large ferns or seed plants. In your answer, consider how the type of forest in which they grew may have affected interactions among small plants growing beneath the tall ones.

*For selected answers, see Appendix A.*

### MasteringBiology®

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# 27

## The Rise of Animal Diversity

▼ **Figure 27.1** What adaptations make a chameleon a fearsome predator?

### KEY CONCEPTS

- 27.1** Animals originated more than 700 million years ago
- 27.2** The diversity of large animals increased dramatically during the “Cambrian explosion”
- 27.3** Diverse animal groups radiated in aquatic environments
- 27.4** Several animal groups had features that facilitated their colonization of land
- 27.5** Animals have transformed ecosystems and altered the course of evolution

### OVERVIEW

## Life Becomes Dangerous

**A**lthough slow moving on its feet, the chameleon in **Figure 27.1** can wield its long, sticky tongue with blinding speed to capture unsuspecting prey. Other animals overwhelm their prey using their strength, speed, or toxins, while still others build traps or blend into their surroundings, enabling them to capture unwary prey. And hunting animals are not the only ones that pose a threat to other organisms. Herbivorous animals can strip the plants they eat bare of leaves or seeds, while parasitic animals weaken their hosts by consuming their tissues or body fluids.

As these examples suggest, animals can make life dangerous for the organisms around them. Most animals are mobile and can detect, capture, and eat other organisms—including those that are mobile themselves and can flee from attack. Indeed, all but the simplest animals have specialized muscle and nerve cells that allow them to move and respond rapidly to changing environmental conditions. Most animals also have a complete digestive tract, an efficient digestive system that has a mouth at one end and an anus at the other. Together, their mobility, nervous system, and digestive tract, accompanied by often complex behaviors, make animals highly effective eating machines.

Animals are so integral to our lives today that it is difficult to imagine what Earth would be like without animals. The fossil record, however, paints an intriguing picture. Large eukaryotes were once soft-bodied and lived in a relatively safe world—until the appearance of animals changed everything. In this chapter, we’ll examine how animals have evolved over time and influenced the world around them.

### CONCEPT 27.1

## Animals originated more than 700 million years ago

Current evidence indicates that animals evolved from single-celled eukaryotes similar to present-day choanoflagellates (see Chapter 25). These early animals have given rise to a vast diversity of living animal species: To date, biologists have named more than 1.3 million species, and estimates of the actual number

(a) *Dickinsonia costata*  
(taxonomic affiliation  
unknown)

(b) The fossil  
mollusc *Kimberella*

### ▲ Figure 27.2 Ediacaran fossils.

Fossils dating to about 560 million years ago include the earliest macroscopic fossils of animals, including these two species. Earlier members of the Ediacaran biota include the alga *Doushantuophyton* (see Figure 25.2).

run far higher—nearly 8 million species according to one recent study. When did this diverse group originate?

## Fossil and Molecular Evidence

Researchers have unearthed 710-million-year-old sediments containing the fossilized remains of steroids that today are primarily produced by a particular group of sponges. Hence, these fossil steroids suggest that animals had arisen by 710 million years ago.

DNA analyses generally agree with this fossil biochemical evidence; for example, one recent molecular clock study

estimated that sponges originated about 700 million years ago. These findings are also consistent with molecular analyses suggesting that the common ancestor of all extant (living) animal species lived about 770 million years ago.

Despite the data from molecular clocks and fossil steroids indicating an earlier origin, the first generally accepted macroscopic fossils of animals date from about 560 million years ago (**Figure 27.2**). These fossils are members of an early group of soft-bodied multicellular eukaryotes known collectively as the **Ediacaran biota**. The name comes from the Ediacara Hills of Australia, where fossils of these organisms were first discovered. Similar fossils have since been found on other continents. Among the Ediacaran fossils that resemble animals, some may be sponges, while others may be related to living cnidarians (sea anemones and their relatives) and molluscs (snails and their relatives). Still others are difficult to classify, as they do not seem to be closely related to any living animals or algae.

## Early-Diverging Animal Groups

As the first animals evolved over time, their descendants gave rise to several early-diverging groups, two of which we'll discuss here: sponges and cnidarians.

## Sponges

Animals in the phylum Porifera are known informally as sponges (**Figure 27.3**). (Recent molecular studies indicate that sponges are monophyletic, and that is the phylogeny we present

Azure vase sponge (*Callyspongia plicifera*)

**3 Choanocytes.** The sponge has a central cavity lined with cells called choanocytes. By beating their flagella, the choanocytes create a current that draws water in through the pores and out through the top of the cavity.

**2 Pores.** Water enters the sponge through pores formed by doughnut-shaped cells that span the body wall.

**1** The outer layer of this sponge consists of tightly packed epidermal cells; its wall has two layers of cells separated by a gelatinous matrix.

**4** The movement of a choanocyte's flagellum also draws water through its collar of finger-like projections. Food particles are trapped in the mucus that coats the projections, engulfed by phagocytosis, and either digested or transferred to amoebocytes.

**5 Amoebocytes.** These cells can transport nutrients to other cells of the sponge body.

▲ **Figure 27.3** Anatomy of a sponge.

here; this remains under debate, however, as some studies suggest that sponges are paraphyletic.) Among the simplest of animals, sponges are sedentary and were mistaken for plants by the ancient Greeks. Most species are marine, and they range in size from a few millimeters to a few meters. Sponges are **filter feeders**: They filter out food particles suspended in the water as they draw it through their body (see Figure 27.3).

Sponges represent a lineage that originates near the root of the phylogenetic tree of animals; thus, they are said to be *basal animals*. Unlike nearly all other animals, sponges lack **tissues**, groups of similar cells that act as a functional unit. However, the sponge body does contain several different cell types. For example, the interior of the body is lined with flagellated **choanocytes**, or collar cells (named for the finger-like projections that form a “collar” around the flagellum). These cells engulf bacteria and other food particles by phagocytosis. Choanocytes resemble the cells of choanoflagellates, a finding that is consistent with the similarities between the DNA sequences of sponges and those of choanoflagellates. Together, these results suggest that animals evolved from a choanoflagellate-like ancestor (see Figure 25.7). Sponges also have mobile cells called **amoebocytes**, named for their use of pseudopodia. As these cells move through the sponge body, they take up food from the surrounding water and from choanocytes, digest it, and carry nutrients to other cells.

### Cnidarians

All animals except sponges and a few other groups are *eumetazoans* (“true animals”), members of a clade of animals that have tissues. One of the oldest lineages in this clade is the phylum Cnidaria, which originated about 680 million years ago according to molecular clock analyses. Cnidarians have diversified into a wide range of sessile and motile forms, including hydrozoans, jellies, and sea anemones (Figure 27.4).

The basic morphology of a cnidarian is a sac with a central digestive compartment, the **gastrovascular cavity**. A single

opening to this cavity functions as both mouth and anus. Cnidarians are carnivores that often use tentacles arranged in a ring around their mouth to capture prey and pass the food into their gastrovascular cavity. Enzymes are then secreted into the cavity, breaking down the prey into a nutrient-rich broth. Cells lining the cavity then absorb these nutrients and complete the digestive process; any undigested remains are expelled through the cnidarian’s mouth/anus.

Muscles and nerves occur in their simplest forms in cnidarians. Movements are coordinated by a noncentralized nerve net. Cnidarians have no brain, and the nerve net is associated with sensory structures distributed around the body. Thus, the animal can detect and respond to stimuli from all directions.

#### CONCEPT CHECK 27.1

1. Summarize fossil and DNA evidence documenting the origin and early diversification of animals.
2. **WHAT IF?** Suppose the most recent common ancestor of choanoflagellates and animals lived 900 million years ago. If extant choanoflagellates arose 890 million years ago, would extant animals also have been alive at that time? Explain.

For suggested answers, see Appendix A.

## CONCEPT 27.2

### The diversity of large animals increased dramatically during the “Cambrian explosion”

As we’ve seen, the oldest fossils of large animals date to 560 million years ago and include members of just a few extant groups—sponges, cnidarians, and molluscs. In fossils formed in the early Cambrian period (between 535 and 525 million years ago), large forms of many other present-day animal phyla suddenly appear, a phenomenon referred to as the **Cambrian explosion**.

What factors may have spurred this rapid (in geologic terms) diversification?

#### Evolutionary Change in the Cambrian Explosion

Strata formed during the Cambrian explosion contain the oldest fossils of about half of all extant animal phyla, including the first arthropods, chordates, and echinoderms (Figure 27.5). Many of these fossils, which include the first animals with hard, mineralized skeletons, look very different from most living animals (Figure 27.6). Even so, paleontologists have established that these

(a) **Hydrozoa**. Some species, such as this one, live as colonial polyps.

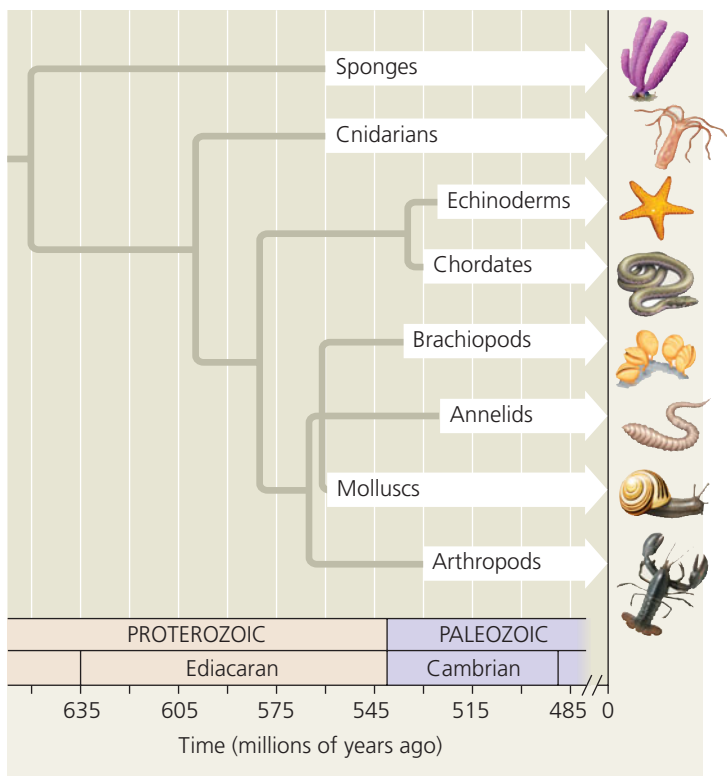

(b) **Scyphozoa**. Many jellies (commonly called jellyfish) are bioluminescent. Some species stun their prey with specialized stinging cells called nematocysts located on their tentacles.

(c) **Anthozoa**. Sea anemones and other anthozoans exist only as polyps. Many anthozoans form symbiotic relationships with photosynthetic algae.

▲ **Figure 27.4 Major groups of cnidarians.**

▲ **Figure 27.5 Appearance of selected animal groups.** The white bars indicate earliest appearances of these animal groups in the fossil record.

**DRAW IT** Circle the branch point that represents the most recent common ancestor of chordates and annelids. What is a minimum estimate of that ancestor's age?

Cambrian fossils are members of extant animal phyla, or at least are close relatives. In particular, most of the fossils from the Cambrian explosion are of **bilaterians**, an enormous clade whose members (unlike sponges and cnidarians) have a complete digestive tract and a two-sided—bilaterally symmetric—form. As we'll discuss later in the chapter, bilaterians include molluscs, arthropods, chordates, and most other living animal phyla.

Entirely new sorts of animals made their debut during the Cambrian explosion. Previously, virtually all large animals were soft-bodied. In addition, the fossils of large pre-Cambrian animals reveal little evidence of predation. Instead, these animals seem to have been grazers (feeding on mats of algae and bacteria), filter feeders, or scavengers, not hunters. In a relatively short period of time (10 million years), predators over 1 m in length emerged that had claws and other features for capturing prey; simultaneously, new defensive adaptations, such as sharp spines

and heavy body armor, appeared in their prey (see Figure 27.6). These and other changes set the stage for many of the key events in the history of life over the last 500 million years.

The increase in the diversity of large animals during the Cambrian explosion was accompanied by a decline in the diversity of Ediacaran life-forms. What caused these trends? Fossil evidence suggests that during the Cambrian period, predators acquired novel adaptations, such as forms of locomotion that helped them catch prey, while prey species acquired new defenses, such as protective shells. As new predator-prey relationships emerged, natural selection may have led to the decline of the soft-bodied Ediacaran species and the rise of various bilaterian phyla. Another hypothesis focuses on an increase in atmospheric oxygen that preceded the Cambrian explosion. More plentiful oxygen would have enabled animals with higher metabolic rates and larger body sizes to thrive, while potentially harming other species. A third hypothesis proposes that the origin of *Hox* genes (see Concept 23.3) and other genetic changes affecting the regulation of developmental genes facilitated the evolution of new body forms. These hypotheses are not mutually exclusive, however; predator-prey relationships, atmospheric changes, and changes in the regulation of development may each have played a role.

## Dating the Origin of Bilaterians

Although the radiation of bilaterians during the Cambrian explosion had an enormous impact on life on Earth, it is possible that many animal phyla originated long before that time. As we've seen, molecular clock analyses suggest that two early-diverging groups, sponges and cnidarians, had evolved by

*Hallucigenia* fossil  
(530 mya)

▲ **Figure 27.6 A Cambrian seascape.** This artist's reconstruction depicts a diverse array of organisms found in fossils from the Burgess Shale site in British Columbia, Canada. The animals include *Pikaia* (eel-like chordate at top left), *Marella* (arthropod swimming at left), *Anomalocaris* (large animal with anterior grasping limbs and a circular mouth), and *Hallucigenia* (animals with toothpick-like spikes on the seafloor and in inset).

700–680 million years ago. Molecular estimates also suggest that bilaterians had evolved by 670 million years ago—135 million years *before* the Cambrian explosion.

Turning to the fossil record, fossil steroids corroborate the molecular dates for the origin of sponges. However, no fossil bilaterians are close in age to the molecular clock estimates for when this group originated. The oldest fossil bilaterian is the mollusc *Kimberella* (see Figure 27.2), which lived 560 million years ago. Thus, the fossil evidence differs from molecular clock estimates by more than 100 million years.

Seeking to resolve this discrepancy, researchers have taken a closer look at the fossil record from the Ediacaran period (635–542 million years ago). Prior to the Ediacaran, eukaryotes were microscopic and smooth-walled, and such forms appeared in the fossil record for hundreds of millions of years (Figure 27.7a). Then eukaryotic life changed dramatically. Some eukaryotic lineages gave rise to large organisms, such as the 600-million-year-old alga shown in Figure 25.2. Organisms in other eukaryotic lineages remained relatively small, but defensive structures such as spines began to appear on their outer surfaces (Figure 27.7b). Additional fossil evidence shows that such well-defended eukaryotes originated more rapidly and persisted in the fossil record for shorter periods of time than did their smooth-walled, pre-Ediacaran counterparts.

What triggered these dramatic changes? Recall from the chapter opening that living animals are dangerous feeding machines because of their mobility, nervous system, and efficient digestive tract. Most bilaterians have these features, and early bilaterians may have decimated populations of the small, soft-bodied organisms on which they fed. Thus, the feeding activities of early bilaterians may have resulted in natural selection for increased size or new defensive structures in the organisms that they ate—exactly the change seen in the fossil record during the Ediacaran period.

Overall, the fossil record and molecular clock results suggest that bilaterians arose sometime between 670 and 635 million years ago. Possibly aided by a later rise in the atmospheric

concentration of oxygen, these early bilaterians then diversified explosively during the Cambrian and beyond.

### CONCEPT CHECK 27.2

1. What is the “Cambrian explosion,” and why is it significant?
2. **WHAT IF?** Suppose a well-defended prey species arose that was difficult for predators to catch or eat. How might this affect ongoing evolutionary changes in predator and prey populations?

For suggested answers, see Appendix A.

## CONCEPT 27.3

### Diverse animal groups radiated in aquatic environments

By the end of the Cambrian explosion, many of the big steps in animal evolution were well under way. Animals with legs or leg-like appendages walked on the ocean floor, and worms burrowed through the sediments. Swimming in the waters above were predators that used sharp claws and mandibles to capture and break apart their prey. Other animals had protective spikes or armor, as well as modified mouthparts that enabled their bearers to filter food from the water.

As these examples suggest, the animals in early Cambrian oceans were very diverse in morphology, way of life, and taxonomic affiliation. We’ll examine that diversity here, beginning with an overview of how to categorize the morphological variation found in different animal groups.

### Animal Body Plans

The diversity in form of the animals that emerged from the Cambrian explosion consists of a relatively small number of major “body plans.” A **body plan** is a particular set of morphological and developmental traits, integrated into a functional whole—the living animal. Note that the term *plan* here does not imply that animal forms are the result of conscious planning or invention. But body plans do provide a succinct way to compare and contrast key animal features. We’ll focus on three aspects of animal body plans: symmetry, tissues, and body cavities.

#### Symmetry

A basic feature of animal bodies is their type of symmetry—or absence of symmetry. (Many sponges, for example, lack symmetry altogether.) Some animals exhibit **radial symmetry**, the type of symmetry found in a flowerpot (Figure 27.8a). Sea anemones, for example, have a top side (where the mouth is located) and a bottom side. But they have no front and back ends and no left and right sides.

By contrast, the two-sided symmetry of a shovel is an example of **bilateral symmetry** (Figure 27.8b). A bilateral animal has two axes of orientation: front to back and top to bottom. Such animals have a **dorsal** (top) side and a **ventral** (bottom)

(a) *Valeria* (800 mya): roughly spherical, no structural defenses, soft-bodied

(b) Spiny acritarch (575 mya): about five times larger than *Valeria* and covered in hard spines

**▲ Figure 27.7 Indirect evidence of the appearance of bilaterians?** The rise in the fossil record of larger, well-defended eukaryotes during the Ediacaran period (635–542 million years ago) suggests that bilaterian animals with a complete digestive tract may have originated by that time.

**(a) Radial symmetry.** A radial animal, such as a sea anemone (phylum Cnidaria), does not have a left side and a right side. Any imaginary slice through the central axis divides the animal into mirror images.

**(b) Bilateral symmetry.** A bilateral animal, such as a lobster (phylum Arthropoda), has a left side and a right side. Only one imaginary cut divides the animal into mirror-image halves.

▲ **Figure 27.8 Body symmetry.** The flowerpot and shovel are included to help you remember the radial-bilateral distinction.

side, a left side and a right side, and an **anterior** (front) end and a **posterior** (back) end. Many animals with a bilaterally symmetric body plan (such as arthropods and mammals) have sensory equipment concentrated at their anterior end, including a central nervous system (“brain”) in the head.

The symmetry of an animal generally fits its lifestyle. Many radial animals are sessile (living attached to a substrate) or planktonic (drifting or weakly swimming, such as jellies). Their symmetry equips them to meet the environment equally well from all sides. In contrast, bilateral animals typically move actively from place to place. Most bilateral animals have a central nervous system that enables them to coordinate the complex movements involved in crawling, burrowing, flying, or swimming.

## Tissues

Animal body plans also vary with regard to tissue organization. Recall that tissues are collections of specialized cells that act as a functional unit; in animals, true tissues are isolated from other tissues by membranous layers. Sponges and a few other groups lack true tissues. In all other animals, the embryo becomes layered during development; these layers, called *germ layers*, form the various tissues and organs of the body (**Figure 27.9**).

**Ectoderm**, the germ layer covering the surface of the embryo, gives rise to the outer covering of the animal and, in some phyla, to the central nervous system. **Endoderm**, the innermost germ layer, gives rise to the lining of the digestive tract (or cavity) and organs such as the liver and lungs of vertebrates.

▲ **Figure 27.9 Tissue layers in bilaterians.** The organ systems of a bilaterally symmetric animal develop from the three germ layers that form in the embryo. Blue represents tissue derived from ectoderm, red from mesoderm, and yellow from endoderm. The internal organs of most bilaterians are suspended in a “body cavity,” a fluid- or air-filled space that helps protect the organs from injury.

Cnidarians and a few other animal groups have only these two germ layers. In contrast, all bilaterally symmetric animals have a third germ layer, called the **mesoderm**, which fills much of the space between the ectoderm and endoderm. In bilaterally symmetric animals, the mesoderm forms the muscles and most other organs between the digestive tract and the outer covering of the animal.

## Body Cavities

Most bilaterians have a **body cavity**, a fluid- or air-filled space located between the digestive tract and the outer body wall (see **Figure 27.9**). This body cavity is also called a *coelom*. The inner and outer layers of tissue that surround the cavity connect and form structures that suspend the internal organs.

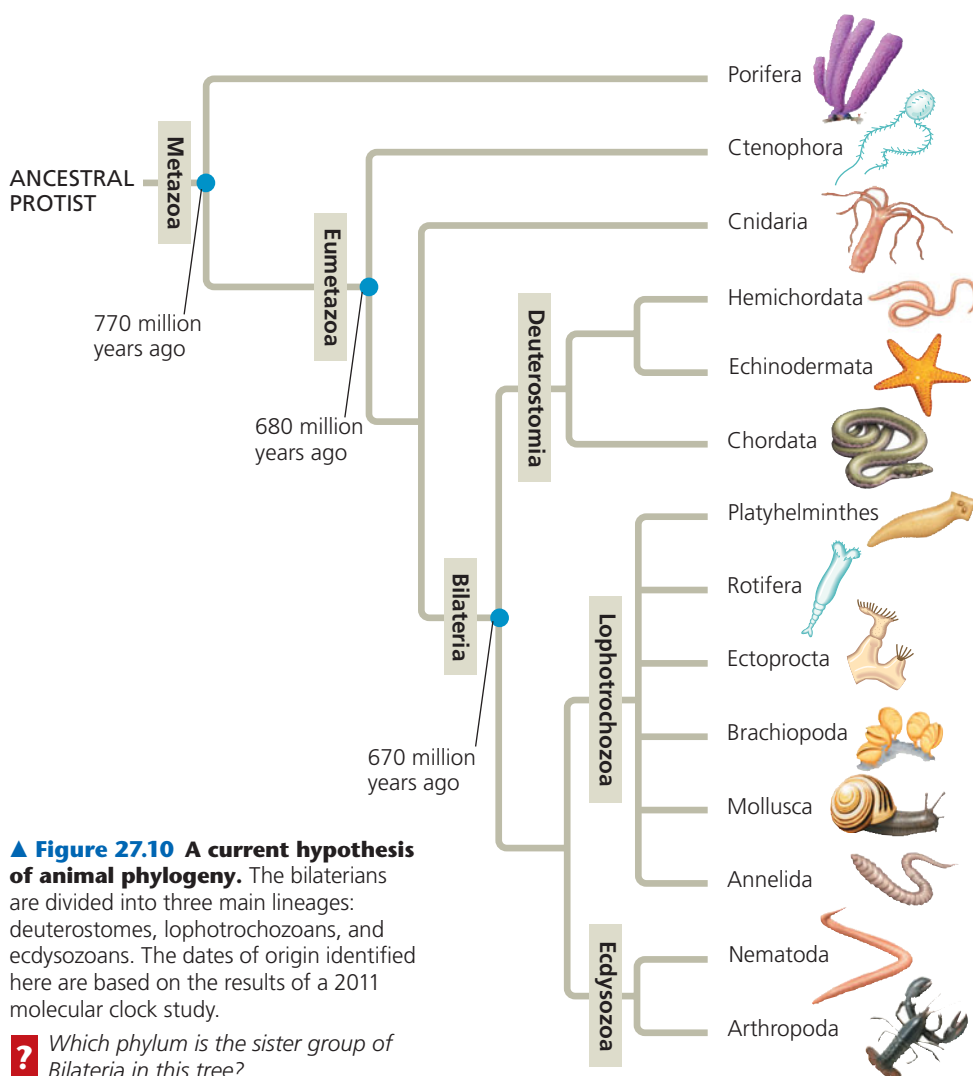

A body cavity has many functions. Its fluid cushions the suspended organs, helping to prevent internal injury. In soft-bodied bilaterians, such as earthworms, the coelom contains noncompressible fluid that acts like a skeleton against which muscles can work. The cavity also enables the internal organs to grow and move independently of the outer body wall. If it were not for your coelom, every beat of your heart or ripple of your intestine would warp your body’s surface.

## The Diversification of Animals

As animals radiated in the early Cambrian, some lineages arose, thrived for a period of time, and then became extinct, leaving no descendants. However, by 500 million years ago, most animal phyla with members alive today were established.

Evolutionary relationships among living animals provide a helpful framework for studying the rise of animals. These relationships have been estimated using ribosomal RNA (rRNA) genes, *Hox* genes, and dozens of protein-coding nuclear genes, as well as mitochondrial genes and morphological traits. Zoologists currently recognize about three dozen animal phyla, 14 of which are shown in **Figure 27.10**. Notice how the following points are reflected in this phylogeny.

1. **All animals share a common ancestor.** Current evidence indicates that animals are monophyletic, forming

▲ **Figure 27.10 A current hypothesis of animal phylogeny.** The bilaterians are divided into three main lineages: deuterostomes, lophotrochozoans, and ecdysozoans. The dates of origin identified here are based on the results of a 2011 molecular clock study.

? Which phylum is the sister group of Bilateria in this tree?

a clade called Metazoa: All extant and extinct animal lineages have descended from a common ancestor.

- Sponges are basal animals.** Among the extant taxa, sponges (phylum Porifera) branch from the base of the animal tree.
- Eumetazoa is a clade of animals with true tissues.** All animals except for sponges and a few others belong to a clade of **eumetazoans** (“true animals”). True tissues evolved in the common ancestor of living eumetazoans. Basal eumetazoans, such as ctenophores and cnidarians, have two germ layers and generally have radial symmetry.
- Most animal phyla belong to the clade Bilateria.** Bilateral symmetry and the presence of three germ layers are shared derived characters that help define the clade Bilateria. This clade contains the majority of animal phyla, and its members are known as **bilaterians**. The Cambrian explosion was primarily a rapid diversification of bilaterians.
- Most animals are invertebrates.** The members of most animal phyla are **invertebrates**, animals that lack a

backbone. Only one animal phylum, Chordata, includes **vertebrates**, animals with a backbone.

With the phylogeny in Figure 27.10 providing the overall context for the rise of animals, let’s examine the bilaterian radiation in more detail; we’ll begin with invertebrates.

## Bilaterian Radiation I: Diverse Invertebrates

As shown in Figure 27.10, bilaterian animals have diversified into three major clades: Lophotrochozoa, Ecdysozoa, and Deuterostomia. The species in these clades dominated life in the Cambrian oceans—and initially, at least, all of these species were invertebrates.

### An Overview of Invertebrate Diversity

Bilaterian invertebrates account for 95% of known animal species. They occupy almost every habitat on Earth, from the scalding water released by deep-sea hydrothermal vents to the frozen ground of Antarctica. Evolution in these varied environments has produced an immense diversity of forms, ranging from tiny worms with a flat body shape to species with features such as silk-spinning glands, pivoting spines, and tentacles covered with suction cups.

Bilaterian invertebrates also show enormous variation in size, from microscopic organisms to organisms that can grow to 18 m long (1.5 times the length of a school bus).

The morphological diversity found in invertebrate animals is mirrored by their taxonomic diversity: There are literally millions of species of invertebrates. The vast majority of these species are members of two of the bilaterian clades that emerged from the Cambrian explosion: Lophotrochozoa and Ecdysozoa (**Figure 27.11**). The third major bilaterian clade, Deuterostomia, also includes some invertebrates.

The seven phyla shown in Figure 27.11 serve as representatives of the great diversity of invertebrate bilaterians. Next, we’ll examine the origin of one of these phyla, Arthropoda, the most species-rich (by far) of all animal groups. We focus on this group because its members were among the first animals to colonize land (see Concept 27.4).

### Arthropod Origins

Zoologists estimate that there are about a billion billion ( $10^{18}$ ) arthropods living on Earth. More than 1 million arthropod

## Lophotrochozoa

Ectoprocts

**Ectoprocta (4,500 species)** Ectoprocts (also known as bryozoans) live as sessile colonies. Most species have a hard exoskeleton studded with pores; ciliated tentacles extend through the pores and trap food particles from the surrounding water.

An octopus

**Mollusca (93,000 species)**

Molluscs (including snails, clams, squids, and octopuses) have a soft body that in many species is protected by a hard shell.

**Annelida (16,500 species)**

Annelids, or segmented worms, are distinguished from other worms by their body segmentation. Earthworms are the most familiar annelids, but the phylum consists primarily of marine and freshwater species.

A fireworm, a marine annelid

## Ecdysozoa

A roundworm

**Nematoda (25,000 species)** Also called roundworms, nematodes are enormously abundant and diverse in the soil and in aquatic habitats; many species parasitize plants and animals. Their most distinctive feature is a tough cuticle that coats the body.

**Arthropoda (1,000,000 species)** The vast majority of known animal species, including insects, millipedes, crabs, and arachnids, are arthropods. All arthropods have a segmented exoskeleton and jointed appendages.

A web-building spider (an arachnid)

## Deuterostomia

An acorn worm

**Hemichordata (85 species)**

Hemichordates share some traits with chordates, such as gill slits and a dorsal nerve cord. The largest group of hemichordates are the acorn worms, marine animals that may grow to more than 2 m in length.

**Echinodermata (7,000 species)**

Echinoderms, such as sea stars, sea urchins, and sand dollars, are marine animals that are bilaterally symmetric as larvae but not as adults. They move and feed using unique “tube feet” whose gripping action results from the secretion of adhesive chemicals.

Sea urchins and a sea star

species have been described, most of which are insects. In fact, two out of every three known species are arthropods, and members of this group can be found in nearly all habitats of the biosphere. By the criteria of species diversity, distribution, and sheer numbers, arthropods must be regarded as the most successful of all animal phyla.

Biologists hypothesize that the diversity and success of **arthropods** are related to their body plan—their segmented body, hard exoskeleton, and jointed appendages (*arthropod* means “jointed feet”). The earliest fossils with this body plan are from the Cambrian explosion (535–525 million years ago), indicating that the arthropods are at least that old.

Along with arthropods, the fossil record of the Cambrian explosion contains many species of *lobopods*, a group from which arthropods may have evolved. Lobopods such as *Hallucigenia* (see Figure 27.6) had segmented bodies, but most of their body segments were identical to one another.

Early arthropods, such as the trilobites, also showed little variation from segment to segment. As arthropods continued to evolve, the segments tended to fuse and become fewer, and the appendages became specialized for a variety of functions. These evolutionary changes resulted not only in great diversification but also in an efficient body plan that permits the division of labor among different body regions.

▲ A fossil trilobite

What genetic changes led to the increasing complexity of the arthropod body plan? Arthropods today have two unusual *Hox* genes, both of which influence segmentation. To test whether these genes could have driven the evolution of increased body segment diversity in arthropods, researchers studied *Hox* genes in onychophorans, close relatives of arthropods (Figure 27.12). Their results indicate that the diversity of arthropod body plans did *not* arise from the acquisition of new *Hox* genes. Instead, the evolution of body segment diversity in arthropods may have been driven by changes in the sequence or regulation of existing *Hox* genes (see Concept 23.3).

## Bilaterian Radiation II: Aquatic Vertebrates

The appearance of large predatory animals about 530 million years ago and the accompanying explosive radiation of bilaterian invertebrates radically altered life in the oceans. In the face of these tumultuous events, it would have been easy to overlook certain slender, 3-cm-long creatures gliding through the water: *Myllokunmingia fengjiaoia* (Figure 27.13). Although lacking armor and appendages, this ancient species was closely related to one of the most successful groups of animals ever to

### ▼ Figure 27.12 Inquiry

#### Did the arthropod body plan result from new *Hox* genes?

**Experiment** One hypothesis suggests that the arthropod body plan resulted from the origin (by a gene duplication event) of two unusual *Hox* genes found in arthropods: *Ultrabithorax* (*Ubx*) and *abdominal-A* (*abd-A*). Researchers tested this hypothesis using onychophorans, a group of invertebrates closely related to arthropods. Unlike many living arthropods, onychophorans have a body plan in which most body segments are identical to one another. If the origin of the *Ubx* and *abd-A* *Hox* genes drove the evolution of body segment diversity in arthropods, these genes probably arose on the arthropod branch of the evolutionary tree:

According to this hypothesis, *Ubx* and *abd-A* would not have been present in the common ancestor of arthropods and onychophorans; hence, onychophorans should not have these genes. The researchers examined the *Hox* genes of the onychophoran *Acanthokara kaputensis*.

**Results** The onychophoran *A. kaputensis* has all arthropod *Hox* genes, including *Ubx* and *abd-A*.

Red indicates the body regions of this onychophoran embryo in which *Ubx* or *abd-A* genes were expressed. (The inset shows this area enlarged.)

Ant = antenna  
J = jaws  
L1–L15 = body segments

**Conclusion** Since *A. kaputensis*, an onychophoran, has the arthropod *Hox* genes, the evolution of increased body segment diversity in arthropods must not have been related to the origin of new *Hox* genes.

**Source** J. K. Grenier et al., Evolution of the entire arthropod *Hox* gene set predated the origin and radiation of the onychophoran/arthropod clade, *Current Biology* 7:547–553 (1997).

**WHAT IF?** If the researchers had found that *A. kaputensis* did not have the *Ubx* and *abd-A* *Hox* genes, how would their conclusion have been affected? Explain.

swim, walk, slither, or fly: the vertebrates, which derive their name from vertebrae, the series of bones that make up the backbone.

Vertebrates are members of the phylum Chordata. As seen in Figure 27.10, **chordates** are bilaterian animals, and within Bilateria, they belong to the animal clade Deuterostomia.

▲ **Figure 27.13** *Mylokunmingia fengjiaoa*, a 530-million-year-old chordate.

Among the deuterostomes that radiated during the Cambrian, we will focus on the chordates.

### Early Chordate Evolution

All chordates share a set of derived characters, though many species possess some of these traits only during embryonic development. **Figure 27.14** illustrates four key characters of chordates: a **notochord**; a dorsal, hollow nerve cord; **pharyngeal slits** (or **pharyngeal clefts**); and a muscular, post-anal tail.

Among extant chordates, a group of blade-shaped animals called *lancelets* (**Figure 27.15a**) closely resemble the idealized chordate shown in Figure 27.14. Lancelets branch at the base of the chordate phylogenetic tree. *Tunicates* (**Figure 27.15b**), another early diverging chordate group, also display key chordate traits, but only as larvae (adult tunicates have a highly modified body plan). These findings suggest that the ancestral chordate may have looked something like a lancelet—that is, it

▲ **Figure 27.14** **Chordate characteristics.** All chordates possess the four highlighted structural trademarks at some point during their development.

(a) Lancelet

(b) Tunicate

▲ **Figure 27.15** Present-day basal groups of chordates.

had an anterior end with a mouth; a notochord; a dorsal, hollow nerve cord; pharyngeal slits; and a post-anal tail.

After the evolution of the basic chordate body plan, another major step in early chordate evolution was the origin of vertebrates. Unlike lancelets and tunicates, vertebrates not only have a backbone, they also have a well-defined head with a brain, eyes and other sensory organs, and a skull.

Some of the fossils that formed during the Cambrian explosion 530 million years ago appear to straddle the transition to vertebrates. Some of these fossil chordates resembled lancelets, yet (unlike lancelets) they had a brain and eyes. *Mylokunmingia*, for example, not only had a brain and eyes; it also had parts of a skull surrounding its eyes and ears, making it one of the earliest chordates with a well-defined head. (The earliest “ears” were organs for maintaining balance, a function still performed by the ears of humans and other living vertebrates.)

### The Rise of Vertebrates

Vertebrates originated about 500 million years ago. With a more complex nervous system and a more elaborate skeleton than those of their ancestors, vertebrates became more efficient at two essential tasks: capturing food and avoiding being eaten.

Some of the earliest fossil vertebrates are of *conodonts*, soft-bodied, jawless vertebrates that hunted by impaling prey on a set of barbed hooks in their mouth. Other early vertebrates had paired fins and an inner ear with two semicircular canals that provided a sense of balance. Like conodonts, these vertebrates lacked jaws, but they had a muscular pharynx, which they may have used to suck in bottom-dwelling organisms or detritus. They were also armored with mineralized bone, which covered varying amounts of their body and may have offered protection from predators.

Only two lineages of jawless vertebrates survive today, the *hagfishes* and *lampreys* (**Figure 27.16**). Living jawless vertebrates are far outnumbered by jawed vertebrates, known as **gnathostomes**. Gnathostomes appeared in the fossil record about 450 million years ago and steadily became more diverse. Their success probably resulted from a combination of anatomical features: Their paired fins and tail allowed them to

## ▼ Figure 27.16 Exploring Vertebrate Diversity

This phylogenetic hypothesis shows the relationships among major clades of vertebrates. Derived characters are listed for some clades; for example, only gnathostomes have a jaw. In some lineages, derived traits have been lost over time or occur in reduced form; for example, hagfishes and lampreys are vertebrates with highly reduced vertebrae.

**Myxini.** Hagfishes (30 species) are scavengers that live and feed on the seafloor. They have slime-secreting glands that function in defense.

**Petromyzontida.** Most of the 35 species of lampreys are parasites that use their mouth (inset) and tongue to bore a hole in the side of a fish. The lamprey then ingests the blood and other tissues of its host.

**Chondrichthyes.** Chondrichthyans (1,000 species) such as this black-tipped reef shark have skeletons made primarily of cartilage; the group also includes rays and chimaeras (ratfishes).

**Actinopterygii.** There are over 27,000 species of ray-finned fishes, including this tropical lionfish that can inject venom through its spines.

**Actinistia.** Coelacanths (1–2 species) were thought to have become extinct 75 million years ago until they were rediscovered in the Indian Ocean in 1938.

**Dipnoi.** Lungfishes (6 species) have both gills and lungs and can gulp air into their lungs.

**Tetrapoda.** Tetrapods (over 29,000 species) have limbs with digits; this group includes a diverse collection of amphibians, reptiles, and mammals (such as this giraffe).

swim efficiently after prey, and their jaws enabled them to grab prey or simply bite off chunks of flesh (**Figure 27.17**).

By 420 million years ago, gnathostomes had diverged into the three lineages of jawed vertebrates that survive today: chondrichthyans, ray-finned fishes, and lobe-fins. (Despite its name, this last group includes humans and other terrestrial animals with legs.)

**Chondrichthyans** Sharks, rays, and their relatives include some of the biggest and most successful vertebrate predators in the oceans today (see Figure 27.16). They belong to the clade Chondrichthyes, which means “cartilage fish.” As their name indicates, the **chondrichthyans** have a skeleton composed predominantly of cartilage, though often impregnated with calcium. There are about 1,000 species of living chondrichthyans, many of which are threatened by overfishing.

**Ray-Finned Fishes** The vast majority of vertebrates belong to the clade of gnathostomes called Osteichthyes. Unlike sharks and their relatives, living **osteichthyans** typically have an ossified (bony) endoskeleton; they also have lungs or lung derivatives. Nearly all the aquatic osteichthyans familiar to us are among the **ray-finned fishes** (see Figure 27.16), named for the bony rays that support their fins. Today, there are more than 27,000 species of ray-finned fishes—almost as many species as in all other vertebrate groups combined.

**Lobe-Fins** Along with the ray-finned fishes, the other major lineage of osteichthyans is the **lobe-fins** (see Figure 27.16). A key derived character of lobe-fins is the presence of rod-shaped bones surrounded by a thick layer of muscle in their pectoral and pelvic fins. During the Devonian (416–359 million years ago), many lobe-fins lived in brackish waters, such

as in coastal wetlands. There they may have used their lobed fins to swim and “walk” underwater across the substrate (as do some living lobe-fins).

Today, only three lineages of lobe-fins survive. Two of these lineages are the coelacanths and the lungfishes (see Figure 27.16), but the third surviving lineage of lobe-fins is far more diverse. As you’ll see in the next section, these organisms adapted to life on land and gave rise to the **tetrapods**, vertebrates with limbs and digits.

### CONCEPT CHECK 27.3

1. Explain what is meant by “body plan” and describe three key features of animal body plans.
2. Describe the major steps in animal evolution shown in Figure 27.10 and evaluate this statement: “The Cambrian explosion actually consists of three explosions, not one.”
3. **MAKE CONNECTIONS** The bilaterian diversification in marine environments from 535 to 400 million years ago demonstrates that evolution is not goal oriented—it is not, for example, directed toward the origin of terrestrial vertebrates. Explain. (Review Concept 23.4.)

For suggested answers, see Appendix A.

## CONCEPT 27.4

### Several animal groups had features facilitating their colonization of land

Following the Cambrian explosion and its transformation of marine communities, some bilaterian animals colonized land, leading to profound changes there as well.

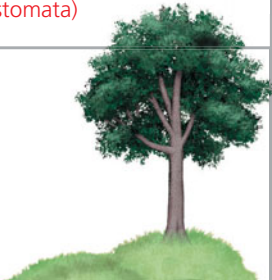

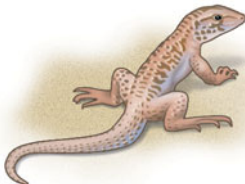

#### Early Land Animals

In contrast to plants, whose ancestors appear to have colonized land only once (see Chapter 26), members of many animal groups made the transition to terrestrial life. Arthropods, for example, invaded land multiple times, including a relatively recent event (4 million years ago) in which a crab lineage colonized the island of Jamaica. The same is true of other animal groups, such as marine snails that have given rise to terrestrial species repeatedly over the course of evolution.

Fossil evidence suggests that arthropods were among the first animals to colonize land, roughly 450 million years ago. This evidence includes fragments of arthropod remains, as well as possible millipede burrows. By 410 million years ago, well-preserved arthropod fossils from several continents indicate that millipedes, centipedes, spiders, and a variety of wingless insects all had colonized land. Vertebrates colonized land 365 million years ago, by which time early forests had also formed. By the end of the Devonian period, 360 million years ago, terrestrial animal communities were broadly similar to those of today and included predators, detritivores (animals that feed on decaying organic matter, such as plant debris), and herbivores.

▲ **Figure 27.17** Fossil of an early gnathostome. A formidable predator, *Dunkleosteus* grew up to 10 m in length. An analysis of its jaw structure concluded that *Dunkleosteus* could exert a force of 560 kg/cm<sup>2</sup> (8,000 pounds per square inch) at the tip of its jaws.

TERRESTRIAL ORGANISM				
		LAND PLANTS	INSECTS	TERRESTRIAL VERTEBRATES

▲ **Figure 27.18** **Descent with modification during the colonization of land.** This chart identifies some key characteristics that enable three major groups of terrestrial organisms—land plants, insects, and terrestrial vertebrates—to live on land. Red type indicates adaptations that have evolved since the lineages diverged from their aquatic ancestors. In land plants, most terrestrial adaptations evolved after the split. In contrast, two large clades of terrestrial animals—the insects and the vertebrates—display many ancestral characteristics that facilitated their transition to life on land.

Land animals often bear a striking resemblance to their aquatic ancestors (**Figure 27.18**). In some cases, the resemblance is so strong that it appears as if the land animals simply walked or crawled ashore, as in terrestrial crabs and snails. In other cases, more extensive changes took place, as in the vertebrate colonization of land that we’ll describe shortly. But even in vertebrates, the evolutionary changes involved in the transition to terrestrial life were less extensive in animals than in plants. For example, the animals that colonized land already had well-developed skeletal, muscular, digestive, and nervous systems. Plants, in contrast, arose from a small green alga whose structure bore little resemblance to those of its descendants—the land plants that now cover Earth.

### Colonization of Land by Arthropods

As mentioned earlier, terrestrial lineages have arisen in several different arthropod groups, including millipedes, spiders and their relatives, crabs, and insects. After describing general

features of arthropods, we’ll focus on their largest clade, the insects.

#### General Characteristics of Arthropods

Over the course of evolution, the appendages of some arthropods have become modified, specializing in functions such as walking, feeding, sensory reception, reproduction, and defense. Like the appendages from which they were derived, these modified structures are jointed and come in pairs. **Figure 27.19** illustrates the diverse appendages and other arthropod characteristics of a lobster.

The body of an arthropod is completely covered by the **cuticle**, an exoskeleton constructed from layers of protein and the polysaccharide chitin. As you know if you’ve ever eaten a crab or lobster, the cuticle can be thick and hard over some parts of the body and thin and flexible over others, such as the joints. The rigid exoskeleton protects the animal and provides points of attachment for the muscles that move the

▲ **Figure 27.19 External anatomy of an arthropod.** Many of the distinctive features of arthropods are apparent in this dorsal view of a lobster. The body is segmented, but this characteristic is obvious only in the abdomen. The appendages (including antennae, pincers, mouthparts, walking legs, and swimming appendages) are jointed. The head bears a pair of compound (multilens) eyes, each situated on a movable stalk. The whole body, including appendages, is covered by an exoskeleton.

appendages. Later, the exoskeleton enabled some arthropods to live on land. The exoskeleton's relative impermeability to water helped prevent desiccation, and its strength provided support when arthropods left the buoyancy of water.

A variety of specialized gas exchange organs have evolved in arthropods. Most aquatic species have gills with thin, feathery extensions that place an extensive surface area in contact with the surrounding water. Terrestrial arthropods generally have internal surfaces specialized for gas exchange. Most insects, for instance, have tracheal systems, branched air ducts leading into the interior from pores in the cuticle. These ducts infiltrate the body, carrying oxygen directly to cells.

## Insects

One of the arthropod groups that colonized land, the insects and their relatives, is more species-rich than all other eukaryotic groups combined (**Figure 27.20**). Insects live in almost every terrestrial habitat and in fresh water, and flying insects fill the air. Insects are rare, though not absent, in marine habitats.

The oldest insect fossils date to about 416 million years ago. Later, an explosion in insect diversity took place when insect flight evolved during the Carboniferous and Permian periods (359–251 million years ago). An animal that can fly can escape predators, find food and mates, and disperse to new habitats more effectively than an animal that must crawl about on the ground. Many insects have one or two pairs

► **Lepidopterans**—moths and butterflies—undergo complete metamorphosis: The larval stage (called a caterpillar), which is specialized for eating and growing, looks completely different from the adult stage, which is specialized for dispersal and reproduction.

◀ **Hymenopterans** include ants, bees, and wasps. They undergo complete metamorphosis and most are highly social insects.

► **Hemipterans** include stink bugs, bed bugs, and other so-called "true bugs." They have piercing mouthparts and undergo incomplete metamorphosis: The young (nymphs) resemble the adults but are smaller and lack wings.

▲ **Figure 27.20 Insect diversity.**

of wings that emerge from the dorsal side of the thorax (**Figure 27.21**). Because the wings are extensions of the cuticle, insects can fly without sacrificing any walking legs. By contrast, the flying vertebrates—birds and bats—have one of their two pairs of walking legs modified into wings, making some of these species clumsy on the ground.

Insects also radiated in response to the origin of new plant species, which provided new sources of food. As you read in Chapter 22, an insect population feeding on a new plant species can diverge from other populations, eventually forming a new species of insect. A fossil record of diverse insect mouthparts, for example, suggests that specialized modes of feeding on gymnosperms and other Carboniferous plants contributed to early adaptive radiations of insects. Later, a major increase in insect diversity appears to have been stimulated by the evolutionary expansion of flowering plants during the

◀ **Figure 27.21 Ladybird beetle in flight.**

mid-Cretaceous period (about 90 million years ago). Although insect and plant diversity decreased during the Cretaceous mass extinction, both groups rebounded over the past 65 million years.

### Terrestrial Vertebrates

Another key event in the colonization of land by animals took place 365 million years ago, when the fins of a lineage of lobe-fins evolved into the limbs and feet of tetrapods. Until then, all vertebrates had shared the same basic fishlike anatomy. After tetrapods moved onto land, they developed many new forms, from leaping frogs to flying eagles to bipedal humans.

The most significant character of tetrapods gives the group its name, which means “four feet” in Greek. In place of pectoral and pelvic fins, tetrapods have limbs with digits. Limbs support a tetrapod’s weight on land, while feet with digits efficiently transmit muscle-generated forces to the ground when the tetrapod walks.

### The Origin of Tetrapods

The Devonian coastal wetlands were home to a wide range of lobe-fins. Those that entered shallow, oxygen-poor water could use their lungs to breathe air. Some species probably used their stout fins to help them move across logs or the muddy bottom.

▲ **Figure 27.22** **Discovery of a “fishapod”: *Tiktaalik*.** Paleontologists were on the hunt for fossils that could shed light on the evolutionary origin of tetrapods. Based on the ages of previously discovered fossils, researchers were looking for a dig site with rocks about 365–385 million years old. Ellesmere Island, in the Canadian Arctic, was one of the few such sites that was also likely to contain fossils, because it was once a river. The search at this site was rewarded by the discovery of fossils of a 375-million-year-old lobe-fin, named *Tiktaalik*. As shown in the chart and photographs, *Tiktaalik* exhibits both fish and tetrapod characters.

Thus, the tetrapod body plan did not evolve “out of nowhere” but was simply a modification of a preexisting body plan.

The discovery in 2006 of a fossil called *Tiktaalik* has provided new details on how this process occurred (**Figure 27.22**). Like a fish, this species had fins, gills, and lungs, and its body was covered in scales. But unlike a fish, *Tiktaalik* had a full set of ribs that would have helped it breathe air and support its body. Also unlike a fish, *Tiktaalik* had a neck and shoulders, allowing it to move its head about. Finally, the bones of *Tiktaalik*’s front fin had the same basic pattern found in all limbed animals: one bone (the humerus), followed by two bones (the radius and ulna), followed by a group of small bones that comprise the wrist. Although it is unlikely that *Tiktaalik* could walk on land, its front fin skeleton suggests that it could prop itself up in water on its fins.

*Tiktaalik* and other extraordinary fossil discoveries have allowed paleontologists to reconstruct how fins became progressively more limb-like over time, culminating in the appearance in the fossil record of the first tetrapods 365 million years ago (**Figure 27.23**). Over the next 60 million years, a great diversity of tetrapods arose. Judging from the morphology and locations of their fossils, most of these early tetrapods probably remained tied to water, a characteristic they share with some members of the most basal group of living tetrapods, the amphibians.

© 2006 Macmillan Publishers, Ltd.

**▲ Figure 27.23 Steps in the origin of limbs with digits.** The white bars on the branches of this diagram place known fossils in time; arrowheads indicate lineages that extend to today. The drawings of extinct organisms are based on fossilized skeletons, but the colors are fanciful.

**WHAT IF?** If the most recent common ancestor of Tulerpeton and living tetrapods originated 380 million years ago, what range of dates would include the origin of amphibians?

▲ Salamanders retain their tails as adults.

▲ Caecilians have no legs and are mainly burrowing animals.

◀ Frogs and toads lack tails as adults.

**▲ Figure 27.24 Amphibian diversity.**

## Amphibians

The **amphibians** are represented today by about 6,150 species of salamanders, frogs, and caecilians (**Figure 27.24**).

Some salamanders are entirely aquatic, but others live on land as adults or throughout life. Most salamanders that live on land walk with a side-to-side bending of the body, a trait also found in early terrestrial tetrapods.

Frogs are better suited than salamanders for moving on land. Adult frogs use their powerful hind legs to hop along the terrain. Although often distinctive in appearance, the animals known as “toads” are simply frogs that have leathery skin or other adaptations for life on land.

Finally, the caecilians are legless and nearly blind. Their lack of legs is a secondary adaptation, as they evolved from a legged ancestor. Caecilians inhabit tropical areas, where most species burrow in moist forest soil.

Most amphibians are found in damp habitats such as swamps and rain forests. Even those adapted to drier habitats spend much of their time in burrows or under moist leaves, where humidity is high.

Over the past 30 years, zoologists have documented a rapid and alarming decline in amphibian populations in locations throughout the world. There appear to be several causes, including the spread of a disease-causing chytrid fungus, habitat loss, climate change, and pollution. These and other factors have not only reduced populations, but also led to extinctions.

## Terrestrial Adaptations in Amniotes

Compared to the amphibians, a more extensive colonization of dry habitats occurred in the **amniotes**, a group of tetrapods whose extant members are the reptiles (including birds, as we’ll discuss shortly) and mammals. Amniotes are named for the major derived character of the clade, the **amniotic egg**, which contains four specialized membranes: the amnion, the chorion, the yolk sac, and the

▲ **Figure 27.25 The amniotic egg.** The embryos of reptiles and mammals form four extraembryonic membranes: the amnion, chorion, yolk sac, and allantois. This diagram shows these membranes in the shelled egg of a reptile.

allantois (**Figure 27.25**). The amniotic egg was a key evolutionary innovation for terrestrial life: It allowed the embryo to develop on land in its own private "pond," reducing the dependence of tetrapods on an aqueous environment for reproduction.

In contrast to the shell-less eggs of amphibians, the amniotic eggs of most reptiles and some mammals have a shell. A shell slows dehydration of the egg in air, an adaptation that helped amniotes to occupy a wider range of terrestrial habitats than amphibians, their closest living relatives. (Seeds played a similar role in the evolution of land plants; see Chapter 26.) Most mammals have dispensed with the eggshell over the course of their evolution, and the embryo avoids desiccation by developing within the amnion inside the mother's body.

### The Origin and Radiation of Amniotes

The most recent common ancestor of living amphibians and amniotes lived about 350 million years ago. Based on where their fossils have been found, the earliest amniotes appear to have lived in warm, moist environments, as did the first tetrapods. Over time, however, early amniotes expanded into a wide range of new environments, including dry and high-latitude regions. The earliest amniotes resembled a small lizard with sharp teeth, a sign that they were predators.

Amniotes today include two large clades of terrestrial vertebrates, reptiles and mammals.

**Reptiles** Living members of the **reptile** clade include tuataras, lizards and snakes, turtles, crocodilians, and birds (**Figure 27.26**). There are about 18,300 species of reptiles, the majority of which are squamates (lizards and snakes; 7,900 species) or birds (10,000 species). Notice in Figure 27.26 that dinosaurs are reptiles and

that birds originated from saurischian dinosaurs (a group that includes *Tyrannosaurus rex*); as a result, birds are also considered reptiles.

Fossils indicate that the earliest reptiles lived about 310 million years ago and resembled lizards. Reptiles have diverged greatly since then, but as a group they share several derived characters. For example, unlike amphibians, reptiles have scales that contain the protein keratin (as does a human nail). Scales help protect the animal's skin from desiccation and abrasion. In addition, most reptiles lay their shelled eggs on land. Fertilization must occur internally, before the eggshell is secreted.

Reptiles such as lizards and snakes are sometimes described as "cold-blooded" because they do not use their metabolism extensively to control their body temperature. However, they do regulate their body temperature through behavioral adaptations. For example, many lizards

bask in the sun when the air is cool and seek shade when the air is warm. A more accurate description of these reptiles is to say that they are **ectothermic**, which means that they absorb external heat as their main source of body heat. However, the reptile clade is not entirely ectothermic; birds are **endothermic**, capable of maintaining body temperature through metabolic activity.

**Mammals** The reptiles we have been discussing represent one of the two living lineages of amniotes. The other amniote lineage is our own, the **mammals**, named for their distinctive mammary glands, which produce milk for offspring. Hair, another mammalian characteristic, and a fat layer under the skin help the body retain heat. Like birds, mammals are endothermic, and most have a high metabolic rate. In addition, whereas the teeth of reptiles are generally uniform in size and shape, the jaws of mammals bear a variety of teeth with sizes and shapes adapted for chewing many kinds of foods. Humans, like most mammals, have teeth modified for shearing (incisors and canine teeth) and for crushing and grinding (premolars and molars; see Figure 33.14).

Mammals originated from a group of amniotes called **synapsids**. Early nonmammalian synapsids lacked hair, had a sprawling gait, and laid eggs. Over the course of 120 million years, these ancestors gave rise to a series of increasingly mammal-like synapsids (see Figure 23.4). Finally, about 180 million years ago, the first true mammals arose. A diverse set of mammals coexisted with dinosaurs from 180 to 65 million years ago, but these species were not abundant and most measured less than 1 m. One possible explanation for their small size is that dinosaurs already occupied ecological niches of large-bodied animals.

## ▼ Figure 27.26 Exploring Reptilian Diversity

The reptile clade consists of five groups with living members, shown below, along with extinct groups such as the plesiosaurs, pterosaurs, and nonflying dinosaurs. The dotted line indicates the uncertain relationship of turtles to other reptiles.

**?** Are plesiosaurs dinosaurs? Are birds? Explain.

**Crocodilians.** Crocodiles and alligators (23 species, collectively called crocodilians) belong to an ancient lineage whose earliest members lived on land more than 200 million years ago. Later, some species adapted to life in water, breathing air through their upturned nostrils.

**Turtles.** The 307 species in this group have a boxlike shell fused to their skeletons. Some turtles live on land, while others live in freshwater or marine habitats, but all are air-breathing.

**Birds.** The anatomy of birds (10,000 species) includes many adaptations that facilitate flight, such as the lightweight “honey-combed” structure of their bones and stiff feathers that contribute to the aerodynamic shapes of their wings.

**Tuataras.** Although their ancestors were widespread during the Cretaceous period, today the two living species of tuataras are found only on 30 islands off the coast of New Zealand.

**Squamates.** Snakes, together with lizards, make up the squamate lineage of reptiles (7,910 species). Snakes are carnivorous, and despite their lack of legs, have adaptations that make them effective predators, including the ability of various species to detect heat, chemicals, or vibrations that signal the presence of prey.

▼ **Figure 27.27 The major mammalian lineages.**

**Monotremes**

Found only in Australia and New Guinea, there are five extant species of monotremes (the platypus and four species of spiny anteaters). Monotremes have hair and produce milk, but they lack nipples. They are the only mammals that lay eggs (inset).

**Marsupials**

Kangaroos, opossums, and koalas are examples of marsupials (324 species). Like eutherians, they have nipples that provide milk and they give birth to live young. Offspring are born early in development; they finish their growth while nursing from a nipple (in their mother's pouch in most species).

**Eutherians**

Most mammals are eutherians, a clade that include primates, whales, rodents, and many other mammal groups (5,010 species). Eutherians have a longer pregnancy than marsupials, and they have a more complex **placenta** (a structure in which nutrients diffuse into the embryo from the mother's blood).

? Monotremes are basal mammals. Draw a phylogenetic tree showing evolutionary relationships among the three lineages.

By 140 million years ago, the three major lineages of mammals had emerged: those leading to **monotremes** (egg-laying mammals), **marsupials** (mammals with a pouch), and **eutherians** (placental mammals) (Figure 27.27). After the extinction of terrestrial dinosaurs (65 million years ago), mammals continued to diversify, ultimately resulting in the more than 5,300 species living today.

## Human Evolution

Humans (*Homo sapiens*) are primates, nested with a group informally called apes (Figure 27.28). Unlike other apes, humans stand upright and are bipedal (walk on two legs). Humans

▲ **Figure 27.28 The human evolutionary tree.** The fossil record shows that monkeys and apes began diverging from other primates about 50 million years ago. The lineages leading to humans branched off from other apes between 6 and 7 million years ago.

also have a larger brain and are capable of language, symbolic thought, artistic expression, and the use of complex tools.

Early human ancestors were bipedal long before their brains increased in size. Consider the 4.4-million-year-old *Ardipithecus ramidus*. This species showed signs of bipedalism, yet its brain (325 cm<sup>3</sup> in volume) was much smaller than that of *H. sapiens* (1,300 cm<sup>3</sup>). By 2.5 million years ago, fossils show that human ancestors walked upright and used tools—yet they still had a brain the size of a softball.

The earliest fossils placed in our genus, *Homo*, include those of *Homo habilis*, which lived 2.4 to 1.6 million years ago. Compared to earlier human ancestors, *H. habilis* had a shorter jaw and a larger brain volume, about 675 cm<sup>3</sup>. Brain size, body size, and tool use continued to increase over time in various fossil *Homo* species, some of which lived as recently as 28,000 years ago. Our own species, *H. sapiens*, appears to have originated in Africa about 200,000 years ago and spread from there around the world (Figure 27.29).

▲ **Figure 27.29 Early fossils of *Homo sapiens*.** These fossilized remains of an adult and a child, discovered in a cave in Israel, are thought to be around 92,000 years old.

We turn now to the ecological and evolutionary effects of animals—including humans.

#### CONCEPT CHECK 27.4

1. Describe two adaptations that have enabled insects to thrive on land.
2. **MAKE CONNECTIONS** Compare and contrast how the colonization of land by plants and by vertebrates exemplifies descent with modification. (Review Concepts 19.2 and 26.1.)
3. **WHAT IF?** Which came first, the chicken or the egg? Explain, basing your answer on evolutionary principles.

For suggested answers, see Appendix A.

## CONCEPT 27.5

### Animals have transformed ecosystems and altered the course of evolution

The rise of animals coincided with one of the most monumental changes in the history of life: the transformation of a microbe-only world to a world filled with large producers, predators, and prey. This change affected all aspects of ecological communities, in the sea and on land.

#### Ecological Effects of Animals

As we saw in Chapter 25, until 600 million years ago, life in the oceans was almost entirely microscopic. Among other differences from life today, there were no large filter feeders in early marine communities. As a result, researchers think that ocean waters were cloudy, thick with microorganisms and suspended organic matter (**Figure 27.30a**). Geologic and fossil evidence suggests that these turbid waters also had low oxygen levels and were dominated by cyanobacteria. Marine ecosystems remained in this condition for over a billion years, despite the fact that algae and a variety of heterotrophic eukaryotes were present for most of that time. What changes did the rise of animals bring?

#### Marine Ecosystems

Fossil biochemical evidence suggests that the abundance of cyanobacteria decreased in the early Cambrian. This decrease may have been caused by the activities of crustaceans and other animals with filter-feeding mouthparts. Such filter feeders can process an enormous amount of water: Every 20 days, animals filter an estimated volume of ocean water equal to that in which most organisms live (the top 500 m). As early filter-feeding animals removed cyanobacteria and other suspended matter from the water, the ocean waters would have become clearer. As a result, algae, which require more light for photosynthesis than do cyanobacteria, increased in abundance and moved to deeper waters (**Figure 27.30b**).

Along with changes in water clarity and a shift to algae as the dominant producers, a different set of feeding relationships also emerged. A host of small animals evolved that ate marine

(a) Ocean conditions before 600 mya

(b) Changes to ocean conditions by 530 mya

▲ **Figure 27.30** A sea change for Earth's oceans.

producers and detritus. Those small animals, in turn, were eaten by larger animals—which were themselves eaten by still larger animals. Overall, the explosion of animal diversity in the early Cambrian marked the end of the microbial world and the beginning of ocean life as we know it today—a world filled with predators, filter feeders, and scavengers of all shapes and sizes.

#### Terrestrial Ecosystems

Before animals joined plants and fungi onshore, terrestrial ecosystems had a simple structure: Producers (early land plants) harnessed energy from the sun and drew essential nutrients from the soil, while decomposers returned nutrients to the soil. By 410 million years ago, animals had transformed these ecosystems. Plants and decomposers continued to be important, of course, but new biotic interactions were also in place: Plants were being consumed by herbivorous animals, and they, in turn, were being eaten by predators. Still other animals (detritivores) consumed organic debris, making for a complex network of ecological interactions—much of it driven by animals.

The lesser snow goose (*Chen caerulescens*), a migratory bird that breeds in marsh lands bordering Canada's Hudson Bay, illustrates the impact of animals on terrestrial communities. These birds feed on grasses and other marsh plants. At low population numbers, lesser snow geese improve the growth of marsh plants. This positive effect may be due to the fact that the birds defecate every few minutes as they feed, thereby adding nitrogen (which plants need to grow) to the soil. At high population numbers, however, the feeding activities of the birds can destroy a marsh, converting it to a mudflat (**Figure 27.31**).

► **Figure 27.31**

**Effects of herbivory.** The area inside the fence, which the geese could not access, shows the original state of the marsh.

## Evolutionary Effects of Animals

The rise of animals also set in motion a series of profound evolutionary changes. As we've seen, many of these changes resulted from the fact that animals can make life dangerous: The origin of mobile, heterotrophic animals with a complete digestive tract drove some species to extinction and initiated ongoing "arms races" between bilaterian predators and prey.

In this section, we'll consider the related topic of whether increases in animal diversity have led to other evolutionary radiations. Then we'll examine the ongoing evolutionary effects of one particular animal species—humans.

### Evolutionary Radiations

Two species that interact can exert selective pressures on one another. A plant (or any other species) that interacts with an animal may evolve in response to selection imposed by the animal—and the animal, in turn, may evolve in response to evolutionary changes in the plant (**Figure 27.32**). In the **Scientific Skills Exercise**, you can interpret data from a study of selection occurring in a predator-prey interaction over time. Such reciprocal selective pressures also occur when the origin of new species in one group of organisms stimulates further radiations in other organisms, especially those that can eat, escape from, or compete effectively with the new group.

As animal groups have diversified, they have often had this effect. For example, the origin of a new group of animals provides new sources of food for *parasites*, organisms that feed on

#### ▼ Figure 27.32 Results of reciprocal selection.

The Madagascar orchid *Angraecum sesquipedale* secretes a sugary nectar solution to the base of its unusually long floral tube. Based on the tube's length, Charles Darwin predicted the existence of a pollinating moth with a 28-cm-long proboscis—long enough to reach the bottom of the tube. Such a moth (*Xanthopan morgani*, shown here) was discovered two decades after Darwin's death.

▲ **Figure 27.33 Reproducing at a younger age.** Age at sexual maturity has dropped over time in heavily fished populations of northern cod (*Gadus morhua*). Size at maturity has also dropped (not shown).

? Fish that reproduce when they are younger and smaller typically have fewer offspring than fish that reproduce when they are older and larger. Predict how evolution in response to fishing will affect the ability of cod populations to recover from overfishing.

the tissues of another organism (the *host*). Many parasites feed on a single host species. As a result, the ongoing diversification of animals has led to evolutionary radiations in many groups of parasites—the animals, fungi, protists, and bacteria that can feed on newly evolved animal hosts.

### Human Impacts on Evolution

As can be seen from satellite photographs or the window of an airplane, humans have dramatically altered the environment. By making large changes to the environment, we have altered the selective pressures faced by many species. This suggests that we are likely causing evolutionary change—and we are. For example, by using antibiotics to kill bacteria, we have (inadvertently) caused the evolution of resistance in bacterial populations (see Concept 19.3). We have also caused evolutionary change in species that we hunt for sport or food. For example, in cod and other fishes harvested for food, commercial fisheries target older and larger fish. This has led to a reduction in the age and size at which individuals reach sexual maturity (**Figure 27.33**). Natural selection has favored fish that mature at a younger age and smaller size because such individuals are more likely to reproduce before they are caught than are individuals that mature when they are older and larger.

In addition to causing evolution by natural selection, our actions may cause a mass extinction, thereby greatly altering the future course of evolution. Species extinction rates have increased greatly in the last 400 years, raising concern that unless dramatic preventative measures are taken, a sixth, human-caused mass extinction may occur (see Chapter 23). Among the many taxa under threat, molluscs have the dubious distinction of being the animal group with the

## Understanding Experimental Design and Interpreting Data

**Is There Evidence of Selection for Defensive Adaptations in Mollusc Populations Exposed to Predators?** The course of animal evolution has been shaped by the interactions of predator and prey species. The fossil record provides evidence that historically, increased risk to prey species from predators is often accompanied by increased incidence and expression of prey defenses.

A team of researchers studied the possible selective pressure exerted by a predator, the European green crab (*Carcinus maenas*), on its prey, the flat periwinkle (*Littorina obtusata*), a mollusc, in the Gulf of Maine. Periwinkles from southern sites in the Gulf have experienced predation by European green crabs for over 100 generations, at about one generation per year. Periwinkles from northern sites in the Gulf have been interacting with the invasive green crabs for relatively few generations, as the invasive crabs spread to the northern Gulf comparatively recently.

Previous research shows that (1) flat periwinkle shells recently collected from the Gulf are thicker than those collected in the late 1800s, and (2) periwinkle populations from southern sites in the Gulf have thicker shells than periwinkle populations from northern sites. In this exercise, you'll interpret the design and results of the researchers' experiment studying the rates of predation by European green crabs on periwinkles from northern and southern populations.

**How the Experiment Was Done** The researchers collected periwinkles and crabs from sites in the northern and southern Gulf of Maine, separated by 450 km of coastline.

A single crab was placed in a cage with eight periwinkles of different sizes. After three days, researchers assessed the fate of the eight periwinkles. Four different treatments were set up, with crabs from northern or southern populations offered periwinkles from northern and southern populations. All crabs were of similar size and included equal numbers of males and females. Each experimental treatment was tested 12 to 14 times.

In a second part of the experiment, the bodies of periwinkles from northern and southern populations were removed from their shells and presented to crabs from northern and southern populations.

**Data from the Experiment**

When the researchers presented the crabs with unshelled periwinkles, all the unshelled periwinkles were consumed in less than an hour.

### Interpret the Data

1. What hypothesis were the researchers testing in this study? What are the independent variables in this study? What are the dependent variables in this study?
2. Why did the research team set up four different treatments?
3. Why did researchers present unshelled periwinkles to the crabs? Explain the significance of the results of this part of the experiment.
4. Summarize the results of the experiment in words. Do these results support the hypothesis you identified in question 1? Explain.
5. Suggest how natural selection may have affected populations of flat periwinkles in the southern Gulf of Maine over the last 100 years.

**Data from** R. Rochette, S. P. Doyle, and T. C. Edgell, Interaction between an invasive decapod and a native gastropod: Predator foraging tactics and prey architectural defenses, *Marine Ecology Progress Series* 330:179–188 (2007).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

▲ Recorded extinctions of animal species  
© 2004 American Institute of Biology Sciences

▲ **Figure 27.34 The silent extinction.** Molluscs account for a largely unheralded but sobering 40% of all documented extinctions of animal species. These extinctions have resulted from habitat loss, pollution, introduced species, overharvesting, and other human actions. Many pearl mussel populations, for example, were driven to extinction by overharvesting for their shells, which were used to make buttons and other goods. Land snails such as the species pictured above are highly vulnerable to the same threats; like pearl mussels, they are among the world's most imperiled animal groups.

▲ An endangered Pacific island land snail, *Partula suturalis*

▲ Workers on a mound of pearl mussels killed to make buttons (ca. 1919)

largest number of documented extinctions (**Figure 27.34**). Pearl mussels, a group of freshwater molluscs that can make natural pearls, are among the world's most endangered animals. Thirty of the pearl mussel species that once lived in North America have become extinct in the last 100 years, and nearly 200 of the 270 that remain are threatened by extinction.

Threats faced by pearl mussels and other molluscs include habitat loss, pollution, and competition or predation by non-native species introduced by people. Is it too late to protect these molluscs? In some locations, reducing water pollution and changing how water is released from dams have led to dramatic rebounds in pearl mussel populations. Such results provide hope that with corrective measures, other endangered species can be revived.

Our discussion of how humans affect evolution brings this unit on the history of life to an end. But this organization isn't meant to imply that life consists of a ladder leading from lowly microorganisms to lofty humanity. The history of life shows that biological diversity is the product of branching phylogeny, not ladderlike "progress," however we choose to measure it. The fact that there are almost as many species of ray-finned fishes alive today as in all other vertebrate groups combined is a clear indication that our finned relatives are not outmoded underachievers that failed to leave the water. Similarly, the ubiquity of diverse prokaryotes throughout the biosphere today is a reminder of the enduring ability of these relatively simple organisms to keep up with the times through adaptive evolution. Biology exalts life's diversity, past and present.

## CONCEPT CHECK 27.5

1. Describe how ocean communities changed in the early Cambrian period, and explain how animals may have influenced those changes.
2. How did the colonization of land by animals affect terrestrial communities?
3. **MAKE CONNECTIONS** Human actions often break large areas of forest or grassland into small remnant parcels that support fewer individuals and are far apart from one another. Predict how gene flow, genetic drift, and extinction risk would differ between the original and the remnant populations. (Review Concept 21.3.)

For suggested answers, see Appendix A.

# 27 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 27.1

#### Animals originated more than 700 million years ago (pp. 528–530)

- The earliest evidence of animal life comes from fossil steroids indicative of sponges that date to 710 million years ago.
- The first fossils of large animals date to 560 million years ago and include sponges as well as fossil organisms that resemble living cnidarians and molluscs.
- Sponges are basal animals that, unlike nearly all other animals, lack true tissues. Cnidarians are one of the oldest lineages of **eumetazoans**, an animal clade whose members have tissues.

? *What features are shared by sponges and choanoflagellates? Interpret these observations.*

### CONCEPT 27.2

#### The diversity of large animals increased dramatically during the "Cambrian explosion" (pp. 530–532)

- Prior to the **Cambrian explosion** (535–525 million years ago), virtually all large animals were soft-bodied and poorly defended.
- Fossils dating to the Cambrian explosion include the oldest known members of many living animal phyla, some of which had features for capturing prey while others had defensive adaptations such as spines and body armor.
- Fossil and molecular evidence suggests that **bilaterians** had emerged by 635 million years ago.

? *What caused the Cambrian explosion? Describe current hypotheses.*

### CONCEPT 27.3

#### Diverse animal groups radiated in aquatic environments (pp. 532–539)

- The diverse animals that emerged from the Cambrian explosion can be categorized by their **body plan**, the morphological and developmental traits that are integrated into a functional whole, the living animal.
- Most living animals are bilaterians, bilaterally symmetric animals with three tissue layers and a complete digestive tract.
- Bilaterally symmetric animals have diverged into three major clades: Lophotrochozoa, Ecdysozoa, and Deuterostomia.
- By 420 million years ago, aquatic bilaterians had radiated into a diverse set of **invertebrate** clades, along with three major clades of **vertebrates**: chondrichthyans, ray-finned fishes, and lobe-fins.

? **DRAW IT** Draw a phylogenetic tree showing relationships among Lophotrochozoa, Cnidaria, Ecdysozoa, Ctenophora, Porifera, and Deuterostomia. On the tree, mark the animal common ancestor as well as the origin of three germ layers, true tissues, and bilateral symmetry.

### CONCEPT 27.4

#### Several animal groups had features facilitating their colonization of land (pp. 539–547)

- Unlike plants, whose ancestors colonized land only once, many animal groups have made the transition to terrestrial life.
- Animals that colonized land were "pre-adapted" for their new environment in that they already had a complete digestive tract and well-developed skeletal, muscle, and nervous systems.
- Arthropods were the first animals to colonize land, about 450 million years ago. Among the arthropods that colonized land, the insects radiated explosively and now contain more known species than all other eukaryotic groups combined.
- Vertebrates colonized land 365 million years ago when early tetrapods arose from aquatic lobe-fins. Amphibians, an early-diverging group of tetrapods, are more dependent on water than are amniotes, a diverse group whose living members include reptiles and mammals.

? *Describe the amniotic egg and evaluate its significance.*

## CONCEPT 27.5

### Animals have transformed ecosystems and altered the course of evolution (pp. 547–550)

- The rise of animals coincided with the change from a microbe-only world to a world filled with large producers, scavengers, predators, and prey.
- The origin of animals with filter-feeding mouthparts may have caused sweeping changes in early oceans, such as an increase in water clarity and a shift from cyanobacteria to algae as the dominant producers.
- The diversification of bilaterians in the sea and on land has changed biotic interactions and stimulated evolutionary radiations in other groups of organisms.
- Human actions have caused evolution by natural selection and have the potential to cause a mass extinction.

**?** Explain how the activities of animals (including humans) can lead to evolutionary change, and provide an example.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- Which of the following clades contains the greatest number of animal species?
  - the vertebrates
  - the bilaterians
  - the sponges
  - the deuterostomes
  - the insects
- Fossil steroid and molecular clock evidence suggests that animals originated
  - between 770 and 710 million years ago.
  - more than 100 million years before the oldest known fossils of large animals.
  - during the Cambrian explosion.
  - after sponges diverged from other metazoans.
  - both a and b
- Which of the following was probably the *least* important factor in bringing about the Cambrian explosion?
  - the emergence of predator-prey relationships among animals
  - the accumulation of diverse adaptations, such as shells and different modes of locomotion
  - the origin of *Hox* genes and other genetic changes affecting the regulation of developmental genes
  - the movement of animals onto land
  - the accumulation of sufficient atmospheric oxygen to support the more active metabolism of mobile animals
- Which of the following could be considered the most recent common ancestor of living tetrapods?
  - a sturdy-finned, shallow-water lobe-fin whose appendages had skeletal supports similar to those of terrestrial vertebrates
  - an armored gnathostome with two pairs of appendages
  - an early ray-finned fish that developed bony skeletal supports in its paired fins
  - a salamander that had legs supported by a bony skeleton but moved with the side-to-side bending typical of fishes
  - an early terrestrial caecilian whose legless condition had evolved secondarily

### Level 2: Application/Analysis

- Which clade does *not* include humans?
  - synapsids
  - lobe-fins
  - lophotrochozoans
  - tetrapods
  - osteichthyans

- In Figure 27.10, the Deuterostomia clade is most closely related to which two main clades?
  - Ctenophora and Cnidaria
  - Lophotrochozoa and Ecdysozoa
  - Cnidaria and Bilateria
  - Platyhelminthes and Rotifera
  - Echinodermata and Hemichordata

### Level 3: Synthesis/Evaluation

#### 7. SCIENTIFIC INQUIRY

**DRAW IT** As a consequence of size alone, organisms that are large tend to have larger brains than organisms that are small. However, some organisms have brains that are considerably larger than expected for an animal of their size. There are high energy costs associated with the development and maintenance of brains that are large relative to body size.

- The fossil record documents trends in which brains that are large relative to body size evolved in certain lineages, including ancestors of humans. In such lineages, what can you infer about the relative costs and benefits of large brains?
- Hypothesize how natural selection might favor the evolution of large brains despite their high maintenance costs.
- Data for 14 bird species are listed below. Graph the data, placing deviation from expected brain size on the *x*-axis and mortality rate on the *y*-axis. What can you conclude about the relationship between brain size and mortality?

Deviation from Expected Brain Size*	-2.4	-2.1	2.0	-1.8	-1.0	0.0	0.3	0.7	1.2	1.3	2.0	2.3	3.0	3.2
Mortality Rate	0.9	0.7	0.5	0.9	0.4	0.7	0.8	0.4	0.8	0.3	0.6	0.6	0.3	0.6

D. Sol et al., Big-brained birds survive better in nature, *Proceedings of the Royal Society B* 274:763–769 (2007).  
 \*Values <0 indicate brain sizes smaller than expected; values >0 indicate sizes larger than expected.

#### 8. FOCUS ON EVOLUTION

In Figure 27.26, circle the monophyletic group that includes dinosaurs. Explain your answer and list the taxa that are in this clade. Knowing that birds are endothermic and crocodiles are ectothermic, can phylogenetic bracketing be used to predict whether dinosaurs other than birds are ectothermic or endothermic?

#### 9. FOCUS ON ORGANIZATION

Early tetrapods had a sprawling gait (like that of a lizard): As the right front foot moved forward, the body twisted to the left and the left rib cage and lung were compressed; the reverse occurred with the next step. Normal breathing, in which both lungs expand equally with each breath, was hindered during walking and prevented during running. In a short essay (100–150 words), explain how the origin of organisms such as dinosaurs, whose gait allowed them to move without compressing their lungs, could have led to emergent properties in biological communities.

For selected answers, see Appendix A.

## MasteringBiology®

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# Unit 5 Plant Form and Function

## 28 Plant Structure and Growth

Plants make their living by harvesting the energy of light by photosynthesis. The ability of plants to photosynthesize efficiently depends on the **structure and function** of roots, stems, and leaves and their **growth**.

## 29 Resource Acquisition, Nutrition, and Transport in Vascular Plants

Land plants inhabit two worlds: above ground where they gather carbon dioxide and sunlight for photosynthesis, and below ground where they acquire water and minerals. In vascular plants, these **resources are transported** throughout the plant by the vascular system.

## 30 Reproduction and Domestication of Flowering Plants

**Reproduction** is a fundamental feature of all life, including plants. In addition to sexual reproduction, many plants have the ability to reproduce asexually. Plant reproduction is central to human survival because it serves as the basis for most agriculture.

## 31 Plant Responses to Internal and External Signals

Plants are exquisitely sensitive organisms; for the most part, they respond to challenges and opportunities in their environments not by movement as do animals but by growth. Many chemical regulators are involved in coordinating **plant responses to the environment**.

# 28

## Plant Structure and Growth

### KEY CONCEPTS

- 28.1** Plants have a hierarchical organization consisting of organs, tissues, and cells
- 28.2** Meristems generate new cells for growth and control the developmental phases and life spans of plants
- 28.3** Primary growth lengthens roots and shoots
- 28.4** Secondary growth increases the diameter of stems and roots in woody plants

### OVERVIEW

## Are Plants Computers?

The object in **Figure 28.1** is not the creation of a computer genius with a flair for the artistic. It is a head of romanesco, an edible relative of broccoli. Romanesco's mesmerizing beauty is attributable to the fact that each of its smaller buds resembles in miniature the entire vegetable. (Mathematicians refer to such repetitive patterns as *fractals*.) If romanesco looks like it was generated by a computer, it's because its growth pattern follows a repetitive sequence of instructions. As in most plants, the growing shoot tips lay down a pattern of stem . . . leaf . . . bud, over and over again. These repetitive developmental patterns are genetically determined and subject to natural selection. For example, a mutation that shortens the stem segments between leaves will generate a bushier plant. If this altered architecture enhances the plant's ability to access resources such as light and, by doing so, to produce more offspring, then this trait will occur more frequently in later generations—evolution will have occurred.

Romanesco is unusual in adhering so rigidly to its basic body organization. Most plants show much greater diversity in their individual forms because the growth of most plants, much more than in animals, is affected by local environmental conditions. All adult lions, for example, have four legs and are roughly the same size, but oak trees vary in the number and arrangement of their branches. This is because plants respond to challenges and opportunities in their local environment by altering their growth. (In contrast, animals typically respond by movement.) Illumination of a plant from the side, for example, creates asymmetries in its basic body plan. Branches grow more quickly from the illuminated side of a shoot than from the shaded side, an architectural change of obvious benefit for photosynthesis. Recognizing the highly adaptive development of plants is critical for understanding how plants acquire resources from their environment.

Chapter 26 described the evolution of plants from green algae to angiosperms. Angiosperms (flowering plants) are the primary producers in many terrestrial ecosystems and are of great agricultural importance. Taxonomists split the angiosperms into two major clades: *monocots*, named for their single cotyledon (seed leaf), and *eudicots*, which typically have two cotyledons. Monocots and eudicots have several other structural differences as well (**Figure 28.2**). In this chapter, we'll explore the structure and growth of both these types of flowering plants.

▼ **Figure 28.1** Computer art?

## CONCEPT 28.1

### Plants have a hierarchical organization consisting of organs, tissues, and cells

Plants, like most animals, are made up of organs, tissues, and cells. An **organ** consists of several types of tissues that together carry out particular functions. A **tissue** is a group of cells, consisting of one or more cell types, that together perform a specialized function. In looking at the hierarchy of plant organs, tissues, and cells, we begin with organs because they are the most familiar plant structures. As you learn about the hierarchy of plant structure, keep in mind how natural selection has produced plant forms that fit plant function at all levels of organization.

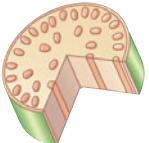

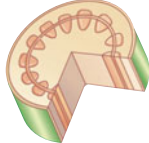

### The Three Basic Plant Organs: Roots, Stems, and Leaves

**EVOLUTION** The basic morphology of vascular plants reflects their evolutionary history as terrestrial organisms that inhabit and draw resources from two very different environments—below the ground and above the ground. They must absorb water and minerals from below the ground surface and CO<sub>2</sub> and light from above. The ability to acquire these resources efficiently is traceable to the evolution of three basic organs—roots, stems, and leaves. These organs form a **root system** and a **shoot system**, the latter consisting of stems and leaves (**Figure 28.3**). Vascular plants rely on both systems for survival. Roots, with few exceptions, are not photosynthetic; they starve unless *photosynthates*, the sugars and other carbohydrates produced during photosynthesis, are imported from the shoot system. Conversely, the shoot system depends on the water and minerals that roots absorb from the soil.

#### Roots

A **root** is an organ that anchors a vascular plant in the soil, absorbs minerals and water, and often stores carbohydrates. Tall, erect plants with large shoot masses generally have a *taproot system*, consisting of one main vertical root, the **taproot**, which penetrates the soil deeply and helps prevent the plant from toppling. In taproot systems, the role of absorption is restricted largely to **lateral roots**, which branch off from the taproot (see Figure 28.3). A taproot, although energetically expensive to make, allows the plant to be taller, thereby giving it access to more favorable light conditions and, in some cases, providing an advantage for pollen and seed dispersal.

Small plants or those that have a trailing growth habit are particularly susceptible to grazing animals that can potentially uproot the plant and kill it. Such plants are most efficiently anchored by a *fibrous root system*, a mat of thin roots spreading out below the soil surface (see Figure 28.2). In plants that have

	Monocots	Eudicots
Embryos	 One cotyledon	 Two cotyledons
Leaf venation	 Veins usually parallel	 Veins usually netlike
Stems	 Vascular tissue scattered	 Vascular tissue usually arranged in ring
Roots	 Root system usually fibrous (no main root)	 Taproot (main root) usually present
Pollen	 Pollen grain with one opening	 Pollen grain with three openings
Flowers	 Floral organs usually in multiples of three	 Floral organs usually in multiples of four or five

**▲ Figure 28.2 A comparison of monocots and eudicots.** These classes of angiosperms are named for the number of cotyledons (seed leaves) they typically possess. Monocots typically have one cotyledon. Eudicots typically have two cotyledons. Monocots include orchids, bamboos, palms, and lilies, as well as grasses, such as wheat, maize, and rice. A few examples of eudicots are beans, sunflowers, maples, and oaks.

▲ **Figure 28.3 An overview of a flowering plant.** The plant body is divided into a root system and a shoot system, connected by vascular tissue (purple strands in this diagram) that is continuous throughout the plant. The plant shown is an idealized eudicot.

fibrous root systems, including most monocots, the embryonic root dies early on and does not form a taproot. Instead, many small roots emerge from the stem. Such roots are said to be *adventitious*, a term describing a plant organ that grows in an unusual location, such as roots arising from stems or leaves. Each root forms its own lateral roots, which in turn form their own lateral roots, thereby creating a thick mat of slender roots. Because these mats of fibrous roots hold the topsoil in place, plants such as grasses that have dense fibrous root systems are especially good for preventing soil erosion.

In most plants, the absorption of water and minerals occurs primarily near the tips of roots, where vast numbers of **root hairs**, thin, finger-like extensions of root epidermal cells, emerge and increase the surface area of the root enormously (**Figure 28.4**). Most terrestrial plant root systems also form

▲ **Figure 28.4 Root hairs of a radish seedling.** Root hairs grow by the thousands near the tip of each root. By increasing the root's surface area, they greatly enhance the absorption of water and minerals from the soil.

*mycorrhizal associations*, symbiotic interactions with soil fungi that increase a plant's ability to absorb minerals (see Figure 29.13).

Many plants have root adaptations with specialized functions (**Figure 28.5**). Some of these arise from the roots, and others are adventitious, developing from stems or, in rare cases, leaves. Some modified roots add support and anchorage. Others store water and nutrients or absorb oxygen from the air.

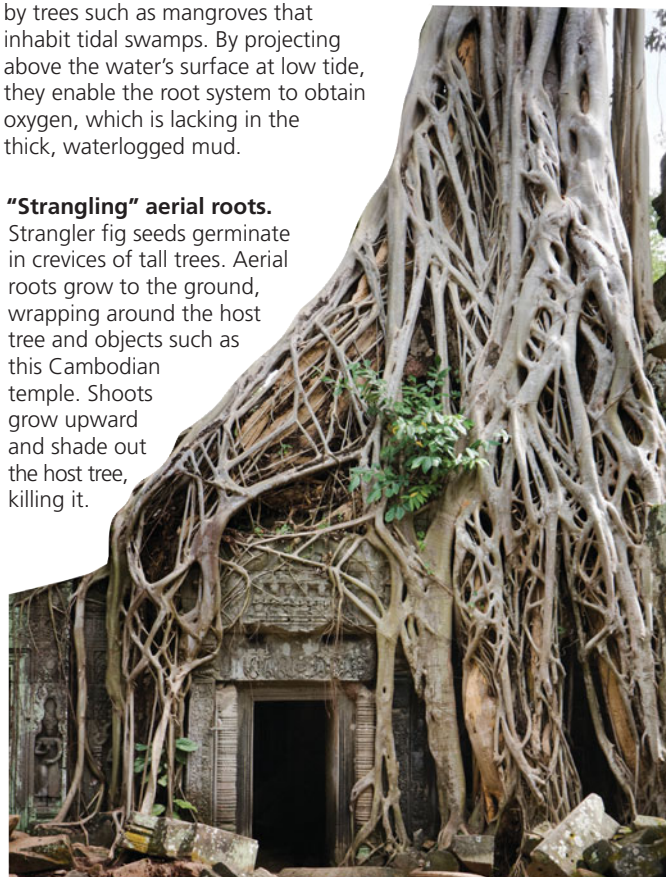

▲ **Pneumatophores.** Also known as air roots, pneumatophores are produced by trees such as mangroves that inhabit tidal swamps. By projecting above the water's surface at low tide, they enable the root system to obtain oxygen, which is lacking in the thick, waterlogged mud.

▲ **Storage roots.** Many plants, such as the common beet, store food and water in their roots.

► **"Strangling" aerial roots.** Strangler fig seeds germinate in crevices of tall trees. Aerial roots grow to the ground, wrapping around the host tree and objects such as this Cambodian temple. Shoots grow upward and shade out the host tree, killing it.

▲ **Figure 28.5 Evolutionary adaptations of roots.**

## Stems

In a typical plant, a **stem** is the organ to which leaves are attached. Its chief function is to elongate and orient the shoot in a way that maximizes photosynthesis by the leaves. Another function of stems is to elevate reproductive structures, thereby facilitating the dispersal of pollen and fruit. Green stems may also perform a limited amount of photosynthesis. Each stem consists of an alternating system of **nodes**, the points at which leaves are attached, and **internodes**, the stem segments between nodes (see Figure 28.3). Most of the growth of a young shoot is concentrated near the shoot tip, which consists of an **apical bud** composed of developing leaves and a compact series of nodes and internodes. Apical buds are not the only types of buds found in shoots. In the upper angle (axil) formed by each leaf and the stem is a dormant **axillary bud**, a structure that can potentially form a lateral branch or, in some cases, a thorn or flower.

Some plants have stems with alternative functions, such as food storage or asexual reproduction. Many of these modified stems, including rhizomes, bulbs, stolons, and tubers, are often mistaken for roots (**Figure 28.6**).

◀ **Rhizomes.** The base of this iris plant is an example of a rhizome, a horizontal shoot that grows just below the surface. Vertical shoots emerge from axillary buds on the rhizome.

▶ **Stolons.** Shown here on a strawberry plant, stolons are horizontal shoots that grow along the surface. These “runners” enable a plant to reproduce asexually, as plantlets form at nodes along each runner.

◀ **Tubers.** Tubers, such as these potatoes, are enlarged ends of rhizomes or stolons specialized for storing food. The “eyes” of a potato are clusters of axillary buds that mark the nodes.

▲ **Figure 28.6** Evolutionary adaptations of stems.

## Leaves

In most vascular plants, the **leaf** is the main photosynthetic organ. In addition to intercepting light, leaves exchange gases with the atmosphere, dissipate heat, and defend themselves from herbivores and pathogens. These functions may have conflicting physiological, anatomical, or morphological requirements. For example, a dense covering of hairs may help repel herbivorous insects but may also trap air near the leaf surface, thereby reducing gas exchange and, consequently, photosynthesis. Because of these conflicting demands and trade-offs, leaves vary extensively in form. In general, however, a leaf consists of a flattened **blade** and a stalk, the **petiole**, which joins the leaf to the stem at a node (see Figure 28.3). Grasses and many other monocots lack petioles; instead, the base of the leaf forms a sheath that envelops the stem. Monocots and eudicots differ in the arrangement of **veins**, the vascular tissue of leaves. Most monocots have parallel major veins that run the length of the blade. Eudicots generally have a branched network of major veins (see Figure 28.2). The morphological features of leaves are often a product of genetic programs that are tweaked to varying extents by environmental influences. Interpret the data in the **Scientific Skills Exercise** (p. 560) to explore the roles of genetics and the environment in determining the leaf morphology of red maple trees.

Almost all leaves are specialized for photosynthesis. However, some species have leaves with adaptations that enable them to perform additional functions, such as support, protection, storage, or reproduction (**Figure 28.7**).

## Dermal, Vascular, and Ground Tissue Systems

All plant organs—roots, stems, and leaves—are composed of three fundamental tissue systems: dermal, vascular, and ground tissue. These tissue systems are continuous throughout the plant, but their specific characteristics and spatial relationships to one another vary in different organs (**Figure 28.8**).

The **dermal tissue system** is the plant’s outer protective covering. Like our skin, it forms the first line of defense against physical damage and pathogens. In nonwoody plants, it is usually a single tissue called the **epidermis**, a layer of tightly packed cells. In leaves and most stems, the **cuticle**, a waxy coating on the epidermal surface, helps prevent water loss. In woody plants, protective tissues called **periderm** replace the epidermis in older regions of stems and roots. In addition to protecting the plant from water loss and disease, the epidermis has specialized characteristics in each organ. For example, a root hair is an extension of an epidermal cell near the tip of a root. *Trichomes* are hairlike outgrowths of the shoot epidermis. In some desert species, trichomes reduce water loss and reflect excess light, but their most common function is to defend against herbivores and pathogens by forming a mechanical barrier or secreting chemicals.

The chief functions of the **vascular tissue system** are to facilitate the transport of materials through the plant and to

► **Tendrils.** The tendrils by which this pea plant clings to a support are modified leaves. After it has “lassoed” a support, a tendril forms a coil that brings the plant closer to the support. Tendrils are typically modified leaves, but some tendrils are modified stems, as in grapevines.

◀ **Spines.** The spines of cacti, such as this prickly pear, are actually leaves; photosynthesis is carried out by the fleshy green stems.

◀ **Storage leaves.** Bulbs, such as this cut onion, have a short underground stem and modified leaves that store food.

◀ **Reproductive leaves.** The leaves of some succulents, such as *Kalanchoë daigremontiana*, produce adventitious plantlets, which fall off the leaf and take root in the soil.

▲ **Figure 28.7** Evolutionary adaptations of leaves.

provide mechanical support. The two types of vascular tissues are xylem and phloem. **Xylem** conducts water and dissolved minerals upward from roots into the shoots. **Phloem** transports sugars, the products of photosynthesis, from where they are made (usually the leaves) to where they are needed—usually roots and sites of growth, such as developing leaves and fruits. The vascular tissue of a root or stem is collectively called the **stele** (the Greek word for “pillar”). The arrangement of the stele varies, depending on the species and organ. In angiosperms, for example, the root stele is a solid central *vascular cylinder* of xylem and phloem, whereas the stele of stems and leaves consists of *vascular bundles*, separate strands containing xylem and phloem (see Figure 28.8). Both xylem and phloem are composed of a variety of cell types, including cells that are highly specialized for transport or support.

Tissues that are neither dermal nor vascular are part of the **ground tissue system**. Ground tissue that is internal to the vascular tissue is known as **pith**, and ground tissue that is external to the vascular tissue is called **cortex**. The ground tissue system is not just filler. It may include cells specialized for functions such as photosynthesis, short-distance transport, storage, or support.

▲ **Figure 28.8** The three tissue systems. The dermal tissue system (blue) provides a protective cover for the entire body of a plant. The vascular tissue system (purple), which transports materials between the root and shoot systems, is also continuous throughout the plant, but is arranged differently in each organ. The ground tissue system (yellow), which is responsible for most of the plant’s metabolic functions, is located between the dermal tissue and the vascular tissue in each organ.

## Common Types of Plant Cells

**Figure 28.9** focuses on the major types of plant cells: parenchyma cells, collenchyma cells, sclerenchyma cells, the water-conducting cells of the xylem, and the sugar-conducting cells of the phloem. Notice the structural adaptations in the different cells that make their specific functions possible. You may also wish to review basic plant cell structure (see Figures 4.7 and 4.25).

### CONCEPT CHECK 28.1

1. How does the vascular tissue system enable leaves and roots to function together in supporting growth and development of the whole plant?
2. **WHAT IF?** If humans were photoautotrophs, making food by capturing light energy for photosynthesis, how might our anatomy be different?
3. **MAKE CONNECTIONS** Explain how central vacuoles and cellulose cell walls contribute to plant growth (see Concepts 4.4 and 4.7).

For suggested answers, see Appendix A.

## Parenchyma Cells

**Parenchyma cells** with chloroplasts  
(in *Elodea* leaf) (LM) 60  $\mu$ m

Mature **parenchyma cells** have primary walls that are relatively thin and flexible, and most lack secondary walls. (See Figure 4.25 to review primary and secondary cell walls.) When mature, parenchyma cells generally have a large central vacuole. Parenchyma cells perform most of the metabolic functions of the plant, synthesizing and storing various organic products. For example, photosynthesis occurs within the chloroplasts of parenchyma cells in the leaf. Some parenchyma cells in stems and roots have colorless plastids that store starch. The fleshy tissue of many fruits is composed mainly of parenchyma cells. Most parenchyma cells retain the ability to divide and differentiate into other types of plant cells under particular conditions—during wound repair, for example. It is even possible to grow an entire plant from a single parenchyma cell.

## Collenchyma Cells

**Collenchyma cells**  
(in *Helianthus* stem) (LM) 5  $\mu$ m

Grouped in strands, **collenchyma cells** (seen here in cross section) help support young parts of the plant shoot. Collenchyma cells are generally elongated cells that have thicker primary walls than parenchyma cells, though the walls are unevenly thickened. Young stems and petioles often have strands of collenchyma cells just below their epidermis. Collenchyma cells provide flexible support without restraining growth. At maturity, these cells are living and flexible, elongating with the stems and leaves they support—unlike sclerenchyma cells, which we discuss next.

## Sclerenchyma Cells

**Sclerenchyma cells** also function as supporting elements in the plant but are much more rigid than collenchyma cells. In sclerenchyma cells, the secondary cell wall, produced after cell elongation has ceased, is thick and contains large amounts of **lignin**, a relatively indigestible strengthening polymer that accounts for more than a quarter of the dry mass of wood. Lignin is present in all vascular plants but not in bryophytes. Mature sclerenchyma cells cannot elongate, and they occur in regions of the plant that have stopped growing in length. Sclerenchyma cells are so specialized for support that many are dead at functional maturity, but they produce secondary walls before the protoplast (the living part of the cell) dies. The rigid walls remain as a “skeleton” that supports the plant, in some cases for hundreds of years.

Two types of sclerenchyma cells, known as **sclereids** and **fibers**, are specialized entirely for support and strengthening. Sclereids, which are boxier than fibers and irregular in shape, have very thick, lignified secondary walls. Sclereids impart the hardness to nutshells and seed coats and the gritty texture to pear fruits. Fibers, which are usually grouped in strands, are long, slender, and tapered. Some are used commercially, such as hemp fibers for making rope and flax fibers for weaving into linen.

## Water-Conducting Cells of the Xylem

The two types of water-conducting cells, **tracheids** and **vessel elements**, are tubular, elongated cells that are dead at functional maturity. Tracheids occur in the xylem of all vascular plants. In addition to tracheids, most angiosperms, as well as a few gymnosperms and a few seedless vascular plants, have vessel elements. When the living cellular contents of a tracheid or vessel element disintegrate, the cell's thickened walls remain behind, forming a nonliving conduit through which water can flow. The secondary walls of tracheids and vessel elements are often interrupted by pits, thinner regions where only primary walls are present (see Figure 4.25 to review primary and secondary walls). Water can migrate laterally between neighboring cells through pits.

Tracheids are long, thin cells with tapered ends. Water moves from cell to cell mainly through the pits, where it does not have to cross thick secondary walls.

Vessel elements are generally wider, shorter, thinner walled, and less tapered than the tracheids. They are aligned end to end, forming long pipes known as **vessels** that in some cases are visible with the naked eye. The end walls of vessel elements have perforation plates that enable water to flow freely through the vessels.

The secondary walls of tracheids and vessel elements are hardened with lignin. This hardening provides support and prevents collapse under the tension of water transport.

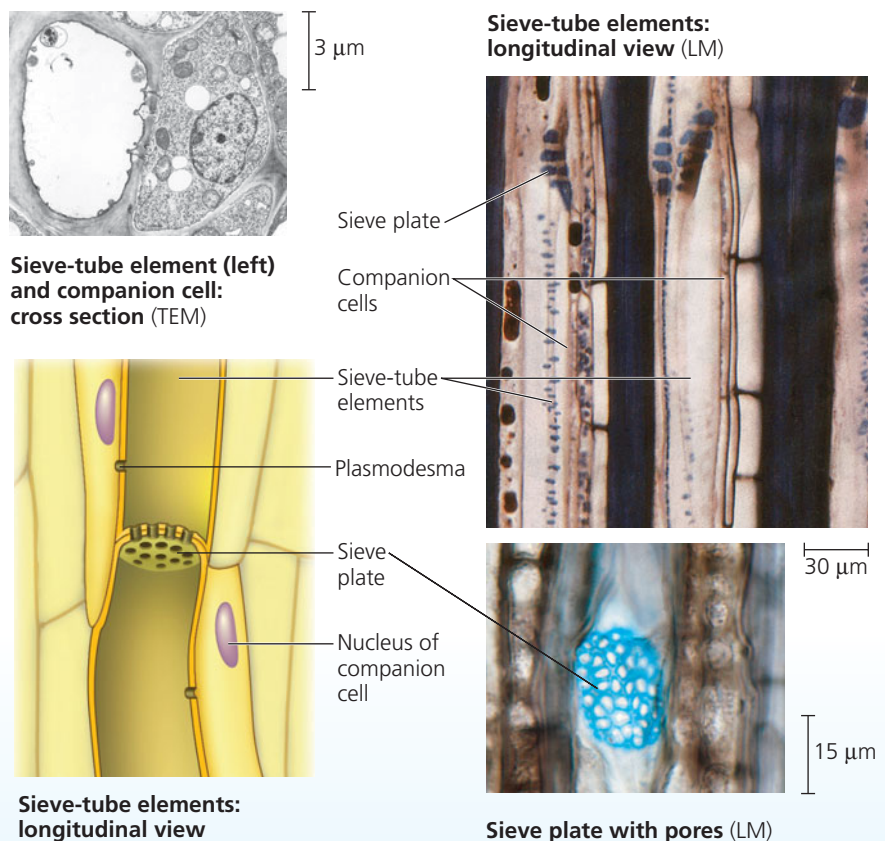

## Sugar-Conducting Cells of the Phloem

Unlike the water-conducting cells of the xylem, the sugar-conducting cells of the phloem are alive at functional maturity. In seedless vascular plants and gymnosperms, sugars and other organic nutrients are transported through long, narrow cells called sieve cells. In the phloem of angiosperms, these nutrients are transported through sieve tubes, which consist of chains of cells that are called **sieve-tube elements**, or sieve-tube members.

Though alive, sieve-tube elements lack a nucleus, ribosomes, a distinct vacuole, and cytoskeletal elements. This reduction in cell contents enables nutrients to pass more easily through the cell. The end walls between sieve-tube elements, called **sieve plates**, have pores that facilitate the flow of fluid from cell to cell along the sieve tube. Alongside each sieve-tube element is a nonconducting cell called a **companion cell**, which is connected to the sieve-tube element by numerous plasmodesmata (see Figure 4.25). The nucleus and ribosomes of the companion cell serve not only that cell itself but also the adjacent sieve-tube element. In some plants, the companion cells in leaves also help load sugars into the sieve-tube elements, which then transport the sugars to other parts of the plant.

Using Bar Graphs to Interpret Data

Nature versus Nurture: Why Are Leaves from Northern Red Maples “Toothier” Than Leaves from Southern Red Maples?

Not all leaves of red maple (*Acer rubrum*) are the same. The “teeth” along the margins of leaves growing in northern locations differ in size and number compared with their southern counterparts. (The leaf seen here has an intermediate appearance.) Are these morphological differences due to genetic differences between northern and southern *A. rubrum* populations, or do they arise from environmental differences between northern and southern locations, such as average temperature, that affect gene expression?

**How the Experiment Was Done** Seeds of *Acer rubrum* were collected from four latitudinally distinct sites: Ontario (Canada), Pennsylvania, South Carolina, and Florida. The seeds collected from the four locations were then grown in a northern location (Rhode Island) and a southern location (Florida). After a few years of growth, leaves were harvested from the four sets of plants growing in the two locations. The average area of single teeth and the average number of teeth per leaf area were determined.

Data from the Experiment

Seed Collection Site	Average Area of a Single Tooth (cm <sup>2</sup> )		Number of Teeth per cm <sup>2</sup> of Leaf Area	
	Grown in Rhode Island	Grown in Florida	Grown in Rhode Island	Grown in Florida
Ontario 43.32°N	0.017	0.017	3.9	3.2
Pennsylvania 42.12°N	0.020	0.014	3.0	3.5
South Carolina 33.45°N	0.024	0.028	2.3	1.9
Florida 30.65°N	0.027	0.047	2.1	0.9

Interpret the Data

1. Make a bar graph for tooth size and a bar graph for number of teeth. (For additional information about bar graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.) From north to south, what is the general trend in tooth size and number of teeth in leaves of *Acer rubrum*?
2. Based on the data above, would you estimate that leaf tooth traits in red maple are largely determined by genetic heritage (genotype) or the capacity for responding to environmental change within a single genotype (phenotypic plasticity) or both? Make specific reference to the data in answering the question.
3. The “toothiness” of leaf fossils of known age has been used by paleoclimatologists to estimate past temperatures in a region. If a 10,000-year-old fossilized red maple leaf from South Carolina had an average of 4.2 teeth per square centimeter of leaf area, what could you infer about the relative temperature of South Carolina 10,000 years ago compared with today? Explain your reasoning.

**Data from** D. L. Royer et al., Phenotypic plasticity of leaf shape along a temperature gradient in *Acer rubrum*, *PLoS ONE* 4(10): e7653 (2009).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

Meristems generate new cells for growth and control the developmental phases and life spans of plants

How do plant organs develop? A major difference between plants and most animals is that plant growth is not limited to an embryonic or juvenile period. Instead, growth occurs throughout the plant’s life, a process known as **indeterminate growth**. Plants are capable of indeterminate growth because they have perpetually undifferentiated tissues called **meristems** that divide when conditions permit, leading to new cells that can elongate. At any given time, a typical plant has embryonic, developing, and mature organs. Except for dormant periods, most plants grow continuously. In contrast, most animals and some plant organs—such as leaves, thorns, and flowers—undergo **determinate growth**; that is, they stop growing after reaching a certain size.

Different Meristems Produce Primary and Secondary Growth

There are two main types of meristems: apical meristems and lateral meristems (**Figure 28.10**). **Apical meristems**, located at the tips of roots and shoots and in axillary buds of shoots, provide additional cells that enable growth in length, a process known as **primary growth**. Primary growth allows roots to extend throughout the soil and shoots to increase their exposure to light. In herbaceous (nonwoody) plants, primary growth produces all, or almost all, of the plant body. Woody plants, however, also grow in circumference in the parts of stems and roots that no longer grow in length. This growth in thickness, known as **secondary growth**, is caused by **lateral meristems** called the vascular cambium and cork cambium. These cylinders of dividing cells extend along the length of roots and stems. The **vascular cambium** adds layers of vascular tissue called secondary xylem (wood) and secondary phloem. The **cork cambium** replaces the epidermis with the thicker, tougher periderm.

The relationship between primary and secondary growth is clearly seen in the winter twig of a deciduous tree. At the shoot tip is the dormant apical bud, enclosed by scales that protect its apical meristem (**Figure 28.11**). In spring, the bud sheds its scales and begins a new spurt of primary growth, producing a series of nodes and internodes. Along each growth segment, nodes are marked by scars that were left when leaves fell. Above each leaf scar is an axillary bud or a branch formed by an axillary bud. Farther down the twig are bud scars from the whorls of scales that enclosed the apical bud during the previous winter. During each growing season, primary growth extends the shoots, and secondary growth increases the diameter of the parts that formed in previous years.

▲ **Figure 28.10** An overview of primary and secondary growth.

The cells within meristems divide relatively frequently, generating additional cells. Some new cells remain in the meristem and produce more cells, while others differentiate and are incorporated into tissues and organs of the growing plant. Cells

that remain as sources of new cells have traditionally been called *initials* but are increasingly being called *stem cells* to correspond to animal stem cells, which also perpetually divide and remain undifferentiated. The new cells displaced from the meristem, called *derivatives*, divide until the cells they produce become specialized in mature tissues.

## Gene Expression and Control of Cell Differentiation

Derivative cells can diverge in structure and function even though they share a common genome. Such cell differentiation depends, to a large degree, on the control of gene expression—the regulation of transcription and translation, resulting in the production of specific proteins. Although cell differentiation depends on the control of gene expression, the fate of a plant cell is determined by its final position in the developing organ.

Evidence suggests that the activation or inactivation of specific genes involved in cell differentiation depends largely on cell-to-cell communication. For example, two cell types arise in the root epidermis of the model plant *Arabidopsis thaliana*: root hair cells and hairless epidermal cells. Cell fate is associated with the position of the epidermal cells. The immature epidermal cells that are in contact with two underlying cells of the root cortex differentiate into root hair cells, whereas the immature epidermal cells in contact with only one cortical cell differentiate into mature hairless cells. Differential expression of a gene called *GLABRA-2* (from the Latin *glaber*, bald) is required for appropriate root hair distribution. Researchers have demonstrated this requirement by coupling the *GLABRA-2*

▲ **Figure 28.11** Three years' growth in a winter twig.

▲ **Figure 28.12 Control of root hair differentiation by a master regulatory gene (LM).**

**WHAT IF?** What would the roots look like if *GLABRA-2* were rendered dysfunctional by a mutation?

gene to a “reporter gene” that causes every cell expressing *GLABRA-2* in the root to turn pale blue following a certain treatment. The *GLABRA-2* gene is normally expressed only in epidermal cells that will not develop root hairs (**Figure 28.12**).

## Meristematic Control of the Transition to Flowering and the Life Spans of Plants

**Vegetative growth**—the production of leaves, stems, and roots (as well as asexual, or vegetative, reproduction)—is only one phase in a plant’s life. Most angiosperms at some point in their life direct some or all of their shoot apical meristems to undergo a transition from vegetative growth to *reproductive growth*, the production of flowers, fruits, and seeds. This transition is triggered by a combination of environmental cues, such as day length, and internal signals, such as hormones. (You will learn more about the roles of these signals in flowering in Chapter 31.) Unlike vegetative growth, which is indeterminate, reproductive growth is determinate: The production of a flower by a shoot apical meristem stops the primary growth of that shoot. Some plants may also go through a juvenile phase during which they are incapable of reproductive growth.

Based on the timing and completeness of a plant species’ switch from vegetative to reproductive growth, flowering plants can be categorized as annuals, biennials, or perennials. *Annuals* complete their life cycle—from germination to flowering to seed production to death—in a single year or less. Many wildflowers are annuals, as are most staple food crops, including legumes and cereal grains such as wheat and rice. *Biennials*, such as turnips, generally require two growing seasons to complete their life cycle, flowering and fruiting only in their second year. *Perennials* live many years and include trees, shrubs, and some grasses.

### CONCEPT CHECK 28.2

1. Distinguish between primary and secondary growth.
2. Roots and stems grow indeterminately, but leaves do not. How might this benefit the plant?
3. **WHAT IF?** A gardener leaves carrots in the ground for two years, thinking their roots will grow larger during the second year since they are biennials. Is this a good idea? Explain.

For suggested answers, see Appendix A.

## CONCEPT 28.3

### Primary growth lengthens roots and shoots

Primary growth arises directly from cells produced by apical meristems. In herbaceous plants, the plant is produced almost entirely by primary growth; in woody plants, only the nonwoody, more recently formed parts of the plant represent primary growth. Although the elongation of both roots and shoots arises from cells derived from apical meristems, the primary growth of roots and primary growth of shoots differ in many ways.

#### Primary Growth of Roots

The tip of a root is covered by a thimble-like **root cap** (**Figure 28.13**), which protects the delicate apical meristem as the root

▲ **Figure 28.13 Primary growth of a typical eudicot root.** The root apical meristem produces all the cells of the root and the root cap. Most lengthening of the root occurs in the zone of elongation. In the micrograph, cells undergoing mitosis in the apical meristem are revealed by staining for cyclin, a protein that plays an important role in cell division (LM).

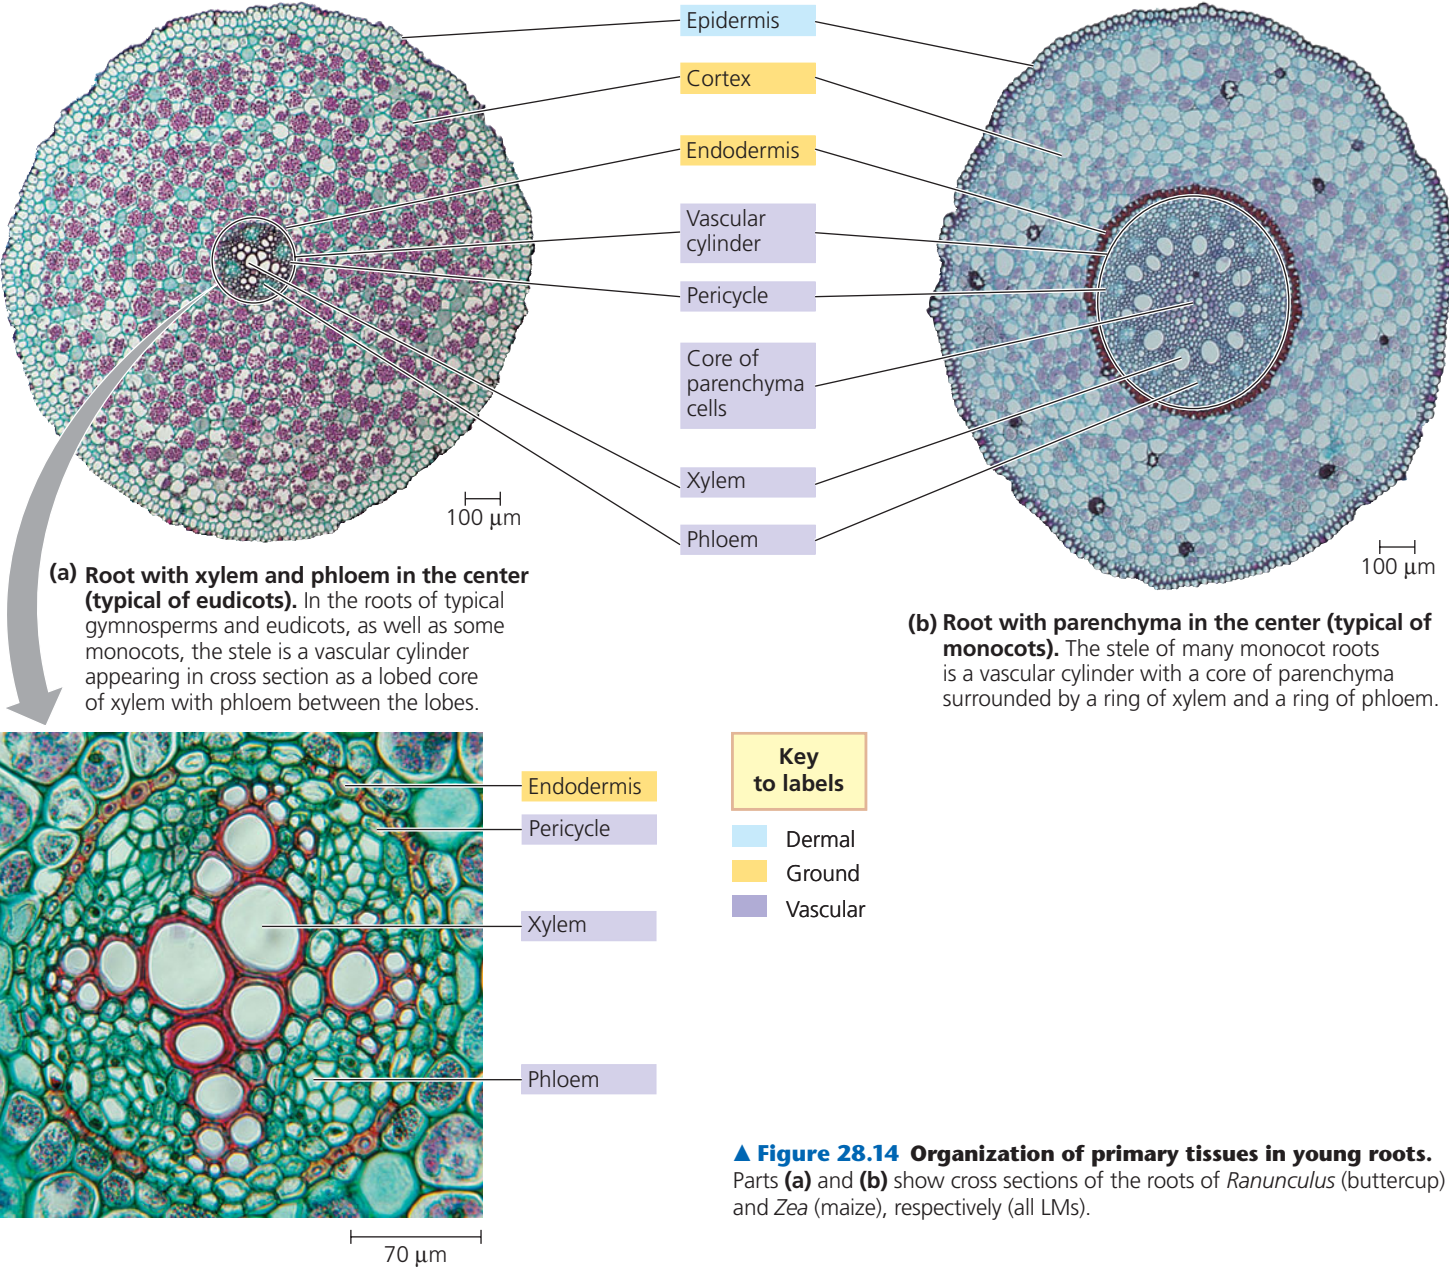

pushes through the abrasive soil during primary growth. The root cap also secretes a polysaccharide slime that lubricates the soil around the tip of the root. Growth occurs just behind the tip in three overlapping zones of cells at successive stages of primary growth. These are the zones of cell division, elongation, and differentiation (see Figure 28.13).

The *zone of cell division* includes the root apical meristem and its derivatives. New root cells are produced in this region, including cells of the root cap. Typically, a few millimeters behind the tip of the root is the *zone of elongation*, where most of the growth occurs as root cells elongate—sometimes to more than ten times their original length. Cell elongation in this zone pushes the tip farther into the soil. Meanwhile, the root apical meristem keeps adding cells to the younger end of the zone of elongation. Even before the root cells finish lengthening, many begin specializing in structure and function; for example, roots hairs start to form. In the *zone*

*of differentiation*, or zone of maturation, cells complete their differentiation and become distinct cell types.

The primary growth of a root produces its epidermis, ground tissue, and vascular tissue. **Figure 28.14** shows in cross section the three primary tissue systems in the young roots of a eudicot (*Ranunculus*, buttercup) and a monocot (*Zea*, maize). These represent two basic patterns of root organization, of which there are many variations, depending on the plant species.

In angiosperm roots, the stele is a vascular cylinder, consisting of a solid core of xylem and phloem tissues (**Figure 28.14a**). In most eudicot roots, the xylem has a starlike appearance in cross section, and the phloem occupies the indentations between the arms of the xylem “star.” In many monocot roots, the vascular tissue consists of a central core of undifferentiated parenchyma cells surrounded by a ring of alternating and differentiated xylem and phloem tissues (**Figure 28.14b**).

**▲ Figure 28.14 Organization of primary tissues in young roots.** Parts (a) and (b) show cross sections of the roots of *Ranunculus* (buttercup) and *Zea* (maize), respectively (all LMIs).

▲ **Figure 28.15 The formation of a lateral root.** A lateral root originates in the pericycle, the outermost layer of the vascular cylinder of a root, and grows out through the cortex and epidermis. In this series of light micrographs, the view of the original root is a cross section, while the view of the lateral root is a longitudinal section.

The ground tissue of roots, consisting mostly of parenchyma cells, is found in the cortex, the region between the vascular cylinder and epidermis. In addition to storing carbohydrates, cortical cells transport water and salts from the root hairs to the center of the root. The cortex, because of its large intercellular spaces, also allows for the *extracellular* diffusion of water, minerals, and oxygen from the root hairs inward. The innermost layer of the cortex is called the **endodermis**, a cylinder one cell thick that forms the boundary with the vascular cylinder. The endodermis is a selective barrier that regulates passage of substances from the soil into the vascular cylinder (see Figure 29.16).

Lateral roots arise from the **pericycle**, the outermost cell layer in the vascular cylinder, which is adjacent to and just inside the endodermis (see Figure 28.14). A lateral root pushes through the cortex and epidermis until it emerges from the established root (**Figure 28.15**).

## Primary Growth of Shoots

A shoot apical meristem is a dome-shaped mass of dividing cells at the shoot tip (**Figure 28.16**). Leaves develop from **leaf primordia** (singular, *primordium*), projections shaped like a cow's horn that emerge along the sides of the shoot apical meristem. Within a bud, young leaves are spaced close together because the internodes are very short. Shoot elongation is due to the lengthening of internode cells below the shoot tip.

Branching, which is also part of primary growth, arises from the activation of axillary buds. Within each axillary bud is a shoot apical meristem. Its dormancy results from inhibition by an active apical bud, a phenomenon called **apical dominance**. Generally, the closer an axillary bud is to an active apical bud, the more inhibited it is. If an animal eats the end of the shoot or if shading results in the light being more intense on the side of the shoot, axillary buds break dormancy and start growing. A growing axillary bud gives rise to a lateral shoot, complete with its own apical bud, leaves, and axillary buds. Removing the apical bud stimulates the growth of axillary buds, resulting

▲ **Figure 28.16 The shoot tip.** Leaf primordia arise from the flanks of the dome of the apical meristem. This is a longitudinal section of the shoot tip of *Coleus* (LM).

in more and longer branches. That is why pruning trees and shrubs and pinching back houseplants will make them bushier. (The hormonal changes underlying apical dominance are discussed in Concept 31.1.)

In some monocots, particularly grasses, meristematic activity occurs at the bases of stems and leaves. These areas, called *intercalary meristems*, allow damaged leaves to rapidly regrow, which accounts for the ability of lawns to grow following mowing. The ability of grasses to regrow leaves by intercalary meristems enables the plant to recover more effectively from damage incurred from grazing herbivores.

▲ **Figure 28.17** Leaf anatomy.

## Tissue Organization of Leaves

**Figure 28.17** provides an overview of leaf structure. The epidermis is interrupted by pores called **stomata** (singular, *stoma*), which allow exchange of  $\text{CO}_2$  and  $\text{O}_2$  between the surrounding air and the photosynthetic cells inside the leaf. In addition to regulating  $\text{CO}_2$  uptake for photosynthesis, stomata are major avenues for the evaporative loss of water. The term *stoma* can refer to the stomatal pore or to the entire stomatal complex consisting of a pore flanked by two specialized epidermal cells called **guard cells**, which regulate the opening and closing of the pore. (We'll discuss stomata in detail in Concept 29.6.)

The ground tissue of a leaf, a region called the **mesophyll** (from the Greek *mesos*, middle, and *phyll*, leaf), is sandwiched between the upper and lower epidermal layers. Mesophyll consists mainly of parenchyma cells specialized for photosynthesis. The mesophyll in the leaves of many eudicots has two distinct layers: palisade mesophyll and spongy mesophyll. *Palisade mesophyll* consists of one or more layers of elongated parenchyma cells on the upper part of the leaf. The *spongy mesophyll* is below the palisade mesophyll. These parenchyma cells are more loosely arranged, with a labyrinth of air spaces through which  $\text{CO}_2$  and  $\text{O}_2$  circulate around the cells and up to the palisade region. The air spaces are particularly large in the

vicinity of stomata, where  $\text{CO}_2$  is taken up from the outside air and  $\text{O}_2$  is released.

The vascular tissue of each leaf is continuous with the vascular tissue of the stem. Veins subdivide repeatedly and branch throughout the mesophyll. This network brings xylem and phloem into close contact with the photosynthetic tissue, which obtains water and minerals from the xylem and loads its sugars and other organic products into the phloem for transport to other parts of the plant. The vascular structure also functions as a framework that reinforces the leaf. Each vein is enclosed by a protective *bundle sheath*, a layer of cells that regulates the movement of substances between the vascular tissue and the mesophyll. Bundle-sheath cells are particularly prominent in leaves of plant species that carry out  $\text{C}_4$  photosynthesis (see Concept 8.3).

## Tissue Organization of Stems

The epidermis covers stems as part of the continuous dermal tissue system. Vascular tissue runs the length of a stem in vascular bundles. Unlike lateral roots, which arise from vascular tissue deep within a root and disrupt the vascular cylinder, cortex, and epidermis as they emerge (see Figure 28.15), lateral shoots develop from axillary bud meristems on the stem's surface and disrupt no other

**(a) Cross section of stem with vascular bundles forming a ring (typical of eudicots).** Ground tissue toward the inside is called pith, and ground tissue toward the outside is called cortex (LM).

**(b) Cross section of stem with scattered vascular bundles (typical of monocots).** In such an arrangement, ground tissue is not partitioned into pith and cortex (LM).

**▲ Figure 28.18 Organization of primary tissues in young stems.**

**?** Why aren't the terms pith and cortex used to describe the ground tissue of monocot stems?

tissues (see Figure 28.16). The vascular bundles of the stem converge with the root's vascular cylinder in a zone of transition located near the soil surface.

In most eudicot species, the vascular tissue of stems consists of vascular bundles arranged in a ring (**Figure 28.18a**). The xylem in each vascular bundle is adjacent to the pith, and the phloem in each bundle is adjacent to the cortex. In most monocot stems, the vascular bundles are scattered throughout the ground tissue rather than forming a ring (**Figure 28.18b**). In the stems of both monocots and eudicots, the ground tissue consists mostly of parenchyma cells. However, collenchyma cells just beneath the epidermis strengthen many stems. Sclerenchyma cells, especially fiber cells, also provide support in those parts of the stems that are no longer elongating. Many economically important products, such as textiles, rope, and paper are derived from plant fibers. Note that “dietary fiber” derives not from plant fiber cells but from the cellulose cell walls of edible plant tissues.

**CONCEPT CHECK 28.3**

1. Contrast primary growth in roots and shoots.
2. **WHAT IF?** If a plant species has vertically oriented leaves, would you expect its mesophyll to be divided into spongy and palisade layers? Explain.
3. **MAKE CONNECTIONS** How are root hairs and microvilli analogous structures? (See Figure 4.7 and the discussion of analogy in Concept 20.2.)

For suggested answers, see Appendix A.

**CONCEPT 28.4**

## Secondary growth increases the diameter of stems and roots in woody plants

Many land plants display secondary growth, the growth in thickness produced by lateral meristems. The advent of secondary growth during plant evolution allowed the production of novel plant forms ranging from massive forest trees to woody vines. All gymnosperm species and many eudicot species undergo secondary growth, but it is rare in monocots. Secondary growth occurs in stems and roots of woody plants, but rarely in leaves. Secondary growth consists of the tissues produced by the vascular cambium and cork cambium. The vascular cambium adds secondary xylem (wood) and secondary phloem, thereby increasing vascular flow and support for the shoots. The cork cambium produces a tough, thick covering of waxy cells that protect the stem from water loss and from invasion by insects, bacteria, and fungi.

In woody plants, primary growth and secondary growth occur simultaneously. As primary growth adds leaves and lengthens stems and roots in the younger regions of a plant, secondary growth increases the diameter of stems and roots in older regions where primary growth has ceased. The process is similar in shoots and roots. **Figure 28.19** provides an overview of growth in a woody stem.

**(a) Primary and secondary growth in a two-year-old woody stem**

- 1 Primary growth from the activity of the apical meristem is nearing completion. The vascular cambium has just formed.
- 2 Although primary growth continues in the apical bud, only secondary growth occurs in this region. The stem thickens as the vascular cambium forms secondary xylem to the inside and secondary phloem to the outside.
- 3 Some initials of the vascular cambium give rise to vascular rays.
- 4 As the vascular cambium's diameter increases, the secondary phloem and other tissues external to the cambium can't keep pace because their cells no longer divide. As a result, these tissues, including the epidermis, will eventually rupture. A second lateral meristem, the cork cambium, develops from parenchyma cells in the cortex. The cork cambium produces cork cells, which replace the epidermis.
- 5 In year 2 of secondary growth, the vascular cambium produces more secondary xylem and phloem, and the cork cambium produces more cork.
- 6 As the stem's diameter increases, the outermost tissues exterior to the cork cambium rupture and are sloughed off.
- 7 In many cases, the cork cambium re-forms deeper in the cortex. When none of the cortex is left, the cambium develops from phloem parenchyma cells.
- 8 Each cork cambium and the tissues it produces form a layer of periderm.
- 9 Bark consists of all tissues exterior to the vascular cambium.

**▲ Figure 28.19 Primary and secondary growth of a woody stem.** The progress of secondary growth can be tracked by examining the sections through sequentially older parts of the stem.

**?** How does the vascular cambium cause some tissues to rupture?

## The Vascular Cambium and Secondary Vascular Tissue

The vascular cambium, a cylinder of meristematic cells only one cell thick, is wholly responsible for the production of secondary vascular tissue. In a typical woody stem, the vascular cambium is located outside the pith and primary xylem and to the inside of the primary phloem and cortex. In a typical woody root, the vascular cambium forms to the exterior of the primary xylem and interior to the primary phloem and pericycle.

Viewed in cross section, the vascular cambium appears as a ring of meristematic cells (see Figure 28.19). As these cambial cells divide, they increase the circumference of the vascular cambium and also add secondary xylem to the inside of the cambium and secondary phloem to the outside (Figure 28.20). Each layer has a larger diameter than the previous layer. In this way, the vascular cambium increases the diameter of roots and stems.

Some of the initials produced by the vascular cambium are elongated and are oriented with their long axis parallel to the axis of the stem or root. They produce cells such as the tracheids, vessel elements, and fibers of the xylem, as well as the sieve-tube elements, companion cells, axially oriented parenchyma, and fibers of the phloem. The other initials are shorter and are oriented perpendicular to the axis of the stem or root. They produce *vascular rays*—radial files of mostly parenchyma cells that connect the secondary xylem and phloem (see Figure 28.19b). The cells of a vascular ray move water and nutrients between the secondary xylem and phloem, store carbohydrates, and aid in wound repair.

As secondary growth continues over many years, layers of secondary xylem (wood) accumulate, consisting mainly of tracheids, vessel elements, and fibers (see Figure 28.9). Tracheids are the only kind of water-conducting cell found in the xylem tissue of most gymnosperms, whereas both tracheids and vessel elements are found in most angiosperms. The walls of secondary xylem cells are heavily lignified and account for the hardness and strength of wood.

In temperate regions, wood that develops early in the spring, known as early (or spring) wood, usually consists of secondary xylem cells with relatively large diameters and thin cell walls (see Figure 28.19b). This structure maximizes delivery of water to new leaves. Wood produced during the rest of the growing season is called late (or summer) wood. It is composed of thick-walled cells that do not transport as much water but provide more support. Because there is a marked contrast between the large cells of the new early wood and the smaller cells of the late wood of the previous growing season, a year's growth appears as a distinct *growth ring* in the cross sections of most tree trunks and roots. Therefore, researchers can estimate a tree's age by counting its growth rings. *Dendrochronology* (from the Greek *dendron*, trees, and *chronos*, time) is the science of analyzing tree growth ring patterns. Growth rings can vary in thickness, depending on seasonal growth. Trees grow well in wet and warm years but may grow hardly at all in cold or dry years. Because a thick ring indicates a warm year and a thin ring indicates a cold or dry one, scientists can use ring patterns to study climate changes.

As a tree or woody shrub ages, the older layers of secondary xylem no longer transport water and minerals (a solution called xylem sap). These layers are called *heartwood* because they are closer to the center of a stem or root (Figure 28.21). The newest, outer layers of secondary xylem still transport xylem sap and are therefore known as *sapwood*. Sapwood allows a large tree to survive even if the center of its trunk is hollow. Because each new layer of secondary xylem has a larger circumference, secondary growth enables the xylem to transport more sap each year, supplying an increasing number of leaves. The heartwood is generally darker than sapwood because of resins and other compounds that permeate the cell cavities and help protect the core of the tree from fungi and wood-boring insects.

Only the youngest secondary phloem, closest to the vascular cambium, functions in sugar transport. As a stem or root increases in circumference, the older secondary phloem is

▲ **Figure 28.20** Secondary growth produced by the vascular cambium.

▲ **Figure 28.21** Anatomy of a tree trunk.

sloughed off, which is one reason secondary phloem does not accumulate as extensively as secondary xylem.

## The Cork Cambium and the Production of Periderm

During the early stages of secondary growth, the epidermis is pushed outward, causing it to split, dry, and fall off the stem or root. It is replaced by tissues produced by the first cork cambium, a cylinder of dividing cells that arises in the outer cortex of stems (see Figure 28.19a) and in the outer layer of the pericycle in roots. The cork cambium gives rise to *cork cells* that accumulate to the exterior of the cork cambium. As cork cells mature, they deposit a waxy, hydrophobic material called *suberin* in their walls and then die. Because cork cells have suberin and are usually compacted together, most of the periderm is impermeable to water and gases, unlike the epidermis. Cork

thus functions as a barrier that helps protect the stem or root from water loss, physical damage, and pathogens. “Cork” is commonly and incorrectly referred to as “bark.” In botany, **bark** includes all tissues external to the vascular cambium. Its main components are the secondary phloem (produced by the vascular cambium) and, external to that, the most recent periderm and all the older layers of periderm (see Figure 28.21).

How can living cells in the interior tissues of woody organs absorb oxygen and respire if they are surrounded by a waxy periderm? Dotting the periderm are small, raised areas called **lenticels**, in which there is more space between cork cells, enabling living cells within a woody stem or root to exchange gases with the outside air. Lenticels often appear as horizontal slits, as shown on the stem in Figure 28.19a.

In examining the parts of plants in a dissected fashion as we have done in this chapter, it is important not to lose sight of the fact that the whole plant functions as an integrated organism. In the following chapters, you’ll learn more about how materials are absorbed and transported by vascular plants (Chapter 29), how flowering plants reproduce (Chapter 30), and how plant functions are coordinated (Chapter 31). When thinking about plants, bear in mind that plant structures largely reflect evolutionary adaptations to the challenges of a photoautotrophic existence on land.

### CONCEPT CHECK 28.4

1. A sign is hammered into a tree 2 m from the tree’s base. If the tree is 10 m tall and elongates 1 m each year, how high will the sign be after 10 years?
2. Would you expect a tropical tree to have distinct growth rings? Why or why not?
3. **WHAT IF?** If a complete ring of bark is removed around a tree trunk (a process called girdling), would the tree die slowly (in weeks) or quickly (in days)? Explain why.

For suggested answers, see Appendix A.

# 28 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 28.1

**Plants have a hierarchical organization consisting of organs, tissues, and cells (pp. 554–560)**

- Vascular plants have shoots consisting of **stems**, **leaves**, and, in angiosperms, **flowers**. **Roots** anchor the plant, absorb and conduct water and minerals, and store food. Leaves are attached to stem **nodes** and are the main **organs** of photosynthesis. **Axillary buds**, in axils of leaves and stems, give rise to branches. Plant organs may be adapted for specialized functions.
- Vascular plants have three tissue systems—dermal, vascular, and ground—which are continuous throughout the plant. **Dermal tissue** protects against pathogens, herbivores, and drought and aids in the absorption of water, minerals, and carbon dioxide.

**Vascular tissues** (**xylem** and **phloem**) facilitate the long-distance transport of substances. **Ground tissues** function in storage, metabolism, and regeneration.

- **Parenchyma cells** are relatively unspecialized and thin-walled cells that retain the ability to divide; they perform most of the plant’s metabolic functions of synthesis and storage. **Collenchyma cells** have unevenly thickened walls; they support young, growing parts of the plant. **Sclerenchyma cells**—fibers and sclereids—have thick, lignified walls that help support mature, nongrowing parts of the plant. **Tracheids** and **vessel elements**, the water-conducting cells of xylem, have thick walls and are dead at functional maturity. **Sieve-tube elements** are living but highly modified cells that are largely devoid of internal organelles; they function in the transport of sugars through the phloem of angiosperms.

**? Describe at least three specializations in plant organs and plant cells that are adaptations to life on land.**

## CONCEPT 28.2

**Meristems generate new cells for growth and control the developmental phases and life spans of plants (pp. 560–562)**

? Which plant organs originate from the activity of meristems?

## CONCEPT 28.3

**Primary growth lengthens roots and shoots (pp. 562–566)**

- The root **apical meristem** is located near the tip of the root, where it generates cells for the growing root axis and the **root cap**.
- The apical meristem of a shoot is located in the **apical bud**, where it gives rise to alternating **internodes** and leaf-bearing nodes.

? How does branching differ in roots versus stems?

## CONCEPT 28.4

**Secondary growth increases the diameter of stems and roots in woody plants (pp. 566–569)**

- The **vascular cambium** is a meristematic cylinder that produces secondary xylem and secondary phloem during **secondary growth**. Older layers of secondary xylem (heartwood) become inactive, whereas younger layers (sapwood) still conduct water.
- The **cork cambium** gives rise to a thick protective covering called the **periderm**, which consists of the cork cambium plus the layers of cork cells it produces.

? What advantages did plants gain from the evolution of secondary growth?

3. Lateral roots arise from the
  - a. periderm.
  - b. vascular cambium.
  - c. pericycle.
  - d. root apical meristem.
  - e. root cap.

### Level 2: Application/Analysis

4. Which of the following arise, directly or indirectly, from meristematic activity?
  - a. secondary xylem
  - b. leaves
  - c. dermal tissue
  - d. tubers
  - e. all of the above
5. Which of the following would not be seen in a cross section through the woody part of a root?
  - a. sclerenchyma cells
  - b. parenchyma cells
  - c. sieve-tube elements
  - d. root hairs
  - e. vessel elements
6. **DRAW IT** On this cross section from a woody eudicot, label a growth ring, late wood, early wood, and a vessel element. Then draw an arrow in the pith-to-cork direction.

### Level 3: Synthesis/Evaluation

7. **SCIENTIFIC INQUIRY**

Grasslands typically do not flourish when large herbivores are removed. In fact, they are soon replaced by broad-leaved herbaceous eudicots, shrubs, and trees. Based on your knowledge of the structure and growth habits of monocots versus eudicots, suggest a reason why.
8. **FOCUS ON EVOLUTION**

Evolutionary biologists have coined the term *exaptation* to describe a common occurrence in the evolution of life: A limb or organ evolves in a particular context but over time takes on a new function (see Concept 23.4). What are some examples of exaptations in plant organs?
9. **FOCUS ON ORGANIZATION**

In a short essay (100–150 words), explain how the evolution of lignin affected vascular plant structure and function.

For selected answers, see Appendix A.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. The innermost layer of the root cortex is the
  - a. core.
  - b. pericycle.
  - c. endodermis.
  - d. pith.
  - e. vascular cambium.
2. Heartwood and sapwood consist of
  - a. bark.
  - b. periderm.
  - c. secondary xylem.
  - d. secondary phloem.
  - e. cork.

# Resource Acquisition, Nutrition, and Transport in Vascular Plants

## KEY CONCEPTS

- 29.1** Adaptations for acquiring resources were key steps in the evolution of vascular plants
- 29.2** Different mechanisms transport substances over short or long distances
- 29.3** Plant roots absorb essential elements from the soil
- 29.4** Plant nutrition often involves relationships with other organisms
- 29.5** Transpiration drives the transport of water and minerals from roots to shoots via the xylem
- 29.6** The rate of transpiration is regulated by stomata
- 29.7** Sugars are transported from sources to sinks via the phloem

## OVERVIEW

### Underground Plants

**T**he Kalahari Desert of southern Africa receives only about 20 cm of precipitation a year, almost entirely during the summer, when daytime temperatures reach a scorching 35–45°C (95–113°F). Many animals escape the heat by seeking shelter underground. A peculiar genus of perennial plants called stone plants (*Lithops*) has a similar, mostly subterranean lifestyle

(**Figure 29.1**). Except for the tips of two succulent leaves that are exposed to the surface, a stone plant lives entirely below ground. Each leaf tip has a region of clear, lens-like cells that allow light to penetrate to the photosynthetic tissues underground. These adaptations enable stone plants to conserve moisture, hide from grazing tortoises, and avoid the potentially harmful temperatures and high light intensities of the desert.

The remarkable growth habit of *Lithops* reminds us that the success of plants depends largely on their ability to gather and conserve resources from their environment. Through natural selection, many plant species have become highly proficient in acquiring or conserving resources that are especially limited in their environment, but there are often trade-offs in such specializations. For example, the mostly subterranean lifestyle of stone plants reduces water loss from evaporation but also reduces photosynthesis. As a result, stone plants grow very slowly.

The first concept in this chapter examines structural features of shoot and root systems that increase their efficiency in acquiring water, minerals, carbon dioxide, and light. Resource acquisition, however, is not the end of the story but the beginning. Resources must be transported within the plant to where they are needed. Therefore, the rest of the chapter focuses on how water, minerals, and the products of photosynthesis (sugars) are transported in vascular plants.

▼ **Figure 29.1** Plants or pebbles?

## CONCEPT 29.1

### Adaptations for acquiring resources were key steps in the evolution of vascular plants

**EVOLUTION** Land plants typically inhabit two worlds—above ground, where their shoot systems acquire sunlight and  $\text{CO}_2$ , and below ground, where their root systems acquire water and minerals. Without adaptations that allow acquisition of these resources, plants could not have colonized land.

The algal ancestors of land plants absorbed water, minerals, and  $\text{CO}_2$  directly from the water in which they lived. Transport in these algae was relatively simple because every cell was close to the source of these substances. The earliest land plants were nonvascular plants that grew photosynthetic shoots above the shallow fresh water in which they lived. These leafless shoots typically had waxy cuticles and few stomata, which allowed them to avoid excessive water loss while still permitting some exchange of  $\text{CO}_2$  and  $\text{O}_2$  for photosynthesis. The anchoring and absorbing functions of early land plants were assumed by the base of the stem or by threadlike rhizoids.

As land plants evolved and increased in number, competition for light, water, and nutrients intensified. Taller plants

with broad, flat appendages had an advantage in absorbing light. This increase in surface area, however, resulted in more evaporation and therefore a greater need for water. Larger shoots also required more anchorage. These needs favored the production of multicellular, branching roots. Meanwhile, as greater shoot heights further separated the photosynthesizing leaves from the nonphotosynthetic parts below ground, natural selection favored plants capable of efficient long-distance transport of water, minerals, and products of photosynthesis.

The evolution of vascular tissue consisting of xylem and phloem made possible the development of extensive root and shoot systems that carry out long-distance transport (see Figure 28.9). The **xylem** transports water and minerals from roots to shoots. The **phloem** transports products of photosynthesis from where they are made or stored to where they are needed. **Figure 29.2** provides an overview of resource acquisition and transport in a vascular plant.

Because plant success depends on photosynthesis, evolution has resulted in many structural adaptations for efficiently acquiring light from the sun,  $\text{CO}_2$  from the air, and water from the ground. Perhaps just as importantly, land plants must minimize the evaporative loss of water, particularly in environments where water is scarce. The adaptations of each species represent compromises between enhancing photosynthesis and minimizing water loss in the species' particular habitat.

▲ **Figure 29.2** An overview of resource acquisition and transport in a vascular plant.

Later in the chapter, we'll discuss how plants enhance CO<sub>2</sub> uptake and minimize water loss by regulating stomatal pores. Here we examine how the basic architecture of shoots and roots helps plants acquire resources.

## Shoot Architecture and Light Capture

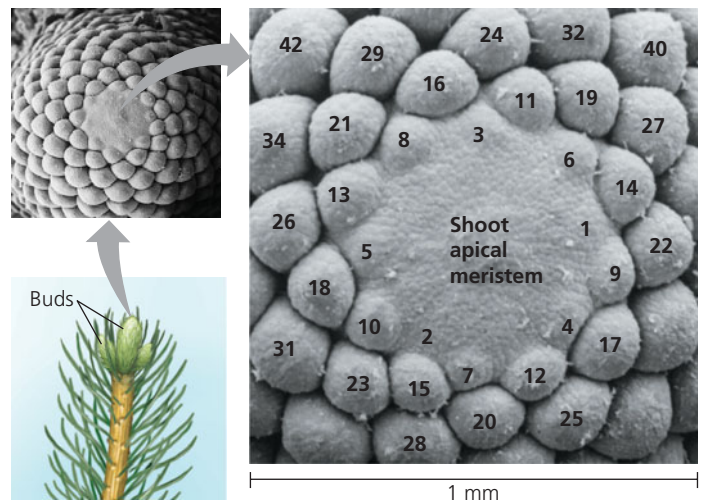

The macroscopic diversity we see in plant species is a reflection of architectural differences in the branching patterns, dimensions, shapes, and orientations of aboveground plant organs—the stems and leaves.

Stems serve as supporting structures for leaves and as conduits for the transport of water and nutrients. The height of the shoots and their branching pattern are two architectural features affecting light capture. Plants that grow tall avoid shading from neighboring plants. Most tall plants require thick stems, which enable greater vascular flow to the leaves and mechanical support for them. Vines are an exception, relying on other structures (usually other plants) to raise their leaves higher. In woody plants, stems become thicker through secondary growth (see Figure 28.10).

Branching generally enables plants to harvest sunlight for photosynthesis more effectively. However, some species, such as the coconut palm, do not branch at all. Why is there so much variation in branching patterns? Plants have only a finite amount of energy to devote to shoot growth. If most of that energy goes into branching, there is less energy to devote toward growing tall, and there is increased risk of being shaded by taller plants. If most of the energy goes into growing tall, the plants are not optimally exploiting the resources above ground. Natural selection has produced a variety of shoot architectures among species, fine-tuning the ability to absorb light in the ecological niche each species occupies.

The arrangement of leaves on a stem, known as **phyllotaxy**, is another architectural feature important in light capture. Phyllotaxy is determined by the shoot apical meristem (see Figure 28.16) and is specific to each species (Figure 29.3). A species may have one leaf per node (alternate, or spiral, phyllotaxy), two leaves per node (opposite phyllotaxy), or more (whorled phyllotaxy). Most angiosperms have alternate phyllotaxy, with leaves arranged in an ascending spiral around the stem, each successive leaf emerging 137.5° from the site of the previous one. Why 137.5°? Mathematical analyses suggest that this angle minimizes shading of the lower leaves by those above. In environments where intense sunlight can harm leaves, the greater shading provided by oppositely arranged leaves may be advantageous.

The **canopy** is the leafy portion of all the plants in a community. The depth of the canopy—how many leaf layers there are from the top of the canopy to the bottom—affects the productivity of each plant. When the canopy is too thick, the shading of the lower leaves on an individual plant may be so great that they photosynthesize less than they respire. When this happens, the nonproductive leaves or branches undergo

**▲ Figure 29.3 Emerging phyllotaxy of Norway spruce.** This SEM, taken from above a shoot tip, shows the pattern of emergence of leaves. The leaves are numbered, with 1 being the youngest. (Some numbered leaves are not visible in the close-up.)

**?** With your finger, trace the progression of leaf emergence, moving from leaf number 29 to 28 and so on. What is the pattern?

programmed cell death and are eventually shed, a process called *self-pruning*.

Another factor affecting light capture is leaf orientation. Some plants have horizontally oriented leaves; others, such as grasses, have leaves that are vertically oriented. In low-light conditions, horizontal leaves capture sunlight much more effectively than vertical leaves. In grasslands or other sunny regions, however, horizontal orientation may expose upper leaves to overly intense light, injuring leaves and reducing photosynthesis. But if a plant's leaves are nearly vertical, light rays are essentially parallel to the leaf surfaces, so no leaf receives too much light, and light penetrates more deeply to the lower leaves.

## Root Architecture and Acquisition of Water and Minerals

Just as carbon dioxide and sunlight are resources exploited by the shoot system, soil contains resources mined by the root system. Plants can rapidly adjust the architecture and physiology of their roots to exploit patches of available nutrients in the soil. The roots of many plants, for example, respond to pockets of low nitrate availability in soils by extending straight through the pockets instead of branching within them. Conversely, when encountering a pocket rich in nitrate, a root will often branch extensively there. Root cells also respond to high soil nitrate levels by synthesizing more proteins involved in nitrate transport and assimilation. Thus, not only does the plant devote more of its mass to exploiting a nitrate-rich patch; the cells also absorb nitrate more efficiently.

Researchers have uncovered a fascinating physiological mechanism that reduces competition within the root system of a plant. Cuttings from the stolons of buffalo grass (*Buchloe dactyloides*) develop fewer and shorter roots in the presence

of cuttings from the same plant than they do in the presence of cuttings from another buffalo grass plant. Although the mechanism underlying this ability to distinguish self from nonself is unknown, avoiding competition between roots of the same plant for the same limited pool of resources certainly seems beneficial.

Plant roots also form mutually beneficial relationships with microorganisms that enable them to exploit soil resources more efficiently. For example, the evolution of mutualistic associations between roots and fungi called mycorrhizae was a critical step in the successful colonization of land by plants (see Figures 26.12 and 26.13). Mycorrhizal hyphae endow the fungus and plant roots with an enormous surface area for absorbing water and minerals. The role of mycorrhizae in plant nutrition will be examined more fully in Concept 29.4.

Once acquired, resources must be transported to other parts of the plant that need them. In the next section, we examine the processes and pathways that enable resources such as water, minerals, and sugars to be transported throughout the plant.

#### CONCEPT CHECK 29.1

1. Why is long-distance transport important for vascular plants?
2. What architectural features influence self-shading?
3. **WHAT IF?** Some plants can detect increased levels of light reflected from leaves of encroaching neighbors. This detection elicits stem elongation, production of erect leaves, and less branching. How do these responses help the plant compete?

For suggested answers, see Appendix A.

## CONCEPT 29.2

### Different mechanisms transport substances over short or long distances

Given the diversity of substances that move through plants and the great range of distances and barriers over which such substances must be transported, it is not surprising that plants employ a variety of transport processes. Before examining

these processes, however, let's consider the two major pathways of transport: the apoplast and the symplast.

### The Apoplast and Symplast: Transport Continuums

Plant tissues may be viewed as having two major compartments—the apoplast and the symplast. The **apoplast** consists of everything external to the plasma membranes of living cells and includes cell walls, extracellular spaces, and the interior of dead cells such as vessel elements and tracheids (see Figure 28.9). The **symplast** consists of the entire mass of cytosol of all the living cells in a plant, as well as the plasmodesmata, the cytoplasmic channels that interconnect them.

The compartmental structure of plants provides three routes for transport within a plant tissue or organ: the apoplastic, symplastic, and transmembrane routes (**Figure 29.4**). In the *apoplastic route*, water and solutes (dissolved chemicals) move along the continuum of cell walls and extracellular spaces. In the *symplastic route*, water and solutes move along the continuum of cytosol. This route requires substances to cross a plasma membrane once, when they first enter the plant. After entering one cell, substances can move from cell to cell via plasmodesmata. In the *transmembrane route*, water and solutes move out of one cell, across the cell wall, and into the neighboring cell, which may pass them to the next cell in the same way. The transmembrane route requires repeated crossings of plasma membranes as substances exit one cell and enter the next. These three routes are not mutually exclusive, and some substances may use more than one route to varying degrees.

### Short-Distance Transport of Solutes Across Plasma Membranes

In plants, as in any organism, the selective permeability of the plasma membrane controls the short-distance movement of substances into and out of cells (see Chapter 5). Both active and passive transport mechanisms occur in plants, and plant cell membranes are equipped with the same general types of pumps and transport proteins (channel proteins, carrier proteins, and cotransporters) that function in other cells. In

◀ **Figure 29.4** Cell compartments and routes for short-distance transport. Some substances may use more than one transport route.

this section, we focus on some ways that plants differ from animals in solute transport across plasma membranes.

Hydrogen ions ( $H^+$ ), rather than sodium ions ( $Na^+$ ), play the primary role in basic transport processes in plant cells. For example, in plant cells the membrane potential (the voltage across the membrane) is established mainly through the pumping of  $H^+$  by proton pumps (Figure 29.5a), rather than the pumping of  $Na^+$  by sodium-potassium pumps. Also,  $H^+$  is most often cotransported in plants, whereas  $Na^+$  is typically cotransported in animals. During cotransport, plant cells use the energy in the  $H^+$  gradient and membrane potential to drive the active transport of many different solutes. For instance, cotransport with  $H^+$  is responsible for absorption of neutral solutes, such as the sugar sucrose, by phloem cells and other plant cells. An  $H^+$ /sucrose cotransporter couples movement of sucrose against its concentration gradient with movement of  $H^+$  down its electrochemical gradient (Figure 29.5b). Cotransport with  $H^+$  also facilitates movement of ions, as in the uptake of nitrate ( $NO_3^-$ ) by root cells (Figure 29.5c).

The membranes of plant cells also have ion channels that allow only certain ions to pass (Figure 29.5d). As in animal cells, most channels are gated, opening or closing in response to stimuli such as chemicals, pressure, or voltage. Later in this chapter, we'll discuss how potassium ( $K^+$ ) ion channels in guard cells function in opening and closing stomata. Ion channels are also involved in producing electrical signals analogous to the action potentials of animals (see Chapter 37). For example, the phloem conducts nerve-like electrical signals that help integrate whole-plant function. However, these signals are 1,000 times slower than in animals and employ calcium ( $Ca^{2+}$ ) activated anion channels rather than the sodium ( $Na^+$ ) ion channels used by animal cells.

## Short-Distance Transport of Water Across Plasma Membranes

The absorption or loss of water by a cell occurs by **osmosis**, the diffusion of free water—water that is not bound to solutes or surfaces—across a membrane (see Figure 5.10). The physical property that predicts the direction in which water will flow is

**(a)  $H^+$  and membrane potential.** The plasma membranes of plant cells use ATP-dependent proton pumps to pump  $H^+$  out of the cell. These pumps contribute to the membrane potential and the establishment of a pH gradient across the membrane. These two forms of potential energy can drive the transport of solutes.

**(b)  $H^+$  and cotransport of neutral solutes.** Neutral solutes such as sugars can be loaded into plant cells by cotransport with  $H^+$  ions.  $H^+$ /sucrose cotransporters, for example, play a key role in loading sugar into the phloem prior to its transport throughout the plant.

**(c)  $H^+$  and cotransport of ions.** Cotransport mechanisms involving  $H^+$  also participate in regulating ion fluxes into and out of cells. For example,  $H^+$ / $NO_3^-$  cotransporters in the plasma membranes of root cells are important for the uptake of  $NO_3^-$  by plant roots.

**(d) Ion channels.** Plant ion channels open and close in response to voltage, stretching of the membrane, and chemical factors. When open, ion channels allow specific ions to diffuse across membranes. For example, a  $K^+$  ion channel is involved in the release of  $K^+$  from guard cells when stomata close.

**▲ Figure 29.5 Solute transport across plant cell plasma membranes.**

**?** Assume that a plant cell has all four of the plasma membrane transport proteins shown above. Assume also that you have specific inhibitors for each of the four transport proteins. Predict what effect the individual application of each inhibitor would have on the cell's membrane potential.

called **water potential**, a quantity that includes the effects of solute concentration and physical pressure. Free water moves from regions of higher water potential to regions of lower water potential if there is no barrier to its flow. For example, if a plant cell is immersed in a solution that has a higher water potential than the cell, water will move into the cell. As the cell gains water, its water potential increases until equilibrium is reached between inside and out, and net water movement ceases. The word *potential* in the term *water potential* refers to water's potential energy—water's capacity to perform work when it moves or is absorbed. The growth of a plant cell, for example, is

primarily driven by water uptake. The expansion of plant cells and seeds can be a powerful force: growing tree roots, for example, can break sidewalks, and the swelling of wet grain within the holds of damaged ships has led to complete hull failure resulting in sinking of the ships. Given the strong forces generated by swelling seeds, it is interesting to consider whether metabolism is involved in water uptake by seeds; this question can be explored by analyzing the data in the **Scientific Skills Exercise**.

Water potential is abbreviated by the Greek letter  $\psi$  (psi, pronounced “sigh”). Plant biologists measure  $\psi$  in a unit of pressure called a **megapascal (MPa)**. By definition, the  $\psi$  of pure water in a container open to the atmosphere under standard conditions (at sea level and at room temperature) is 0 MPa.

### How Solutes and Pressure Affect Water Potential

Solute concentration and physical pressure are the major determinants of water potential in hydrated plants, as expressed in the *water potential equation*:

$$\psi = \psi_s + \psi_p$$

where  $\psi$  is the water potential,  $\psi_s$  is the solute potential (osmotic potential), and  $\psi_p$  is the pressure potential. The **solute**

**potential ( $\psi_s$ )** of a solution is directly proportional to its molarity. Solute potential is also called *osmotic potential* because solutes affect the direction of osmosis. The solutes in plants are typically ions and sugars. By definition, the  $\psi_s$  of pure water is 0. When solutes are added, they bind water molecules. As a result, there are fewer free water molecules, reducing the capacity of the water to move and do work. In this way, an increase in solutes has a negative effect on water potential, which is why the  $\psi_s$  of a solution is always expressed as a negative number. For example, a 0.1 M solution of a sugar has a  $\psi_s$  of  $-0.23$  MPa. As the solute concentration increases,  $\psi_s$  becomes more negative.

**Pressure potential ( $\psi_p$ )** is the physical pressure on a solution. Unlike  $\psi_s$ ,  $\psi_p$  can be positive or negative relative to atmospheric pressure. For example, the water in the hollow, nonliving xylem cells (tracheids and vessel elements) of a plant is often under a negative pressure potential (tension) of less than  $-2$  MPa. Conversely, much like the air in a tire’s inner tube, the water in living cells is usually under positive pressure due to the osmotic uptake of water. Specifically, the cell contents press the plasma membrane against the cell wall, and the

## Scientific Skills Exercise

### Calculating and Interpreting Temperature Coefficients

#### Does the Initial Uptake of Water by Seeds Depend on Temperature?

One way to answer this question is to soak seeds in water at different temperatures and measure the rate of water uptake at each temperature. The collected data can be used to calculate the temperature coefficient,  $Q_{10}$ , the factor by which a physiological process or reaction rate increases when the temperature is raised by  $10^\circ\text{C}$ :

$$Q_{10} = \left( \frac{k_2}{k_1} \right)^{\frac{10}{t_2 - t_1}}$$

where  $t_2$  = higher temperature ( $^\circ\text{C}$ ),  $t_1$  = lower temperature,  $k_2$  = reaction rate at  $t_2$ , and  $k_1$  = reaction rate at  $t_1$ . (Note that if  $t_2 - t_1 = 10$ , as in this exercise, the math is simplified.)

$Q_{10}$  values may be used to make inferences about the physiological process under investigation. Chemical (metabolic) processes involving large-scale protein shape changes are highly dependent on temperature and have higher  $Q_{10}$  values, closer to 2 or 3. In contrast, many, but not all, physical parameters are relatively independent of temperature and have  $Q_{10}$  values closer to 1. For example, the  $Q_{10}$  of the change in the viscosity of water is 1.2–1.3. In this exercise, you will calculate  $Q_{10}$  using data for radish seeds (*Raphanus sativus*) to assess whether the initial uptake of water by seeds is more likely to be a physical or a chemical process.

**How the Experiment Was Done** Samples of radish seeds were weighed and placed in water at four different temperatures. After 30 minutes, the seeds were removed, blotted dry, and reweighed. The researchers then calculated the percent increase in mass due to water uptake for each sample.

#### Data from the Experiment

Temperature	% Increase in Mass Due to Water Uptake after 30 Minutes
$5^\circ\text{C}$	18.5%
$15^\circ\text{C}$	26.0%
$25^\circ\text{C}$	31.0%
$35^\circ\text{C}$	36.2%

#### Interpret the Data

- Based on the data, does the initial uptake of water by radish seeds vary with temperature? What is the relationship between temperature and water uptake?
- (a) Using the data for  $35^\circ\text{C}$  and  $25^\circ\text{C}$ , calculate  $Q_{10}$  for water uptake by radish seeds. Repeat the calculation using the data for  $25^\circ\text{C}$  and  $15^\circ\text{C}$  and the data for  $15^\circ\text{C}$  and  $5^\circ\text{C}$ . (b) What is the average  $Q_{10}$ ? (c) Do your results imply that the uptake of water by radish seeds is mainly a physical process or a chemical (metabolic) process? (d) Given that the  $Q_{10}$  for the change in the viscosity of water is 1.2–1.3, could the slight temperature dependence of water uptake by seeds be a reflection of the slight temperature dependence of the viscosity of water?
- Besides temperature, what other independent variables could you alter to test whether radish seed swelling is essentially a physical process or a chemical process?
- Would you expect plant growth to have a  $Q_{10}$  closer to 1 or 3? Why?

**Data from** J. D. Murphy and D. L. Noland, Temperature effects on seed imbibition and leakage mediated by viscosity and membranes, *Plant Physiology* 69:428–431 (1982).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

(a) Initial conditions: cellular  $\psi >$  environmental  $\psi$ . The cell loses water and plasmolyzes. After plasmolysis is complete, the water potentials of the cell and its surroundings are the same.

(b) Initial conditions: cellular  $\psi <$  environmental  $\psi$ . There is a net uptake of water by osmosis, causing the cell to become turgid. When this tendency for water to enter is offset by the back pressure of the elastic wall, water potentials are equal for the cell and its surroundings. (The volume change of the cell is exaggerated in this diagram.)

▲ **Figure 29.6 Water relations in plant cells.** In these experiments, flaccid cells (cells in which the protoplast contacts the cell wall but lacks turgor pressure) are placed in two environments. Blue arrows indicate initial net water movement.

cell wall then presses against the **protoplast** (the living part of the cell, which includes the plasma membrane), producing what is called **turgor pressure**. This internal pressure is critical for plant function because it helps maintain the stiffness of plant tissues and also serves as the driving force for cell elongation. The key point to remember as you read about the water relations of plants is that *water moves from regions of higher water potential to regions of lower water potential*.

### Water Movement Across Plant Cell Membranes

Now let's consider how water potential affects absorption and loss of water by a living plant cell. First, imagine a cell that is **flaccid** (limp) as a result of losing water. The cell has a  $\psi_P$  of 0 MPa. Suppose this flaccid cell is bathed in a solution of higher solute concentration (more negative solute potential) than the cell itself (**Figure 29.6a**). Since the external solution has the lower (more negative) water potential, water diffuses out of the cell. The cell's protoplast undergoes **plasmolysis**—that is, it shrinks and pulls away from the cell wall. If we place the same flaccid cell in pure water ( $\psi = 0 \text{ MPa}$ ) (**Figure 29.6b**), the cell, because it contains solutes, has a lower water potential than the water, and water enters the cell by osmosis. The contents of the cell begin to swell and press the plasma membrane against the cell wall. The partially elastic wall, exerting turgor pressure, confines the pressurized protoplast. When this pressure is enough to offset the tendency for water to enter because of the solutes in the cell, then  $\psi_P$  and  $\psi_S$  are equal, and  $\psi = 0$ . This matches the water potential of the extracellular environment—in this example, 0 MPa. A dynamic equilibrium has been reached, and there is no further net movement of water.

In contrast to a flaccid cell, a walled cell with a greater solute concentration than its surroundings is **turgid**, or very firm. When turgid cells push against each other, the tissue stiffens.

▲ **Figure 29.7 A moderately wilted plant can regain its turgor when watered.**

The effects of turgor loss are seen during **wilting**, when leaves and stems droop as a result of cells losing water (**Figure 29.7**).

### Aquaporins: Facilitating Diffusion of Water

A difference in water potential determines the *direction* of water movement across membranes, but how do water molecules actually cross the membranes? The movement of water molecules across biological membranes is too rapid to be explained by unaided diffusion. In most cases, transport proteins called **aquaporins** (see Figure 5.1) facilitate the transmembrane transport of water. By opening and closing, these selective channels affect the *rate* at which water moves osmotically across the membrane.

### Long-Distance Transport: The Role of Bulk Flow

Long-distance transport in plants occurs through **bulk flow**, the movement of liquid in response to a pressure gradient. The bulk flow of material always occurs from higher to lower

pressure. Unlike osmosis, bulk flow is independent of solute concentration. Long-distance bulk flow occurs within the tracheids and vessel elements of the xylem and within the sieve-tube elements of the phloem. The structures of these conducting cells facilitate bulk flow. Mature tracheids and vessel elements are dead cells (see Figure 28.9) and therefore have no cytoplasm, and the cytoplasm of sieve-tube elements is almost devoid of internal organelles. If you have ever dealt with a partially clogged drain, you know that the volume of flow depends on the pipe's diameter. Clogs reduce the effective diameter of the drainpipe. Such experiences help us understand how the structures of plant cells specialized for bulk flow fit their function. Like the unplugging of a kitchen drain, the absence or reduction of cytoplasm in a plant's "plumbing" allows for efficient bulk flow through the xylem and phloem.

Diffusion, active transport, and bulk flow act in concert to transport resources throughout the whole plant. In the following sections, we examine in more detail the transport of water and minerals from roots to shoots, the control of evaporation, and the transport of sugars.

### CONCEPT CHECK 29.2

1. If a plant cell immersed in distilled water has a  $\psi_s$  of  $-0.7$  MPa and a  $\psi$  of  $0$  MPa, what is the cell's  $\psi_p$ ? If you put it in an open beaker of solution that has a  $\psi$  of  $-0.4$  MPa, what would be its  $\psi_p$  at equilibrium?
2. How would a reduction in the number of aquaporin channels affect a plant cell's ability to adjust to new osmotic conditions?
3. **WHAT IF?** What would happen if you put plant protoplasts in pure water? Explain.

For suggested answers, see Appendix A.

## CONCEPT 29.3

### Plant roots absorb essential elements from the soil

Water, air, and soil minerals all contribute to plant growth. The water content of a plant can be measured by comparing the plant's mass before and after drying. Typically, 80–90% of a plant's fresh mass is water. Some 96% of the remaining dry mass consists of carbohydrates such as cellulose that are produced by photosynthesis. Thus, the components of carbohydrates—carbon, oxygen, and hydrogen—are the most abundant elements in dried plant residue. Inorganic substances from the soil, although essential for plant survival, generally account for only about 4% of a plant's dry mass.

### Macronutrients and Micronutrients

The inorganic substances in plants consist of more than 50 chemical elements. In studying the chemical composition of plants, we must distinguish elements that are essential from

those that are merely present in the plant. A chemical element is considered an **essential element** only if it is required for a plant to complete its life cycle and produce another generation.

To determine which chemical elements are essential, researchers often use **hydroponic culture**, in which plants are grown in mineral solutions instead of soil (**Figure 29.8**). Such studies have helped identify 17 essential elements needed by all plants (**Table 29.1**). Hydroponic culture is also used on a small scale to grow some greenhouse crops.

Nine of the essential elements are called **macronutrients** because plants require them in relatively large amounts. Six of these are the major components of organic compounds forming a plant's structure: carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulfur. The other three macronutrients are potassium, calcium, and magnesium. Of all the mineral nutrients, nitrogen contributes the most to plant growth and crop yields. Plants require nitrogen as a component of proteins, nucleic acids, chlorophyll, and other important organic molecules.

### ▼ Figure 29.8 Research Method

#### Hydroponic Culture

**Application** In hydroponic culture, plants are grown in mineral solutions without soil. One use of hydroponic culture is to identify essential elements in plants.

**Technique** Plant roots are bathed in aerated solutions of known mineral composition. Aerating the water provides the roots with oxygen for cellular respiration. (Note: The flasks would normally be opaque to prevent algal growth.) A mineral, such as potassium, can be omitted to test whether it is essential.

**Results** If the omitted mineral is essential, mineral deficiency symptoms occur, such as stunted growth and discolored leaves. By definition, the plant would not be able to complete its life cycle. Deficiencies of different elements may have different symptoms, which can aid in diagnosing mineral deficiencies in soil.

**Table 29.1** Essential Elements in Plants

Element	Form Primarily Absorbed by Plants	% Mass in Dry Tissue	Major Functions
<b>Macronutrients</b>			
Carbon	CO <sub>2</sub>	45%	Major component of plant's organic compounds
Oxygen	CO <sub>2</sub>	45%	Major component of plant's organic compounds
Hydrogen	H <sub>2</sub> O	6%	Major component of plant's organic compounds
Nitrogen	NO <sub>3</sub> <sup>-</sup> , NH <sub>4</sub> <sup>+</sup>	1.5%	Component of nucleic acids, proteins, hormones, chlorophyll, coenzymes
Potassium	K <sup>+</sup>	1.0%	Major solute functioning in water balance; operation of stomata
Calcium	Ca <sup>2+</sup>	0.5%	Important in formation and stability of cell walls and in maintenance of membrane structure and permeability; activates some enzymes; regulates many responses of cells to stimuli
Magnesium	Mg <sup>2+</sup>	0.2%	Component of chlorophyll; cofactor and activator of many enzymes
Phosphorus	H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> , HPO <sub>4</sub> <sup>2-</sup>	0.2%	Component of nucleic acids, phospholipids, ATP, several coenzymes
Sulfur	SO <sub>4</sub> <sup>2-</sup>	0.1%	Component of proteins, coenzymes
<b>Micronutrients</b>			
Chlorine	Cl <sup>-</sup>	0.01%	Required for water-splitting step of photosynthesis; functions in water balance
Iron	Fe <sup>3+</sup> , Fe <sup>2+</sup>	0.01%	Component of cytochromes; cofactor of some enzymes; needed for photosynthesis
Manganese	Mn <sup>2+</sup>	0.005%	Active in formation of amino acids; activates some enzymes; required for water-splitting step of photosynthesis
Boron	H <sub>2</sub> BO <sub>3</sub> <sup>-</sup>	0.002%	Cofactor in chlorophyll synthesis; may be involved in carbohydrate transport and nucleic acid synthesis; role in cell wall function
Zinc	Zn <sup>2+</sup>	0.002%	Active in formation of chlorophyll; cofactor of some enzymes; needed for DNA transcription
Copper	Cu <sup>+</sup> , Cu <sup>2+</sup>	0.001%	Component of many redox and lignin-biosynthetic enzymes
Nickel	Ni <sup>2+</sup>	0.001%	Cofactor for an enzyme functioning in nitrogen metabolism
Molybdenum	MoO <sub>4</sub> <sup>2-</sup>	0.0001%	Essential for mutualistic relationship with nitrogen-fixing bacteria; cofactor in nitrate reduction

**MAKE CONNECTIONS** Humans require the minerals fluorine, selenium, and chromium in their diet (Concept 33.1), and they obtain these minerals from plants. However, these minerals are not essential for plant survival. How can plants be a source of these minerals when they don't need them to complete their life cycle?

The remaining eight essential elements are known as **micronutrients** because plants need them in only tiny quantities. They are chlorine, iron, manganese, boron, zinc, copper, nickel, and molybdenum. Sodium is a ninth essential micronutrient for plants that use the CAM or C<sub>4</sub> pathway of photosynthesis. Too much of a nutrient can, of course, damage plants.

Micronutrients function in plants mainly as cofactors, non-protein helpers in enzymatic reactions (see Concept 6.4). Iron, for example, is a metallic component of cytochromes, the proteins in the electron transport chains of chloroplasts and mitochondria. It is because micronutrients generally play catalytic roles that plants need only tiny quantities. The requirement for molybdenum, for instance, is so modest that there is only one atom of this rare element for every 60 million atoms of hydrogen in dried plant material. Yet a deficiency of molybdenum or any other micronutrient can weaken or kill a plant.

## Symptoms of Mineral Deficiency

The symptoms of a deficiency depend partly on the mineral's function as a nutrient. For example, a deficiency of magnesium, a component of chlorophyll, causes *chlorosis*, yellowing of the leaves. In some cases, the relationship between a mineral deficiency and its symptoms is less direct. For instance, iron deficiency can cause chlorosis even though chlorophyll contains no iron, because iron ions are required as a cofactor in one of the enzymatic steps of chlorophyll synthesis.

Mineral deficiency symptoms depend not only on the role of the nutrient but also on its mobility within the plant. If a nutrient moves about freely, symptoms appear first in older organs, because young, growing tissues are a greater sink for nutrients that are in short supply. For example, magnesium is relatively mobile and is shunted preferentially to young leaves. Therefore, a plant deficient in magnesium first shows signs of chlorosis in its older leaves. In contrast, a deficiency of a mineral that is relatively immobile affects young parts of the plant first. Older tissues may have adequate amounts that they retain during periods of short supply. For example, iron does not move freely within a plant, and an iron deficiency causes yellowing of young

▲ **Figure 29.9 The most common mineral deficiencies, as seen in maize leaves.** Mineral deficiency symptoms may vary in different species. In maize, phosphate-deficient plants have reddish purple margins, particularly in young leaves. Potassium-deficient maize plants exhibit “firing,” or drying, along tips and margins of older leaves. Nitrogen deficiency is evident in a yellowing that starts at the tip and moves along the center (midrib) of older leaves.

leaves before any effect on older leaves is visible. The mineral requirements of a plant also change with the age of the plant. Young seedlings, for example, rarely show mineral deficiency symptoms because their mineral needs are met largely by the mineral reserves stored in the seeds themselves.

The symptoms of a mineral deficiency in a given plant species are often distinctive enough to aid in diagnosis (**Figure 29.9**). Deficiencies of phosphorus, potassium, and especially nitrogen are most common. Micronutrient shortages are less common and reflect local differences in soil composition. The amount of a micronutrient needed to correct a deficiency is usually quite small. For example, a zinc deficiency in fruit trees can usually be cured by hammering a few zinc nails into each tree trunk. Moderation is important because overdoses of many nutrients can be detrimental or toxic to plants. Too much nitrogen, for example, can lead to excessive vine growth in tomato plants at the expense of good fruit production.

## Soil Management

Ancient farmers recognized that yields on a particular plot of land decreased over the years. Moving to uncultivated areas, they observed the same pattern of reduced yields over time. Eventually, they realized that fertilization could make soil a renewable resource that enabled crops to be cultivated season after season at a fixed location. This sedentary agriculture facilitated a new way of life. People began to build permanent dwellings—the first villages. They also stored food for use between harvests, and food surpluses enabled some members of these early communities to specialize in nonfarming occupations. In short, the early discovery of soil fertilization helped prepare the way for modern societies.

## Fertilization

In natural ecosystems, mineral nutrients are usually recycled by the excretion of animal wastes and the decomposition of **humus**, the remains of dead organisms and other organic matter. Agriculture, however, is not a natural ecosystem. The lettuce you eat, for example, contains minerals extracted from a farmer’s field. As you excrete wastes, these minerals are deposited far from their original source. Over many harvests, the farmer’s field will eventually become depleted of nutrients. Nutrient depletion is a major cause of global soil degradation. Farmers must reverse nutrient depletion by fertilization, the addition of mineral nutrients to the soil.

Today, most farmers in industrialized nations use fertilizers containing minerals that are either mined or prepared by energy-intensive processes. These fertilizers are usually enriched in nitrogen (N), phosphorus (P), and potassium (K)—the nutrients most commonly deficient in depleted soils. You may have seen fertilizers labeled with a three-number code, called the N–P–K ratio. A fertilizer marked “15–10–5,” for instance, is 15% N (as ammonium or nitrate), 10% P (as phosphate), and 5% K (as the mineral potash).

Manure, fishmeal, and compost are called “organic” fertilizers because they are of biological origin and contain decomposing organic material. Before plants can use organic material, however, it must be decomposed into the inorganic nutrients that roots can absorb. Whether from organic fertilizer or a chemical factory, the minerals a plant extracts are in the same form. However, organic fertilizers release them gradually, whereas minerals in commercial fertilizers are immediately available but may not be retained by the soil for long. A drawback of modern fertilization practices is that minerals not absorbed by roots are often leached from the soil by rainwater or irrigation. To make matters worse, mineral runoff into lakes may lead to explosions in algal populations that can deplete oxygen levels and decimate fish populations.

## Adjusting Soil pH

Soil pH is an important factor that influences mineral availability by its effect on cation exchange and the chemical form of minerals. Depending on the soil pH, a particular mineral may be bound too tightly to soil particles or may be in a chemical form that the plant cannot absorb. Most plants prefer slightly acidic soil because the high  $H^+$  concentrations can displace positively charged minerals from soil particles, making them more available for absorption. Adjusting soil pH for optimal crop growth is tricky because a change in  $H^+$  concentration may make one mineral more available but another less available. At pH 8, for instance, plants can absorb calcium, but iron is almost unavailable. The soil pH should be matched to a crop’s mineral needs. If the soil is too alkaline, adding sulfate will lower the pH. Soil that is too acidic can be adjusted by adding lime (calcium carbonate or calcium hydroxide).

When the soil pH dips to 5 or lower, toxic aluminum ions ( $\text{Al}^{3+}$ ) become more soluble and are absorbed by roots, stunting root growth and preventing the uptake of calcium, a needed plant nutrient. Some plants can cope with high  $\text{Al}^{3+}$  levels by secreting organic anions that bind  $\text{Al}^{3+}$  and render it harmless. However, low soil pH and  $\text{Al}^{3+}$  toxicity continue to pose serious problems, especially in tropical regions, where the pressure of producing food for a growing population is often most acute.

Soil mismanagement is a major problem facing the world. More than 30% of the world's farmland has reduced productivity stemming from poor soil conditions, such as chemical contamination, mineral deficiencies, acidity, salinity, and poor drainage. As the world's population continues to grow, the demand for food increases. Because soil quality is a major determinant of crop yield, the need to manage soil resources prudently has never been greater.

## The Living, Complex Ecosystem of Soil

The successful cultivation of plants in soil-free hydroponic systems demonstrates that plants do not need soil to complete their life cycles. Still, most terrestrial plants do grow in soil, and it is from the topsoil that they usually acquire mineral nutrients. Thus, an understanding of the properties of soil is important for understanding plants and their growth. We begin by discussing the basic physical properties of soil: its texture and composition.

### Soil Texture

The texture of soil depends on the size of its particles. Soil particles can range from coarse sand (0.02–2 mm in diameter) to silt (0.002–0.02 mm) to microscopic clay particles (less than 0.002 mm). These different-sized particles arise ultimately from the weathering of rock. Water freezing in the crevices of rocks causes mechanical fracturing, and weak acids in the soil break rocks down chemically. When organisms penetrate the rock, they accelerate breakdown by chemical and mechanical means. Plant roots, for example, secrete acids that dissolve the rock, and their growth in fissures leads to mechanical fracturing. The mineral particles released by weathering become mixed with living organisms and humus, forming topsoil.

In the topsoil, plants are nourished by the soil solution, the water and dissolved minerals in the pores between soil particles. The pores also contain air pockets. After a heavy rainfall, water drains away from the larger spaces in the soil, but smaller spaces retain water because water molecules are attracted to the negatively charged surfaces of clay and other soil particles.

The most fertile topsoils are **loams**, which are composed of roughly equal amounts of sand, silt, and clay. Loamy soils have enough small silt and clay particles to provide ample surface area for the adhesion and retention of minerals and water. Meanwhile, the large spaces between sand particles enable efficient diffusion of oxygen to the roots. Sandy soils generally don't retain enough water to support vigorous plant growth,

and clayey soils tend to retain too much water. When soil does not drain adequately, the air is replaced by water, and the roots suffocate from lack of oxygen. Typically, the most fertile topsoils have pores that are about half water and half air, providing a good balance between aeration, drainage, and water storage capacity. The physical properties of soils can be adjusted by adding soil amendments, such as peat moss, compost, manure, or sand.

### Topsoil Composition

A topsoil's composition encompasses its inorganic (mineral) and organic chemical components. The organic components include the many life-forms that inhabit the soil.

**Inorganic Components** The surface charges of soil particles determine their ability to bind many nutrients. Most soil particles are negatively charged. Negatively charged ions (anions)—such as the plant nutrients nitrate ( $\text{NO}_3^-$ ), phosphate ( $\text{H}_2\text{PO}_4^-$ ), and sulfate ( $\text{SO}_4^{2-}$ )—do not bind to the negatively charged soil particles and are therefore easily lost by leaching, the percolation of water through the soil. By comparison, positively charged ions (cations)—such as potassium ( $\text{K}^+$ ), calcium ( $\text{Ca}^{2+}$ ), and magnesium ( $\text{Mg}^{2+}$ )—bind more strongly to soil particles and are less easily lost by leaching.

Roots, however, do not absorb mineral cations directly from soil particles; they absorb them from the soil solution. Mineral cations enter the soil solution by **cation exchange**, a process in which cations are displaced from soil particles by other cations, particularly  $\text{H}^+$  (**Figure 29.10**). Therefore, a soil's capacity to exchange cations is determined by the number of cation adhesion sites and by the soil's pH. Soils with higher capacities generally have a larger reserve of mineral nutrients.

▲ **Figure 29.10** Cation exchange in soil.

**?** Which are more likely to be leached from the soil by heavy rains—cations or anions? Explain.

**Organic Components** Humus, which consists of the organic material produced by decomposition of fallen leaves, feces, dead organisms, and other organic matter by bacteria and fungi, is the major organic component of topsoil. Humus prevents clay particles from packing together and forms a crumbly soil that retains water but is still porous enough to aerate roots adequately. Humus also increases the soil's capacity to exchange cations and serves as a reservoir of mineral nutrients that return gradually to the soil as microorganisms decompose the organic matter.

**Living Components** Topsoil is home to an astonishing number and variety of organisms. A teaspoon of topsoil has about 5 billion bacteria, which cohabit with fungi, algae and other protists, insects, earthworms, nematodes, and plant roots. The activities of all these organisms affect the soil's physical and chemical properties. Earthworms, for example, consume organic matter and derive their nutrition from the bacteria and fungi growing on this material. They excrete wastes and move large amounts of material to the soil surface. In addition, they move organic matter into deeper layers of the soil. In effect, earthworms mix and clump the soil particles, allowing for better gaseous diffusion and retention of water. Plant roots also affect soil texture and composition. For example, by binding the soil, they reduce erosion, and by excreting acids, they lower soil pH.

#### CONCEPT CHECK 29.3

1. Are some essential elements more important than others? Explain.
2. **WHAT IF?** If an element increases the growth rate of a plant, can it be defined as an essential element?
3. **MAKE CONNECTIONS** Based on Figure 7.17, explain why ethanol accumulates in plant roots subjected to waterlogging.

For suggested answers, see Appendix A.

## CONCEPT 29.4

### Plant nutrition often involves relationships with other organisms

To this point, we have portrayed plants as exploiters of soil resources. But plants and soil have a two-way relationship. Dead plants provide much of the energy needed by soil microorganisms. Moreover, secretions from living roots support a wide variety of microbes in the near-root environment. Here we'll focus on some *mutualistic*—mutually beneficial—relationships between plants and soil bacteria or fungi. Then we'll look at some nonmutualistic forms of plant nutrition involving other organisms.

#### Soil Bacteria and Plant Nutrition

Some soil bacteria engage in mutually beneficial chemical exchanges with plant roots. Others enhance the decomposition of organic materials and increase nutrient availability. Some even live inside roots and convert nitrogen from the air.

#### Rhizobacteria

**Rhizobacteria** are soil bacteria with especially large populations in the **rhizosphere**, the soil layer that surrounds the plant's roots. Different soils vary greatly in the types and number of rhizobacteria they harbor. Microbial activity within a plant's rhizosphere is 10 to 100 times higher than in nearby soil because the roots secrete nutrients such as sugars, amino acids, and organic acids. Up to 20% of a plant's photosynthetic production fuels the organisms in this miniature ecosystem. As a result of diverse plant-microbe interactions, the composition of this microbial population often differs greatly from the surrounding soil and the rhizospheres of other plant species. Each rhizosphere contains a unique and complex cocktail of root secretions and microbial products.

Rhizobacteria known as *plant-growth-promoting rhizobacteria* enhance plant growth by a variety of mechanisms. Some produce chemicals that stimulate plant growth. Others produce antibiotics that protect roots from disease. Still others absorb toxic metals or make nutrients more available to roots. Inoculation of seeds with plant-growth-promoting rhizobacteria can increase crop yield and reduce the need for fertilizers and pesticides. How do the bacteria benefit by interacting with plants? Nutrients secreted by roots supply most of the energy in the rhizosphere, so bacterial adaptations that help a plant thrive also help the bacteria.

#### Bacteria in the Nitrogen Cycle

Unlike other soil minerals, ammonium ions ( $\text{NH}_4^+$ ) and nitrate ions ( $\text{NO}_3^-$ )—the forms of nitrogen that plants can use—are not derived from the weathering of rocks. Although lightning produces small amounts of  $\text{NO}_3^-$  that get carried to the soil in rain, most soil nitrogen comes from the activity of bacteria (**Figure 29.11**). From a global perspective, no mineral nutrient is more limiting to plant growth than nitrogen, which is required in large amounts for synthesizing proteins and nucleic acids.

The **nitrogen cycle**, also discussed in Figure 42.13, describes transformations of nitrogen and nitrogenous compounds in nature. When a plant or animal dies or an animal expels waste, the initial form of nitrogen is organic. Decomposers called *ammonifying bacteria* convert the organic nitrogen within the remains back to ammonium ( $\text{NH}_4^+$ ), a process called ammonification. Other sources of soil  $\text{NH}_4^+$  are *nitrogen-fixing bacteria*, which convert gaseous nitrogen ( $\text{N}_2$ ) to  $\text{NH}_3$ , which in turn picks up another  $\text{H}^+$  in the soil solution to form  $\text{NH}_4^+$ .

Plants can also acquire nitrogen in the form of  $\text{NO}_3^-$  (nitrate). Soil  $\text{NO}_3^-$  is largely formed by a two-step process called *nitrification*, which consists of the oxidation of  $\text{NH}_4^+$  to nitrite ( $\text{NO}_2^-$ ), followed by the oxidation of nitrite to nitrate ( $\text{NO}_3^-$ ). Different types of *nitrifying bacteria* mediate each step. After the roots absorb  $\text{NO}_3^-$ , a plant enzyme reduces it back to  $\text{NH}_4^+$ , which other enzymes incorporate into amino acids and

▲ **Figure 29.11 The roles of soil bacteria in the nitrogen nutrition of plants.** Ammonium is made available to plants by two types of soil bacteria: those that fix atmospheric  $N_2$  (nitrogen-fixing bacteria) and those that decompose organic material (ammonifying bacteria). Although plants absorb some ammonium from the soil, they absorb mainly nitrate, which is produced from ammonium by nitrifying bacteria. Plants reduce nitrate back to ammonium before incorporating the nitrogen into organic compounds.

other organic compounds. Most plant species export nitrogen from roots to shoots via the xylem as  $NO_3^-$  or organic compounds synthesized in the roots. Some soil nitrogen is lost, particularly in anaerobic soils, when denitrifying bacteria convert  $NO_3^-$  to  $N_2$ , which diffuses into the atmosphere.

### Nitrogen-Fixing Bacteria: A Closer Look

Although Earth's atmosphere is 79% nitrogen ( $N_2$ ), plants cannot use gaseous  $N_2$  directly because there is a triple bond between the two nitrogen atoms, making the molecule almost inert. For  $N_2$  to be of use to plants, it must be reduced to  $NH_3$  by a process called **nitrogen fixation**. All  $N_2$ -fixing organisms are bacteria, and some that carry out this process are free-living (see Figure 29.11). One of the more important bacteria involved in  $N_2$  fixation is the genus *Rhizobium*, which forms intimate associations with the roots of legumes (such as peas and soybeans) and markedly alters their root structure. Although *Rhizobium* can be free-living in the soil, it cannot fix  $N_2$  in its free state, nor can legume roots fix  $N_2$  without the bacteria.

The multistep conversion of  $N_2$  to  $NH_3$  by  $N_2$  fixation can be summarized as follows:

The reaction is driven by the enzyme complex *nitrogenase*. Because the process of  $N_2$  fixation requires 8 ATP molecules for each  $NH_3$  synthesized,  $N_2$ -fixing bacteria require a rich supply of carbohydrates from decaying material, root secretions, or (in the case of *Rhizobium*) the vascular tissue of roots.

The mutualism between *Rhizobium* (“root living”) bacteria and legume roots involves dramatic changes in root structure. Along a legume’s roots are swellings called **nodules**, composed of plant cells that have been “infected” by *Rhizobium* (Figure 29.12). Inside each nodule, *Rhizobium* bacteria assume a form called **bacteroids**, which are contained within vesicles formed in the root cells. Legume-*Rhizobium* relationships generate more usable nitrogen for plants than all industrial fertilizers used today—and at virtually no cost to the farmer.

▲ **Figure 29.12 Soybean root nodules.** The spherical structures along this soybean root system are nodules containing *Rhizobium* bacteria. The bacteria fix nitrogen and obtain photosynthetic products made by the plant.

The location of the bacteroids inside living, nonphotosynthetic cells facilitates  $N_2$  fixation, which requires an anaerobic environment. Lignified external layers of root nodules also limit gas exchange. Some root nodules appear reddish because of a molecule called leghemoglobin (*leg-* for “legume”), an iron-containing protein that binds reversibly to oxygen (similar to the hemoglobin in human red blood cells). This protein is an oxygen “buffer,” reducing the concentration of free oxygen and thereby providing an anaerobic environment for  $N_2$  fixation while regulating the oxygen supply for the intense cellular respiration required to produce ATP for  $N_2$  fixation.

Each legume species is associated with a particular strain of *Rhizobium*. The symbiotic relationship between a legume and  $N_2$ -fixing bacteria is mutualistic in that the bacteria supply the host plant with fixed nitrogen while the plant provides the bacteria with carbohydrates and other organic compounds. The root nodules use most of the ammonium produced to make amino acids, which are then transported up to the shoot through the xylem.

## Fungi and Plant Nutrition

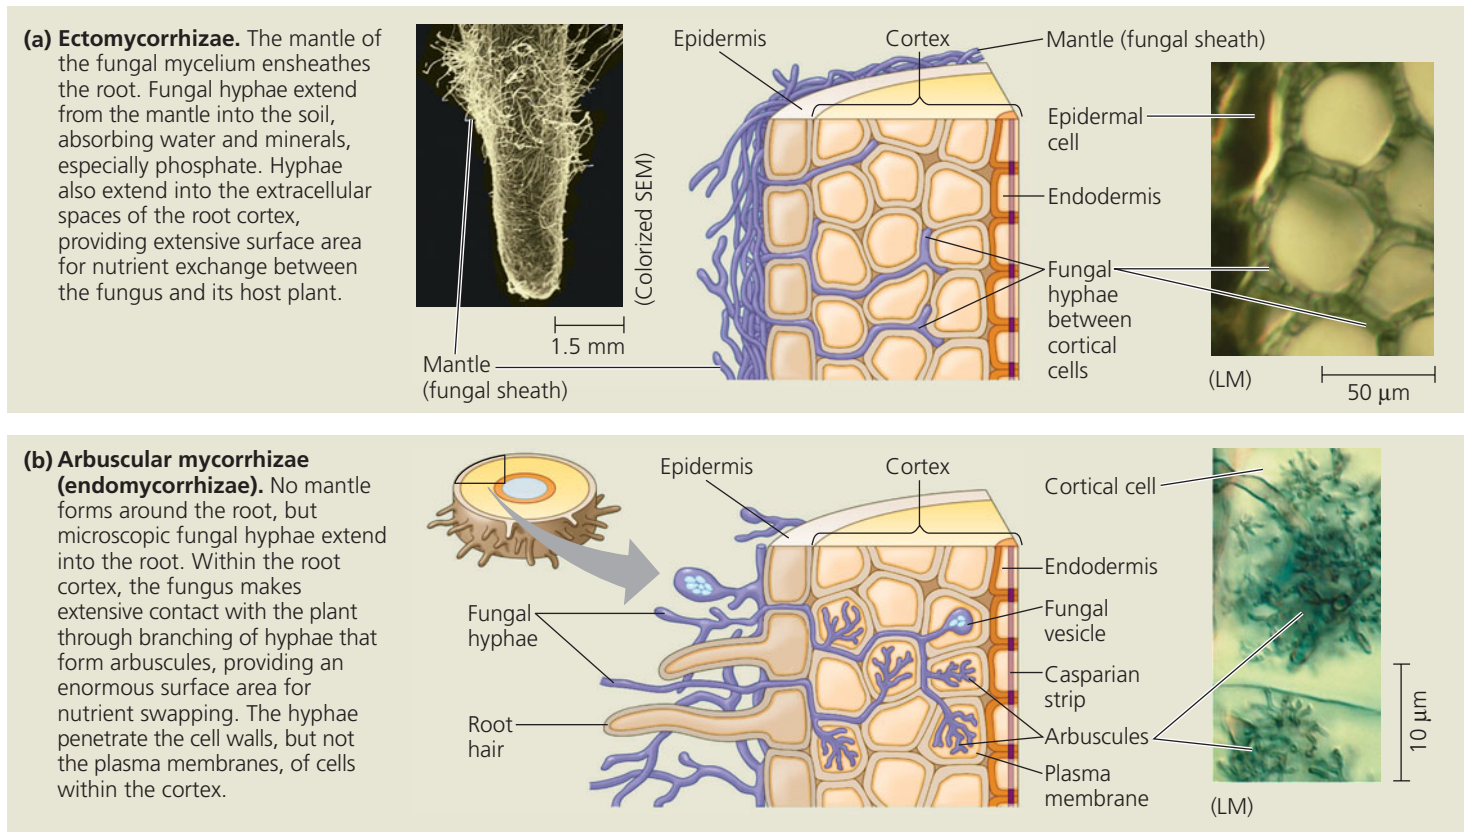

**Mycorrhizae** (“fungus roots”) are mutualistic associations of roots and fungi that play a major role in plant nutrition. The host plant provides the fungus with a steady supply of sugar. Meanwhile, the fungus increases the surface area for water

uptake and also supplies the plant with phosphate and other minerals absorbed from the soil. The fungi of mycorrhizae also secrete growth factors that stimulate roots to grow and branch, as well as antibiotics that help protect the plant from soil pathogens.

### The Two Main Types of Mycorrhizae

One type of mycorrhiza—the **ectomycorrhizae**—forms a dense sheath, or mantle, of mycelia (mass of branching hyphae) over the surface of the root (**Figure 29.13a**). Fungal hyphae extend from the mantle into the soil, greatly increasing the surface area for water and mineral absorption. Hyphae also grow into the root cortex, forming an apoplastic network within the extracellular spaces that facilitates nutrient exchange. Of the 10% of plant families that have species that form ectomycorrhizae, the majority are woody, including members of the pine, birch, and eucalyptus families.

**Arbuscular mycorrhizae** are more common than ectomycorrhizae and are found in over 85% of plant species, including most crops. Unlike ectomycorrhizae, they do not form a dense mantle ensheathing the root (**Figure 29.13b**). Arbuscular mycorrhizal associations start when microscopic soil hyphae respond to the presence of a root by growing toward it, establishing contact, and growing along its surface. Hyphae penetrate between epidermal cells and then enter the root cortex. These hyphae digest small patches of the cortical cell walls, but

▲ **Figure 29.13** Mycorrhizae.

they do not actually pierce the plasma membrane and enter the cytoplasm. Instead, a hypha grows into a tube formed by invagination of the root cell's membrane. The process is analogous to poking a finger gently into a balloon without popping it; your finger is like the fungal hypha, and the balloon skin is like the root cell's membrane. After the fungal hyphae have penetrated in this way, some branch densely, forming structures called arbuscules ("little trees"), which are important sites of nutrient transfer between the fungus and the plant. Within the hyphae themselves, oval vesicles may form, possibly serving as food storage sites for the fungus. To the unaided eye, arbuscular mycorrhizae look like "normal" roots with root hairs, but a microscope reveals the enormous extent of the mutualistic relationship.

### Agricultural and Ecological Importance of Mycorrhizae

Roots can form mycorrhizal symbioses only if exposed to the appropriate species of fungus. In most ecosystems, these fungi are present in the soil, but if seeds are collected in one environment and planted in foreign soil, the plants may show signs of malnutrition (particularly phosphorus deficiency), resulting from the absence of fungal partners. Treating seeds with mycorrhizal fungal spores can help seedlings form mycorrhizae and improve crop yield.

Mycorrhizal associations are also important in understanding ecological relationships. Invasive exotic plants sometimes colonize areas by disrupting interactions between native organisms. For example, garlic mustard (*Alliaria petiolata*), introduced into New England from Europe during the 1800s, has invaded woodlands throughout the eastern and middle United States, suppressing tree seedlings and other native plants. Recent evidence suggests that its invasive properties may stem from its ability to slow the growth of other plant species by preventing the growth of arbuscular mycorrhizal fungi (Figure 29.14).

### Epiphytes, Parasitic Plants, and Carnivorous Plants

Almost all plant species have mutualistic symbiotic relationships with soil fungi or bacteria or both. Though rarer, there are also plant species with nutritional adaptations that use other organisms in nonmutualistic ways. Figure 29.15 provides an overview of three unusual adaptations: epiphytes, parasitic plants, and carnivorous plants.

#### CONCEPT CHECK 29.4

1. Why is the study of the rhizosphere critical to understanding plant nutrition?
2. How do soil bacteria and mycorrhizae contribute to plant nutrition?
3. **WHAT IF?** A soybean farmer finds that the older leaves of his plant are turning yellow following a long period of wet weather. Suggest a reason why.

For suggested answers, see Appendix A.

#### ▼ Figure 29.14 Inquiry

### Does the invasive weed garlic mustard disrupt mutualistic associations between native tree seedlings and arbuscular mycorrhizal fungi?

**Experiment** Kristina Stinson, of Harvard University, and colleagues investigated the effect of invasive garlic mustard (shown in the photo) on the growth of native tree seedlings and associated mycorrhizal fungi. In one experiment, they grew seedlings of three North American trees—sugar maple, red maple, and white ash—in four different soils. Two of the soil samples were collected from a location where garlic mustard was growing, and one of these samples was sterilized. The other two soil samples were collected from a location devoid of garlic mustard, and one of these was sterilized.

After four months of growth, the researchers harvested the shoots and roots and determined the dried biomass. The roots were also analyzed for percent colonization by arbuscular mycorrhizal fungi.

**Results** Native tree seedlings grew more slowly and were less able to form mycorrhizal associations when grown either in sterilized soil or in unsterilized soil collected from a location that had been invaded by garlic mustard.

**Conclusion** The data support the hypothesis that garlic mustard suppresses growth of native trees by affecting the soil in a way that disrupts mutualistic associations between the trees and arbuscular mycorrhizal fungi.

**Source** K. A. Stinson et al., Invasive plant suppresses the growth of native tree seedlings by disrupting belowground mutualisms, *PLoS Biol* (Public Library of Science: Biology) 4(5): e140 (2006).

**Inquiry in Action** Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers*.

**WHAT IF?** What effect would applying inorganic phosphate to soil invaded by garlic mustard have on the plant's ability to outcompete native species?

## Epiphytes

An **epiphyte** (from the Greek *epi*, upon, and *phyton*, plant) is a plant that grows on another plant. Epiphytes produce and gather their own nutrients; they do not tap into their hosts for sustenance. Usually anchored to the branches or trunks of living trees, epiphytes absorb water and minerals from rain, mostly through leaves rather than roots. Some examples are staghorn ferns, bromeliads, and many orchids, including the vanilla plant.

► **Staghorn fern**, an epiphyte

## Parasitic Plants

Unlike epiphytes, parasitic plants absorb water, minerals, and sometimes products of photosynthesis from their living hosts. Many species have roots that function as haustoria, nutrient-absorbing projections that tap into the host plant. Some parasitic species, such as orange-colored, spaghetti-like dodder (genus *Cuscuta*), lack chlorophyll entirely, whereas others, such as mistletoe (genus *Phoradendron*), are photosynthetic. Still others, such as Indian pipe (*Monotropa uniflora*), absorb nutrients from the hyphae of mycorrhizae associated with other plants.

◄ **Mistletoe**, a photosynthetic parasite

▲ **Dodder**, a nonphotosynthetic parasite (orange)

▲ **Indian pipe**, a nonphotosynthetic parasite of mycorrhizae

## Carnivorous Plants

Carnivorous plants are photosynthetic but supplement their mineral diet by capturing insects and other small animals. They live in acid bogs and other habitats where soils are poor in nitrogen and other minerals. Pitcher plants such as *Nepenthes* and *Sarracenia* have water-filled funnels into which prey slip and drown, eventually to be digested by enzymes. Sundews (genus *Drosera*) exude a sticky fluid from tentacle-like glands on highly modified leaves. Stalked glands secrete sweet mucilage that attracts and ensnares insects, and they also release digestive enzymes. Other glands then absorb the nutrient "soup." The highly modified leaves of Venus flytrap (*Dionaea muscipula*) close quickly but partially when a prey hits two trigger hairs in rapid enough succession. Smaller insects can escape, but larger ones are trapped by the teeth lining the margins of the lobes. Excitation by the prey causes the trap to narrow more and digestive enzymes to be released.

## Transpiration drives the transport of water and minerals from roots to shoots via the xylem

An average-sized tree, despite having neither heart nor muscle, transports nearly 800 L of water on a warm, sunny day. How do trees accomplish this feat? To answer this question, we'll follow each step in the journey of water and minerals from the tips of roots to leaves.

### Absorption of Water and Minerals by Root Cells

Although all living plant cells absorb nutrients across their plasma membranes, the cells near the tips of roots are particularly important because most of the absorption of water and minerals occurs there. In this region, the epidermal cells are permeable to water, and many are differentiated into root hairs, modified cells that account for much of the absorption of water by roots (see Figure 28.4). The root hairs absorb the

soil solution, which consists of water molecules and dissolved mineral ions that are not bound tightly to soil particles. The soil solution is drawn into the hydrophilic walls of epidermal cells and passes freely along the cell walls and the extracellular spaces into the root cortex. This flow enhances the exposure of the cells of the cortex to the soil solution, providing a much greater membrane surface area for absorption than the surface area of the epidermis alone. Although the soil solution usually has a low mineral concentration, active transport enables roots to accumulate essential minerals to concentrations hundreds of times greater than in the soil.

### Transport of Water and Minerals into the Xylem

Water and minerals that pass from the soil into the root cortex cannot be transported to the rest of the plant until they enter the xylem of the vascular cylinder, or stele. The **endodermis**, the innermost layer of the cortex, functions as a last checkpoint for the selective passage of minerals into the vascular cylinder (**Figure 29.16**). Minerals already in the symplast when they reach the endodermis continue through

▼ **Figure 29.16** Transport of water and minerals from root hairs to the xylem.

? How does the Casparian strip force water and minerals to pass through the plasma membranes of endodermal cells?

the plasmodesmata of endodermal cells and pass into the vascular cylinder. These minerals were already screened by the plasma membrane they had to cross to enter the symplast in the epidermis or cortex. Those minerals that reach the endodermis via the apoplast encounter a dead end that blocks their passage into the vascular cylinder. This barrier, located in the transverse and radial walls of each endodermal cell, is the **Casparian strip**, a belt made of suberin, a waxy material impervious to water and dissolved minerals (see Figure 29.16). The Casparian strip forces water and minerals that are passively moving through the apoplast to cross the plasma membrane of an endodermal cell before they can enter the vascular cylinder. The endodermis, with its Casparian strip, ensures that no minerals can reach the vascular tissue of the root without crossing a selectively permeable plasma membrane. The endodermis also prevents solutes that have accumulated in the xylem from leaking back into the soil solution.

The last segment in the soil-to-xylem pathway is the passage of water and minerals into the tracheids and vessel elements of the xylem. These water-conducting cells lack protoplasts when mature and are therefore parts of the apoplast. Endodermal cells, as well as living cells within the vascular cylinder, discharge minerals from their protoplasts into their own cell walls. Both diffusion and active transport are involved in this transfer of solutes from symplast to apoplast, and the water and minerals are now free to enter the tracheids and vessel elements, where they are transported to the shoot system by bulk flow.

## Bulk Flow Transport via the Xylem

Water and minerals from the soil enter the plant through the epidermis of roots, cross the root cortex, and pass into the vascular cylinder. From there the **xylem sap**, the water and dissolved minerals in the xylem, gets transported long distances by bulk flow to the veins that branch throughout each leaf. As noted earlier, bulk flow is much faster than diffusion or active transport. Peak velocities in the transport of xylem sap can range from 15 to 45 m/hr for trees with wide vessel elements. Stems and leaves depend on this efficient delivery system for their supply of water and minerals. Xylem sap rises to heights of more than 120 m in the tallest trees, largely by being pulled upward.

The process of transporting xylem sap involves the loss of an astonishing amount of water by **transpiration**, the loss of water vapor from leaves and other aerial parts of the plant. A single maize plant, for example, transpires 60 L of water (the equivalent of 170 12-ounce bottles) during a growing season. A maize crop growing at a typical density of 60,000 plants per hectare transpires almost 4 million L of water per hectare every growing season (about 400,000 gallons of water per acre per growing season). Unless the transpired water is replaced by water transported up from the roots, the leaves will wilt, and the plants may eventually die.

## Pulling Xylem Sap:

### The Cohesion-Tension Hypothesis

The xylem sap that rises through a tree does not require living cells to do so. Early researchers demonstrated that leafy stems with their lower end immersed in toxic solutions of copper sulfate or acid readily draw these poisons up if the stem is cut below the surface of the liquid. As the toxic solutions ascend, they kill all living cells in their path, eventually arriving in the transpiring leaves and killing the leaf cells as well. Nevertheless, the uptake of the toxic solutions and the loss of water from the dead leaves can continue for weeks.

The **cohesion-tension hypothesis** is almost universally accepted by plant biologists as the mechanism underlying the ascent of xylem sap. According to this hypothesis, transpiration provides the pull for the ascent of xylem sap, and the cohesion of water molecules transmits this pull along the entire length of the xylem from shoots to roots. Hence, xylem sap is normally under negative pressure, or tension. Since transpiration is a “pulling” process, our exploration of the rise of xylem sap by the cohesion-tension mechanism begins not with the roots but with the leaves, where the driving force for transpirational pull begins.

**Transpirational Pull** Stomata on a leaf’s surface lead to a maze of internal air spaces that expose the mesophyll cells to the CO<sub>2</sub> required for photosynthesis. The air in these spaces is saturated with water vapor. On most days, the air outside the leaf is drier; that is, it has lower water potential than the air inside the leaf. Therefore, water vapor in the air spaces of a leaf diffuses down its water potential gradient and exits the leaf via the stomata. Transpiration refers to this loss of water vapor from plants by diffusion and evaporation.

But how does loss of water vapor from the leaf translate into a pulling force for upward movement of water through a plant? The negative pressure potential that causes water to move up through the xylem develops at the surface of mesophyll cell walls in the leaf (**Figure 29.17**). The cell wall acts like a very thin capillary network. Water adheres to the cellulose microfibrils and other hydrophilic components of the cell wall. As water evaporates from the water film that covers the cell walls of mesophyll cells, the air-water interface retreats farther into the cell wall. Because of the high surface tension of water, the curvature of the interface induces a tension, or negative pressure potential, in the water. As more water evaporates from the cell wall, the curvature of the air-water interface increases and the pressure of the water becomes more negative. Water molecules from the more hydrated parts of the leaf are then pulled toward this area, reducing the tension. These pulling forces are transferred to the xylem because each water molecule is cohesively bound to the next by hydrogen bonds. Thus, transpirational pull depends on several of the properties of water discussed in Chapter 2: adhesion, cohesion, and surface tension.

The role of negative pressure potential in transpiration is consistent with the water potential equation because negative

**▲ Figure 29.17 Generation of transpirational pull.** Negative pressure (tension) at the air-water interface in the leaf is the basis of transpirational pull, which draws water out of the xylem.

pressure potential (tension) *lowers* water potential (see Figure 29.6). Because water moves from areas of higher water potential to areas of lower water potential, the more negative pressure potential at the air-water interface causes water in xylem cells to be “pulled” into mesophyll cells, which lose water to the air spaces, the water eventually diffusing out through stomata. In this way, the negative water potential of leaves provides the “pull” in transpirational pull. The transpirational pull on xylem sap is transmitted all the way from the leaves to the root tips and even into the soil solution (**Figure 29.18**).

#### ► Figure 29.18 Ascent of xylem sap.

Hydrogen bonding forms an unbroken chain of water molecules extending from leaves to the soil. The force driving the ascent of xylem sap is a gradient of water potential ( $\psi$ ). For bulk flow over long distance, the  $\psi$  gradient is due mainly to a gradient of the pressure potential ( $\psi_p$ ). Transpiration results in the  $\psi_p$  at the leaf end of the xylem being lower than the  $\psi_p$  at the root end. The  $\psi$  values shown on the left side of the figure are a “snapshot.” They may vary during daylight, but the direction of the  $\psi$  gradient remains the same.

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Water Transport in Plants.

**Cohesion and Adhesion in the Ascent of Xylem Sap** Cohesion and adhesion facilitate the transport of water by bulk flow. Cohesion is the attractive force between molecules of the same substance. Water has an unusually high cohesive force due to the hydrogen bonds each water molecule can potentially make with other water molecules. Water's cohesive force within the xylem gives it a tensile strength equivalent to that of a steel wire of similar diameter. The cohesion of water makes it possible to pull a column of xylem sap from above without the water molecules separating. Water molecules exiting the xylem in the leaf tug on adjacent water molecules, and this pull is relayed, molecule by molecule, down the entire column of water in the xylem. Meanwhile, the strong adhesion of water molecules (again by hydrogen bonds) to the hydrophilic walls of xylem cells helps offset the downward force of gravity.

The upward pull on the sap creates tension within the vessel elements and tracheids, which are like elastic pipes. Positive pressure causes an elastic pipe to swell, whereas tension pulls the walls of the pipe inward. On a warm day, a decrease in the diameter of a tree trunk can even be measured. As transpirational pull puts the vessel elements and tracheids under tension, their thick secondary walls prevent them from collapsing, much as wire rings maintain the shape of a vacuum-cleaner hose. The tension produced by transpirational pull lowers water potential in the root xylem to such an extent that water flows passively from the soil, across the root cortex, and into the vascular cylinder.

Transpirational pull can extend down to the roots only through an unbroken chain of water molecules. Cavitation, the formation of a water vapor pocket, breaks the chain. It is more common in wide vessel elements than in tracheids and can occur during drought stress or when xylem sap freezes in winter. The air bubbles resulting from cavitation expand and block the water channels of the xylem. The interruption of xylem sap transport by cavitation is not always permanent. The chain of water molecules can detour around the air bubbles through pits between adjacent tracheids or vessel elements (see Figure 28.9). Moreover, secondary growth adds a layer of new xylem each year, and only the youngest, outermost secondary xylem layers transport water. Finally, an active though minor force called *root pressure* enables some small plants to refill blocked vessel elements.

## Xylem Sap Ascent by Bulk Flow: A Review

In the long-distance transport of water from roots to leaves by bulk flow, the movement of fluid is driven by a water potential difference at opposite ends of xylem tissue. The water potential difference is created at the leaf end of the xylem by the evaporation of water from leaf cells. Evaporation lowers the water potential at the air-water interface, thereby generating the negative pressure (tension) that pulls water through the xylem.

Bulk flow in the xylem differs from diffusion in some key ways. First, it is driven by differences in pressure potential ( $\psi_p$ ); solute potential ( $\psi_s$ ) is not a factor. Therefore, the water

potential gradient within the xylem is essentially a pressure gradient. Also, the flow does not occur across plasma membranes of living cells, but instead within hollow, dead cells. Furthermore, it moves the entire solution together—not just water or solutes—and at much greater speed than diffusion.

The plant expends no energy to lift xylem sap by bulk flow. Instead, the absorption of sunlight drives most of transpiration by causing water to evaporate from the moist walls of mesophyll cells and by lowering the water potential in the air spaces within a leaf. Thus, the ascent of xylem sap, like the process of photosynthesis, is ultimately solar powered.

### CONCEPT CHECK 29.5

1. A scientist adds a water-soluble inhibitor of photosynthesis to roots of a transpiring plant, but photosynthesis is not reduced. Why?
2. **WHAT IF?** Suppose an *Arabidopsis* mutant lacking functional aquaporin proteins has a root mass three times greater than that of wild-type plants. Suggest an explanation.
3. **MAKE CONNECTIONS** How are the Casparian strip and tight junctions similar? See Figure 4.27.

For suggested answers, see Appendix A.

## CONCEPT 29.6

### The rate of transpiration is regulated by stomata

Leaves generally have large surface areas and high surface-to-volume ratios. The large surface area enhances light absorption for photosynthesis. The high surface-to-volume ratio aids in  $\text{CO}_2$  absorption during photosynthesis as well as in the release of  $\text{O}_2$ , a by-product of photosynthesis. Upon diffusing through the stomata,  $\text{CO}_2$  enters a honeycomb of air spaces formed by the spongy mesophyll cells (see Figure 28.17). Because of the irregular shapes of these cells, the leaf's internal surface area may be 10 to 30 times greater than the external surface area.

Although large surface areas and high surface-to-volume ratios increase the rate of photosynthesis, they also increase water loss by way of the stomata. Thus, a plant's tremendous requirement for water is largely a consequence of the shoot system's need for ample exchange of  $\text{CO}_2$  and  $\text{O}_2$  for photosynthesis. By opening and closing the stomata, guard cells help balance the plant's requirement to conserve water with its requirement for photosynthesis.

### Stomata: Major Pathways for Water Loss

About 95% of the water a plant loses escapes through stomata, although these pores account for only 1–2% of the external leaf surface. The waxy cuticle limits water loss through the remaining surface of the leaf. Each stoma is flanked by a pair of guard cells. Guard cells control the diameter of the stoma by changing shape, thereby widening or narrowing the gap between the

two guard cells. Under the same environmental conditions, the amount of water lost by a leaf depends largely on the number of stomata and the average size of their pores.

The stomatal density of a leaf is under both genetic and environmental control. For example, desert plants are genetically programmed to have lower stomatal densities than do marsh plants. Stomatal density, however, is a developmentally plastic feature of many plants. High light exposures and low  $\text{CO}_2$  levels during leaf development lead to increased density in many species. By measuring the stomatal density of dried herbarium specimens, scientists have gained insight into the levels of atmospheric  $\text{CO}_2$  in the past. A recent British survey found that stomatal density of many woodland species has decreased since 1927, when a similar survey was made. This observation is consistent with other findings that atmospheric  $\text{CO}_2$  levels increased dramatically during the late 20th century.

## Mechanisms of Stomatal Opening and Closing

When guard cells absorb water from neighboring cells, they become more turgid. In most angiosperm species, the cell walls of guard cells are uneven in thickness, and the cellulose microfibrils are oriented in a direction that causes the guard cells to bow outward when turgid (Figure 29.19a). This bowing outward increases the size of the pore between the guard cells. When the cells lose water and become flaccid, they become less bowed, and the pore closes.

The changes in turgor pressure in guard cells result primarily from the reversible absorption and loss of potassium ions ( $\text{K}^+$ ). Stomata open when guard cells actively accumulate  $\text{K}^+$  from neighboring epidermal cells (Figure 29.19b). The flow of  $\text{K}^+$  across the plasma membrane of the guard cell is coupled to the generation of a membrane potential by proton pumps (see Figure 29.5a). Stomatal opening correlates with active transport of  $\text{H}^+$  out of the guard cell. The resulting voltage (membrane potential) drives  $\text{K}^+$  into the cell through specific membrane channels. The absorption of  $\text{K}^+$  causes the water potential to become more negative within the guard cells, and the cells become more turgid as water enters by osmosis. Stomatal closing results from a loss of  $\text{K}^+$  from guard cells to neighboring cells, which leads to an osmotic loss of water. Aquaporins also help regulate the osmotic swelling and shrinking of guard cells.

## Stimuli for Stomatal Opening and Closing

In general, stomata are open during the day and mostly closed at night, preventing the plant from losing water under conditions when photosynthesis cannot occur. At least three cues contribute to stomatal opening at dawn: light,  $\text{CO}_2$  depletion, and an internal “clock” in guard cells.

The light stimulates guard cells to accumulate  $\text{K}^+$  and become turgid. This response is triggered by illumination of blue-light receptors in the plasma membrane of guard cells. Activation of these receptors stimulates the activity of proton

**Guard cells turgid/Stoma open      Guard cells flaccid/Stoma closed**

**(a) Changes in guard cell shape and stomatal opening and closing (surface view).** Guard cells of a typical angiosperm are illustrated in their turgid (stoma open) and flaccid (stoma closed) states. The radial orientation of cellulose microfibrils in the cell walls causes the guard cells to increase more in length than width when turgor increases. Since the two guard cells are tightly joined at their tips, they bow outward when turgid, causing the stomatal pore to open.

**(b) Role of potassium ions ( $\text{K}^+$ ) in stomatal opening and closing.** The transport of  $\text{K}^+$  (symbolized here as red dots) across the plasma membrane and vacuolar membrane causes the turgor changes of guard cells. The uptake of anions, such as malate and chloride ions (not shown), also contributes to guard cell swelling.

**▲ Figure 29.19 Mechanisms of stomatal opening and closing.**

pumps in the plasma membrane of the guard cells, in turn promoting absorption of  $\text{K}^+$ .

The stomata also open in response to depletion of  $\text{CO}_2$  within the leaf’s air spaces as a result of photosynthesis. As  $\text{CO}_2$  concentrations decrease during the day, the stomata progressively open if sufficient water is supplied to the leaf.

A third cue, the internal “clock” in the guard cells, ensures that stomata continue their daily rhythm of opening and closing. This rhythm occurs even if a plant is kept in a dark location. All eukaryotic organisms have internal clocks that regulate cyclic processes. Cycles with intervals of approximately 24 hours are called **circadian rhythms**, which you’ll learn more about in Chapter 31.

Drought stress can also cause stomata to close. A hormone called **abscisic acid (ABA)** is produced in roots and leaves in response to water deficiency and signals guard cells to close stomata. This response reduces wilting but also restricts  $\text{CO}_2$  absorption, thereby slowing photosynthesis. ABA also directly

inhibits photosynthesis. Water availability is so tied to plant productivity not because water is needed as a substrate in photosynthesis but because freely available water allows plants to keep stomata open and take up more  $\text{CO}_2$ .

## Effects of Transpiration on Wilting and Leaf Temperature

As long as most stomata remain open, transpiration is greatest on days that are sunny, warm, dry, and windy because these environmental factors increase evaporation. If transpiration cannot pull sufficient water to the leaves, the shoot becomes slightly wilted as cells lose turgor pressure. Although plants respond to such mild drought stress by rapidly closing stomata, some evaporative water loss still occurs through the cuticle. Under prolonged drought conditions, the leaves can become irreversibly injured.

Transpiration also results in evaporative cooling, which can lower a leaf's temperature by as much as  $10^\circ\text{C}$  compared with the surrounding air. This cooling prevents the leaf from reaching temperatures that could lead to protein denaturation.

► Ocotillo (*Fouquieria splendens*) is common in the southwestern region of the United States and northern Mexico. It is leafless during most of the year, thereby avoiding excessive water loss (right). Immediately after a heavy rainfall, it produces small leaves (below and inset). As the soil dries, the leaves quickly shrivel and die.

## Adaptations That Reduce Evaporative Water Loss

Many species of desert plants avoid drying out by completing their short life cycles during the brief rainy seasons. Rain comes infrequently in deserts, but when it arrives, the vegetation is transformed as dormant seeds of annual species quickly germinate and bloom, completing their life cycle before dry conditions return. Longer-lived species have unusual physiological or morphological adaptations that enable them to withstand the harsh desert conditions. Plants adapted to arid environments, such as the stone plants (see Figure 29.1), are called **xerophytes** (from the Greek *xero*, dry). **Figure 29.20** shows other examples. Many xerophytes, such as cacti, have highly reduced leaves that resist excessive water loss; they carry out photosynthesis mainly in their stems. The stems of many xerophytes are fleshy because they store water for use during long dry periods.

Another adaptation to arid habitats is **crassulacean acid metabolism (CAM)**, a specialized form of photosynthesis found in succulents of the family Crassulaceae and several

▼ Oleander (*Nerium oleander*), shown in the inset, is commonly found in arid climates. Its leaves have a thick cuticle and multiple-layered epidermal tissue that reduce water loss. Stomata are recessed in cavities called "crypts," an adaptation that reduces the rate of transpiration by protecting the stomata from hot, dry wind. Trichomes help minimize transpiration by breaking up the flow of air, allowing the chamber of the crypt to have a higher humidity than the surrounding atmosphere (LM).

► The long, white hairlike bristles along the stem of the old man cactus (*Cephalocereus senilis*) help reflect the intense sunlight of the Mexican desert.

▲ **Figure 29.20** Some xerophytic adaptations.

other families. Because the leaves of CAM plants take in  $\text{CO}_2$  at night, the stomata can remain closed during the day, when evaporative stresses are greater.

### CONCEPT CHECK 29.6

1. The pathogenic fungus *Fusicoccum amygdali* secretes a toxin called fusicoccin that activates the plasma membrane proton pumps of plant cells and leads to uncontrolled water loss. Suggest a mechanism by which the activation of proton pumps could lead to severe wilting.
2. **WHAT IF?** If you buy cut flowers, why might the florist recommend cutting the stems underwater and then transferring the flowers to a vase while the cut ends are still wet?
3. **MAKE CONNECTIONS** Explain why the evaporation of water from leaves lowers their temperature. See Concept 2.5.

For suggested answers, see Appendix A.

## CONCEPT 29.7

### Sugars are transported from sources to sinks via the phloem

The unidirectional flow of water and minerals from soil to roots to leaves through the xylem is largely in an upward direction. In contrast, the movement of photosynthates often runs in the opposite direction, transporting sugars from mature leaves to lower parts of the plant, such as root tips that require large amounts of sugars for energy and growth. The transport of the products of photosynthesis, known as **translocation**, is carried out by another tissue, the phloem.

#### Movement from Sugar Sources to Sugar Sinks

Sieve-tube elements are specialized cells in angiosperms that serve as conduits for translocation. Arranged end to end, they form long sieve tubes (see Figure 28.9). Between these cells are sieve plates, structures that allow the flow of sap along the

sieve tube. **Phloem sap**, the solution that flows through sieve tubes, differs markedly from the xylem sap that is transported by tracheids and vessel elements. By far the most prevalent solute in phloem sap is sugar, typically sucrose in most species. The sucrose concentration may be as high as 30% by weight, giving the sap a syrupy thickness. Phloem sap may also contain amino acids, hormones, and minerals.

In contrast to the unidirectional transport of xylem sap from roots to leaves, phloem sap moves from sites of sugar production to sites of sugar use or storage (see Figure 29.2). A **sugar source** is a plant organ that is a net producer of sugar, by photosynthesis or by breakdown of starch. A **sugar sink** is an organ that is a net consumer or depository of sugar. Growing roots, buds, stems, and fruits are sugar sinks. Although expanding leaves are sugar sinks, mature leaves, if well illuminated, are sugar sources. A storage organ, such as a tuber or a bulb, may be a source or a sink, depending on the season. When stockpiling carbohydrates in the summer, it is a sugar sink. After breaking dormancy in the spring, it becomes a sugar source because its starch is broken down to sugar, which is carried to the growing shoot tips.

Sinks usually receive sugar from the nearest sugar sources. For each sieve tube, the direction of transport depends on the locations of the sugar source and sugar sink that are connected by that tube. Therefore, neighboring sieve tubes may carry sap in opposite directions if they originate and end in different locations.

Sugar must be transported, or loaded, into sieve-tube elements before being exported to sugar sinks. In some species, it moves from mesophyll cells to sieve-tube elements via the symplast, passing through plasmodesmata. In other species, it moves by symplastic and apoplastic pathways. During apoplastic loading, sugar is accumulated by nearby sieve-tube elements, either directly or through the companion cells (**Figure 29.21a**). In some plants, the walls of the companion

(a) Sucrose manufactured in mesophyll cells can travel via the symplast (blue arrows) to sieve-tube elements. In some species, sucrose exits the symplast near sieve tubes and travels through the apoplast (red arrow). It is then actively accumulated from the apoplast by sieve-tube elements and their companion cells.

(b) A chemiosmotic mechanism is responsible for the active transport of sucrose into companion cells and sieve-tube elements. Proton pumps generate an  $\text{H}^+$  gradient, which drives sucrose accumulation with the help of a cotransport protein that couples sucrose transport to the diffusion of  $\text{H}^+$  back into the cell.

▲ **Figure 29.21** Loading of sucrose into phloem.

cells feature many ingrowths, enhancing solute transfer between apoplast and symplast.

In most plants, sugar movement into the phloem requires active transport because sucrose is more concentrated in sieve-tube elements and companion cells than in mesophyll. Proton pumping and  $H^+$ /sucrose cotransport enable sucrose to move from mesophyll cells to sieve-tube elements or companion cells (Figure 29.21b).

Sucrose is unloaded at the sink end of a sieve tube. The process varies by species and organ. However, the concentration of free sugar in the sink is always lower than in the sieve tube because the unloaded sugar is consumed during growth and metabolism of the cells of the sink or converted to insoluble polymers such as starch. As a result of this sugar concentration gradient, sugar molecules diffuse from the phloem into the sink tissues, and water follows by osmosis.

### Bulk Flow by Positive Pressure: The Mechanism of Translocation in Angiosperms

Phloem sap flows from source to sink at rates as great as 1 m/hr, much faster than diffusion or cytoplasmic streaming. The translocation of phloem sap through sieve tubes by bulk flow is driven by positive pressure, or *pressure flow* (Figure 29.22). The building of pressure at the source and reduction of that pressure at the sink cause sap to flow from source to sink. Sinks vary in energy demands and capacity to unload sugars. Sometimes there are more sinks than can be supported by sources. In such cases, a plant might abort some flowers, seeds, or fruits—a phenomenon called *self-thinning*. Removing sinks can also be a horticulturally useful practice. For example, since large apples command a much better price than small ones, growers sometimes remove flowers or young fruits so that their trees produce fewer but larger apples.

▲ Figure 29.22 Bulk flow by positive pressure (pressure flow) in a sieve tube.

#### CONCEPT CHECK 29.7

1. Identify plant organs that are sugar sources, organs that are sugar sinks, and organs that might be either. Explain.
2. Why can xylem transport water and minerals using dead cells, whereas phloem requires living cells?
3. **WHAT IF?** Apple growers in Japan sometimes make a nonlethal spiral slash around the bark of trees that will be removed after the growing season. This makes the apples sweeter. Why?

For suggested answers, see Appendix A.

## 29 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 29.1

##### Adaptations for acquiring resources were key steps in the evolution of vascular plants (pp. 572–574)

- Leaves typically function in gathering sunlight and  $CO_2$ . Stems serve as supporting structures for leaves and as conduits for the long-distance transport of water and nutrients. Roots mine the soil for water and minerals and anchor the whole plant.

- Natural selection has produced plant architectures that fine-tune resource acquisition in the ecological niche in which the plant species naturally exists.

? How did the evolution of xylem and phloem contribute to the successful colonization of land by vascular plants?

#### CONCEPT 29.2

##### Different mechanisms transport substances over short or long distances (pp. 574–578)

- The selective permeability of the plasma membrane controls the movement of substances into and out of cells. Both active and passive transport mechanisms occur in plants.
- Plant tissues have two major compartments: the **apoplast** (everything outside the cells' plasma membranes) and the **symplast** (the cytosol and connecting plasmodesmata).

- The direction of water movement depends on the **water potential**, a quantity incorporating solute concentration and physical pressure. The osmotic uptake of water by plant cells and the resulting internal pressure that builds up make plant cells **turgid**.
- Long-distance transport occurs through **bulk flow**, the movement of liquid in response to a pressure gradient. Bulk flow occurs within the tracheids and vessel elements of the xylem and within the sieve-tube elements of the phloem.

**?** *Is xylem sap usually pulled or pushed up the plant?*

## CONCEPT 29.3

### Plant roots absorb essential elements from the soil (pp. 578–582)

- **Macronutrients**, elements required in relatively large amounts, include carbon, oxygen, hydrogen, nitrogen, and other major ingredients of organic compounds. **Micronutrients**, elements required in very small amounts, typically have catalytic functions as cofactors of enzymes.
- Deficiency of a mobile nutrient usually affects older organs more than younger ones; the reverse is true for nutrients that are less mobile within a plant. Macronutrient deficiencies are most common, particularly deficiencies of nitrogen, phosphorus, and potassium.
- Soil particles of various sizes derived from the breakdown of rock are found in soil. Soil particle size affects the availability of water, oxygen, and minerals in the soil.
- A soil's composition refers to its inorganic and organic components. Topsoil is a complex ecosystem teeming with bacteria, fungi, protists, animals, and the roots of plants.

**?** *Do plants need soil to grow? Explain.*

## CONCEPT 29.4

### Plant nutrition often involves relationships with other organisms (pp. 582–586)

- **Rhizobacteria** derive their energy from the **rhizosphere**, a microbe-enriched ecosystem intimately associated with roots. Plant secretions support the energy needs of the rhizosphere. Some rhizobacteria produce antibiotics, whereas others make nutrients more available for plants. Most are free-living, but some live inside plants. Plants satisfy most of their huge needs for nitrogen from the bacterial decomposition of humus and the fixation of gaseous  $N_2$ .
- $N_2$ -fixing bacteria convert atmospheric  $N_2$  to nitrogenous minerals that plants can absorb as a nitrogen source for organic synthesis. The most efficient mutualism between plants and nitrogen-fixing bacteria occurs in the nodules formed by *Rhizobium* bacteria growing in the roots of legumes. These bacteria obtain sugar from the plant and supply the plant with fixed nitrogen.
- **Mycorrhizae** are mutualistic associations formed between roots and certain soil fungi that aid in the absorption of minerals and water.
- **Epiphytes** grow on the surfaces of other plants but acquire water and minerals from rain. Parasitic plants absorb nutrients from host plants. Carnivorous plants supplement their mineral nutrition by digesting animals.

**?** *Do all plants gain their energy directly from photosynthesis? Explain.*

## CONCEPT 29.5

### Transpiration drives the transport of water and minerals from roots to shoots via the xylem (pp. 587–590)

- Water and minerals from the soil enter the plant through the epidermis of roots, cross the root cortex, and then pass into the vascular cylinder by way of the selectively permeable cells of the **endodermis**. From the vascular cylinder, the **xylem sap** is transported long distances by bulk flow to the veins that branch throughout each leaf.
- The **cohesion-tension hypothesis** proposes that the movement of xylem sap is driven by a water potential difference created at the leaf end of the xylem by the evaporation of water from leaf cells. Evaporation lowers the water potential at the air-water interface, thereby generating the negative pressure that pulls water through the xylem.

**?** *Why is the ability of water molecules to form hydrogen bonds important for the movement of xylem sap?*

## CONCEPT 29.6

### The rate of transpiration is regulated by stomata (pp. 590–593)

- **Transpiration** is the loss of water vapor from plants. **Wilting** occurs when the water lost by transpiration is not replaced by absorption from roots.
- Stomata are the major pathway for water loss from plants. Guard cells widen or narrow the stomatal pores. When guard cells take up  $K^+$ , the pore widens. The opening and closing of stomata are controlled by light,  $CO_2$ , the drought hormone **abscisic acid**, and a **circadian rhythm**.
- Reduced leaves and CAM photosynthesis are examples of adaptations to arid environments.

**?** *Why are stomata necessary?*

## CONCEPT 29.7

### Sugars are transported from sources to sinks via the phloem (pp. 593–594)

- Mature leaves are the main **sugar sources**, although storage organs can be seasonal sources. Growing organs such as roots, stems, and fruits are the main **sugar sinks**.
- Phloem loading depends on the active transport of sucrose. Sucrose is cotransported with  $H^+$ , which diffuses down a gradient generated by proton pumps. Loading of sugar at the source and unloading at the sink maintain a pressure difference that keeps sap flowing through a sieve tube.

**?** *Why is phloem transport considered an active process?*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- Which structure or compartment is part of the symplast?
  - the interior of a vessel element
  - the interior of a sieve tube
  - the cell wall of a mesophyll cell
  - an extracellular air space
  - a Casparian strip

2. Which of the following is an adaptation that enhances the uptake of water and minerals by roots?
  - a. mycorrhizae
  - b. cavitation
  - c. active uptake by vessel elements
  - d. rhythmic contractions by cortical cells
  - e. pumping through plasmodesmata
3. The inorganic nutrient most often lacking in plants is
  - a. carbon.
  - b. nitrogen.
  - c. phosphorus.
  - d. potassium.
  - e. molybdenum.
4. Movement of xylem sap from roots to leaves
  - a. occurs through the apoplast of sieve-tube elements.
  - b. usually depends on tension, or negative pressure potential.
  - c. depends on active transport.
  - d. depends on the pumping of water through aquaporins.
  - e. results mainly from diffusion.

### Level 2: Application/Analysis

5. What would enhance water uptake by a plant cell?
  - a. decreasing the  $\psi$  of the surrounding solution
  - b. increasing the pressure exerted by the cell wall
  - c. the loss of solutes from the cell
  - d. increasing the  $\psi$  of the cytoplasm
  - e. positive pressure on the surrounding solution
6. A plant cell with a  $\psi_s$  of  $-0.65$  MPa maintains a constant volume when bathed in a solution that has a  $\psi_s$  of  $-0.30$  MPa and is in an open container. The cell has a
  - a.  $\psi_p$  of  $+0.65$  MPa.
  - b.  $\psi$  of  $-0.65$  MPa.
  - c.  $\psi_p$  of  $+0.35$  MPa.
  - d.  $\psi_p$  of  $+0.30$  MPa.
  - e.  $\psi$  of  $0$  MPa.
7. Compared with a cell with few aquaporin proteins in its membrane, a cell containing many aquaporin proteins will
  - a. have a faster rate of osmosis.
  - b. have a lower water potential.
  - c. have a higher water potential.
  - d. have a faster rate of active transport.
  - e. accumulate water by active transport.
8. A mineral deficiency is likely to affect older leaves more than younger leaves if
  - a. the mineral is a micronutrient.
  - b. the mineral is very mobile within the plant.
  - c. the mineral is required for chlorophyll synthesis.
  - d. the mineral is a macronutrient.
  - e. the older leaves are in direct sunlight.
9. Two groups of tomatoes were grown in the laboratory, one with humus added to the soil and the other a control without humus. The leaves of the plants grown without humus were yellowish (less green) compared with those of the plants grown in humus-enriched soil. The best explanation for this difference is that
  - a. the healthy plants used carbohydrates in the decomposing leaves of the humus for energy to make chlorophyll.
  - b. the humus made the soil more loosely packed, so water penetrated more easily to the roots.
  - c. the humus contained minerals such as magnesium and iron, needed for the synthesis of chlorophyll.
  - d. the heat released by the decomposing leaves of the humus caused more rapid growth and chlorophyll synthesis.
  - e. the healthy plants absorbed chlorophyll from the humus.

10. **DRAW IT** Trace the uptake of water and minerals from root hairs to the endodermis in a root, following a symplastic route and an apoplastic route. Label the routes on the diagram below.

### Level 3: Synthesis/Evaluation

#### 11. SCIENTIFIC INQUIRY

Acid precipitation has an abnormally high concentration of hydrogen ions ( $H^+$ ). One effect of acid precipitation is to deplete the soil of nutrients such as calcium ( $Ca^{2+}$ ), potassium ( $K^+$ ), and magnesium ( $Mg^{2+}$ ). Suggest a hypothesis to explain how acid precipitation washes the nutrients from the soil. How might you test your hypothesis?

#### 12. SCIENTIFIC INQUIRY

A Minnesota gardener notes that the plants immediately bordering a walkway are stunted compared with those farther away. Suspecting that the soil near the walkway may be contaminated from salt added to the walkway in winter, the gardener tests the soil. The composition of the soil near the walkway is identical to that farther away except that it contains an additional  $50$  mM NaCl. Assuming that the NaCl is completely ionized, calculate how much it will lower the solute potential of the soil at  $20^\circ C$  using the *solute potential equation*:

$$\psi_s = -iCRT$$

where  $i$  = the ionization constant ( $2$  for NaCl);  $C$  = the molar concentration (in moles/liter);  $R$  = the pressure constant ( $R = 0.00831$  liter MPa/mole K); and  $T$  = temperature in Kelvin ( $273 + ^\circ C$ ). How would this change in the solute potential of the soil affect the water potential of the soil? In what way would the change in the water potential of the soil affect the movement of water in or out of the roots?

#### 13. FOCUS ON EVOLUTION

Large brown algae called kelps can grow as tall as  $25$  m. Kelps consist of a holdfast anchored to the ocean floor, blades that float at the surface and collect light, and a long stalk connecting the blades to the holdfast (see Figure 25.14). Specialized cells in the stalk, although nonvascular, can transport sugar. Suggest a reason why these structures analogous to sieve-tube elements might have evolved in kelps.

#### 14. FOCUS ON INTERACTIONS

The soil in which plants grow teems with organisms from every taxonomic kingdom. In a short essay ( $100$ – $150$  words), discuss examples of how the mutualistic interactions of plants with bacteria, fungi, and animals improve plant nutrition.

For selected answers, see Appendix A.

# Reproduction and Domestication of Flowering Plants

▼ **Figure 30.1** Why is this bee trying to mate with this flower?

## KEY CONCEPTS

- 30.1** Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle
- 30.2** Flowering plants reproduce sexually, asexually, or both
- 30.3** People modify crops through breeding and genetic engineering

## OVERVIEW

### Flowers of Deceit

**M**ale long-horned bees (*Eucera longicornis*) often attempt to copulate with flowers of the Mediterranean orchid *Ophrys scolopax* (**Figure 30.1**). During this encounter, a yellow sac of pollen becomes glued to the insect's body. Eventually frustrated, the bee flies off and deposits the pollen onto another *Ophrys* flower that has become the object of his misplaced ardor. *Ophrys* flowers offer no reward such as nectar to the male bees, only sexual frustration. So what makes the male bees so enamored of this orchid? The traditional answer has been that the shape and color of the orchid's largest petal and its bristles vaguely resemble the female bee. These

visual cues, however, are only part of the deception: some *Ophrys* orchids also emit chemicals with a scent similar to that produced by sexually receptive female bees.

This orchid and its bee pollinators are one example of the amazing ways in which angiosperms (flowering plants) reproduce sexually with spatially distant members of their own species. Sex, however, is not their only means of reproduction. Many species also reproduce asexually, creating offspring that are genetically identical to the parent.

An unusual aspect of the orchid and bee example is that the insect does not profit from interacting with the flower. In fact, by wasting time and energy, the bee is probably rendered less fit. More typically, a plant lures an animal pollinator to its flowers not with offers of sex but with rewards of energy-rich nectar or pollen. Thus, both plant and pollinator benefit. Participating in such mutually beneficial relationships with other organisms is common in the plant kingdom. In fact, in recent evolutionary times, some flowering plants have formed relationships with an animal that not only disperses their seeds but also provides the plants with water and mineral nutrients and vigorously protects them from encroaching competitors, pathogens, and predators.

In return for these favors, the animal typically gets to eat a fraction of some part of the plants, such as their seeds or fruits. The plants involved in these relationships are called crops; the animals are humans.

Since the origins of crop domestication over 10,000 years ago, plant breeders have genetically manipulated the traits of a few hundred wild angiosperm species by artificial selection, transforming them into the crops we grow today. Genetic engineering has dramatically increased the variety of ways and the speed with which we can now modify plants.

In Chapter 26, we approached plant reproduction from an evolutionary perspective, tracing the descent of land plants from algal ancestors. Because

angiosperms are the most important group of plants in agriculture and in most terrestrial ecosystems, we'll explore their reproductive biology in detail in this chapter. After discussing the sexual and asexual reproduction of angiosperms, we'll examine the role that people have played in domesticating crop species, as well as the controversies surrounding modern plant biotechnology.

## CONCEPT 30.1

### Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle

The life cycles of plants are characterized by an alternation of generations, in which multicellular haploid ( $n$ ) and multicellular diploid ( $2n$ ) generations alternate, producing each other (see Figures 10.6b and 26.6). The diploid plant, the sporophyte, produces haploid spores by meiosis. These spores divide by mitosis, giving rise to the multicellular gametophytes, the male and female haploid plants that produce gametes (sperm and eggs). **Fertilization**, the fusion of gametes, results in diploid zygotes, which divide by mitosis and form new sporophytes. In angiosperms, the sporophyte is the dominant generation: It is larger, more conspicuous, and longer-lived than the gametophyte. Over the course of seed plant evolution, gametophytes became reduced in size and wholly dependent on the sporophyte for nutrients. Angiosperm gametophytes are the most reduced of all plants, consisting of only a few cells. The key traits of the angiosperm life cycle can be remembered as the “three Fs”—flowers, double fertilization, and fruits.

#### Flower Structure and Function

Flowers, the reproductive shoots of angiosperm sporophytes, are typically composed of four types of floral organs: **carpels**, **stamens**, **petals**, and **sepals** (Figure 30.2). When viewed from above, these organs appear as concentric whorls. Carpels form the first (innermost) whorl, stamens form the second, petals form the third, and sepals form the fourth (outermost) whorl. All four types of floral organs are attached to a part of the stem called the **receptacle**. Unlike vegetative shoots, flowers are determinate shoots; they cease growing after the flower and fruit are formed.

Carpels and stamens are reproductive organs; sepals and petals are sterile. A carpel has an **ovary** at its base and a long, slender neck called the **style**. At the top of the style is a sticky structure called the **stigma** that captures pollen. Within the ovary are one or more **ovules**; the number of ovules depends on the species. The flower shown in Figure 30.2 has a single carpel, but many species have multiple carpels. In most species, two or more carpels are fused into a single structure; the result is an ovary with two or more chambers, each containing one or more ovules. The term **pistil** is sometimes used to refer to a single carpel or two or more fused carpels. A stamen consists of a stalk called the *filament* and a terminal structure

▲ Figure 30.2 The structure of an idealized flower.

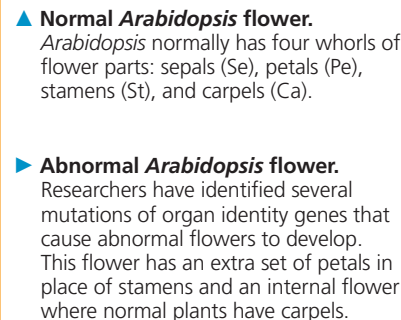

called the **anther**; within the anther are chambers called microsporangia (pollen sacs) that produce pollen. Petals are typically more brightly colored than sepals and advertise the flower to insects and other animal pollinators. Sepals, which enclose and protect unopened floral buds, usually resemble leaves more than the other floral organs do.

**Complete flowers** have all four basic floral organs (see Figure 30.2). Some species have **incomplete flowers**, lacking sepals, petals, stamens, or carpels. For example, most grass flowers lack petals. Some incomplete flowers are sterile, lacking functional stamens and carpels; others are *unisexual*, lacking either stamens or carpels. Flowers also vary in size, shape, color, odor, organ arrangement, and time of opening. Some are borne singly, while others are arranged in showy clusters called **inflorescences**. For example, a daisy is actually an inflorescence consisting of a central disk composed of hundreds of tiny complete flowers surrounded by sterile, incomplete flowers that look like white petals. Much of floral diversity represents adaptations to specific pollinators.

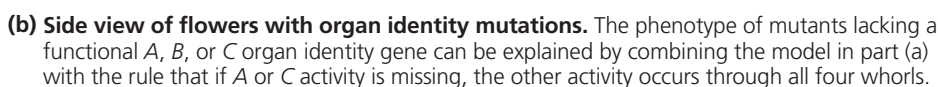

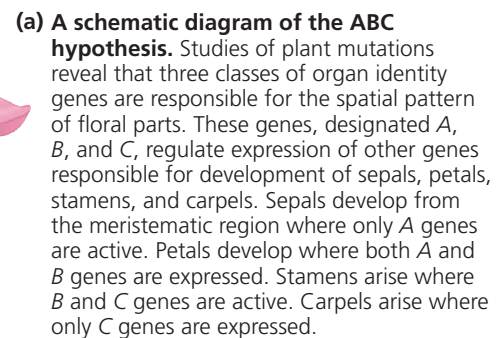

#### Flower Formation

The flowers of a given plant species typically appear suddenly at a specific time of year. Such synchrony promotes outbreeding, the main advantage of sexual reproduction. Flower formation involves a developmental switch in the shoot apical meristem from a vegetative to a reproductive growth mode. This transition into a *floral meristem* is triggered by a combination of environmental cues, such as day length, and internal signals. (You'll learn more about the roles of these signals in flowering in Chapter 31.) Once the transition to flowering has begun, the order of each organ's emergence from the floral meristem determines whether it will develop into a sepal, petal, stamen, or carpel. Several organ identity genes have been identified that encode transcription factors that regulate the development of this floral organization. A mutation in one of these genes can

By studying flower mutants, researchers have developed a model called the **ABC hypothesis** to explain how three floral organ identity genes direct the formation of the four types of floral organs. According to the slightly simplified version of the ABC hypothesis presented in **Figure 30.4a**, each class of organ identity genes is switched on in two specific whorls of the floral meristem. Normally, *A* genes are switched on in the two outer whorls (sepals and petals), *B* genes are switched on in the two middle whorls (petals and stamens), and *C* genes are switched on in the two inner whorls (stamens and carpels). Sepals arise from those parts of the floral meristems in which only *A* genes are active, petals where *A* and *B* genes are active,

**MAKE CONNECTIONS** Provide another example of a homeotic gene mutation that leads to organs being produced in the wrong place (see Concept 16.1).

**WHAT IF?** What would a flower look like if the A genes and B genes were inactivated?

stamens where *B* and *C* genes are active, and carpels where only *C* genes are active. The ABC hypothesis can account for the phenotypes of mutants lacking *A*, *B*, or *C* gene activity, with one addition: Where gene *A* activity is present, it inhibits *C*, and vice versa. If either *A* or *C* is missing, the other takes its place. **Figure 30.4b** shows the floral patterns of mutants lacking each of the three classes of organ identity genes and depicts how the hypothesis accounts for their floral phenotypes.

## Development of Female Gametophytes (Embryo Sacs)

**Figure 30.5** shows the angiosperm life cycle. We will start with the development of a female gametophyte **1**. As a carpel develops, one or more immature seeds (ovules) form deep within its ovary, its swollen base. A female gametophyte, also known as an **embryo sac**, develops inside each ovule. The process of embryo

▲ **Figure 30.5** The life cycle of an angiosperm.

sac formation—one variation of which we'll discuss here—occurs in a tissue called the megasporangium within each ovule. Two *integuments* (layers of protective sporophytic tissue that will develop into the seed coat) surround each megasporangium except at a gap called the *micropyle*. Female gametophyte development begins when one cell in the megasporangium of each ovule, the *megasporeocyte* (or megaspore mother cell), enlarges and undergoes meiosis, producing four haploid **megaspores**. Only one megaspore survives; the others degenerate.

The nucleus of the surviving megaspore divides by mitosis three times without cytokinesis, resulting in one large cell with eight haploid nuclei. This multinucleate mass is then divided by membranes to form an embryo sac. At the micropylar end of the embryo sac, two cells called synergids flank the egg and help attract and guide the pollen tube to the embryo sac. At the opposite end of the embryo sac are three antipodal cells of unknown function. The other two nuclei, called polar nuclei, are not partitioned into separate cells but share the cytoplasm of the large central cell of the embryo sac. The ovule, which will become a seed, now consists of the embryo sac, surrounded by the megasporangium (which eventually withers) and two surrounding integuments.

### Development of Male Gametophytes in Pollen Grains

As stamens are produced, each anther develops four microsporangia, also called pollen sacs. Within the microsporangia are many diploid cells called *microsporocytes*, or microspore mother cells (see Figure 30.5, ②). Each microsporocyte undergoes meiosis, forming four haploid **microspores**. Each microspore then undergoes mitosis, producing a haploid male gametophyte consisting of only two cells: the *generative cell* and the *tube cell*. Together, these two cells *and* the spore wall constitute a **pollen grain**. The spore wall, which consists of material produced by both the microspore and the anther, usually exhibits an elaborate pattern unique to the species. During maturation of the male gametophyte, the generative cell passes into the tube cell: The tube cell now has a completely free-standing cell inside it. After the microsporangium breaks open and releases its pollen, a pollen grain may be transferred to a receptive surface of a stigma—the act of pollination. There, the tube cell produces the **pollen tube**, a long cellular protuberance that delivers sperm to the female gametophyte. Pollen tubes can grow very quickly, at rates of 1 cm/hr or more. As a pollen tube elongates through the style, the generative cell usually divides and produces two sperm cells, which remain inside the tube cell. The pollen tube grows through the style and into the ovary, where it releases the sperm cells in the vicinity of the female gametophyte.

### Pollination

In angiosperms, **pollination** is the transfer of pollen from an anther to a stigma. It is accomplished by wind or animals

(**Figure 30.6**). In wind-pollinated species, including grasses and many trees, the release of enormous quantities of smaller-sized pollen compensates for the randomness of dispersal by the wind. At certain times of the year, the air is loaded with pollen grains, as anyone who has a pollen allergy can attest. Some species of aquatic plants rely on water to disperse pollen. Most angiosperm species, however, depend on insects, birds, or other animal pollinators to transfer pollen directly from one flower to another. If pollination is successful, a pollen grain produces a pollen tube, which then grows down into the ovary via the style.

### Double Fertilization

At the time of pollination, the pollen grain typically consists of only the tube cell and the generative cell. After a pollen grain lands on a suitable stigma, it absorbs water and germinates by producing a pollen tube, which grows between the cells of the style toward the ovary (**Figure 30.7**). The nucleus of the generative cell divides by mitosis and forms two sperm. In response to chemical attractants produced by the synergids, the tip of the pollen tube grows toward the micropyle. Its arrival initiates the death of one of the two synergids, thereby providing a passageway into the embryo sac for the two sperm that are discharged from the pollen tube.

Upon reaching the female gametophyte, one sperm fertilizes the egg, forming the zygote. The other sperm combines with the two polar nuclei, forming a triploid ( $3n$ ) nucleus in the center of the large central cell of the female gametophyte. This large cell will give rise to the **endosperm**, a food-storing tissue of the seed. The union of two sperm cells with different nuclei of the female gametophyte is called **double fertilization**. Double fertilization ensures that endosperm develops only in ovules where the egg has been fertilized, thereby preventing angiosperms from squandering nutrients on infertile ovules.

### Seed Development, Form, and Function

After double fertilization, each ovule develops into a seed, and the ovary develops into a fruit enclosing the seed(s). As the embryo develops from the zygote, the seed stockpiles proteins, oils, and starch to varying degrees, depending on the species. Initially, carbohydrates and other nutrients are stored in the seed's endosperm, but later the swelling cotyledons (seed leaves) of the embryo take over this function in some species.

### Endosperm Development

Endosperm usually develops before the embryo does. After double fertilization, the triploid nucleus of the ovule's central cell divides, forming a multinucleate "supercell" that has a milky consistency. This liquid mass, the endosperm, becomes multicellular when cytokinesis partitions the cytoplasm by forming membranes between the nuclei. Eventually, these "naked" cells produce cell walls, and the endosperm becomes solid. Coconut "milk" and "meat" are examples of liquid and

Most angiosperm species rely on a living (biotic) or nonliving (abiotic) pollinating agent that can move pollen from the anther of a flower on one plant to the stigma of a flower on another plant. Approximately 80% of all angiosperm pollination is biotic, employing animal go-betweens. Among abiotically pollinated species, 98% rely on wind and 2% on water.

## Abiotic Pollination by Wind

Since the reproductive success of wind-pollinated angiosperms does not depend on attracting pollinators, there has been no selective pressure favoring colorful or scented flowers. Accordingly, the flowers of wind-pollinated species are often small, green, and inconspicuous, and they produce neither nectar nor scent. Most temperate trees and grasses are wind-pollinated. The flowers of hazel (*Corylus avellana*) and many other temperate, wind-pollinated trees appear in early spring, when leaves are not present to interfere with pollen movement. The relative inefficiency of wind pollination is compensated for by production of enormous numbers of pollen grains.

▲ Hazel carpellate flower (carpels only)

▲ Hazel staminate flower (stamens only)

## Pollination by Insects

▲ Common dandelion under normal light

▲ Common dandelion under ultraviolet light

About 65% of all flowering plants require insects for pollination; the percentage is even greater for major crops. Pollinating insects include bees, moths, butterflies, flies, and beetles. Bees are the most important, and there is great concern that honeybee populations are in decline. Pollinating bees depend on pollen and the sugary solution called nectar for food. The main function of nectar, which is produced by nectaries at the base of many flowers, is to “reward” the pollinator. Typically, bee-pollinated flowers have a delicate, sweet fragrance. Bees are attracted to bright colors, primarily yellow and blue. Red appears dull to them, but they can see ultraviolet radiation. Many bee-pollinated flowers, such as the common dandelion (*Taraxacum officinale*), have markings called “nectar guides” that help insects locate the nectaries (nectar-producing glands); some of these markings are visible to human eyes only under ultraviolet light.

## Pollination by Bats

Bat-pollinated flowers are light-colored and aromatic, attracting their nocturnal pollinators. The lesser long-nosed bat (*Leptonycteris curasoae yerbabuenae*) pollinates agave and cactus flowers in the southwestern United States and Mexico as it feeds on their nectar and pollen.

▶ Long-nosed bat feeding on cactus flower at night

## Pollination by Birds

Bird-pollinated flowers, such as columbine flowers, are usually large and bright red or yellow, but they have little odor since many birds do not have a well-developed sense of smell. Nectar helps meet the high energy demands of pollinating birds. The petals of bird-pollinated flowers are often fused, forming a bent floral tube that fits the curved beak of the bird.

▶ Hummingbird drinking nectar of columbine flower

▲ **Figure 30.7** Growth of the pollen tube and double fertilization.

solid endosperm, respectively. The white fluffy part of popcorn is also endosperm.

In grains and most other species of monocots, as well as many eudicots, the endosperm stores nutrients that can be used by the seedling after germination. In other eudicot seeds, the food reserves of the endosperm are completely exported to the cotyledons before the seed completes its development; consequently, the mature seed lacks endosperm.

### Embryo Development

The first mitotic division of the zygote splits the fertilized egg into a basal cell and a terminal cell (**Figure 30.8**). The terminal cell eventually gives rise to most of the embryo. The basal cell continues to divide, producing a thread of cells called the *suspensor*, which anchors the embryo to the parent plant. The

suspensor helps in transferring nutrients to the embryo from the parent plant and, in some species, from the endosperm. As the suspensor elongates, it pushes the embryo deeper into the nutritive and protective tissues. Meanwhile, the terminal cell divides several times and forms a spherical proembryo (early embryo) attached to the suspensor. The cotyledons begin to form as bumps on the proembryo. A eudicot, which typically has two cotyledons, is heart-shaped at this stage. Only one cotyledon develops in monocots.

▲ **Figure 30.8** The development of a eudicot plant embryo.

By the time the ovule becomes a mature seed and the integuments harden and thicken into the seed coat, the zygote has given rise to an embryonic plant with rudimentary organs.

Soon after the rudimentary cotyledons appear, the embryo elongates. Cradled between the two cotyledons is the embryonic shoot apex. At the opposite end of the embryo's axis, where the suspensor attaches, an embryonic root apex forms. After the seed germinates—indeed, for the rest of the plant's life—the apical meristems at the apices of shoots and roots sustain primary growth (see Figure 28.10).

### Structure of the Mature Seed

During the last stages of its maturation, the seed dehydrates until its water content is only about 5–15% of its weight. The embryo, which is surrounded by a food supply (cotyledons, endosperm, or both), enters **dormancy**; that is, it stops growing and its metabolism nearly ceases. The embryo and its food supply are enclosed by a hard, protective **seed coat** formed from the integuments of the ovule. In some species, dormancy is imposed by the presence of an intact seed coat rather than by the embryo itself.

You can take a closer look at one type of eudicot seed by splitting open the seed of a common garden bean. The embryo consists of an elongate structure, the embryonic axis, attached to two large cotyledons (**Figure 30.9a**). Below where the cotyledons are attached, the embryonic axis is called the **hypocotyl** (from the Greek *hypo*, under). The hypocotyl terminates in the **radicle**, or embryonic root. The portion of the embryonic axis above where the cotyledons are attached and below the first pair of miniature leaves is the **epicotyl** (from the Greek *epi*, on, over). The epicotyl, young leaves, and shoot apical meristem are collectively called the *plumule*.

The cotyledons of the common garden bean are packed with starch before the seed germinates because they absorbed carbohydrates from the endosperm when the seed was developing. However, the seeds of some eudicot species, such as castor beans (*Ricinus communis*), retain their food supply in the endosperm and have very thin cotyledons (**Figure 30.9b**). The cotyledons absorb nutrients from the endosperm and transfer them to the rest of the embryo when the seed germinates.

The embryos of monocots possess only a single cotyledon (**Figure 30.9c**). Grasses, including maize and wheat, have a specialized cotyledon called a *scutellum* (from the Latin *scutella*, small shield, a reference to its shape). The scutellum, which has a large surface area, is pressed against the endosperm, from which it absorbs nutrients during germination. The embryo of a grass seed is enclosed within two protective sheathes: a **coleoptile**, which covers the young shoot, and a **coleorhiza**, which covers the young root. Both structures aid in soil penetration after germination.

Seed weights range from less than 1  $\mu\text{g}$  for some orchids to 20 kg for coco-de-mer palms. Orchid seeds have almost no food reserves and must bond symbiotically with mycorrhizae prior to germination. Large, endosperm-rich palm seeds are an adaptation for seedling establishment on nutrient-poor beaches.

(a) **Common garden bean, a eudicot with thick cotyledons.** The fleshy cotyledons store food absorbed from the endosperm before the seed germinates.

(b) **Castor bean, a eudicot with thin cotyledons.** The narrow, membranous cotyledons (shown in edge and flat views) absorb food from the endosperm when the seed germinates.

(c) **Maize, a monocot.** Like all monocots, maize has only one cotyledon. Maize and other grasses have a large cotyledon called a scutellum. The rudimentary shoot is sheathed in a structure called the coleoptile, and the coleorhiza covers the young root.

### ▲ Figure 30.9 Seed structure.

**MAKE CONNECTIONS** In addition to cotyledon number, what are some other ways that the structures of monocots and eudicots differ? (See Figure 28.2.)

### Seed Dormancy: An Adaptation for Tough Times

Environmental conditions required to break seed dormancy vary among species. Seeds of some species germinate as soon as they are in a suitable environment. Others remain dormant, even if sown in a favorable place, until a specific environmental cue causes them to break dormancy.

The requirement for specific cues to break seed dormancy increases the chances that germination will occur at a time and place most advantageous to the seedling. Seeds of many desert plants, for instance, germinate only after a substantial rainfall. If they were to germinate after a mild drizzle, the soil might soon become too dry to support the seedlings. Where natural fires are common, many seeds require intense heat or smoke to break dormancy; seedlings are therefore most abundant after fire has cleared away competing vegetation. Where winters are

harsh, seeds may require extended exposure to cold before they germinate; seeds sown during summer or fall will therefore not germinate until the following spring, ensuring a long growth season before the next winter. Certain small seeds, such as those of some lettuce varieties, require light for germination and will break dormancy only if buried shallow enough for the seedlings to poke through the soil surface. Some seeds have coats that must be weakened by chemical attack as they pass through an animal's digestive tract and thus are usually carried a considerable distance before germinating from dropped feces.

The length of time a dormant seed remains viable and capable of germinating varies from a few days to decades or even longer, depending on the plant species and environmental conditions. The oldest carbon-14–dated seed that has grown into a viable plant was a 2,000-year-old date palm seed recovered from excavations of Herod's palace in Israel. Most seeds are durable enough to last a year or two until conditions are favorable for germinating. Thus, the soil has a bank of ungerminated seeds that may have accumulated for several years. This is one reason vegetation reappears so rapidly after an environmental disruption such as fire.

### Seed Germination and Seedling Development

Seed germination depends on **imbibition**, the uptake of water due to the low water potential of the dry seed. Imbibing water causes the seed to expand and rupture its coat and also triggers metabolic changes in the embryo that enable it to resume growth. Following hydration, enzymes begin digesting the storage materials of the endosperm or cotyledons, and the nutrients are transferred to the growing regions of the embryo.

The first organ to emerge from the germinating seed is the radicle, the embryonic root. Next, the shoot tip must break through the soil surface. In garden beans and many other eudicots, a hook forms in the hypocotyl, and growth pushes the hook above ground (**Figure 30.10a**). In response to light, the hypocotyl straightens, the cotyledons separate, and the delicate epicotyl, now exposed, spreads its first true leaves (as distinct from the cotyledons, or seed leaves). These leaves expand, become green, and begin making food by photosynthesis. The cotyledons shrivel and fall away from the seedling, their food reserves having been exhausted by the germinating embryo.

Some monocots, such as maize and other grasses, use a different method for breaking ground when they germinate (**Figure 30.10b**). The coleoptile, the sheath enclosing and protecting the embryonic shoot, pushes upward through the soil and into the air. The shoot tip then grows straight up through the tunnel provided by the tubular coleoptile and eventually breaks out through the coleoptile's tip.

### Fruit Form and Function

While the seeds are developing from ovules, the ovary of the flower is developing into a **fruit**, which protects the enclosed

**(a) Common garden bean.** In common garden beans, straightening of a hook in the hypocotyl pulls the cotyledons from the soil.

**(b) Maize.** In maize and other grasses, the shoot grows straight up through the tube of the coleoptile.

### ▲ Figure 30.10 Two common types of seed germination.

**?** How do bean and maize seedlings protect their shoot systems as they push through the soil?

seeds and, when mature, aids in their dispersal by wind or animals. Fertilization triggers hormonal changes that cause the ovary to begin its transformation into a fruit. If a flower has not been pollinated, fruit typically does not develop, and the entire flower usually withers and falls away.

During fruit development, the ovary wall becomes the *pericarp*, the thickened wall of the fruit. In some fruits, such as soybean pods, the ovary wall dries out completely at maturity, whereas in other fruits, such as grapes, it remains fleshy. In still others, such as peaches, the inner part of the ovary becomes stony (the pit) while the outer parts stay fleshy. As the ovary grows, the other parts of the flower usually wither and are shed. For example, the pointed tip of a pea pod is the shriveled remains of the pea flower's stigma.

Fruits are classified into several types based on their developmental origins. A fruit that is derived from a single

carpel or several fused carpels is called a **simple fruit** (Figure 30.11a). An **aggregate fruit** results from a single flower that has more than one separate carpel, each forming a small fruit (Figure 30.11b). These “fruitlets” are clustered together on a single receptacle, as in a raspberry. A **multiple fruit** develops from an inflorescence, a group of flowers tightly clustered together. When the walls of the many ovaries start to thicken, they fuse together and become incorporated into one fruit, as in a pineapple (Figure 30.11c).

In some angiosperms, other floral parts contribute to what we commonly call the fruit. Such fruits are called **accessory fruits**. In apple flowers, the ovary is embedded in the receptacle, and the fleshy part of this simple fruit is derived mainly from the enlarged receptacle; only the apple core develops from the ovary (Figure 30.11d).

A fruit usually ripens about the same time that its seeds complete their development. Whereas the ripening of a dry fruit, such as a soybean pod, involves the aging and drying out of fruit tissues, the process in a fleshy fruit is more elaborate. Complex interactions of hormones result in an edible fruit that entices animals that help disperse the seeds. The fruit’s “pulp” becomes softer as a result of enzymes digesting components of

the cell walls. The color usually changes from green to a more overt color, such as red, orange, or yellow. The fruit becomes sweeter as organic acids or starch molecules are converted to sugar, which may reach a concentration of as much as 20% in a ripe fruit. Figure 30.12 examines some mechanisms of fruit dispersal in more detail.

In this section, you have learned about the unique features of sexual reproduction in angiosperms—flowers, fruits, and double fertilization. Next, we’ll examine asexual reproduction.

### CONCEPT CHECK 30.1

- WHAT IF?** If flowers had shorter styles, pollen tubes would more easily reach the embryo sac. Suggest an explanation for why very long styles have evolved in most flowering plants.
- WHAT IF?** In some species, sepals look like petals, and both are collectively called “tepals.” Suggest a possible extension to the ABC hypothesis that could account for the origin of tepals.
- MAKE CONNECTIONS** Does the life cycle of animals have any structures analogous to plant gametophytes? Explain your answer (see Figure 10.6).

For suggested answers, see Appendix A.

▲ **Figure 30.11** Developmental origins of fruits.

## ▼ Figure 30.12 Exploring Fruit and Seed Dispersal

A plant's life depends on finding fertile ground. But a seed that falls and sprouts beneath the parent plant will stand little chance of competing successfully for nutrients. To prosper, seeds must be widely dispersed. Plants use biotic dispersal agents as well as abiotic agents such as water and wind.

### Dispersal by Water

► Some buoyant seeds and fruits can survive months or years at sea. In coconut, the seed embryo and fleshy white "meat" (endosperm) are within a hard layer (endocarp) surrounded by a thick and buoyant fibrous husk.

### Dispersal by Wind

► With a wingspan of 12 cm, the giant seed of the tropical Asian climbing gourd *Alsomitra macrocarpa* glides through the air of the rain forest in wide circles when released.

▼ The winged fruit of a maple spins like a helicopter blade, slowing descent and increasing the chance of being carried farther by horizontal winds.

► Tumbleweeds break off at the ground and tumble across the terrain, scattering their seeds.

▲ Some seeds and fruits are attached to umbrella-like "parachutes" that are made of intricately branched hairs and often produced in puffy clusters. These dandelion "seeds" (actually one-seeded fruits) are carried aloft by the slightest gust of wind.

### Dispersal by Animals

◀ The sharp, tack-like spines on the fruits of puncture vine (*Tribulus terrestris*) can pierce bicycle tires and injure animals, including humans. When these painful "tacks" are removed and discarded, the seeds are dispersed.

► Seeds in edible fruits are often dispersed in feces, such as the black bear feces shown here. Such dispersal may carry seeds far from the parent plant.

◀ Some animals, such as squirrels, hoard seeds or fruits in underground caches. If the animal dies or forgets the cache's location, the buried seeds are well positioned to germinate.

► Ants are chemically attracted to seeds with "food bodies" rich in fatty acids, amino acids, and sugars. The ants carry the seed to their underground nest, where the food body (the lighter-colored portion shown here) is removed and fed to larvae. Due to the seed's size, unwieldy shape, or hard coating, the remainder is usually left intact in the nest, where it germinates.

## Flowering plants reproduce sexually, asexually, or both

Imagine chopping off your finger and watching it develop into an exact copy of you. If this could actually occur, it would be an example of **asexual reproduction**, in which offspring are derived from a single parent without fusion of egg and sperm. The result would be a clone, an asexually produced, genetically identical organism. Asexual reproduction is common in angiosperms, as well as in other plants, and for some plant species it is the predominant mode of reproduction.

### Mechanisms of Asexual Reproduction

Asexual reproduction in plants is typically an extension of the capacity for indeterminate growth. Plant growth can be sustained or renewed indefinitely by meristems, regions of undifferentiated, dividing cells (see Concept 28.2). In addition, parenchyma cells throughout the plant can divide and differentiate into more specialized types of cells, enabling plants to regenerate lost parts. Detached vegetative fragments of some plants can develop into whole offspring; for example, pieces of a potato with an “eye” (vegetative bud) can each regenerate a whole plant. Such **fragmentation**, the separation of a parent plant into parts that develop into whole plants, is one of the most common modes of asexual reproduction. The adventitious plantlets on *Kalanchoë* leaves exemplify an unusual type of fragmentation (see Figure 28.7). In other cases, the root system of a single parent, such as an aspen tree, can give rise to many adventitious shoots that become separate shoot systems (**Figure 30.13**). One aspen clone in Utah has been estimated to be composed of 47,000 stems of genetically identical trees. Although it is likely that some of the root system connections

▲ **Figure 30.13 Asexual reproduction in aspen trees.** Some aspen groves, such as those shown here, consist of thousands of trees descended by asexual reproduction. Each grove of trees derives from the root system of one parent. Thus, the grove is a clone. Notice that genetic differences between groves descended from different parents result in different timing for the development of fall color.

have been severed, making some of the trees isolated from the rest of the clone, each tree still shares a common genome.

An entirely different mechanism of asexual reproduction has evolved in dandelions and some other plants. These plants can sometimes produce seeds without pollination or fertilization. This asexual production of seeds is called **apomixis** (from the Greek words meaning “away from the act of mixing”) because there is no joining or, indeed, production of sperm and egg. Instead, a diploid cell in the ovule gives rise to the embryo, and the ovules mature into seeds, which in the dandelion are dispersed by windblown fruits. Thus, these plants clone themselves by an asexual process but have the advantage of seed dispersal, usually associated with sexual reproduction. Introducing apomixis into hybrid crops is of great interest to plant breeders because apomixis would allow hybrid plants to pass on their desirable genomes intact to their offspring.

### Advantages and Disadvantages of Asexual Versus Sexual Reproduction

**EVOLUTION** An advantage of asexual reproduction is that there is no need for a pollinator. This may be beneficial if plants of the same species are sparsely distributed and unlikely to be visited by the same pollinator. Asexual reproduction also allows the plant to pass on all of its genetic legacy intact to its progeny. In contrast, when reproducing sexually, a plant passes on only half of its alleles. If a plant is superbly suited to its environment, asexual reproduction can be advantageous. A vigorous plant can potentially clone many copies of itself, and if the environmental circumstances remain stable, these offspring will also be genetically well adapted to the same environmental conditions under which the parent flourished.

Generally, the progeny produced by asexual reproduction are stronger than seedlings produced by sexual reproduction. The offspring usually arise from mature vegetative fragments from the parent plant, which is why asexual reproduction in plants is also known as **vegetative reproduction**. In contrast, seed germination is a precarious stage in a plant’s life. The tough seed gives rise to a fragile seedling that may face exposure to predation, competition, and other hazards. In the wild, only a small fraction of seedlings survive to become parents themselves. Production of enormous numbers of seeds compensates for the odds against individual survival and gives natural selection ample genetic variations to screen. However, this is an expensive means of reproduction in terms of the resources consumed in flowering and fruiting.

Because sexual reproduction generates variation in offspring and populations, it can be advantageous in unstable environments where evolving pathogens and other fluctuating conditions affect survival and reproductive success. In contrast, the genotypic uniformity of asexually produced plants puts them at great risk of local extinction if there is a catastrophic environmental change, such as a new strain of disease. Moreover, seeds (which are almost always produced sexually)

facilitate the dispersal of offspring to more distant locations. Finally, seed dormancy allows growth to be suspended until environmental conditions become more favorable. In the **Scientific Skills Exercise**, you can use data to determine which species of monkey flower are mainly asexual reproducers and which are mainly sexual reproducers.

Although sexual reproduction involving two genetically different plants has the benefit of producing the most genetically diverse offspring, some plants, such as garden peas, usually self-fertilize. This process, called “selfing,” is a desirable attribute in some crop plants because it ensures that every ovule will develop into a seed. In many angiosperm species, however, mechanisms have evolved that make it difficult or impossible for a flower to fertilize itself, as we’ll discuss next.

## Mechanisms That Prevent Self-Fertilization

The various mechanisms that prevent self-fertilization contribute to genetic variety by ensuring that the sperm and egg come from different parents. In the case of **dioecious** species, plants cannot self-fertilize because different individuals have either staminate flowers (lacking carpels) or carpellate flowers (lacking stamens) (**Figure 30.14a**). Other plants have flowers with functional stamens and carpels that mature at different times or are structurally arranged in such a way that it is unlikely that an animal pollinator could transfer pollen from an anther to a stigma of the same flower (**Figure 30.14b**). However, the most common anti-selfing mechanism in flowering plants is **self-incompatibility**, the ability of a plant to reject its own pollen and the pollen of closely related individuals. If a pollen grain lands on a stigma of a flower of the same or a closely related individual, a biochemical block prevents the pollen from completing its development and fertilizing an egg.

Researchers are unraveling the molecular mechanisms involved in self-incompatibility. Recognition of “self” pollen is based on genes for self-incompatibility, called *S*-genes. In the gene pool of a plant population, there can be dozens of alleles of an *S*-gene. If a pollen grain has an allele that matches an allele of the stigma on which it lands, either the pollen fails to germinate or it germinates but its tube fails to grow through the style to the ovary.

There are two types of self-incompatibility—gametophytic and sporophytic. In gametophytic self-incompatibility, the *S*-allele in the pollen genome governs the blocking of fertilization. For example, an  $S_1$  pollen grain from an  $S_1S_2$  parental sporophyte cannot fertilize eggs of an  $S_1S_2$  flower but can fertilize an  $S_2S_3$  flower. An  $S_2$  pollen grain cannot fertilize either flower. In some plant families, self-incompatibility of this kind involves the enzymatic destruction of RNA within a pollen tube. RNA-hydrolyzing enzymes are produced by the style and enter the pollen tube. If the pollen tube is a “self” type, these enzymes destroy its RNA.

In sporophytic self-incompatibility, fertilization is blocked by *S*-allele gene products in tissues of the parental sporophyte that adhere to the pollen grain wall. For example, neither an  $S_1$

(a) Some species, such as *Sagittaria latifolia* (common arrowhead), are dioecious, having plants that produce only staminate flowers (left) or carpellate flowers (right).

(b) Some species, such as *Oxalis alpina* (alpine woodsorrel), produce two types of flowers on different individuals: “thrums,” which have short styles and long stamens, and “pins,” which have long styles and short stamens. An insect foraging for nectar would collect pollen on different parts of its body; thrum pollen would be deposited on pin stigmas, and vice versa.

▲ **Figure 30.14** Some floral adaptations that prevent self-fertilization.

nor  $S_2$  pollen grain from an  $S_1S_2$  parental sporophyte can fertilize eggs of an  $S_1S_2$  flower or  $S_2S_3$  flower due to the  $S_1S_2$  parental tissue attached to the pollen wall. Sporophytic incompatibility involves a signal transduction pathway in epidermal cells of the stigma that prevents germination of the pollen grain.

Plant breeders frequently hybridize different varieties of a crop plant to combine the best traits of the varieties and counter the loss of vigor that can often result from excessive inbreeding. To obtain hybrid seeds, plant breeders prevent self-fertilization either by laboriously removing the anthers from the parent plants that provide the seeds (as Mendel did) or by developing male-sterile plants. The latter option is increasingly common. Eventually, it may also be possible to impose self-incompatibility genetically on crop species that are normally self-compatible. Basic research on the mechanisms of self-incompatibility may thus have agricultural applications.

## Totipotency, Vegetative Reproduction, and Tissue Culture

In a multicellular organism, any cell that can divide and asexually generate a clone of the original organism is said to be **totipotent**. Totipotency is found to a high degree in many plants and is generally associated with meristematic tissues. In some plants, however, even differentiated cells can dedifferentiate and become meristematic.

## Using Positive and Negative Correlations to Interpret Data

### Do Monkey Flower Species Differ in Allocating Energy

**to Sexual Versus Asexual Reproduction?** Over the course of its lifespan, a plant captures only a finite amount of resources and energy, which must be allocated to best meet the plant's individual requirements for maintenance, growth, defense, and reproduction. Researchers examined how five species of monkey flower (genus *Mimulus*) use their resources for sexual and asexual reproduction.

### How the Experiment Was Done

After growing specimens of each species in separate pots in the open, the researchers determined averages for nectar volume, nectar concentration, seeds produced per flower, and the number of times the plants were visited by broad-tailed hummingbirds (*Selasphorus platycircus*, shown above). Using greenhouse-grown specimens, they determined the average number of rooted branches per gram fresh shoot weight for each species. The phrase *rooted branches* refers to asexual reproduction through horizontal shoots that develop roots.

### Data from the Experiment

Species	Nectar Volume (μL)	Nectar Concentration (% wt of sucrose/total wt)	Seeds per Flower	Visits per Flower	Rooted Branches per Gram Shoot Weight
<i>M. rupestris</i>	4.93	16.6	2.2	0.22	0.673
<i>M. eastwoodiae</i>	4.94	19.8	25.0	0.74	0.488
<i>M. nelsonii</i>	20.25	17.1	102.5	1.08	0.139
<i>M. verbenaceus</i>	38.96	16.9	155.1	1.26	0.091
<i>M. cardinalis</i>	50.00	19.9	283.7	1.75	0.069

### Interpret the Data

1. A correlation is a way to describe the relationship between two variables. In a positive correlation, as the values of one of the variables increase, the values of the second variable also increase. In a negative correlation, as the values of one of the variables increase, the values of the second variable decrease. Or there may be no correlation between two variables. If researchers know how two variables are correlated, they can make a prediction about one variable based on what they know about the other variable. (a) Which variable(s) is (are) positively correlated with the volume of nectar production in this genus? (b) Which is (are) negatively correlated? (c) Which show(s) no clear relationship?
2. (a) Which *Mimulus* species would you categorize as mainly asexual reproducers? Why? (b) Which species would you categorize as mainly sexual reproducers? Why?
3. (a) Which species would probably fare better in response to a pathogen that infects all *Mimulus* species? (b) Which species would fare better if a pathogen were to cause hummingbird populations to dwindle? Explain.

**Data from** S. Sutherland and R. K. Vickery, Jr., Trade-offs between sexual and asexual reproduction in the genus *Mimulus*. *Oecologia*, 76:330–335 (1988).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

## Vegetative Propagation and Grafting

Vegetative reproduction occurs naturally in many plants, but it can often be facilitated or induced by humans, in which case it is called **vegetative propagation**. Most houseplants, woody ornamentals, and orchard trees, for example, are asexually reproduced from plant fragments called cuttings. In most cases, shoot cuttings are used. At the cut end of the shoot, a mass of dividing, undifferentiated cells called a **callus** forms, and adventitious roots then develop from the callus. If the shoot fragment includes a node, then adventitious roots form without a callus stage.

In a modification of vegetative reproduction from cuttings, a twig or bud from one plant can be grafted onto a plant of a closely related species or a different variety of the same species. Grafting makes it possible to combine the best qualities of different species or varieties into a single plant. The plant that provides the root system is called the **stock**; the twig grafted onto the stock is referred to as the **scion**. For example, scions from French varieties of vines that produce superior wine

grapes are grafted onto rootstocks of American varieties that produce inferior grapes but are more resistant to certain soil pathogens. The genes of the scion determine the quality of the fruit. During grafting, a callus first forms between the adjoining cut ends of the scion and stock; cell differentiation then completes the functional unification of the grafted individuals.

## Test-Tube Cloning and Related Techniques

Plant biologists have adopted *in vitro* methods to clone plants for research or horticulture. Whole plants can be obtained by culturing small pieces of tissue from the parent plant on an artificial medium containing nutrients and hormones. The cells or tissues can come from any part of a plant, but growth may vary depending on the plant part, species, and artificial medium. In some media, the cultured cells divide and form a callus of undifferentiated cells (**Figure 30.15a**). When the concentrations of hormones and nutrients are manipulated appropriately, a callus can sprout shoots and roots with fully differentiated cells (**Figure 30.15b and c**). If desired, the plantlets

## CONCEPT 30.3

### People modify crops through breeding and genetic engineering

People have intervened in the reproduction and genetic makeup of plants since the dawn of agriculture. Maize, for example, owes its existence to humans. Left on its own in nature, maize would soon become extinct for the simple reason that it cannot spread its seeds. Maize kernels are not only permanently attached to the central axis (the “cob”) but also permanently protected by tough, overlapping leaf sheathes (the “husk”) (**Figure 30.16**). These attributes arose by artificial selection by humans. (See Chapter 19 to review the basic concept of artificial selection.) Despite having no understanding of the scientific principles underlying plant breeding, early farmers domesticated most of our crop species over a relatively short period about 10,000 years ago. But genetic modification began long before people started altering crops by artificial selection. For example, the wheat species we rely on for much of our food evolved by the natural hybridization between different species of grasses. Such hybridization is common in plants and has long been exploited by breeders to introduce genetic variation for artificial selection and crop improvement.

#### Plant Breeding

The art of recognizing valuable traits is important in plant breeding. Breeders scrutinize their fields carefully and travel far and wide searching for domesticated varieties or wild relatives with desirable traits. Such traits occasionally arise spontaneously through mutation, but the natural rate of mutation is too slow and unreliable to produce all the mutations that breeders would like to study. Breeders sometimes hasten mutations by treating large batches of seeds or seedlings with radiation or chemicals.

▲ **Figure 30.16 Maize: a product of artificial selection.** Modern maize (bottom) was derived from teosinte (top). Teosinte kernels are tiny, and each row has a husk that must be removed to get at the kernel. The seeds are loose at maturity, allowing dispersal, which probably made harvesting difficult for early farmers. Ancient farmers selected seeds from plants with larger cob and kernel size as well as the permanent attachment of seeds to the cob and the encasing of the entire cob by a tough husk.

▲ **Figure 30.15 Laboratory cloning of a garlic plant.**

(a) A root from a garlic clove gave rise to this callus culture, a mass of undifferentiated cells. (b and c) The differentiation of a callus into a plantlet depends on the nutrient levels and hormone concentrations in the artificial medium, as can be seen in these cultures grown for different lengths of time.

can then be transferred to soil, where they continue their growth. A single plant can be cloned into thousands of copies by dividing calluses as they grow.

Plant tissue culture is important in eliminating weakly pathogenic viruses from vegetatively propagated varieties. Although the presence of weak viruses may not be obvious, yield or quality may be substantially reduced as a result of infection. Strawberry plants, for example, are susceptible to more than 60 viruses, and typically the plants must be replaced each year because of viral infection. However, the distribution of viruses in a plant is not uniform, and the apical meristems are sometimes virus-free. Therefore, apical meristems can be excised and used to produce virus-free material for tissue culture.

Plant tissue culture also facilitates genetic engineering. Most techniques for the introduction of foreign genes into plants require small pieces of plant tissue or single plant cells as the starting material. Test-tube culture makes it possible to regenerate genetically modified (GM) plants from a single plant cell into which the foreign DNA has been incorporated. In the next section, we’ll take a closer look at some of the promises and challenges surrounding the use of GM plants in agriculture.

#### CONCEPT CHECK 30.2

1. What are three ways that flowering plants avoid self-fertilization?
2. The seedless banana, the world’s most popular fruit, is losing the battle against two fungal epidemics. Why do such epidemics generally pose a greater risk to asexually propagated crops?
3. Self-fertilization, or selfing, seems to have obvious disadvantages as a reproductive “strategy” in nature, and it has even been called an “evolutionary dead end.” So it is surprising that about 20% of angiosperm species primarily rely on selfing. Suggest a reason why selfing might be advantageous and still be an evolutionary dead end.

For suggested answers, see Appendix A.

When a desirable trait is identified in a wild species, the wild species is crossed with a domesticated variety. Generally, those progeny that have inherited the desirable trait from the wild parent have also inherited many traits that are not desirable for agriculture, such as small fruits or low yields. The progeny that express the desired trait are again crossed with members of the domesticated species and their progeny examined for the desired trait. This process is continued until the progeny with the desired wild trait resemble the original domesticated parent in their other agricultural attributes.

While most breeders cross-pollinate plants of a single species, some breeding methods rely on hybridization between two distant species of the same genus. Such crosses sometimes result in the abortion of the hybrid seed during development. Often in these cases, the embryo begins to develop, but the endosperm does not. Hybrid embryos are sometimes rescued by surgically removing them from the ovule and culturing them *in vitro*.

## Plant Biotechnology and Genetic Engineering

Plant biotechnology has two meanings. In the general sense, it refers to innovations in the use of plants (or substances obtained from plants) to make products of use to people—an endeavor that began in prehistory. In a more specific sense, biotechnology refers to the use of GM organisms in agriculture and industry. Indeed, in the last two decades, genetic engineering has become such a powerful force that the terms *genetic engineering* and *biotechnology* have become synonymous in the media.

Unlike traditional plant breeders, modern plant biotechnologists, using techniques of genetic engineering, are not limited to the transfer of genes between closely related species or genera. For example, traditional breeding techniques could not be used to insert a desired gene from daffodil into rice because the many intermediate species between rice and daffodil and their common ancestor are extinct. In theory, if breeders had the intermediate species, over the course of several centuries they could probably introduce a daffodil gene into rice by traditional hybridization and breeding methods. With genetic engineering, however, such gene transfers can be done more quickly, more specifically, and without the need for intermediate species. The term **transgenic** is used to describe organisms that have been engineered to express a gene from another species.

In the remainder of this chapter, we examine the prospects and controversies surrounding the use of GM crops. The advocates of plant biotechnology contend that the genetic engineering of crop plants is the key to overcoming some of the most pressing problems of the 21st century, including world hunger and fossil fuel dependency.

### Reducing World Hunger and Malnutrition

Currently, 800 million people suffer from nutritional deficiencies, with 40,000 dying each day of malnutrition, half of them children. There is much disagreement about the causes of such

hunger. Some argue that food shortages arise from inequities in distribution and that the dire poor simply cannot afford food. Others regard food shortages as evidence that the world is overpopulated—that the human species has exceeded the carrying capacity of the planet (see Chapter 40). Whatever the social and demographic causes of malnutrition, increasing food production is a humane objective. Because land and water are the most limiting resources, the best option is to increase yields on already existing farmland. Indeed, there is very little “extra” land that can be farmed, especially if the few remaining pockets of wilderness are to be preserved. Based on conservative estimates of population growth, farmers will have to produce 40% more grain per hectare to feed the human population in 2030. Plant biotechnology can help make these crop yields possible.

The commercial use of transgenic crops has been one of the most dramatic examples of rapid technology adoption in the history of agriculture. These crops include varieties and hybrids of cotton, maize, and potatoes that contain genes from the bacterium *Bacillus thuringiensis*. These “transgenes” encode a protein (*Bt* toxin) that is toxic to insect pests. The use of such plant varieties greatly reduces the need for chemical insecticides. The *Bt* toxin used in crops is produced in the plant as a harmless protoxin that only becomes toxic if activated by alkaline conditions, such as occur in the guts of insects. Because vertebrates have highly acidic stomachs, protoxin consumed by humans or farm animals is rendered harmless by denaturation.

Considerable progress has also been made in developing transgenic crops that tolerate certain herbicides. The cultivation of these plants may reduce production costs by enabling farmers to “weed” crops with herbicides that do not damage the transgenic crop plants, instead of using heavy tillage, which can cause soil erosion. Researchers are also engineering plants with enhanced resistance to disease. In one case, a transgenic papaya that is resistant to a ring spot virus was introduced into Hawaii, thereby saving its papaya industry.

The nutritional quality of plants is also being improved. For example, some 250,000 to 500,000 children go blind each year because of vitamin A deficiencies. More than half of these children die within a year of becoming blind. In response to this crisis, genetic engineers have created “Golden Rice,” a transgenic variety supplemented with two daffodil genes that enable it to produce grain with increased levels of beta-carotene, a precursor of vitamin A. Another target for improvement by genetic engineering is cassava, a staple for 800 million of the poorest people on our planet (**Figure 30.17**).

### Reducing Fossil Fuel Dependency

Global sources of inexpensive fossil fuels, particularly oil, are rapidly being depleted. Moreover, most climatologists attribute global warming mainly to the rampant burning of fossil fuels, such as coal and oil, and the resulting release of the greenhouse gas CO<sub>2</sub>. How can the world meet its energy demands in the 21st century in an economical and nonpolluting way? In certain

► **Figure 30.17 Fighting world hunger with transgenic cassava (*Manihot esculenta*).** This starchy root crop is the primary food for 800 million of the world's poor, but it does not provide a balanced diet. Moreover, it must be processed to remove chemicals that release cyanide, a toxin. Transgenic cassava plants have been developed with greatly increased levels of iron and beta-carotene (a vitamin A precursor). Researchers have also created cassava plants with root masses twice the normal size that contain almost no cyanide-producing chemicals.

localities, wind or solar power may become economically viable, but such alternative energy sources are unlikely to fill the global energy demands completely. Many scientists predict that **biofuels**—fuels derived from living biomass—could produce a sizable fraction of the world's energy needs in the not-too-distant future. **Biomass** is the total mass of organic matter in a group of organisms in a particular habitat. The use of biofuels from plant biomass would reduce the net emission of CO<sub>2</sub>. Whereas burning fossil fuels increases atmospheric CO<sub>2</sub> concentrations, biofuel crops reabsorb by photosynthesis the CO<sub>2</sub> emitted when biofuels are burned, creating a cycle that is carbon neutral.

In working to create biofuel crops from wild precursors, scientists are focusing their domestication efforts on fast-growing plants, such as switchgrass (*Panicum virgatum*) and poplar (*Populus trichocarpa*), that can grow on soil that is too poor for food production. Scientists do not envisage the plant biomass being burned directly. Instead, the polymers in cell walls, such as cellulose and hemicellulose, which constitute the most abundant organic compounds on Earth, would be broken down into sugars by enzymatic reactions. These sugars, in turn, would be fermented into alcohol, which would be distilled to yield biofuels. Currently, the enzymes and pretreatment processes involved in converting cellulosic biomass to ethanol are very expensive. In addition to increasing plant polysaccharide content and overall biomass, researchers are trying to genetically engineer plants with cell wall properties, such as reduced lignin content, that will lower the costs of biofuel production.

## The Debate over Plant Biotechnology

Much of the debate about GM organisms (GMOs) in agriculture is political, social, economic, or ethical and therefore outside the scope of this book. But we *should* consider the biological concerns about GM crops. Some biologists, particularly ecologists, are concerned about the unknown risks associated with the release of GMOs into the environment. The debate centers on the extent to which GMOs could harm the environment or human health. Those who want to proceed more slowly with agricultural biotechnology (or end it) are

concerned about the unstoppable nature of the “experiment.” If a drug trial produces unanticipated harmful results, the trial is stopped. But we may not be able to stop the “trial” of introducing novel organisms into the biosphere. Here, we examine some of the proposed negative consequences of using GM crops, including their effects on human health and nontarget organisms and the potential for transgene escape.

## Issues of Human Health

Many GMO opponents worry that genetic engineering may inadvertently transfer allergens, molecules to which some people are allergic, from a species that produces an allergen to a plant used for food. However, biotechnologists are already engaged in removing genes that encode allergenic proteins from soybeans and other crops. So far, there is no credible evidence that GM plants specifically designed for human consumption have adverse effects on human health. In fact, some GM foods are potentially healthier than non-GM foods. For example, *Bt* maize (the transgenic variety with the *Bt* toxin) contains 90% less of a fungal toxin that causes cancer and birth defects than non-*Bt* maize. Called fumonisin, this toxin is highly resistant to degradation and has been found in alarmingly high concentrations in some batches of processed maize products, ranging from cornflakes to beer. Fumonisin is produced by a fungus (*Fusarium*) that infects insect-damaged maize. Because *Bt* maize generally suffers less insect damage than non-GM maize, it contains much less fumonisin.

Nevertheless, because of health concerns, GMO opponents lobby for the clear labeling of all foods containing products of GMOs. Some also argue for strict regulations against the mixing of GM foods with non-GM foods during food transport, storage, and processing. Biotechnology advocates, however, note that similar demands were not made when “transgenic” crops produced by traditional plant-breeding techniques were put on the market. There are, for example, some commercially grown varieties of wheat derived by traditional plant-breeding techniques that contain entire chromosomes (and thousands of genes) from rye.

## Possible Effects on Nontarget Organisms

Many ecologists are concerned that the growing of GM crops might have unforeseen effects on nontarget organisms. One laboratory study indicated that the larvae (caterpillars) of monarch butterflies responded adversely and even died after eating milkweed leaves (their preferred food) heavily dusted with pollen from transgenic *Bt* maize. This study has since been discredited, affording a good example of the self-correcting nature of science. As it turns out, when the original researcher shook the male maize inflorescences onto the milkweed leaves in the laboratory, the filaments of stamens, opened microsporangia, and other floral parts also rained onto the leaves. Subsequent research found that it was these other floral parts, *not* the pollen, that contained *Bt* toxin in high concentrations.

Unlike pollen, these floral parts would not be carried by the wind to neighboring milkweed plants when shed under natural field conditions. Only one *Bt* maize line, accounting for less than 2% of commercial *Bt* maize production (and now discontinued), produced pollen with high *Bt* toxin concentrations.

In considering the negative effects of *Bt* pollen on monarch butterflies, we must also weigh the effects of an alternative to the cultivation of *Bt* maize—the spraying of non-*Bt* maize with chemical pesticides. Recent studies have shown that such spraying is much more harmful to nearby monarch populations than is *Bt* maize production. Although the effects of *Bt* maize pollen on monarch butterfly larvae appear to be minor, the controversy has emphasized the need for accurate field testing of all GM crops and the importance of targeting gene expression to specific tissues to improve safety.

### Addressing the Problem of Transgene Escape

Perhaps the most serious concern raised about GM crops is the possibility of the introduced genes escaping from a transgenic crop into related weeds through crop-to-weed hybridization. The fear is that the spontaneous hybridization between a crop engineered for herbicide resistance and a wild relative might give rise to a “superweed” that would have a selective advantage over other weeds in the wild and would be much more difficult to control in the field. GMO advocates point out that the likelihood of transgene escape depends on the ability of the crop and weed to hybridize and on how the transgenes affect the overall fitness of the hybrids. A desirable crop trait—a dwarf phenotype, for example—might be disadvantageous to a weed growing in the wild. In other instances, there are no weedy relatives nearby with which to hybridize; soybean, for example, has no wild relatives in the United States. However, canola, sorghum, and many other crops do hybridize readily with weeds, and crop-to-weed transgene escape has occurred. In 2003 a transgenic variety of creeping bentgrass (*Agrostis stolonifera*) genetically engineered to resist the herbicide glyphosate escaped from an experimental plot in Oregon following a windstorm. Despite efforts to eradicate the escapee, 62% of the *Agrostis* plants found in the vicinity three years later were glyphosate resistant. So far, the ecological impact of this event appears to be minor, but that not may be the case with future transgenic escapes.

Many different strategies are being pursued with the goal of preventing transgene escape. For example, if male sterility could be engineered into plants, these plants would still produce seeds and fruit if pollinated by nearby nontransgenic plants, but they would produce no viable pollen. A second approach involves genetically engineering apomixis into transgenic crops. When a seed is produced by apomixis, the embryo and endosperm develop without fertilization. The transfer of this trait to transgenic crops would therefore minimize the possibility of transgene escape via pollen because plants could be male-sterile without compromising seed or fruit production. A third approach is to engineer the transgene into the chloroplast DNA of the crop. Chloroplast DNA in many plant species is inherited strictly from the egg, so transgenes in the chloroplast cannot be transferred by pollen. A fourth approach for preventing transgene escape is to genetically engineer flowers that develop normally but fail to open. Consequently, self-pollination would occur, but pollen would be unlikely to escape from the flower. This solution would require modifications to flower design. Several floral genes have been identified that could be manipulated to this end.

The continuing debate about GMOs in agriculture exemplifies one of this textbook’s recurring ideas: the relationship of science and technology to society. Technological advances almost always involve some risk of unintended outcomes. In plant biotechnology, zero risk is probably unattainable. Therefore, scientists and the public must assess on a case-by-case basis the possible benefits of transgenic products versus the risks that society is willing to take. The best scenario is for these discussions and decisions to be based on sound scientific information and rigorous testing rather than on reflexive fear or blind optimism.

#### CONCEPT CHECK 30.3

1. Compare traditional plant-breeding methods with genetic engineering.
2. Why does *Bt* maize have less fumonisin than non-GM maize?
3. **WHAT IF?** In a few species, chloroplast genes are inherited only from sperm. How might this influence efforts to prevent transgene escape?

For suggested answers, see Appendix A.

# 30 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 30.1

#### Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle (pp. 598–607)

- Angiosperm reproduction involves an alternation of generations between a multicellular diploid sporophyte generation and multicellular haploid gametophyte generation. Flowers, produced by the sporophyte, function in sexual reproduction.
- The four floral organs are sepals, petals, stamens, and carpels. **Sepals** protect the floral bud. **Petals** help attract pollinators. **Stamens** bear **anthers** in which haploid **microspores** develop into **pollen grains** containing a male gametophyte. **Carpels** contain **ovules** (immature seeds) in their swollen bases. Within the ovules, **embryos sacs** (female gametophytes) develop from **megaspores**.
- **Pollination**, which precedes **fertilization**, is the placing of pollen on the **stigma** of a carpel. After pollination, the **pollen tube** discharges two sperm into the female gametophyte. Two sperm are needed for **double fertilization**, a process in which one sperm fertilizes the egg, forming a zygote and eventually an embryo, while the other sperm combines with the polar nuclei, giving rise to food-storing **endosperm**.
- The **seed coat** encloses the embryo along with a food supply stocked in either the endosperm or the **cotyledons**. Seed **dormancy** ensures that seeds germinate only when conditions for seedling survival are optimal. The breaking of dormancy often requires environmental cues, such as temperature or lighting changes.
- The **fruit** protects the enclosed seeds and aids in wind dispersal or in the attraction of seed-dispersing animals.

? *What changes occur to the four types of floral parts as a flower changes into a fruit?*

### CONCEPT 30.2

#### Flowering plants reproduce sexually, asexually, or both (pp. 608–611)

- **Asexual reproduction** enables successful plants to proliferate quickly. Sexual reproduction generates most of the genetic variation that makes evolutionary adaptation possible.
- Plants have evolved many mechanisms to avoid self-fertilization, including having male and female flowers on different individuals (**dioecious** species), asynchronous production of male and female parts within a single flower, and **self-incompatibility**, in which pollen grains that bear an allele identical to one in the female are rejected.
- Plants can be cloned from single cells, which can be genetically manipulated before being allowed to develop into a plant.

? *What are the advantages of asexual and sexual reproduction?*

### CONCEPT 30.3

#### People modify crops through breeding and genetic engineering (pp. 611–614)

- Hybridization of different varieties and even species of plants is common in nature and has been used by breeders, ancient and modern, to introduce new genes into crops. After two plants are successfully hybridized, plant breeders select those progeny that have the desired traits.
- In genetic engineering, genes from unrelated organisms are incorporated into plants. Genetically modified (GM) plants have the potential of increasing the quality and quantity of food worldwide and may also become increasingly important as biofuels.
- Two important GM crops are Golden Rice, which provides more vitamin A, and *Bt* maize, which is insect resistant.
- There are concerns about the unknown risks of releasing GM organisms into the environment, but the potential benefits of **transgenic** crops need to be considered.

? *Give three examples of how genetic engineering has improved food quality or agricultural productivity.*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. A seed develops from
  - a. an ovum.
  - b. a pollen grain.
  - c. an ovule.
  - d. an ovary.
  - e. an embryo.
2. A fruit is
  - a. a mature ovary.
  - b. a mature ovule.
  - c. a seed plus its integuments.
  - d. a fused carpel.
  - e. an enlarged embryo sac.
3. Double fertilization means that
  - a. flowers must be pollinated twice to yield fruits and seeds.
  - b. every egg must receive two sperm to produce an embryo.
  - c. one sperm is needed to fertilize the egg, and a second sperm is needed to fertilize the polar nuclei.
  - d. the egg of the embryo sac is diploid.
  - e. every sperm has two nuclei.
4. “Golden Rice”
  - a. is resistant to various herbicides, making it practical to weed rice fields with those herbicides.
  - b. is resistant to a virus that commonly attacks rice fields.
  - c. includes bacterial genes that produce a toxin that reduces damage from insect pests.
  - d. produces larger, golden grains that increase crop yields.
  - e. contains daffodil genes that increase vitamin A content.
5. Which statement concerning grafting is correct?
  - a. Stocks and scions refer to twigs of different species.
  - b. Stocks come from vines, but scions come from trees.
  - c. Stocks provide root systems for grafting.
  - d. Grafting creates new species.
  - e. Stocks and scions must come from unrelated species.

## Level 2: Application/Analysis

6. Some dioecious species have the XY genotype for male and XX for female. After double fertilization, what would be the genotypes of the embryos and endosperm nuclei?
  - a. embryo X/endosperm XX or embryo Y/endosperm XY
  - b. embryo XX/endosperm XX or embryo XY/endosperm XY
  - c. embryo XX/endosperm XXX or embryo XY/endosperm XYY
  - d. embryo XX/endosperm XXX or embryo XY/endosperm XXY
  - e. embryo XY/endosperm XXX or embryo XX/endosperm XXY
7. A small flower with green petals is most likely
  - a. bee-pollinated.
  - b. bird-pollinated.
  - c. bat-pollinated.
  - d. wind-pollinated.
  - e. moth-pollinated.
8. The pollen produced by wind-pollinated plants is often smaller than the pollen produced by animal-pollinated plants. A reason for this might be that
  - a. wind-pollinated plants, in general, are smaller than animal-pollinated plants.
  - b. wind-pollinated plants release pollen in the spring, before the plant has stored enough energy to make large pollen grains.
  - c. small pollen grains can be carried farther by the wind.
  - d. animal pollinators are more facile at picking up large pollen grains.
  - e. wind-pollinated flowers don't need large pollen grains because they don't have to attract animal pollinators.
9. The black dots that cover strawberries are actually individual fruits from a flower with multiple carpels. The fleshy and tasty portion of a strawberry derives from the receptacle of the flower. Therefore, a strawberry is
  - a. both a multiple fruit and an aggregate fruit.
  - b. both a multiple fruit and an accessory fruit.
  - c. both a simple fruit and an aggregate fruit.
  - d. both an aggregate fruit and an accessory fruit.
  - e. a simple fruit with many seeds.
10. **DRAW IT** Draw and label the parts of a flower.

## Level 3: Synthesis/Evaluation

### 11. SCIENTIFIC INQUIRY

Critics of GM foods have argued that foreign genes may disturb normal cellular functioning, causing unexpected and potentially harmful substances to appear inside cells. Toxic intermediary substances that normally occur in very small amounts may arise in larger amounts, or new substances may appear. The disruption may also lead to loss of substances that help maintain normal metabolism. If you were your nation's chief scientific advisor, how would you respond to these criticisms?

### 12. SCIENCE, TECHNOLOGY, AND SOCIETY

People have engaged in genetic manipulation for millennia, producing plant and animal varieties through selective breeding and hybridization processes that significantly modify the genomes of organisms. Why do you think modern genetic engineering, which often entails introducing or modifying only one or a few genes, has met with so much public opposition? Should some forms of genetic engineering be of greater concern than others? Explain.

### 13. FOCUS ON EVOLUTION

With respect to sexual reproduction, some plant species are fully self-fertile, others are fully self-incompatible, and some exhibit a "mixed strategy" with partial self-incompatibility. These reproductive strategies differ in their implications for evolutionary potential. How might these three strategies fare in a small founder population (see Chapter 21)?

### 14. FOCUS ON ORGANIZATION

In a short essay (100–150 words), discuss how the ability of a flower to reproduce with other flowers of the same species is an emergent property that arises from its floral parts and their organization.

*For selected answers, see Appendix A.*

# Plant Responses to Internal and External Signals

▼ **Figure 31.1** How do plants detect light?

## KEY CONCEPTS

- 31.1** Plant hormones help coordinate growth, development, and responses to stimuli
- 31.2** Responses to light are critical for plant success
- 31.3** Plants respond to a wide variety of stimuli other than light
- 31.4** Plants respond to attacks by herbivores and pathogens

## OVERVIEW

### The Race to Live

**T**hese tender barley seedlings, their stored seed reserves nearing exhaustion, have reached a critical point in their lives (**Figure 31.1**). If they fail to attain sufficient light, they will not be able to outcompete their neighbors in the race for resources, and they will perish. It is not surprising, therefore, that mechanisms have evolved in plants that enable them to adjust their growth and development according to the spectral composition of the light available. But how are differences in light quality detected? The sensing of light by plants

involves the activation of signal transduction pathways that, in the big picture, are not too far removed from some of the pathways that you use to interact with your environment. In effect, at the levels of signal *reception* and signal *transduction*, your cells are not all that different from those of a barley seedling—certainly the similarities far outweigh the differences. As an animal, however, your *responses* to environmental stimuli are generally quite different from those of plants. Animals commonly respond to environmental challenges and opportunities by movement; plants, such as these young barley seedlings, by altering their growth and development.

Architectural modifications due to altered growth are essentially changes in spatial orientation, but plants must also adjust themselves according to changes in time. The passage of seasons is an example of a temporal variable that plants need to measure to compete successfully. Plants also do not exist in isolation: They interact positively or negatively with a wide range of organisms. All of these physical and chemical interac-

tions and all of the internal chemical changes they initiate involve signal transduction pathways of comparable complexity. In this chapter, first we'll discuss the internal chemicals (hormones) that regulate plant growth and development; then we'll explore how plants perceive and respond to light and other environmental signals.

## CONCEPT 31.1

### Plant hormones help coordinate growth, development, and responses to stimuli

A **hormone**, in the original meaning of the term, is a signaling molecule that is produced in tiny amounts by one part of an organism's body and transported to other parts, where it binds to a specific receptor and triggers responses

in target cells and tissues. In animals, hormones are usually transported through the circulatory system, a criterion often included in definitions of the term. Many plant biologists, however, argue that the hormone concept, which originated from studies of animals, is too limiting to describe plant physiological processes. For example, plants don't have circulating blood to transport hormone-like signaling molecules. Moreover, some signaling molecules that are considered plant hormones act only locally. Finally, some signaling molecules in plants, such as sucrose, typically occur at concentrations hundreds of thousands times greater than that of a typical hormone. Nevertheless, they are transported through plants and activate signal transduction pathways that greatly alter the functioning of plants in a manner similar to a hormone. Thus, many plant biologists prefer the broader term *plant growth regulator* to describe organic compounds, whether natural or synthetic, that modify or control one or more specific physiological processes within a plant. Currently, the terms *plant hormone* and *plant growth regulator* are used about equally, but for historical continuity we will use the term *plant hormone* and adhere to the criterion that plant hormones are active at very low concentrations.

Plant hormones are produced in very low concentrations, but a tiny amount of hormone can have a profound effect on plant growth and development. Virtually every aspect of plant growth and development is under hormonal control to some degree. Each hormone has multiple effects, depending on its site of action, its concentration, and the developmental stage of the plant. Conversely, multiple hormones can influence a single process. Response to a hormone usually depends not so much on the amount of that hormone as on its relative concentration compared with other hormones. It is often the interactions between different hormones, rather than hormones acting in isolation, that control growth and development. These interactions will become apparent in the following survey of hormone function.

## The Discovery of Plant Hormones

The idea that chemical messengers exist in plants emerged from a series of classic experiments on how stems respond to light. As you know, the shoots of plants grow toward light (see Figure 31.1). Any growth response that results in plant organs curving toward or away from stimuli is called a **tropism** (from the Greek *tropos*, turn). The growth of a plant organ toward light or away from it is called **phototropism**; shoots generally exhibit positive phototropism, whereas roots exhibit negative phototropism. In nature, positive phototropism directs shoot growth toward the sunlight that powers photosynthesis. This response involves cells on the darker side elongating faster than the cells on the brighter side.

Charles Darwin and his son Francis conducted some of the earliest experiments on phototropism (Figure 31.2). They observed that a grass seedling ensheathed in its coleoptile

### ▼ Figure 31.2 Inquiry

#### What part of a grass coleoptile senses light, and how is the signal transmitted?

**Experiment** In 1880, Charles and Francis Darwin removed and covered parts of grass coleoptiles to determine what part senses light. In 1913, Peter Boysen-Jensen separated coleoptiles with different materials to determine how the signal for phototropism is transmitted.

#### Results

#### Darwin and Darwin: Phototropism occurs only when the tip is illuminated.

#### Boysen-Jensen: Phototropism occurs when the tip is separated by a permeable barrier but not an impermeable barrier.

**Conclusion** The Darwins' experiment suggested that only the tip of the coleoptile senses light. The phototropic bending, however, occurred at a distance from the site of light perception (the tip). Boysen-Jensen's results suggested that the signal for the bending is a light-activated mobile chemical.

**Sources** C. R. Darwin, *The power of movement in plants*, John Murray, London (1880). P. Boysen-Jensen, *Concerning the performance of phototropic stimuli on the Avena coleoptile*, *Berichte der Deutschen Botanischen Gesellschaft (Reports of the German Botanical Society)* 31:559–566 (1913).

**WHAT IF?** How could you experimentally determine which colors of light cause the most phototropic bending?

(see Figure 30.10b) could bend toward light only if the tip of the coleoptile was present. If the tip was removed, the coleoptile did not curve. The seedling also failed to grow toward light if the tip was covered with an opaque cap; but neither a transparent cap over the tip nor an opaque shield placed below the coleoptile tip prevented the phototropic response. It was the tip of the coleoptile, the Darwins concluded, that was responsible for sensing light. However, they noted that the differential growth response that led to curvature of the coleoptile occurred some distance below the tip. The Darwins postulated that some signal was transmitted downward from the tip to the elongating region of the coleoptile. A few decades later, the Danish scientist Peter Boysen-Jensen demonstrated that the signal was a mobile chemical substance. He separated the tip from the remainder of the coleoptile by a cube of gelatin, which prevented cellular contact but allowed chemicals to pass through. These seedlings responded normally, bending toward light. However, if the tip was experimentally separated from the lower coleoptile by an impermeable barrier, such as the mineral mica, no phototropic response occurred.

In 1926, Frits Went extracted the chemical messenger for phototropism by modifying the experiments of Boysen-Jensen (**Figure 31.3**). Went removed the coleoptile tip and placed it on a cube of agar, a gelatinous material. The chemical messenger moving from the tip, Went reasoned, should diffuse into the agar, and the agar block should then be able to substitute for the coleoptile tip. Went placed the agar blocks on decapitated coleoptiles that were kept in the dark. A block that was centered on top of the coleoptile caused the stem to grow straight upward. However, when the block was placed off center, the coleoptile began to bend away from the side with the agar block, as though growing toward light. Went concluded that the agar block contained a chemical produced in the coleoptile tip, that this chemical stimulated growth as it passed down the coleoptile, and that a coleoptile curved toward light because of a higher concentration of the growth-promoting chemical on the darker side of the coleoptile. For this chemical messenger, or hormone, Went chose the name auxin (from the Greek *auxein*, to increase). The major type of auxin was later purified, and its chemical structure was then determined to be indoleacetic acid (IAA).

These classic experiments involving grass coleoptiles support the idea that an asymmetric distribution of auxin moving down from the coleoptile tip causes cells on the darker side to elongate faster than cells on the brighter side. But studies of phototropism in organs other than grass coleoptiles provide less support for this idea. There is no evidence that illumination from one side causes asymmetric distribution of auxin in stems of sunflowers or other eudicots. There *is*, however, asymmetric distribution of certain substances that may act as growth *inhibitors*, and these substances are more concentrated on the lighted side of a stem.

### ▼ Figure 31.3 Inquiry

#### Does asymmetric distribution of a growth-promoting chemical cause a coleoptile to grow toward the light?

**Experiment** In 1926, Frits Went's experiment identified how a growth-promoting chemical causes a coleoptile to grow toward light. He placed coleoptiles in the dark and removed their tips, putting some tips on agar cubes that he predicted would absorb the growth-promoting chemical. On a control coleoptile, he placed a cube that lacked the chemical. On others, he placed cubes containing the chemical, either centered on top of the coleoptile to distribute the chemical evenly or offset to increase the concentration on one side.

**Results** The coleoptile grew straight if the growth-promoting chemical was distributed evenly. If the chemical was distributed unevenly, the coleoptile curved away from the side with the cube, as if growing toward light, even though it was grown in the dark.

**Conclusion** Went concluded that a coleoptile curves toward light because its dark side has a higher concentration of the growth-promoting chemical, which he named auxin.

 A related Experimental Inquiry Tutorial can be assigned in MasteringBiology.

**WHAT IF?** Triiodobenzoic acid (TIBA) inhibits auxin transport. If a tiny agar bead containing TIBA were placed off center on the tip of an intact coleoptile, which way would the coleoptile bend: toward the side with the bead or away from it? Explain.

## A Survey of Plant Hormones

The discovery of auxin stimulated the search for other plant hormones. **Table 31.1** previews some major classes of plant hormones: auxin, cytokinins, gibberellins, brassinosteroids, abscisic acid, and ethylene (this list is by no means exhaustive).

### Auxin

The term **auxin** is used for any chemical substance that promotes elongation of coleoptiles, although auxins have multiple functions in flowering plants. The major natural auxin in plants is indoleacetic acid (IAA), although several other compounds, including some synthetic ones, have auxin activity. (Unless mentioned otherwise, we will use the term *auxin* synonymously with IAA.)

Auxin is produced predominantly in shoot tips and is transported from cell to cell down the stem at a rate of about 1 cm/hr. It moves only from tip to base, not in the reverse direction. This unidirectional transport of auxin is called *polar transport*. Polar transport is unrelated to gravity; experiments have shown that auxin travels upward when a stem or coleoptile segment is placed upside down. Rather, the polarity of auxin movement is attributable to the polar distribution of auxin transport protein in the cells. Concentrated at the basal end of a cell, the auxin transporters move the hormone out of the cell.

The auxin can then enter the apical end of the neighboring cell (**Figure 31.4**). Auxin has a variety of effects, including stimulating cell elongation and regulating plant architecture.

**The Role of Auxin in Cell Elongation** One of auxin’s chief functions is to stimulate elongation of cells within young developing shoots. As auxin from the shoot tip (see Figure 28.16) moves down to the region of cell elongation, the hormone stimulates cell growth, probably by binding to a receptor in the plasma membrane. Auxin stimulates growth only over a certain concentration range, from about  $10^{-8}$  to  $10^{-4}$  M. At higher concentrations, auxin may inhibit cell elongation by inducing the production of ethylene, a hormone that generally hinders growth. We’ll return to this hormonal interaction when we discuss ethylene.

According to a model called the *acid growth hypothesis*, proton pumps play a major role in the growth response of cells to auxin. In a shoot’s region of elongation, auxin stimulates the plasma membrane’s proton (H<sup>+</sup>) pumps. This pumping of H<sup>+</sup> increases the voltage across the membrane (membrane potential) and lowers the pH in the cell wall within minutes (**Figure 31.5**). Acidification of the wall activates enzymes called **expansins** that break the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents,

Table 31.1 Overview of Plant Hormones		
Hormone	Where Produced or Found in Plant	Major Functions
Auxin (IAA)	Shoot apical meristems and young leaves are the primary sites of auxin synthesis. Root apical meristems also produce auxin, although the root depends on the shoot for much of its auxin. Developing seeds and fruits contain high levels of auxin, but it is unclear whether it is newly synthesized or transported from maternal tissues.	Stimulates stem elongation (low concentration only); promotes the formation of lateral and adventitious roots; regulates development of fruit; enhances apical dominance; functions in phototropism and gravitropism; promotes vascular differentiation; retards leaf abscission.
Cytokinins	These are synthesized primarily in roots and transported to other organs, although there are many minor sites of production as well.	Regulate cell division in shoots and roots; modify apical dominance and promote lateral bud growth; promote movement of nutrients into sink tissues; stimulate seed germination; delay leaf senescence.
Gibberellins	Meristems of apical buds and roots, young leaves, and developing seeds are the primary sites of production.	Stimulate stem elongation, pollen development, pollen tube growth, fruit growth, and seed development and germination; regulate sex determination and the transition from juvenile to adult phases.
Brassinosteroids	These compounds are present in all plant tissues, although different intermediates predominate in different organs. Internally produced brassinosteroids act near the site of synthesis.	Promote cell expansion and cell division in shoots; promote root growth at low concentrations; inhibit root growth at high concentrations; promote xylem differentiation and inhibit phloem differentiation; promote seed germination and pollen tube elongation.
Abscisic acid (ABA)	Almost all plant cells have the ability to synthesize abscisic acid, and its presence has been detected in every major organ and living tissue; may be transported in the phloem or xylem.	Inhibits growth; promotes stomatal closure during drought stress; promotes seed dormancy and inhibits early germination; promotes leaf senescence; promotes desiccation tolerance.
Ethylene	This gaseous hormone can be produced by most parts of the plant. It is produced in high concentrations during senescence, leaf abscission, and the ripening of some types of fruit. Synthesis is also stimulated by wounding and stress.	Promotes ripening of many types of fruit, leaf abscission, and the triple response in seedlings (inhibition of stem elongation, promotion of lateral expansion, and horizontal growth); enhances the rate of senescence; promotes root and root hair formation; promotes flowering in the pineapple family.

## ▼ Figure 31.4 Inquiry

### What causes polar movement of auxin from shoot tip to base?

**Experiment** To investigate how auxin is transported unidirectionally, Leo Gälweiler and colleagues designed an experiment to identify the location of the auxin transport protein. They used a greenish yellow fluorescent molecule to label antibodies that bind to the auxin transport protein. Then they applied the antibodies to longitudinally sectioned *Arabidopsis* stems.

**Results** The light micrograph on the left shows that auxin transport proteins are not found in all stem tissues, but only in the xylem parenchyma. In the light micrograph on the right, a higher magnification reveals that these proteins are primarily localized at the basal ends of the cells.

**Conclusion** The results support the hypothesis that concentration of the auxin transport protein at the basal ends of cells mediates the polar transport of auxin.

**Source** L. Gälweiler et al., Regulation of polar auxin transport by At-PIN1 in *Arabidopsis* vascular tissue, *Science* 282:2226–2230 (1998).

**WHAT IF?** If auxin transport proteins were equally distributed at both ends of the cells, would polar auxin still be possible? Explain.

loosening the wall's fabric. Increasing the membrane potential enhances ion uptake into the cell, which causes osmotic uptake of water and increased turgor. Increased turgor and increased cell wall plasticity enable the cell to elongate.

Auxin also rapidly alters gene expression, causing cells in the region of elongation to produce new proteins within minutes. Some of these proteins are short-lived transcription factors that repress or activate the expression of other genes. For sustained growth after this initial spurt, cells must make more cytoplasm and wall material. Auxin also stimulates this sustained growth response.

**Auxin's Role in Plant Development** The polar transport of auxin is a central element controlling the spatial organization, or *pattern formation*, of the developing plant. Auxin is synthesized in shoot tips, and it carries integrated information about the development, size, and environment of individual branches. This flow of information controls branching patterns. A reduced flow of auxin from a branch, for example, indicates that the branch is not being sufficiently productive: New branches are needed elsewhere. Thus, lateral buds below the branch are released from dormancy and begin to grow.

The transport of auxin also plays a key role in establishing *phyllotaxy* (see Figure 29.3), the arrangement of leaves on the stem. A leading model proposes that polar auxin transport in the shoot tip generates local peaks in auxin concentration that determine the site of leaf primordium formation and thereby the different phyllotaxies found in nature.

Auxin, cytokinins, and newly discovered plant hormones called strigolactones interact in the control of apical dominance, the ability of the apical bud to suppress the development of axillary buds. If the apical bud, the primary source of auxin, is removed, the inhibition of axillary buds is removed and the plant becomes bushier. Applying auxin to the cut

**3** Wedge-shaped expansins (red), activated by low pH, separate cellulose microfibrils (brown) from cross-linking polysaccharides (green). The exposed cross-linking polysaccharides are now more accessible to cell wall-loosening enzymes (purple).

**2** The cell wall becomes more acidic.

**1** Auxin increases the activity of proton pumps.

**4** Cell wall-loosening enzymes (purple) cleave cross-linking polysaccharides (green), allowing cellulose microfibrils to slide. The extensibility of the cell wall is increased. Turgor causes the cell to expand.

**5** With the cellulose loosened, the cell can elongate.

▲ Figure 31.5 Cell elongation in response to auxin: the acid growth hypothesis.

surface of the decapitated shoot resuppresses the growth of the lateral buds.

**Practical Uses for Auxins** Auxins, both natural and synthetic, have many commercial applications. For example, the natural auxin indolebutyric acid (IBA) is used in the vegetative propagation of plants by cuttings. (The formation of lateral roots in intact plants is one case where IBA seems to be a more important auxin than IAA.) Treating a detached leaf or stem with powder containing IBA often causes adventitious roots to form near the cut surface.

Certain synthetic auxins, including 2,4-dichlorophenoxyacetic acid (2,4-D), are widely used as herbicides. Monocots, such as maize and turfgrass, can rapidly inactivate such synthetic auxins. However, eudicots cannot and therefore die from hormonal overdose. Spraying cereal fields or turf with 2,4-D eliminates eudicot (broadleaf) weeds.

Developing seeds produce auxin, which promotes fruit growth. In tomato plants grown in greenhouses, often fewer seeds are produced, resulting in poorly developed tomato fruits. However, spraying synthetic auxins on greenhouse-grown tomato vines induces normal fruit development, making the greenhouse-cultivated tomatoes commercially viable.

## Cytokinins

Trial-and-error attempts to find chemical additives that would enhance the growth and development of plant cells in tissue culture led to the discovery of **cytokinins**. In the 1940s, researchers stimulated the growth of plant embryos in culture by adding coconut milk, the liquid endosperm of a coconut's giant seed. Subsequent researchers found that they could induce cultured tobacco cells to divide by adding degraded DNA samples. The active ingredients of both experimental additives turned out to be modified forms of adenine, a component of nucleic acids. These growth regulators were named cytokinins because they stimulate cytokinesis, or cell division. The most common natural cytokinin is zeatin, so named because it was discovered first in maize (*Zea mays*). The effects of cytokinins on cell division and differentiation, apical dominance, and aging are well documented.

**Control of Cell Division and Differentiation** Cytokinins are produced in actively growing tissues, particularly in roots, embryos, and fruits. Cytokinins produced in roots reach their target tissues by moving up the plant in the xylem sap. Acting in concert with auxin, cytokinins stimulate cell division and influence the pathway of differentiation. The effects of cytokinins on cells growing in tissue culture provide clues about how this class of hormones may function in an intact plant. When a piece of parenchyma tissue from a stem is cultured in the absence of cytokinins, the cells grow very large but do not divide. But if cytokinins are added along with auxin, the cells divide. Cytokinins alone have no effect. The ratio of cytokinins to auxin

controls cell differentiation. When the concentrations of these two hormones are at certain levels, the mass of cells continues to grow, but it remains a cluster of undifferentiated cells called a callus (see Figure 30.15). If cytokinin levels increase, shoot buds develop from the callus. If auxin levels increase, roots form.

**Anti-Aging Effects** Cytokinins slow the aging of certain plant organs by inhibiting protein breakdown, stimulating RNA and protein synthesis, and mobilizing nutrients from surrounding tissues. If leaves removed from a plant are dipped in a cytokinin solution, they stay green much longer than otherwise.

## Gibberellins

In the early 1900s, farmers in Asia noticed that some rice seedlings in their paddies grew so tall and spindly that they toppled over before they could mature. In 1926, it was discovered that a fungus of the genus *Gibberella* causes this “foolish seedling disease.” By the 1930s, it was determined that the fungus causes hyperelongation of rice stems by secreting a chemical, which was given the name **gibberellin**. In the 1950s, researchers determined that plants also produce gibberellins (GAs). Since that time, scientists have identified more than 100 different gibberellins that occur naturally in plants, although a much smaller number occur in each plant species. “Foolish rice” seedlings, it seems, suffer from too much gibberellin. Gibberellins have a variety of effects, such as stem elongation, fruit growth, and seed germination.

**Stem Elongation** The major sites of gibberellin production are young roots and leaves. Gibberellins are best known for stimulating stem and leaf growth by enhancing cell elongation *and* cell division. One hypothesis proposes that they activate enzymes that loosen cell walls, facilitating entry of expansin proteins. Thus, gibberellins act in concert with auxin to promote stem elongation.

The effects of gibberellins in enhancing stem elongation are evident when certain dwarf (mutant) varieties of plants are treated with gibberellins. For instance, some dwarf pea plants grow tall if treated with gibberellins. But there is often no response if the gibberellins are applied to wild-type plants. Apparently, these plants already produce an optimal dose of the hormone. The most dramatic example of gibberellin-induced stem elongation is *bolting*, rapid growth of the floral stalk (**Figure 31.6a**).

**Fruit Growth** In many plants, both auxin and gibberellins must be present for fruit to develop. The most important commercial application of gibberellins is in the spraying of Thompson seedless grapes (**Figure 31.6b**). The hormone makes the individual grapes grow larger, a trait valued by the consumer. The gibberellin sprays also make the internodes of the grape bunch elongate, allowing more space for the individual grapes. By enhancing air circulation between the grapes, this increase in space also makes it harder for yeasts and other microorganisms to infect the fruit.

(a) Some plants develop in a rosette form, low to the ground with very short internodes, as in the *Arabidopsis* plant shown at the left. As the plant switches to reproductive growth, a surge of gibberellins induces bolting: Internodes elongate rapidly, elevating floral buds that develop at stem tips (right).

(b) The Thompson seedless grape bunch on the left is from an untreated control vine. The bunch on the right is growing from a vine that was sprayed with gibberellin during fruit development.

▲ **Figure 31.6 Effects of gibberellins on stem elongation and fruit growth.**

**Germination** The embryo of a seed is a rich source of gibberellins. After water is imbibed, the release of gibberellins from the embryo signals the seed to break dormancy and germinate. Some seeds that normally require particular environmental conditions to germinate, such as exposure to light or low temperatures, break dormancy if they are treated with gibberellins. Gibberellins support the growth of cereal seedlings by stimulating the synthesis of digestive enzymes such as  $\alpha$ -amylase that mobilize stored nutrients (**Figure 31.7**).

► **Figure 31.7 Mobilization of nutrients by gibberellins during the germination of grain seeds such as barley.**

1 After a seed imbibes water, the embryo releases gibberellin (GA), which sends a signal to the aleurone, the thin outer layer of the endosperm.

2 The aleurone responds to GA by synthesizing and secreting digestive enzymes that hydrolyze nutrients stored in the endosperm. One example is  $\alpha$ -amylase, which hydrolyzes starch.

3 Sugars and other nutrients absorbed from the endosperm by the scutellum (cotyledon) are consumed during growth of the embryo into a seedling.

## Brassinosteroids

**Brassinosteroids** are steroids similar to cholesterol and the sex hormones of animals. They induce cell elongation and division in stem segments and seedlings at concentrations as low as  $10^{-12}$  M. They also slow leaf abscission (leaf drop) and promote xylem differentiation. These effects are so qualitatively similar to those of auxin that it took years for plant physiologists to determine that brassinosteroids were not types of auxins.

The identification of brassinosteroids as plant hormones arose from studies of an *Arabidopsis* mutant that exhibited morphological features similar to those of light-grown plants even when grown in the dark. The researchers discovered that the mutation affects a gene that normally codes for an enzyme similar to one involved in steroid synthesis in mammals. They also found that this brassinosteroid-deficient mutant could be restored to the wild-type phenotype by applying brassinosteroids.

## Abscisic Acid

In the 1960s, one research group studying the chemical changes that precede bud dormancy and leaf abscission in deciduous trees and another team investigating chemical changes preceding abscission of cotton fruits isolated the same compound, **abscisic acid (ABA)**. Ironically, ABA is no longer thought to play a primary role in bud dormancy or leaf abscission, but it is very important in other functions. Unlike the growth-stimulating hormones we have discussed so far—auxin, cytokinins, gibberellins, and brassinosteroids—ABA *slows* growth. ABA often antagonizes the actions of growth hormones, and the ratio of ABA to one or more growth hormones determines the

final physiological outcome. We will consider here two of ABA's many effects: seed dormancy and drought tolerance.

**Seed Dormancy** Seed dormancy increases the likelihood that seeds will germinate only when there are sufficient amounts of light, temperature, and moisture for the seedlings to survive (see Chapter 30). What prevents seeds dispersed in autumn from germinating immediately, only to die in winter? What mechanisms ensure that such seeds do not germinate until spring? For that matter, what prevents seeds from germinating in the dark, moist interior of the fruit? The answer to these questions is ABA. The levels of ABA may increase 100-fold during seed maturation. The high levels of ABA in maturing seeds inhibit germination and induce the production of proteins that help the seeds withstand the extreme dehydration that accompanies maturation.

Many types of dormant seeds germinate when ABA is removed or inactivated. The seeds of some desert plants break dormancy only when heavy rains wash ABA out of them. Other seeds require light or prolonged exposure to cold to inactivate ABA. Often, the ratio of ABA to gibberellins determines whether seeds remain dormant or germinate, and adding ABA to seeds that are primed to germinate makes them dormant again. Low levels of ABA or ABA sensitivity can lead to precocious (early) germination (**Figure 31.8**). Precocious germination of red mangrove seeds, due to low ABA levels, is actually an adaptation that helps the young seedlings to plant themselves like darts in the soft mud below the parent tree.

**Drought Tolerance** ABA plays a major role in drought signaling. When a plant begins to wilt, ABA accumulates in the leaves and causes stomata to close rapidly, reducing transpiration and preventing further water loss. By affecting second messengers such as calcium, ABA causes potassium channels in the plasma membrane of guard cells to open, leading to a massive loss of potassium ions from the cells. The accompanying osmotic loss of water reduces guard cell turgor and leads to closing of the stomatal pores (see Figure 29.19). In some cases, water shortage stresses the root system before the shoot system, and ABA transported from roots to leaves may function as an “early warning system.”

## Ethylene

During the 1800s, when coal gas was used as fuel for streetlights, leakage from gas pipes caused nearby trees to drop leaves prematurely. In 1901, the gas **ethylene** was demonstrated to be the active factor in coal gas. But the idea that it is a plant hormone was not widely accepted until the advent of a technique called gas chromatography simplified its identification.

Plants produce ethylene in response to stresses such as drought, flooding, mechanical pressure, injury, and infection. Ethylene is also produced during fruit ripening and programmed cell death and in response to high concentrations

◀ Red mangrove (*Rhizophora mangle*) seeds produce only low levels of ABA, and their seeds germinate while still on the tree. In this case, early germination is a useful adaptation. When released, the radicle of the dart-like seedling deeply penetrates the soft mudflats in which the mangroves grow.

▲ Precocious germination in this maize mutant is caused by lack of a functional transcription factor required for ABA action.

▲ **Figure 31.8** Precocious germination of wild-type mangrove and mutant maize seeds.

of externally applied auxin. Indeed, many effects previously ascribed to auxin, such as inhibition of root elongation, may be due to auxin-induced ethylene production. We will focus here on four of ethylene's many effects: response to mechanical stress, senescence, leaf abscission, and fruit ripening.

**The Triple Response to Mechanical Stress** Imagine a pea seedling pushing upward through the soil, only to come up against a stone. As it pushes against the obstacle, the stress in its delicate tip induces the seedling to produce ethylene. The hormone then instigates a growth maneuver known as the **triple response** that enables the shoot to avoid the obstacle. The three parts of this response are a slowing of stem elongation, a thickening of the stem (which makes it stronger), and a curvature that causes the stem to start growing horizontally. As the effects of the initial ethylene pulse lessen, the stem resumes vertical growth. If it again contacts a barrier, another burst of ethylene is released, and horizontal growth resumes. However, if the upward touch detects no solid object, then ethylene production decreases, and the stem, now clear of the obstacle, resumes its normal upward growth. It is ethylene that induces the stem to grow horizontally rather than the physical obstruction itself; when ethylene is applied to normal seedlings growing free of physical impediments, they still undergo the triple response.

(a) ***ein* mutant.** An ethylene-insensitive (*ein*) mutant fails to undergo the triple response in the presence of ethylene. (b) ***ctr* mutant.** A constitutive triple-response (*ctr*) mutant undergoes the triple response even in the absence of ethylene.

▲ **Figure 31.9 Ethylene triple-response *Arabidopsis* mutants.**

Studies of *Arabidopsis* mutants with abnormal triple responses are an example of how biologists identify a signal transduction pathway. Scientists isolated ethylene-insensitive (*ein*) mutants, which fail to undergo the triple response after exposure to ethylene (Figure 31.9a). Some types of *ein* mutants are insensitive to ethylene because they lack a functional ethylene receptor. Mutants of a different sort undergo the triple response even out of soil, in the air, where there are no physical obstacles. Some of these mutants have a regulatory defect that causes them to produce ethylene at rates 20 times normal. The phenotype of such ethylene-overproducing (*eto*) mutants can be restored to wild-type by treating the seedlings with inhibitors of ethylene synthesis. Other mutants, called constitutive triple-response (*ctr*) mutants, undergo the triple response in air but do not respond to inhibitors of ethylene synthesis (Figure 31.9b). (Constitutive genes are genes that are continually expressed in all cells of an organism.) In *ctr* mutants, ethylene signal transduction is permanently turned on, even though ethylene is not present.

The affected gene in *ctr* mutants codes for a protein kinase. The fact that this mutation *activates* the ethylene response suggests that the normal kinase product of the wild-type allele is a *negative* regulator of ethylene signal transduction. Thus, binding of the hormone ethylene to the ethylene receptor normally leads to inactivation of the kinase; and the inactivation of this negative regulator allows synthesis of the proteins required for the triple response.

**Senescence** Consider the shedding of a leaf in autumn or the death of an annual after flowering. Or think about the final step in differentiation of a vessel element, when its living contents

are destroyed, leaving a hollow tube behind. Such events involve **senescence**—the programmed death of certain cells or organs or the entire plant. Cells, organs, and plants genetically programmed to die on a schedule do not simply shut down cellular machinery and await death. Instead, at the molecular level, the onset of the programmed cell death called *apoptosis* is a very busy time in a cell's life, requiring new gene expression. During apoptosis, newly formed enzymes break down many chemical components, including chlorophyll, DNA, RNA, proteins, and membrane lipids. The plant salvages many of the breakdown products. A burst of ethylene is almost always associated with the apoptosis of cells during senescence.

**Leaf Abscission** The loss of leaves from deciduous trees helps prevent desiccation during seasonal periods when the availability of water to the roots is severely limited. Before dying leaves abscise, many essential elements are salvaged from them and stored in stem parenchyma cells. These nutrients are recycled back to developing leaves the following spring. Autumn leaf color is due to newly made red pigments as well as yellow and orange carotenoids (see Concept 8.2) that were already present in the leaf and are rendered visible by the breakdown of the dark green chlorophyll in autumn.

When an autumn leaf falls, it detaches from the stem at an abscission layer that develops near the base of the petiole (Figure 31.10). The small parenchyma cells of this layer have very thin walls, and there are no fiber cells around the vascular tissue. The abscission layer is further weakened when enzymes hydrolyze polysaccharides in the cell walls. Finally, the weight of the leaf, with the help of the wind, causes a separation within the abscission layer. Even before the leaf falls, a layer of cork forms a protective scar on the twig side of the abscission layer, preventing pathogens from invading the plant.

▲ **Figure 31.10 Abscission of a maple leaf.** Abscission is controlled by a change in the ratio of ethylene to auxin. The abscission layer is seen in this longitudinal section as a vertical band at the base of the petiole. After the leaf falls, a protective layer of cork becomes the leaf scar that helps prevent pathogens from invading the plant (LM).

A change in the ratio of ethylene to auxin controls abscission. An aging leaf produces less and less auxin, rendering the cells of the abscission layer more sensitive to ethylene. As the influence of ethylene on the abscission layer prevails, the cells produce enzymes that digest the cellulose and other components of cell walls.

**Fruit Ripening** Immature fleshy fruits are generally tart, hard, and green—features that help protect the developing seeds from herbivores. After ripening, the mature fruits help *attract* animals that disperse the seeds (see Figure 30.12). In many cases, a burst of ethylene production in the fruit triggers the ripening process. The enzymatic breakdown of cell wall components softens the fruit, and the conversion of starches and acids to sugars makes the fruit sweet. The production of new scents and colors helps advertise ripeness to animals, which eat the fruits and disperse the seeds.

A chain reaction occurs during ripening: Ethylene triggers ripening, and ripening triggers more ethylene production. The result is a huge burst in ethylene production. Because ethylene is a gas, the signal to ripen spreads from fruit to fruit. If you pick or buy green fruit, you may be able to speed ripening by storing the fruit in a paper bag, allowing ethylene to accumulate. On a commercial scale, many kinds of fruits are ripened in huge storage containers in which ethylene levels are enhanced. In other cases, fruit producers take measures to slow ripening caused by natural ethylene. Apples, for instance, are stored in bins flushed with carbon dioxide. Circulating the air prevents ethylene from accumulating, and carbon dioxide inhibits synthesis of new ethylene. Stored in this way, apples picked in autumn can still be shipped to grocery stores the following summer.

#### CONCEPT CHECK 31.1

1. Fusicoccin is a fungal toxin that stimulates the plasma membrane  $H^+$  pumps of plant cells. How would it affect the growth of isolated stem sections?
2. **WHAT IF?** If a plant has the double mutation *ctr* and *ein*, what is its triple-response phenotype? Explain your answer.
3. **MAKE CONNECTIONS** What type of feedback process is exemplified by the production of ethylene during fruit ripening? Explain. (See Concept 32.2.)

For suggested answers, see Appendix A.

## CONCEPT 31.2

### Responses to light are critical for plant success

Light is an especially important environmental factor in the lives of plants. In addition to being required for photosynthesis, light triggers many key events in plant growth and development, collectively known as **photomorphogenesis**. Light reception also allows plants to measure the passage of days and seasons.

### Photomorphogenesis

As an example of photomorphogenesis, consider a sprouting potato (**Figure 31.11a**). This modified underground stem, or tuber, has sprouted shoots from its “eyes” (axillary buds). These shoots, however, scarcely resemble those of a typical plant. Instead of sturdy stems and broad green leaves, this plant has ghostly pale stems and unexpanded leaves, as well as short, stubby roots. These morphological adaptations for growing in darkness, collectively referred to as **etiolation**, make sense if we consider that a young potato plant in nature usually encounters continuous darkness when sprouting underground. Under these circumstances, expanded leaves would be a hindrance to soil penetration and would be damaged as the shoots pushed through the soil. Because the leaves are unexpanded and underground, there is little evaporative loss of water and little requirement for an extensive root system to replace the water lost by transpiration. Moreover, the energy expended in producing green chlorophyll would be wasted because there is no light for photosynthesis. Instead, a potato plant growing in the dark allocates as much energy as possible to elongating its stems. This adaptation enables the shoots to break ground before the nutrient reserves in the tuber are exhausted.

When a shoot reaches light, the plant undergoes profound changes, collectively called **de-etiolation** (informally known as greening). Stem elongation slows; leaves expand; roots elongate; and the shoot produces chlorophyll. In short, it begins to resemble a typical plant (**Figure 31.11b**). How do light signals initiate this remarkable change in form? As in all signal transduction processes, the signal must first be detected by a receptor protein.

Plants detect not only the presence of light signals but also their direction, intensity, and wavelength (color). A graph called an **action spectrum** depicts the relative effectiveness

(a) **Before exposure to light.** A dark-grown potato has tall, spindly stems and nonexpanded leaves—morphological adaptations that enable the shoots to penetrate the soil. The roots are short, but there is little need for water absorption because little water is lost by the shoots.

(b) **After a week's exposure to natural daylight.** The potato plant begins to resemble a typical plant with broad green leaves, short sturdy stems, and long roots. This transformation begins with the reception of light by a specific pigment, phytochrome.

▲ **Figure 31.11** Light-induced de-etiolation (greening) of dark-grown potatoes.

of different wavelengths of radiation in driving a particular process, such as photosynthesis (see Figure 8.9b). Action spectra are useful in studying *any* process that depends on light, including phototropism (**Figure 31.12**). By comparing action spectra of various plant responses, researchers determine which responses are mediated by the same photoreceptor (pigment). They also compare action spectra with absorption spectra of pigments; a close correspondence for a given pigment suggests that the pigment is the photoreceptor mediating the response. In the case of photomorphogenesis, action spectra reveal that red and blue light are the most important colors. In

(a) This action spectrum illustrates that only light wavelengths below 500 nm (blue and violet light) induce curvature.

(b) When coleoptiles are exposed to light of various wavelengths as shown here, violet light induces slight curvature toward the light and blue light induces the most curvature. The other colors do not induce any curvature.

▲ **Figure 31.12** Action spectrum for blue-light-stimulated phototropism in maize coleoptiles. Phototropic bending toward light is controlled by phototropin, a photoreceptor sensitive to blue and violet light, particularly blue light.

fact, there are two major classes of photoreceptors in plants: **blue-light photoreceptors** and **phytochromes**, photoreceptors that absorb mostly red light.

### Blue-Light Photoreceptors

Blue light initiates a variety of responses in plants, including phototropism, the light-induced opening of stomata (see Figure 29.19), and the light-induced slowing of hypocotyl elongation that occurs when a seedling breaks ground. The biochemical identity of the blue-light photoreceptor was so elusive that in the 1970s, plant physiologists began to call this receptor “cryptochrome” (from the Greek *kryptos*, hidden, and *chrom*, pigment). In the 1990s, molecular biologists analyzing *Arabidopsis* mutants found that plants use different types of pigments to detect blue light. *Cryptochromes*, molecular relatives of DNA repair enzymes, are involved in the blue-light-induced inhibition of stem elongation that occurs, for example, when a seedling first emerges from the soil. *Phototropin* is a protein kinase involved in mediating blue-light-mediated stomatal opening, chloroplast movements in response to light, and phototropic curvatures, such as those studied by the Darwins.

### Phytochrome Photoreceptors

Phytochromes, another class of photoreceptors, regulate many plant responses to light, including seed germination and shade avoidance.

**Phytochromes and Seed Germination** Studies of seed germination led to the discovery of phytochromes. Because of limited nutrient reserves, many types of seeds, especially small ones, germinate only when the light environment and other conditions are near optimal. Such seeds often remain dormant for years until light conditions change. For example, the death of a shading tree or the plowing of a field may create a favorable light environment.

In the 1930s, scientists determined the action spectrum for light-induced germination of lettuce seeds. They exposed water-swollen seeds to a few minutes of single-colored light of various wavelengths and then stored the seeds in the dark. After two days, the researchers counted the number of seeds that had germinated under each light regimen. They found that red light of wavelength 660 nm increased the germination percentage of lettuce seeds maximally, whereas far-red light—that is, light of wavelengths near the upper edge of human visibility (730 nm)—*inhibited* germination compared with dark controls (**Figure 31.13**). What happens when the lettuce seeds are subjected to a flash of red light followed by a flash of far-red light or, conversely, to far-red light followed by red light? The *last* flash of light determines the seeds’ response: The effects of red and far-red light are reversible.

The photoreceptors responsible for the opposing effects of red and far-red light are phytochromes. So far, researchers have identified five phytochromes in *Arabidopsis*, each with a slightly

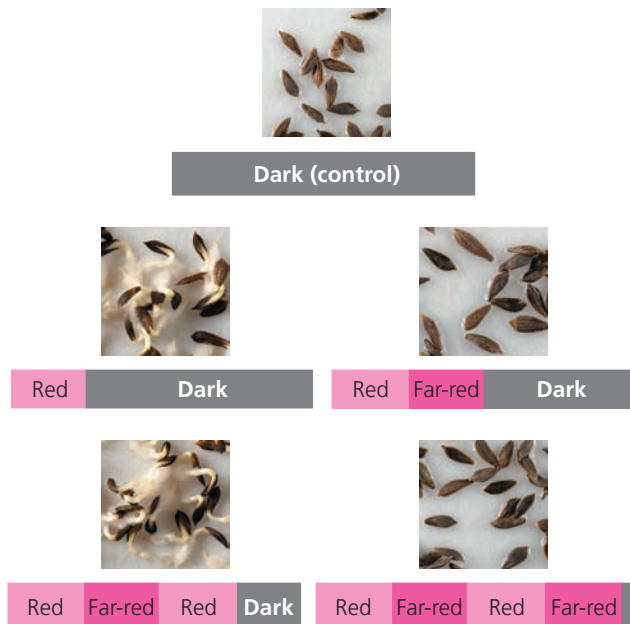

## ▼ Figure 31.13 Inquiry

### How does the order of red and far-red illumination affect seed germination?

**Experiment** Scientists at the U.S. Department of Agriculture briefly exposed batches of lettuce seeds to red light or far-red light to test the effects on germination. After the light exposure, the seeds were placed in the dark, and the results were compared with control seeds that were not exposed to light.

**Results** The bar below each photo indicates the sequence of red light exposure, far-red light exposure, and darkness. The germination rate increased greatly in groups of seeds that were last exposed to red light (left). Germination was inhibited in groups of seeds that were last exposed to far-red light (right).

**Conclusion** Red light stimulates germination, and far-red light inhibits germination. The final light exposure is the determining factor. The effects of red and far-red light are reversible.

**Source** H. Borthwick et al., A reversible photoreaction controlling seed germination, *Proceedings of the National Academy of Sciences, USA* 38:662–666 (1952).

**WHAT IF?** Phytochrome responds faster to red light than to far-red light. If the seeds had been placed in white light instead of the dark after their red and far-red light treatments, would the results have been different? Explain.

different polypeptide component. In most phytochromes, the light-absorbing portion is photoreversible, converting back and forth between two forms, depending on the color of light it is exposed to. In its  $P_r$  form, a phytochrome absorbs red (r) light maximally and is converted to the  $P_{fr}$  form; in its  $P_{fr}$  form, it absorbs far-red (fr) light and is converted to its  $P_r$  form (Figure 31.14). This  $P_r \leftrightarrow P_{fr}$  interconversion is a switching mechanism that controls various light-induced events in the life of the plant.  $P_{fr}$  is the form of phytochrome that triggers many of a plant's developmental responses to light. For example,  $P_r$  in lettuce seeds exposed to red light is converted to  $P_{fr}$ ,

▲ **Figure 31.14 Phytochrome: a molecular switching mechanism.** Absorption of red light causes  $P_r$  to change to  $P_{fr}$ . Far-red light reverses this conversion.

stimulating the cellular responses that lead to germination. When red-illuminated seeds are then exposed to far-red light,  $P_{fr}$  is converted back to  $P_r$ , inhibiting the germination response.

How does phytochrome switching explain light-induced germination in nature? Plants synthesize phytochrome as  $P_r$ , and if seeds are kept in the dark, the pigment remains almost entirely in the  $P_r$  form (see Figure 31.14). Sunlight contains both red light and far-red light, but the conversion to  $P_{fr}$  is faster than the conversion to  $P_r$ . Therefore, the ratio of  $P_{fr}$  to  $P_r$  increases in sunlight. When seeds are exposed to adequate sunlight, the production and accumulation of  $P_{fr}$  will trigger their germination.

**Phytochromes and Shade Avoidance** The phytochrome system also provides the plant with information about the *quality* of light. Because sunlight includes both red and far-red radiation, during the day the  $P_r \leftrightarrow P_{fr}$  interconversion reaches a dynamic equilibrium, with the ratio of the two phytochrome forms indicating the relative amounts of red and far-red light. This sensing mechanism enables plants to adapt to changes in light conditions. Consider, for example, the “shade avoidance” response of a tree that requires relatively high light intensity. If other trees in a forest shade this tree, the phytochrome ratio shifts in favor of  $P_r$  because the forest canopy screens out more red light than far-red light. This is because the chlorophyll pigments in the leaves of the canopy absorb red light and allow far-red light to pass through. The shift in the ratio of red to far-red light induces the tree to allocate more of its resources to growing taller. In contrast, direct sunlight increases the proportion of  $P_{fr}$ , which stimulates branching and inhibits vertical growth.

In addition to helping plants detect light, phytochrome helps a plant keep track of the passage of days and seasons. To understand phytochrome's role in these timekeeping processes, we must first examine the nature of the plant's internal clock.

## Biological Clocks and Circadian Rhythms

Many plant processes, such as transpiration and the synthesis of certain enzymes, undergo a daily oscillation. Some of these cyclic variations are responses to the changes in light levels and temperature that accompany the 24-hour cycle of day and night. We can control these external factors by growing plants

▲ **Figure 31.15** Sleep movements of a bean plant (*Phaseolus vulgaris*). The movements are caused by reversible changes in the turgor pressure of cells on opposing sides of the pulvini, motor organs of the leaf.

in growth chambers under rigidly maintained conditions of light and temperature. But even under artificially constant conditions, many physiological processes in plants, such as the opening and closing of stomata and the production of photosynthetic enzymes, continue to oscillate with a frequency of about 24 hours. For example, many legumes lower their leaves in the evening and raise them in the morning (**Figure 31.15**). A bean plant continues these “sleep movements” even if kept in constant light or constant darkness; the leaves are not simply responding to sunrise and sunset. Such cycles, with a frequency of about 24 hours and not directly controlled by any known environmental variable, are called **circadian rhythms** (from the Latin *circa*, approximately, and *dies*, day).

Recent research supports the idea that the molecular “gears” of the circadian clock really are internal and not a daily response to some subtle but pervasive environmental cycle, such as geomagnetism or cosmic radiation. Organisms, including plants and people, continue their rhythms even after being placed in deep mine shafts or orbiting in spacecraft, conditions that alter these subtle geophysical periodicities. However, daily signals from the environment can entrain (set) the circadian clock to a period of precisely 24 hours.

If an organism is kept in a constant environment, its circadian rhythms deviate from a 24-hour period (a period is the duration of one cycle). These free-running periods, as they are called, vary from about 21 to 27 hours, depending on the particular rhythmic response. The sleep movements of bean plants, for instance, have a period of 26 hours when the plants are kept in the free-running condition of constant darkness. Deviation of the free-running period from exactly 24 hours does not mean that biological clocks drift erratically. Free-running clocks are still keeping perfect time, but they are not synchronized with the outside world. To understand the mechanisms underlying circadian rhythms, we must distinguish between the clock and the rhythmic processes it controls. For example, the leaves of the bean plant in Figure 31.15 are the clock’s “hands” but are not the essence of the clock itself. If bean leaves are restrained for several hours and then

released, they will reestablish the position appropriate for the time of day. We can interfere with a biological rhythm, but the underlying clockwork continues to tick.

At the heart of the molecular mechanisms underlying circadian rhythms are oscillations in the transcription of certain genes. Mathematical models propose that the 24-hour period arises from negative-feedback loops involving the transcription of a few central “clock genes.” Some clock genes may encode transcription factors that inhibit, after a time delay, the transcription of the gene that encodes the transcription factor itself. Such negative-feedback loops, together with a time delay, are enough to produce oscillations.

### The Effect of Light on the Biological Clock

As we have discussed, the free-running period of the circadian rhythm of bean leaf movements is 26 hours. Consider a bean plant placed at dawn in a dark cabinet for 72 hours: Its leaves would not rise again until 2 hours after natural dawn on the second day, 4 hours after natural dawn on the third day, and so on. Shut off from environmental cues, the plant becomes desynchronized. Desynchronization happens to humans when we fly across time zones; when we reach our destination, the clocks on the wall are not synchronized with our internal clocks. Most organisms are probably prone to jet lag.

The factor that entrains the biological clock to precisely 24 hours every day is light. Both phytochromes and blue-light photoreceptors can entrain circadian rhythms in plants, but our understanding of how phytochromes do this is more complete. The mechanism involves turning cellular responses on and off by means of the  $P_r \leftrightarrow P_{fr}$  switch.

Consider again the photoreversible system in Figure 31.14. In darkness, the phytochrome ratio shifts gradually in favor of the  $P_r$  form, partly as a result of turnover in the overall phytochrome pool. The pigment is synthesized in the  $P_r$  form, and enzymes destroy more  $P_{fr}$  than  $P_r$ . In some plant species,  $P_{fr}$  present at sundown slowly converts to  $P_r$ . In darkness, there is no means for the  $P_r$  to be reconverted to  $P_{fr}$ , but upon illumination, the  $P_{fr}$  level suddenly increases again as  $P_r$  is rapidly converted. This increase in  $P_{fr}$  each day at dawn resets the biological clock: Bean leaves reach their most extreme night position 16 hours after dawn.

In nature, interactions between phytochrome and the biological clock enable plants to measure the passage of night and day. The relative lengths of night and day, however, change over the course of the year (except at the equator). Plants use this change to adjust their activities in synchrony with the seasons.

### Photoperiodism and Responses to Seasons

Imagine the consequences if a plant produced flowers when pollinators were not present or if a deciduous tree produced leaves in the middle of winter. Seasonal events are of critical importance in the life cycles of most plants. Seed germination, flowering, and the onset and breaking of bud dormancy are

all stages that usually occur at specific times of the year. The environmental stimulus that plants use most often to detect the time of year is the photoperiod, the relative lengths of night and day. A physiological response to photoperiod, such as flowering, is called **photoperiodism**.

### Photoperiodism and Control of Flowering

An early clue to how plants detect seasons came from a mutant variety of tobacco, Maryland Mammoth, that grew tall but failed to flower during summer. It finally bloomed in a greenhouse in December. Researchers determined that the shortening days of winter stimulated this variety to flower. If the plants were kept in light-tight boxes so that lamps could manipulate “day” and “night,” flowering occurred only if the day length was 14 hours or shorter. It did not flower during summer because at Maryland’s latitude, the summer days were too long.

The researchers called Maryland Mammoth a **short-day plant** because it apparently required a light period *shorter* than a critical length to flower. Chrysanthemums, poinsettias, and some soybean varieties are also short-day plants, which generally flower in late summer, fall, or winter. Another group of plants flower only when the light period is *longer* than a certain number of hours. These **long-day plants** generally flower in late spring or early summer. Spinach, for example, flowers when days are 14 hours or longer. Radishes, lettuce, irises, and many cereal varieties are also long-day plants. **Day-neutral plants**, such as tomatoes, rice, and dandelions, are unaffected by photoperiod and flower when they reach a certain stage of maturity, regardless of day length.

**Critical Night Length** In the 1940s, researchers learned that flowering and other responses to photoperiod are actually controlled by night length, not day length. Many of these scientists worked with cocklebur (*Xanthium strumarium*), a short-day plant that flowers only when days are 16 hours or shorter (and nights are at least 8 hours long). These researchers found that if the light portion of the photoperiod is broken by a brief exposure to darkness, flowering proceeds. However, if the dark part of the photoperiod is interrupted by even a few minutes of dim light, cocklebur will not flower, and this turned out to be true for other short-day plants as well (**Figure 31.16a**). Cocklebur is unresponsive to day length, but it requires at least 8 hours of continuous darkness to flower. Short-day plants are really long-night plants, but the older term is embedded firmly in the lexicon of plant physiology. Similarly, long-day plants are actually short-night plants. A long-day plant grown on photoperiods of long nights that would not normally induce flowering will flower if the period of continuous darkness is interrupted by a few minutes of light (**Figure 31.16b**). Notice that we distinguish long-day from short-day plants *not* by an absolute night length but by whether the critical night length sets a maximum (long-day plants) or minimum (short-day plants) number of hours of darkness required for flowering. In both cases, the

▲ **Figure 31.16** Photoperiodic control of flowering.

actual number of hours in the critical night length is specific to each species of plant.

Red light is the most effective color in interrupting the nighttime portion of the photoperiod. Action spectra and photoreversibility experiments show that phytochrome is the pigment that detects the red light (**Figure 31.17**). For example, if a flash of red (R) light during the dark period is followed by a flash of far-red (FR) light, then the plant detects no interruption of night length. As in the case of phytochrome-mediated seed germination, red/far-red photoreversibility occurs.

Plants detect night length very precisely; some short-day plants will not flower if night is even 1 minute shorter than the critical length. Some plant species always flower on the same day each year. It appears that plants use their biological clock, entrained by night length with the help of phytochrome, to tell the season of the year. The floriculture (flower-growing) industry applies this knowledge to produce flowers out of season. Chrysanthemums, for instance, are short-day plants that normally bloom in fall, but their blooming can be stalled until Mother’s Day in May by punctuating each long night with a flash of light, thus turning one long night into two short nights.

Some plants bloom after a single exposure to the photoperiod required for flowering. Other species need several successive days of the appropriate photoperiod. Still others respond to a photoperiod only if they have been previously exposed to some other environmental stimulus, such as a period of cold. Winter wheat, for example, will not flower unless it has been exposed to several weeks of temperatures below 10°C. The use of pretreatment with cold to induce flowering is called

▲ **Figure 31.17 Reversible effects of red and far-red light on photoperiodic response.** A flash of red (R) light shortens the dark period. A subsequent flash of far-red (FR) light cancels the red flash's effect.

? How would a single flash of full-spectrum light affect each plant?

**vernalization** (from the Latin for “spring”). Several weeks after winter wheat is vernalized, a photoperiod with long days (short nights) induces flowering.

### A Flowering Hormone?

Although flowers form from apical or axillary bud meristems, it is leaves that detect changes in photoperiod and produce signaling molecules that cue buds to develop as flowers. In many short-day and long-day plants, exposing just one leaf to the appropriate photoperiod is enough to induce flowering. Indeed, as long as one leaf is left on the plant, photoperiod is detected and floral buds are induced. If all leaves are removed, the plant is insensitive to photoperiod.

Classic experiments revealed that the floral stimulus could move across a graft from an induced plant to a noninduced plant and trigger flowering in the latter. Moreover, the flowering stimulus appears to be the same for short-day and long-day plants, despite the different photoperiodic conditions required for leaves to send this signal (**Figure 31.18**). The hypothetical signaling molecule for flowering, called **florigen**, remained unidentified for over 70 years as scientists focused on small hormone-like molecules. However, large macromolecules, such as mRNA and proteins, can move by the symplastic route via plasmodesmata and regulate plant development. It now appears that florigen is a protein. A gene called *FLOWERING LOCUS T (FT)* is activated in leaf cells during conditions favoring flowering, and the FT protein travels through the

▲ **Figure 31.18 Experimental evidence for a flowering hormone.** If grown individually under short-day conditions, a short-day plant will flower and a long-day plant will not. However, both will flower if grafted together and exposed to short days. This result indicates that a flower-inducing substance (florigen) is transmitted across grafts and induces flowering in both short-day and long-day plants.

**WHAT IF?** If flowering were inhibited in both parts of the grafted plants, what would you conclude?

sympasm to the shoot apical meristem and initiates the transition of a bud's meristem from a vegetative to a flowering state.

### CONCEPT CHECK 31.2

1. If an enzyme in field-grown soybean leaves is most active at noon and least active at midnight, is its activity under circadian regulation?
2. **WHAT IF?** If a plant flowers in a controlled chamber with a daily cycle of 10 hours of light and 14 hours of darkness, is it a short-day plant? Explain.
3. **MAKE CONNECTIONS** Plants detect the quality of their light environment by using blue-light photoreceptors and red-light-absorbing phytochromes. Suggest a reason why plants are so sensitive to these colors of light. (See Figure 8.9.)

For suggested answers, see Appendix A.

## CONCEPT 31.3

### Plants respond to a wide variety of stimuli other than light

Plants are immobile, but mechanisms have evolved by natural selection that enable them to adjust to a wide range of environmental circumstances by developmental or physiological means. Light is so important in the life of a plant that we devoted the entire previous section to a plant's reception of and response to this one environmental factor. In this section, we examine responses to some of the other environmental stimuli that a plant commonly encounters.

## Gravity

Because plants are photoautotrophs, it is not surprising that mechanisms for growing toward sunlight have evolved. But what environmental cue does the shoot of a young seedling use to grow upward when it is completely underground and there is no light for it to detect? Similarly, what environmental factor prompts the young root to grow downward? The answer to both questions is gravity.

Place a plant on its side, and it adjusts its growth so that the shoot bends upward and the root curves downward. In their responses to gravity, or **gravitropism**, roots display positive gravitropism (**Figure 31.19a**) and shoots exhibit negative gravitropism. Gravitropism occurs as soon as a seed germinates, ensuring that the root grows into the soil and the shoot grows toward sunlight, regardless of how the seed is oriented when it lands.

Plants may detect gravity by the settling of **statoliths**, dense cytoplasmic components that settle under the influence of gravity to the lower portions of the cell. The statoliths of vascular plants are specialized plastids containing dense starch grains (**Figure 31.19b**). In roots, statoliths are located in certain cells of the root cap. According to one hypothesis, the aggregation of statoliths at the low points of these cells triggers a redistribution of calcium, which causes lateral transport of auxin within the root. The calcium and auxin accumulate on the lower side of the root's zone of elongation. At high concentration, auxin inhibits cell elongation, an effect that slows growth on the root's lower side. The more rapid elongation of cells on the upper side eventually causes the root to grow straight downward.

**(a)** Over the course of hours, a horizontally oriented primary root of maize bends gravitropically until its growing tip becomes vertically oriented (LMs).

**(b)** Within minutes after the root is placed horizontally, plastids called statoliths begin settling to the lowest sides of root cap cells. This settling may be the gravity-sensing mechanism that leads to redistribution of auxin and differing rates of elongation by cells on opposite sides of the root (LMs).

▲ **Figure 31.19 Positive gravitropism in roots: the statolith hypothesis.**

Falling statoliths, however, may not be indispensable for gravitropism. For example, there are mutants of *Arabidopsis* and tobacco that lack statoliths but are still capable of gravitropism, though the response is slower than in wild-type plants. It could be that the entire cell helps the root sense gravity by mechanically pulling on proteins that tether the protoplast to the cell wall, stretching the proteins on the “up” side and compressing the proteins on the “down” side of the root cells. Dense organelles, in addition to starch granules, may also contribute by distorting the cytoskeleton as they are pulled by gravity. Statoliths, because of their density, may enhance gravitational sensing by a mechanism that simply works more slowly in their absence.

## Mechanical Stimuli

Trees in windy environments usually have shorter, stockier trunks than trees of the same species growing in more sheltered locations. The advantage of this stunted morphology is that it enables the plant to resist strong gusts of wind. The term **thigmomorphogenesis** (from the Greek *thigma*, touch) refers to the changes in form that result from mechanical perturbation. Plants are very sensitive to mechanical stress: Even the act of measuring the length of a leaf with a ruler alters its subsequent growth. Rubbing the stems of a young plant a couple of times daily results in plants that are shorter than controls (**Figure 31.20**).

Some plant species have become, over the course of their evolution, “touch specialists.” Acute responsiveness to mechanical stimuli is an integral part of these plants’ “life strategies.” Most vines and other climbing plants have tendrils that coil rapidly around supports (see Figure 28.7). These grasping organs usually grow straight until they touch something; the contact stimulates a coiling response caused by differential growth of cells on opposite sides of the tendril. This directional growth in response to

▲ **Figure 31.20 Thigmomorphogenesis in *Arabidopsis*.** The shorter plant on the left was rubbed twice a day. The untouched plant (right) grew much taller.

touch is called **thigmotropism**, and it allows the vine to take advantage of whatever mechanical supports it comes across as it climbs upward toward a forest canopy.

Other examples of touch specialists are plants that undergo rapid leaf movements in response to mechanical stimulation. For example, when the compound leaf of the sensitive plant *Mimosa pudica* is gently touched, its leaflets fold together

(Figure 31.21). This response, which takes only a second or two, results from a rapid loss of turgor in specialized motor cells

located at the base of each leaflet. The motor cells suddenly become flaccid after stimulation because they lose potassium ions, causing water to leave the cells by osmosis. It takes about 10 minutes for the cells to regain their turgor and restore the “unstimulated” form of the leaf. The function of the sensitive plant’s behavior invites speculation. Perhaps by folding its leaves and reducing its surface area when jostled, the plant appears less leafy and appetizing to herbivores.

A remarkable feature of rapid leaf movements is the mode of transmission of the stimulus through the plant. If one leaflet on a sensitive plant is touched, first that leaflet responds, then the adjacent leaflet responds, and so on, until all the leaflet pairs have folded together. From the point of stimulation, the signal that produces this response travels at a speed of about 1 cm/sec. An electrical impulse traveling at the same rate can be detected when electrodes are attached to the leaf. These impulses, called **action potentials**, resemble nerve impulses in animals, though the action potentials of plants are thousands of times slower. Action potentials have been discovered in many species of algae and plants and may be used as a form of internal communication. For example, in the Venus flytrap (*Dionaea muscipula*), action potentials are transmitted from sensory hairs in the trap to the cells that respond by closing the trap (see Figure 29.15). In the case of *Mimosa pudica*, more violent stimuli, such as touching a leaf with a hot needle, causes *all* the leaves and leaflets on a plant to droop, but this whole-plant response involves the spread of signaling molecules released from the injured area to other parts of the shoot.

## Environmental Stresses

Certain factors in the environment may change severely enough to have a potentially adverse effect on a plant’s survival, growth, and reproduction. Environmental stresses, such as flooding, drought, or extreme temperatures, can have a devastating impact on crop yields in agriculture. In natural ecosystems, plants that cannot tolerate an environmental stress will either succumb or be outcompeted by other plants. Thus, environmental stresses are an important factor in determining the geographic ranges of plants. Here we’ll consider some

(a) Unstimulated state (leaflets spread apart)

(b) Stimulated state (leaflets folded)

▲ **Figure 31.21** Rapid turgor movements by the sensitive plant (*Mimosa pudica*).

of the more common **abiotic** (nonliving) stresses that plants encounter. In the last section of this chapter, we’ll examine the defensive responses of plants to common **biotic** (living) stresses, such as herbivores and pathogens.

### Drought

On a dry, sunny day, a plant may wilt because its water loss by transpiration exceeds water absorption from the soil. Prolonged drought, of course, will kill a plant, but plants have control systems that enable them to cope with less extreme water deficits.

Many of a plant’s responses to water deficit help the plant conserve water by reducing the rate of transpiration. Water deficit in a leaf causes stomata to close, thereby slowing transpiration dramatically (see Figure 29.19). Water deficit stimulates increased synthesis and release of ABA in the leaves and roots; this hormone helps keep stomata closed by acting on guard cell membranes. Leaves respond to water deficit in several other ways. For example, when the leaves of grasses wilt, they roll into a tubelike shape that reduces transpiration by exposing less leaf surface to dry air and wind. Other plants, such as ocotillo (see Figure 29.20), shed their leaves in response to seasonal drought. Although these leaf responses conserve water, they also reduce photosynthesis, which is one reason why a drought diminishes crop yield. Plants can even take advantage of “early warnings” in the form of chemical signals from wilting neighbors and prime themselves to respond more readily and intensely to impending drought stress—a phenomenon you’ll explore in the **Scientific Skills Exercise**.

### Flooding

Too much water is also problematic for plants. An overwatered houseplant may suffocate because the soil lacks the air spaces that provide oxygen for cellular respiration in the roots. Some plants are structurally adapted to very wet habitats. For example, the submerged roots of mangroves, which inhabit coastal marshes, are continuous with aerial roots exposed to oxygen (see Figure 28.5). But how do less specialized plants cope with oxygen deprivation in waterlogged soils? Oxygen deprivation stimulates the production of ethylene, which

## Interpreting Experimental Results from a Bar Graph

**Do Drought-Stressed Plants Communicate Their Condition to Their Neighbors?** Researchers wanted to learn if plants can communicate drought-induced stress to neighboring plants and, if so, whether they use aboveground or belowground signals.

### How the Experiment Was Done

Eleven potted pea plants (*Pisum sativum*) were placed equidistantly in a row. The root systems of plants 6–11 were connected to their immediate neighbors by tubes, which allowed chemicals to move from the roots of one plant to the roots of the next plant without moving through the soil. The root systems of plants 1–6 were not connected. Osmotic shock was inflicted on plant 6 using a highly concentrated solution of mannitol, a natural sugar commonly used to mimic drought stress in vascular plants.

Fifteen minutes following the osmotic shock to plant 6, researchers measured the width of stomatal openings in leaves from all the plants. A control experiment was also done in which water was added to plant 6 instead of mannitol.

### Data from the Experiment

► Pea plant (*Pisum sativum*)

### Interpret the Data

1. How do the widths of the stomatal openings of plants 6–8 and plants 9 and 10 compare with those of the other plants in the experiment? What does this indicate about the state of plants 6–8 and 9 and 10? (For information about reading graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
2. Do the data support the idea that plants can communicate their drought-stressed condition to their neighbors? If so, do the data indicate that the communication is via the shoot system or the root system? Make specific reference to the data in answering both questions.
3. Why was it necessary to make sure that chemicals could not move through the soil from one plant to the next?
4. When the experiment was run for 1 hour rather than 15 minutes, the results were about the same except that the stomatal openings of plants 9–11 were comparable to those of plants 6–8. Suggest a reason why.
5. Why was water added to plant 6 instead of mannitol in the control experiment? What do the results of the control experiment indicate?

**Data from** O. Falik et al., Rumor has it...: Relay communication of stress cues in plants, *PLoS ONE* 6(11): e23625 (2011).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

causes some cells in the root cortex to die. The destruction of these cells creates air tubes that function as “snorkels,” providing oxygen to the submerged roots (**Figure 31.22**).

### Salt Stress

An excess of sodium chloride or other salts in the soil threatens plants for two reasons. First, by lowering the water potential of the soil solution, salt can cause a water deficit in plants even though the soil has plenty of water. As the water potential of the soil solution becomes more negative, the water potential gradient from soil to roots is lowered, thereby reducing

water uptake (see Chapter 29). Another problem with saline soil is that sodium and certain other ions are toxic to plants when their concentrations are too high. Many plants can respond to moderate soil salinity by producing solutes that are well tolerated at high concentrations: These mostly organic compounds keep the water potential of cells more negative than that of the soil solution without admitting toxic quantities of salt. However, most plants cannot survive salt stress for long. The exceptions are *halophytes*, salt-tolerant plants with adaptations such as salt glands that pump salts out across the leaf epidermis.

**▲ Figure 31.22 A developmental response of maize roots to flooding and oxygen deprivation.** (a) A cross section of a control root grown in an aerated hydroponic medium. (b) A root grown in a nonaerated hydroponic medium. Ethylene-stimulated apoptosis (programmed cell death) creates the air tubes (SEMs).

### Heat Stress

Excessive heat may harm and even kill a plant by denaturing its enzymes. Transpiration helps cool leaves by evaporative cooling. On a warm day, for example, the temperature of a leaf may be 3–10°C below the ambient air temperature. Hot, dry weather also tends to dehydrate many plants; the closing of stomata in response to this stress conserves water but then sacrifices evaporative cooling. This dilemma is one reason why very hot, dry days take a toll on most plants. Most plants have a backup response that enables them to survive heat stress. Above a certain temperature—about 40°C for most plants in temperate regions—plant cells begin synthesizing **heat-shock proteins**, which help protect other proteins from denaturing.

### Cold Stress

One problem plants face when the temperature of the environment falls is a change in the fluidity of cell membranes. When a membrane cools below a critical point, membranes lose their fluidity as the lipids become locked into crystalline structures. This alters solute transport across the membrane and also adversely affects the functions of membrane proteins. Plants respond to cold stress by altering the lipid composition of their membranes. For example, membrane lipids increase in their proportion of unsaturated fatty acids, which have shapes that help keep membranes more fluid at low temperatures. Such membrane modification requires from several hours to days, which is one reason why unseasonably cold temperatures are generally more stressful to plants than the more gradual seasonal drop in air temperature.

Freezing is another type of cold stress. At subfreezing temperatures, ice forms in the cell walls and intercellular spaces of most plants. The cytosol generally does not freeze at the cooling rates encountered in nature because it contains more solutes than

the very dilute solution found in the cell wall, and solutes lower the freezing point of a solution. The reduction in liquid water in the cell wall caused by ice formation lowers the extracellular water potential, causing water to leave the cytoplasm. The resulting increase in the concentration of ions in the cytoplasm is harmful and can lead to cell death. Whether the cell survives depends largely on how well it resists dehydration. In regions with cold winters, native plants are adapted to cope with freezing stress. For example, before the onset of winter, the cells of many frost-tolerant species increase cytoplasmic levels of specific solutes, such as sugars, that are well tolerated at high concentrations and that help reduce the loss of water from the cell during extracellular freezing. The unsaturation of membrane lipids also increases, thereby maintaining proper levels of membrane fluidity.

**EVOLUTION** Many organisms, including certain vertebrates, fungi, bacteria, and many species of plants, have special proteins that hinder ice crystals from growing, helping the organism escape freezing damage. First described in Arctic fish in the 1950s, these *antifreeze proteins* permit survival at temperatures below 0°C. Antifreeze proteins bind to small ice crystals and inhibit their growth or, in the case of plants, prevent the crystallization of ice. The five major classes of antifreeze proteins differ markedly in their amino acid sequences but have a similar three-dimensional structure, suggesting convergent evolution. Surprisingly, antifreeze proteins from winter rye are homologous to antifungal proteins called PR proteins that you'll learn about later in the chapter, but they are produced in response to cold temperatures and shorter days, not fungal pathogens. Progress is being made in increasing the freezing tolerance of crop plants by genetically engineering antifreeze protein genes into their genomes.

### CONCEPT CHECK 31.3

1. Thermal images are photographs of the heat emitted by an object. Researchers have used thermal imaging of plants to isolate mutants that overproduce abscisic acid. Suggest a reason why these mutants are warmer than wild-type plants under conditions that are normally nonstressful.
2. A greenhouse worker finds that potted chrysanthemums nearest to the aisles are often shorter than those in the middle of the bench. Explain this "edge effect," a common problem in horticulture.
3. **WHAT IF?** If you removed the root cap from a root, would the root still respond to gravity? Explain.

For suggested answers, see Appendix A.

## Plants respond to attacks by herbivores and pathogens

**EVOLUTION** Through natural selection, plants have evolved many types of interactions with other species in their communities. Some interspecific interactions are mutually beneficial, such as the associations of plants with mycorrhizal fungi (see Figure 29.13) or with pollinators (see Figure 30.6). Many plant interactions with other organisms, however, do not benefit the plant. As primary producers, plants are at the base of most food webs and are subject to attack by a wide range of plant-eating (herbivorous) animals. A plant is also subject to infection by diverse pathogens that can damage tissues or even kill the plant. Plants counter these threats with defense systems that deter herbivory and prevent infection or combat pathogens that infect the plant.

### Defenses Against Herbivores

Herbivory—animals eating plants—is a stress that plants face in any ecosystem. Plants prevent excessive herbivory by using both physical defenses, such as thorns and trichomes, and chemical defenses, such as the production of distasteful or toxic compounds.

Some plants even “recruit” predatory animals that help defend the plant against specific herbivores. Consider the insects called parasitoid wasps, which inject their eggs into caterpillars feeding on plants. The eggs hatch within the caterpillars, and the larvae eat through their organic containers from the inside out. The plant, which benefits from the destruction of the herbivorous caterpillars, has an active role in this drama. A leaf damaged by caterpillars releases volatile compounds that attract parasitoid wasps. The stimulus for this response is a combination of physical damage to the leaf caused by the munching caterpillar and a specific compound in the caterpillar’s saliva (**Figure 31.23**).

The volatile molecules a plant releases in response to herbivore damage can also function as an early warning system for nearby plants of the same species. For example, lima bean plants infested with spider mites release a cocktail of volatile chemicals that signal “news” of the attack to neighboring, noninfested lima bean plants. In response to these volatile compounds, the neighbors instigate biochemical changes that make themselves less susceptible, including the release of volatile chemicals that attract another predatory mite species that feeds on spider mites. Researchers have even transgenically engineered *Arabidopsis* plants to produce two volatile chemicals that normally are not made by *Arabidopsis* but which have been found to attract carnivorous predatory mites in other plants. The predatory mites become attracted to the genetically modified *Arabidopsis*, a finding that could have implications for the genetic engineering of insect resistance in crop plants.

© 1997 AAAS

▲ **Figure 31.23** A maize leaf “recruiting” a parasitoid wasp as a defensive response to an armyworm caterpillar, an herbivore.

### Defenses Against Pathogens

A plant’s first line of defense against infection is the physical barrier presented by the epidermis and periderm of the plant body (see Figure 28.19). This first defense system, however, is not impenetrable. The mechanical wounding of leaves by herbivores, for example, opens up portals for invasion by pathogens. Even when plant tissues are intact, viruses, bacteria, and the spores and hyphae of fungi can still enter the plant through natural openings in the epidermis, such as stomata.

When a pathogen invades a plant, the plant mounts a second line of defense, a chemical attack that destroys the pathogen and prevents its spread from the site of infection. This second defense system is enhanced by the plant’s ability to recognize certain pathogens. Successful pathogens cause disease because they evade recognition or suppress the host’s defense mechanisms.

### Host-Pathogen Coevolution

Pathogens against which a plant has little specific defense are **virulent** pathogens. Strains of pathogens that mildly harm but do not kill the host plant are said to be **avirulent** pathogens. Virulent pathogens are the exceptions. If they were not, hosts and pathogens would soon perish together. Complete resistance to a pathogen often comes at an energetic cost to the plant, however, and in the absence of the pathogen, resistant plants are outcompeted by those with less resistance. Of course, plants with no resistance will succumb to a pathogen outbreak. Thus, a “compromise” has evolved between plants and most of their pathogens: The pathogen gains enough access to its host to enable it to perpetuate itself without severely damaging or killing the plant.

**Gene-for-gene recognition** is a form of plant disease resistance in which pathogen-derived molecules called *effectors* are recognized by one of the hundreds of resistance (R) proteins encoded by resistance genes in a plant’s genome. Protein effectors, encoded by the pathogen’s avirulence (*Avr*) genes, can facilitate infection in plants that lack the appropriate R protein

by redirecting the host's metabolism to the pathogen's advantage. In plants that do have the appropriate R protein, however, effector proteins can directly trigger a suite of strong defense responses. The recognition of effectors by R proteins triggers signal transduction pathways that activate an arsenal of defense responses, including a local defense called the hypersensitive response and a general defense called systemic acquired resistance. Local and systemic responses to pathogens require extensive genetic reprogramming and commitment of cellular resources. Therefore, a plant activates these defenses only after detecting an invading pathogen.

### The Hypersensitive Response

The **hypersensitive response** is a defense response that causes cell and tissue death near the infection site, thereby restricting the spread of a pathogen. After the cells at the infection site mount a chemical defense and seal off the area, they destroy themselves. As indicated in **Figure 31.24**, the hypersensitive response is initiated when pathogen effectors bind to R proteins and stimulate the production of phytoalexins, which are compounds having fungicidal and bactericidal properties. The hypersensitive response also induces production of *PR*

*proteins* (pathogenesis-related proteins), many of which are enzymes that hydrolyze components in the cell walls of pathogens. Infection also stimulates the formation of lignin and the cross-linking of molecules within the plant cell wall, responses that hinder the spread of the pathogen to other parts of the plant. We can see the result of a hypersensitive response as lesions on a leaf, as shown at the upper right in the figure. As “sick” as such a leaf appears, it will still survive, and its defensive response will help protect the rest of the plant.

### Systemic Acquired Resistance

The hypersensitive response is localized and specific. However, as noted previously, pathogen invasions can also produce signaling molecules that “sound the alarm” of infection to the whole plant. The resulting **systemic acquired resistance** arises from the plant-wide expression of defense genes. It is nonspecific, providing protection against a diversity of pathogens that lasts for days. The search for a signaling molecule that moves from the infection site to elicit systemic acquired resistance led to the identification of *methylsalicylic acid* as the most likely candidate. Methylsalicylic acid is produced around the infection site and carried by the phloem throughout the

▲ **Figure 31.24** Defense responses against an avirulent pathogen. Plants can often prevent the systemic spread of infection by instigating a hypersensitive response. This response helps isolate the pathogen by producing lesions that form “rings of death” around the sites of infection.

plant, where it is converted to **salicylic acid** in areas remote from the sites of infection. Salicylic acid activates a signal transduction pathway that induces the production of PR proteins and resistance to pathogen attack (see Figure 31.24).

Plant disease epidemics, such as potato late blight, which caused the Irish potato famine of the 1840s, can lead to incalculable human misery (see Concept 25.4). Other diseases, such as chestnut blight (see Concept 26.5) and sudden oak death (see Concept 41.5), can dramatically alter community structures. Plant epidemics are often the result of infected plants or timber being inadvertently transported around the world. As global commerce increases, such epidemics will become increasingly common. To prepare for such outbreaks, plant biologists are stockpiling the seeds of wild relatives of crop plants in special storage facilities. Scientists hope that undomesticated relatives may have genes that will be able to curb the next plant epidemic. These scientists, along with thousands

of other plant biologists, are extending an age-old tradition of curiosity about the green organisms that feed our species and the biosphere.

CONCEPT CHECK 31.4

- 1. What are some drawbacks of spraying fields with general-purpose insecticides?
- 2. Chewing insects mechanically damage plants and lessen the surface area of leaves for photosynthesis. In addition, these insects make plants more vulnerable to pathogen attack. Suggest a reason why.
- 3. **WHAT IF?** Suppose a scientist finds that a population of plants growing in a breezy location is more prone to herbivory by insects than a population of the same species growing in a sheltered area. Suggest a hypothesis to account for this observation.

For suggested answers, see Appendix A.

# 31 Chapter Review

## SUMMARY OF KEY CONCEPTS

CONCEPT 31.1

Plant hormones help coordinate growth, development, and responses to stimuli (pp. 617–626)

- Hormones control plant growth and development by affecting the division, elongation, and differentiation of cells. Some hormones also mediate the responses of plants to environmental stimuli.

Plant Hormone	Major Responses
Auxin	Stimulates cell elongation; regulates branching and organ bending
Cytokinins	Stimulate plant cell division; promote later bud growth; slow organ death
Gibberellins	Promote stem elongation; help seeds break dormancy and use stored reserves
Brassinosteroids	Chemically similar to the sex hormones of animals; induce cell elongation and division
Absciscic acid	Promotes stomatal closure in response to drought; promotes seed dormancy
Ethylene	Mediates fruit ripening

**?** Is there any truth to the old adage “One bad apple spoils the whole bunch”? Explain.

CONCEPT 31.2

Responses to light are critical for plant success (pp. 626–631)

- **Blue-light photoreceptors** control hypocotyl elongation, stomatal opening, and phototropism.

- **Phytochromes** act like molecular “on-off” switches. Red light turns phytochrome “on,” and far-red light turns it “off”:

Phytochrome regulates shade avoidance and the germination of many seed types.

- Many daily rhythms in plant behavior are controlled by an internal circadian clock. Free-running circadian cycles are approximately 24 hours long but are entrained to exactly 24 hours by dawn and dusk effects on phytochrome form.
- Phytochrome conversion also provides information about the relative lengths of day and night (photoperiod) and hence the time of year. Photoperiodism regulates the time of flowering in many species. **Short-day plants** require a night longer than a critical length to flower. **Long-day plants** need a night length shorter than a critical period to flower.

**?** Why did plant physiologists propose the existence of a mobile molecule (florigen) that triggers flowering?

CONCEPT 31.3

Plants respond to a wide variety of stimuli other than light (pp. 631–635)

- **Gravitropism** is the bending of an organ in response to gravity. Roots show positive gravitropism, and stems show negative gravitropism. **Statoliths**, starch-filled plastids, enable plant roots to detect gravity.
- Plants are highly sensitive to touch. **Thigmotropism** is a growth response to touch. Rapid leaf movements involve transmission of electrical impulses called action potentials.

- Plants are sensitive to environmental stresses, including drought, flooding, high salinity, and extremes of temperature.

Environmental Stress	Major Response
Drought	ABA production, reducing water loss by closing stomata
Flooding	Formation of air tubes that help roots survive oxygen deprivation
Salt	Avoiding osmotic water loss by producing solutes tolerated at high concentrations
Heat	Synthesis of heat-shock proteins, which reduce protein denaturation at high temperatures
Cold	Adjusting membrane fluidity; avoiding osmotic water loss; producing antifreeze proteins

**?** *Plants that have acclimated to drought stress are often more resistant to freezing stress as well. Suggest a reason why.*

## CONCEPT 31.4

### Plants respond to attacks by herbivores and pathogens (pp. 636–638)

- In addition to physical defenses such as thorns and trichomes, plants produce distasteful or toxic chemicals, as well as attractants that recruit animals that destroy herbivores.
- The **hypersensitive response** seals off an infection and destroys both pathogen and host cells in the region. **Systemic acquired resistance** is a generalized defense response in organs distant from the infection site.

**?** *How do chewing insects make plants more susceptible to pathogens?*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- The hormone that helps plants respond to drought is
  - auxin.
  - gibberellin.
  - cytokinin.
  - ethylene.
  - abscisic acid.
- Auxin enhances cell elongation in all of these ways *except*
  - increased uptake of solutes.
  - gene activation.
  - acid-induced denaturation of cell wall proteins.
  - increased activity of plasma membrane proton pumps.
  - cell wall loosening.
- Charles and Francis Darwin discovered that
  - auxin is responsible for phototropic curvature.
  - auxin can pass through agar.
  - light destroys auxin.
  - light is perceived by the tips of coleoptiles.
  - red light is most effective in shoot phototropism.

### Level 2: Application/Analysis

- The signaling molecule for flowering might be released earlier than usual in a long-day plant exposed to flashes of
  - far-red light during the night.
  - red light during the night.
  - red light followed by far-red light during the night.
  - far-red light during the day.
  - red light during the day.

- If a long-day plant has a critical night length of 9 hours, which 24-hour cycle would prevent flowering?
  - 16 hours light/8 hours dark
  - 14 hours light/10 hours dark
  - 15.5 hours light/8.5 hours dark
  - 4 hours light/8 hours dark/4 hours light/8 hours dark
  - 8 hours light/8 hours dark/light flash/8 hours dark

### Level 3: Synthesis/Evaluation

#### 8. SCIENTIFIC INQUIRY

A field biologist notes that a caterpillar quits feeding on a certain plant after a while, rejects nearby uneaten plants, and begins feeding anew on plants some distance away from the original. The biologist hypothesizes that insect-damaged leaves emit volatile “alarm” chemicals that signal nearby plants to initiate plant defense responses. Suggest a test of this hypothesis.

#### 9. FOCUS ON EVOLUTION

As a general rule, light-sensitive germination is more pronounced in small seeds compared with large seeds. Suggest a reason why.

#### 10. FOCUS ON INTERACTIONS

In a short essay (100–150 words), summarize phytochrome’s role in altering shoot growth for the enhancement of light capture.

For selected answers, see Appendix A.

# Unit 6 Animal Form and Function

## 32 Homeostasis and Endocrine Signaling

The activities of the cells, tissues, and organs that make up the animal body are controlled and coordinated by hormones, which are signals from the **endocrine** system, and by the nervous system. One major result is **homeostasis**, the maintenance of a balanced internal environment.

## 33 Animal Nutrition

Animals meet their **nutritional** needs by the stepwise digestion of ingested food and the efficient absorption of released nutrients.

## 34 Circulation and Gas Exchange

Cells and tissues throughout a multilayered animal body rely on **circulation** and **gas exchange** systems to carry out an interchange of oxygen, nutrients, and wastes with the external environment.

## 35 The Immune System

An **immune system** provides barriers to infection and distinguishes self from non-self in initiating defense against foreign cells and viruses.

## 36 Reproduction and Development

Sexual **reproduction** involves the fertilization of egg by sperm. In animals, a process of embryonic **development** involves cell division, specialization, and movement.

## 37 Neurons, Synapses, and Signaling

**Neurons** receive, retrieve, and transmit information by **signaling** along cellular extensions and across specialized cell junctions called **synapses**.

## 38 Nervous and Sensory Systems

**Sensory** receptors tuned to chemicals, light, vibrations, and other stimuli transfer information to the **nervous system** for processing and integration.

## 39 Motor Mechanisms and Behavior

Animals respond to their environment through **motor mechanisms**, including muscle contractions, that bring about **behavior**.

# Homeostasis and Endocrine Signaling

▼ **Figure 32.1** How do long legs help this scavenger survive in the scorching desert heat?

## KEY CONCEPTS

- 32.1** Feedback control maintains the internal environment in many animals
- 32.2** Endocrine signals trigger homeostatic mechanisms in target tissues
- 32.3** A shared system mediates osmoregulation and excretion in many animals
- 32.4** Hormonal circuits link kidney function, water balance, and blood pressure

## OVERVIEW

### Diverse Forms, Common Challenges

**T**he desert ant (*Cataglyphis*) in **Figure 32.1** is a scavenger, devouring insects that have succumbed to the daytime heat of the Sahara Desert. To gather corpses for feeding, the ant forages when surface temperatures on the sun-baked sand exceed 60°C (140°F), well above the thermal limit for virtually all animals. How, then, does the desert ant survive in these conditions? To answer this question, we need to look more closely at the ant's **anatomy**, or biological form.

Over the course of its life, an ant faces the same fundamental challenges as any other animal, whether hydra, hawk, or human. All animals must obtain nutrients and oxygen, fight off infection, and produce offspring. Given that they share these and other basic requirements, why do species vary so enormously in makeup, complexity, organization, and appearance? The answer is adaptation: Natural selection favors those variations in a population that increase relative fitness (see Chapter 21). The evolutionary adaptations that enable survival vary among environments and species, but they frequently result in a close match of form to function.

Because form and function are correlated, examining anatomy often provides clues to **physiology**—biological function. In the case of the desert ant, researchers noted that its stilt-like legs are disproportionately long, elevating the rest of the ant 4 mm above the sand. At this height, the ant's body is exposed to a temperature 6°C lower than that at ground level. The ant's long legs also facilitate rapid locomotion: Researchers have found that desert ants can run as fast as 1 m/sec, close to the top speed recorded for any running arthropod. Speedy sprinting minimizes the time that the ant is exposed to the sun. Thus, long legs are adaptations that allow the desert ant to be active during the heat of the day, when competition for food and the risk of predation are lowest.

In this chapter, we will begin our study of animal form and function by examining the organization of cells and tissues in the animal body, the systems for coordinating the activities of different body parts, and the general means by which animals control their internal environment. In the second half of the chapter, we'll apply these general ideas to two challenges of particular relevance for desert animals: regulating body temperature and maintaining proper balance of body salts and water.

# Feedback control maintains the internal environment in many animals

For animals, as for other multicellular organisms, having many cells facilitates specialization. For example, a hard outer covering can protect against predators, and large muscles can enable rapid escape. In a multicellular body, the immediate environment of most cells is the internal body fluid. Control systems that regulate the composition of this solution allow the animal to maintain a relatively stable internal environment, even if the external environment is variable. To understand how these control systems operate, we first need to explore the layers of organization that characterize animal bodies.

## Hierarchical Organization of Animal Bodies

Cells form a working animal body through their emergent properties, which arise from successive levels of structural and functional organization. Cells are organized into **tissues**, groups of cells with a similar appearance and a common function. Different types of tissues are further organized into functional units called **organs**. (The simplest animals, such as sponges, lack organs or even true tissues.) Groups of organs that work together provide an additional level of organization and coordination and make up an **organ system** (**Table 32.1**). Thus, for example, the skin is an organ of the *integumentary system*, which protects against infection and helps regulate body temperature.

Many organs contain tissues with distinct physiological roles. In some cases, the roles are different enough that we consider the organ to belong to more than one organ system. The pancreas, for instance, produces enzymes critical to the function of the digestive system and also regulates the level of sugar in the blood as a vital part of the endocrine system.

Just as viewing the body’s organization from the “bottom up” (from cells to organ systems) reveals emergent properties, a “top-down” view of the hierarchy reveals the multilayered basis of specialization. Consider the human digestive system: the mouth, pharynx, esophagus, stomach, small and large intestines, accessory organs, and anus. Each organ has specific roles in digestion. One function of the stomach, for example, is to initiate the breakdown of proteins. This process requires a churning motion powered by stomach muscles, as well as digestive juices secreted by the stomach lining. Producing digestive juices, in turn, requires highly specialized cell types: One cell type secretes a protein-digesting enzyme, a second generates concentrated hydrochloric acid, and a third produces mucus, which protects the stomach lining.

The specialized and complex organ systems of animals are built from a limited set of cell and tissue types. For example, lungs and blood vessels have different functions but are lined by tissues that are of the same basic type and that therefore share many properties. Animal tissues are commonly grouped into four main types: epithelial, connective, muscle, and nervous (**Figure 32.2**). In later chapters, we’ll provide examples of how these tissue types contribute to the specific functions of the organ systems that are summarized in Table 32.1.

Table 32.1 Organ Systems in Mammals		
Organ System	Main Components	Main Functions
Digestive	Mouth, pharynx, esophagus, stomach, intestines, liver, pancreas, anus	Food processing (ingestion, digestion, absorption, elimination)
Circulatory	Heart, blood vessels, blood	Internal distribution of materials
Respiratory	Lungs, trachea, other breathing tubes	Gas exchange (uptake of oxygen; disposal of carbon dioxide)
Immune and lymphatic	Bone marrow, lymph nodes, thymus, spleen, lymph vessels, white blood cells	Body defense (fighting infections and cancer)
Excretory	Kidneys, ureters, urinary bladder, urethra	Disposal of metabolic wastes; regulation of osmotic balance of blood
Endocrine	Pituitary, thyroid, pancreas, adrenal, and other hormone-secreting glands	Coordination of body activities (such as digestion and metabolism)
Reproductive	Ovaries or testes and associated organs	Reproduction
Nervous	Brain, spinal cord, nerves, sensory organs	Coordination of body activities; detection of stimuli and formulation of responses to them
Integumentary	Skin and its derivatives (such as hair, claws, skin glands)	Protection against mechanical injury, infection, dehydration; thermoregulation
Skeletal	Skeleton (bones, tendons, ligaments, cartilage)	Body support, protection of internal organs, movement
Muscular	Skeletal muscles	Locomotion and other movement

## Epithelial Tissue

Occurring as sheets of closely packed cells, **epithelial tissue** covers the outside of the body and lines organs and cavities. Epithelial tissue functions as a barrier against mechanical injury, pathogens, and fluid loss. It also forms active interfaces with the environment. For example, the **epithelium** (plural, *epithelia*) that lines the intestines secretes digestive juices and absorbs nutrients.

All epithelia are polarized, meaning that they have two different sides. The *apical* surface faces the lumen (cavity) or outside of the organ and is therefore exposed to fluid or air. The *basal* surface is attached to a *basal lamina*, a dense mat of extracellular matrix that separates the epithelium from the underlying tissue.

## Muscle Tissue

Vertebrates have three types of **muscle tissue**: skeletal, smooth, and cardiac. All muscle cells consist of filaments containing the proteins actin and myosin, which together enable muscles to contract. Attached to bones by tendons, **skeletal muscle**, or striated muscle, is responsible for voluntary movements. The arrangement of contractile units along the cells gives them a striped (striated) appearance. **Smooth muscle**, which lacks striations and has spindle-shaped cells, is found in the walls of many internal organs. Smooth muscles are responsible for involuntary activities, such as churning of the stomach and constriction of arteries. **Cardiac muscle**, which is striated like skeletal muscle, forms the contractile wall of the heart.

## Nervous Tissue

**Nervous tissue** functions in the receipt, processing, and transmission of information. **Neurons** are the basic units of the nervous system. A neuron receives nerve impulses from other neurons via its cell body and multiple extensions called dendrites. Neurons transmit impulses to neurons, muscles, or other cells via extensions called axons, which are often bundled together into nerves. Nervous tissue also contains support cells called **glial cells**, or simply **glia**. The various types of glia help nourish, insulate, and replenish neurons and in some cases modulate neuron function. In many animals, a concentration of nervous tissue forms a brain, an information-processing center.

### Nervous tissue in brain

### Blood

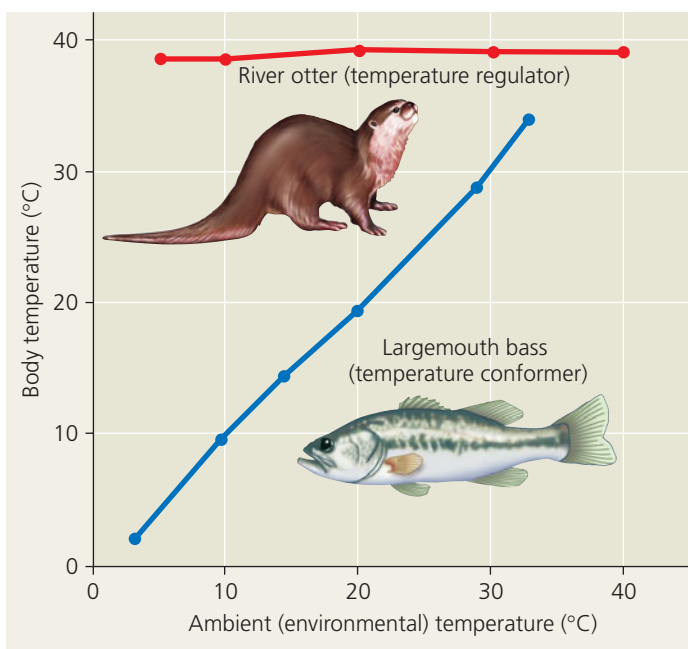

### Loose connective tissue surrounding stomach

## Connective Tissue

**Connective tissue** consists of cells scattered through an extracellular matrix, often consisting of a web of fibers embedded in a liquid, jellylike, or solid foundation. Within the matrix are numerous cells called *fibroblasts*, which secrete fiber proteins, and *macrophages*, which engulf foreign particles and cell debris.

In vertebrates, the many forms of connective tissue include loose connective tissue, which holds skin and other organs in place; fibrous connective tissue, found in tendons and ligaments; adipose tissue, which stores fat; blood, which consists of cells and cell fragments suspended in a liquid called plasma; cartilage, which provides flexible support in the spine and elsewhere; and bone, a hard mineral of calcium, magnesium, and phosphate ions in a matrix of collagen.

▲ **Figure 32.3 Regulating and conforming.** The river otter regulates its body temperature, keeping it stable across a wide range of environmental temperatures. The largemouth bass allows its internal environment to conform to the water temperature.

## Regulating and Conforming

Many organ systems play a role in managing an animal's internal environment, a task that can present a major challenge—Imagine if your body temperature soared every time you took a hot shower or drank a freshly brewed cup of coffee. Faced with environmental fluctuations, animals manage their internal environment by either regulating or conforming (**Figure 32.3**).

An animal is a **regulator** for an environmental variable if it uses internal mechanisms to control internal change in the face of external fluctuation. The otter in Figure 32.3 is a regulator for temperature, keeping its body at a temperature that is largely independent of that of the water in which it swims. In contrast, an animal is a **conformer** for a particular variable if it allows its internal condition to change in accordance with external changes. The bass in Figure 32.3 conforms to the temperature of the lake it inhabits. As the water warms or cools, so does the bass's body.

Note that an animal may regulate some internal conditions while allowing others to conform to the environment. For example, even though the bass conforms to the temperature of the surrounding water, it regulates the solute concentration in its blood and **interstitial fluid**, the fluid that surrounds body cells.

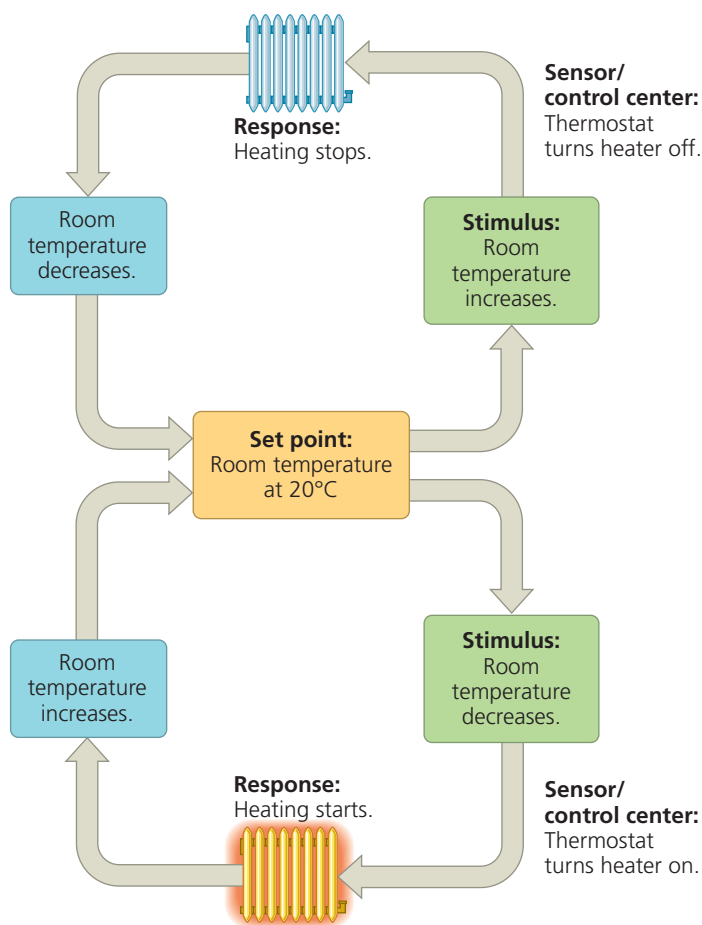

## Homeostasis

The steady body temperature of a river otter and the stable concentration of solutes in a freshwater bass are examples of **homeostasis**, which means “steady state,” referring to the

maintenance of internal balance. In achieving homeostasis, animals maintain a relatively constant internal environment even when the external environment changes significantly.

Many animals exhibit homeostasis for a range of physical and chemical properties. For example, humans maintain a fairly constant body temperature of about 37°C (98.6°F), a blood pH within 0.1 pH unit of 7.4, and a blood glucose concentration that is predominantly in the range of 70–110 mg per 100 mL of blood.

Before exploring homeostasis in animals, let's first consider a nonliving example: the regulation of room temperature (**Figure 32.4**). Let's assume you want to keep a room at 20°C (68°F), a comfortable temperature for normal activity. You adjust a control device—the thermostat—to 20°C and allow a thermometer in the thermostat to monitor temperature. If the room temperature falls below 20°C, the thermostat responds by turning on a radiator, furnace, or other heater. Heat is produced until the room reaches 20°C, at which point the

▲ **Figure 32.4 A nonliving example of temperature regulation: control of room temperature.** Regulating room temperature depends on a control center (a thermostat) that detects temperature change and activates mechanisms that reverse that change.

**WHAT IF?** How would adding an air conditioner to the system contribute to homeostasis?

thermostat switches off the heater. Whenever the temperature in the room again drifts below 20°C, the thermostat activates another heating cycle.

Like a home heating system, an animal achieves homeostasis by maintaining a variable, such as body temperature or solute concentration, at or near a particular value, or **set point**. Fluctuations in the variable above or below the set point serve as the **stimulus** detected by a receptor, or **sensor**. Upon receiving a signal from the sensor, a *control center* generates output that triggers a **response**, a physiological activity that helps return the variable to the set point.

Just as in the regulatory circuit shown in Figure 32.4, homeostasis in animals relies largely on **negative feedback**, a control mechanism that reduces, or “damps,” the stimulus. For example, when you exercise vigorously, you produce heat, which increases your body temperature. Your nervous system detects this increase and triggers sweating. As you sweat, the evaporation of moisture from your skin cools your body, helping return your body temperature to its set point.

Homeostasis moderates but doesn’t eliminate changes in the internal environment. Additional fluctuation occurs if a variable has a *normal range*—an upper and lower limit—rather than a set point. This is equivalent to a heating system that begins producing heat when the temperature drops to 19°C (66°F) and stops heating when the temperature reaches 21°C (70°F).

Although the set points and normal ranges for homeostasis are usually stable, certain regulated changes in the internal environment are essential. Some of these changes are associated with a particular stage in life, such as the radical shift in hormone balance during puberty. Others are cyclic, such as the monthly variation in hormone levels responsible for a woman’s menstrual cycle (see Figure 36.13).

## Thermoregulation: A Closer Look

As a physiological example of homeostasis, we’ll examine **thermoregulation**, the process by which animals maintain an internal temperature within a normal range. Body temperatures below or above an animal’s normal range can reduce the efficiency of enzymatic reactions, alter the fluidity of cellular membranes, and affect other temperature-sensitive biochemical processes, potentially with fatal results.

### Endothermy and Ectothermy

Heat for thermoregulation can come from either internal metabolism or the external environment. Humans and other mammals, as well as birds, are **endothermic**, meaning that they are warmed mostly by heat generated by metabolism. In contrast, amphibians, many fishes and nonavian reptiles, and most invertebrates are **ectothermic**, meaning that they gain most of their heat from external sources.

Endotherms can maintain a stable body temperature even in the face of large fluctuations in the environmental

(a) A walrus, an endotherm

(b) A lizard, an ectotherm

### ▲ Figure 32.5 Endothermy and ectothermy.

temperature. In a cold environment, an endotherm generates enough heat to keep its body substantially warmer than its surroundings (**Figure 32.5a**). In a hot environment, endothermic vertebrates have mechanisms for cooling their bodies, enabling them to withstand heat loads that are intolerable for most ectotherms.

Although ectotherms do not generate enough heat for thermoregulation, many adjust body temperature by behavioral means, such as seeking out shade or basking in the sun (**Figure 32.5b**). Because their heat source is largely environmental, ectotherms generally need to consume much less food than endotherms of equivalent size—an advantage if food supplies are limited. Overall, ectothermy is an effective and successful strategy in most environments, as shown by the abundance and diversity of ectothermic animals.

Note, however, that endothermy and ectothermy are not mutually exclusive. For example, a bird is mainly endothermic, but it may warm itself in the sun on a cold morning, much as an ectothermic lizard does.

### Balancing Heat Loss and Gain

Thermoregulation depends on an animal’s ability to control the exchange of heat with its environment. An organism, like any object, exchanges heat by four physical processes. These

**Radiation** is the emission of electromagnetic waves by all objects warmer than absolute zero. Here, a lizard absorbs heat radiating from the distant sun and radiates a smaller amount of energy to the surrounding air.

**Evaporation** is the removal of heat from the surface of a liquid that is losing some of its molecules as gas. Evaporation of water from a lizard's moist surfaces that are exposed to the environment has a strong cooling effect.

**Convection** is the transfer of heat by the movement of air or liquid past a surface, as when a breeze contributes to heat loss from a lizard's dry skin or when blood moves heat from the body core to the extremities.

**Conduction** is the direct transfer of thermal motion (heat) between molecules of objects in contact with each other, as when a lizard sits on a hot rock.

▲ **Figure 32.6** Heat exchange between an organism and its environment.

processes—radiation, evaporation, convection, and conduction—account for the flow of heat both within an organism and between an organism and its external environment (**Figure 32.6**). Note that heat is always transferred from an object of higher temperature to one of lower temperature.

Numerous adaptations that enhance thermoregulation have evolved in animals. Mammals and birds, for instance, have insulation that reduces the flow of heat between an animal's body and its environment. Such insulation may include hair or feathers as well as layers of fat formed by adipose tissue, such as a whale's thick blubber. In response to cold, most land mammals and birds raise their fur or feathers. This action traps a thicker layer of air, thereby increasing the insulating power of the fur or feathers. Humans, lacking a fur or feather layer, must rely primarily on fat for insulation. However, we still get “goose bumps,” a vestige of hair raising inherited from our furry ancestors.

Canada goose

**Key**  
 Warm blood  
 Cool blood  
 Blood flow  
 Heat transfer

- 1 Arteries carrying warm blood to the animal's extremities are in close contact with veins conveying cool blood in the opposite direction, back toward the trunk of the body. This arrangement facilitates heat transfer from arteries to veins along the entire length of the blood vessels.
- 2 Near the end of the leg, where arterial blood has been cooled to far below the animal's core temperature, the artery can still transfer heat to the even colder blood in an adjacent vein. The blood in the veins continues to absorb heat as it passes warmer and warmer blood traveling in the opposite direction in the arteries.
- 3 As the blood in the veins approaches the center of the body, it is almost as warm as the body core, minimizing the heat loss that results from supplying blood to body parts immersed in cold water.

▲ **Figure 32.7** A countercurrent heat exchanger.

## Circulatory Adaptations for Thermoregulation

Circulatory systems provide a major route for heat flow between the interior and exterior of the body. Adaptations that regulate the extent of blood flow near the body surface or that trap heat within the body core play a significant role in thermoregulation.

In response to changes in the temperature of their surroundings, many animals alter the amount of blood (and hence heat) flowing between their body core and their skin. Nerve signals that relax the muscles of the vessel walls result in *vasodilation*, a widening of superficial blood vessels (those near the body surface). As a consequence of the increase in vessel diameter, blood flow in the skin increases. In endotherms, vasodilation usually warms the skin and increases the transfer of body heat to the environment by radiation, conduction, and convection (see **Figure 32.6**). The reverse process, *vasoconstriction*, reduces blood flow and heat transfer by decreasing the diameter of superficial vessels.

In many birds and mammals, reducing heat loss from the body relies on **countercurrent exchange**, the transfer of heat (or solutes) between fluids that are flowing in opposite directions. In a countercurrent heat exchanger, arteries and veins are located adjacent to each other (**Figure 32.7**). As warm blood moves from the body core in the arteries, it transfers heat to the colder blood returning from the extremities in the veins. Because blood flows through the arteries and veins in opposite directions, heat is transferred along the entire length of the exchanger, maximizing the rate of heat exchange.

## Acclimatization in Thermoregulation

Acclimatization—a physiological adjustment to environmental changes—contributes to thermoregulation in many animal species. In birds and mammals, acclimatization to seasonal temperature changes often includes adjusting insulation—growing a thicker coat of fur in the winter and shedding it in the summer, for example. These changes help endotherms keep a constant body temperature year-round.

Acclimatization in ectotherms often includes adjustments at the cellular level. Cells may produce variants of enzymes that have the same function but different optimal temperatures. Also, the proportions of saturated and unsaturated lipids in membranes may change; unsaturated lipids help keep membranes fluid at lower temperatures (see Figure 5.5). Some ectotherms that experience subzero body temperatures produce antifreeze proteins that prevent ice formation in their cells. In the Arctic and Southern (Antarctic) Oceans, these compounds enable certain fishes to survive in water as cold as  $-2^{\circ}\text{C}$  ( $28^{\circ}\text{F}$ ), below the freezing point of unprotected body fluids (about  $-1^{\circ}\text{C}$ , or  $30^{\circ}\text{F}$ ).

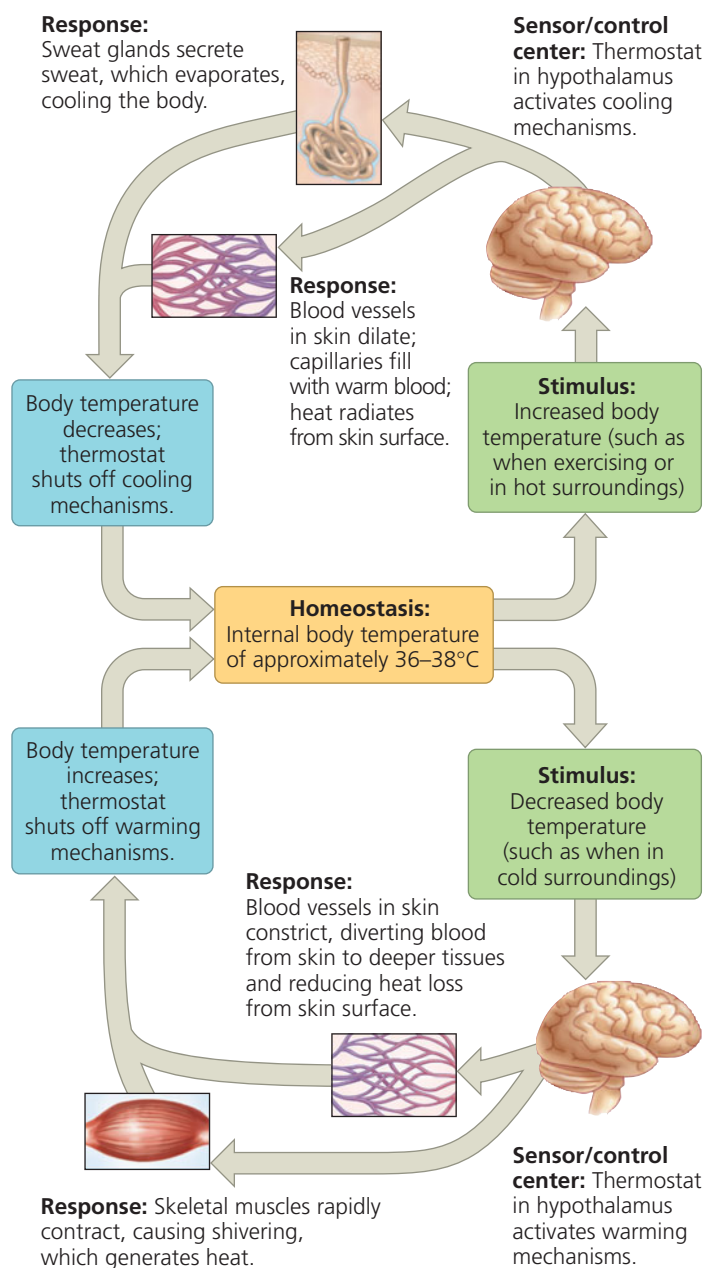

## Physiological Thermostats and Fever

The regulation of body temperature in humans and other mammals is based on feedback mechanisms. The sensors for thermoregulation are concentrated in a brain region called the **hypothalamus**. Within the hypothalamus, a group of nerve cells functions as a thermostat, responding to body temperatures outside a normal range by activating mechanisms that promote heat loss or gain (**Figure 32.8**).

Warm receptors signal the hypothalamic thermostat when body temperature increases, and cold receptors signal when it decreases. At body temperatures below the normal range, the thermostat inhibits heat loss mechanisms while activating mechanisms that either save heat, including vasoconstriction of vessels in the skin, or generate heat, such as shivering. In response to elevated body temperature, the thermostat shuts down heat retention mechanisms and promotes cooling of the body by vasodilation of vessels in the skin, sweating, or panting.

In the course of certain bacterial and viral infections, mammals and birds develop *fever*, an elevated body temperature. Many experiments have shown that fever reflects an increase in the biological thermostat's set point. For example, artificially raising the temperature of the hypothalamus in an infected animal reduces fever in the rest of the body.

Although only endotherms develop fever, lizards exhibit a related response. When infected with certain bacteria, the desert iguana (*Dipsosaurus dorsalis*) seeks a warmer environment and then maintains a body temperature that is elevated by  $2\text{--}4^{\circ}\text{C}$  ( $4\text{--}7^{\circ}\text{F}$ ). Similar observations in fishes, amphibians, and even cockroaches indicate that raising body temperature in this way in response to infection is a common feature of many animal species.

▲ **Figure 32.8** The thermostatic function of the hypothalamus in human thermoregulation.

### CONCEPT CHECK 32.1

1. Is it accurate to define homeostasis as a constant internal environment? Explain.
2. **MAKE CONNECTIONS** How does negative feedback in thermoregulation differ from feedback inhibition in an enzyme-catalyzed biosynthetic process (see Figure 6.19)?
3. **WHAT IF?** Suppose at the end of a hard run on a hot day you find that there are no drinks left in the cooler. If, out of desperation, you dunk your head into the cooler, how might the ice-cold water affect the rate at which your body temperature returns to normal?

For suggested answers, see Appendix A.

## Endocrine signals trigger homeostatic mechanisms in target tissues

To maintain homeostasis and carry out other activities of the animal body, including behavior, the tissues, organs, and organ systems must act in concert with one another. What signals are used to coordinate activity? How do the signals move within the body? There are two sets of answers to these questions, reflecting the two major systems for coordinating and controlling an animal's responses to stimuli: the endocrine and nervous systems (**Figure 32.9**).

▼ **Figure 32.9** Signaling in the endocrine and nervous systems.

## Coordination and Control Functions of the Endocrine and Nervous Systems

In the **endocrine system**, signaling molecules released into the bloodstream by endocrine cells are carried to all locations in the body. In the **nervous system**, neurons transmit signals along dedicated routes connecting specific locations in the body. In each system, the type of pathway used is the same whether the signal's ultimate target is at the other end of the body or just a few cells away.

The signaling molecules broadcast throughout the body by the endocrine system are called **hormones** (from the Greek *horman*, to excite). Different hormones cause distinct effects, and only cells that have receptors for a particular hormone respond (see Figure 32.9a). Depending on which cells have receptors for that hormone, the hormone may have an effect in just a single location or in sites throughout the body. It takes many seconds for hormones to be released into the bloodstream and carried throughout the body. The effects are often long-lasting, however, because hormones can remain in the bloodstream for minutes or even hours.

In the nervous system, signals called nerve impulses travel to specific target cells along communication lines consisting mainly of axons (see Figure 32.9b). Four types of cells can receive nerve impulses: other neurons, muscle cells, endocrine cells, and exocrine cells. Unlike the endocrine system, the nervous system conveys information by the *pathway* the signal takes. For example, a person can distinguish different musical notes because each note's frequency activates different neurons connecting the ear to the brain.

Communication in the nervous system usually involves more than one type of signal. Nerve impulses travel along axons, sometimes over long distances, as changes in voltage. In contrast, passing information from one neuron to another often involves very short-range chemical signals. Overall, transmission in the nervous system is extremely fast; nerve impulses take only a fraction of a second to reach the target and last only a fraction of a second.

Because the two major communication systems of the body differ in signal type, transmission, speed, and duration, they are adapted to different functions. The endocrine system is especially well adapted for coordinating gradual changes that affect the entire body, such as growth, development, reproduction, metabolic processes, and digestion. The nervous system is well suited for directing immediate and rapid responses to the environment, especially in controlling fast locomotion and behavior.

Although the functions of the endocrine and nervous systems are distinct, the two systems often work in close coordination. Both contribute to homeostasis. In the remainder of this chapter, we'll explore endocrine regulation in the context of homeostasis. Later chapters will discuss the role of both the endocrine and nervous systems in processes such as digestion and reproduction. At the end of the

unit, in Chapters 37–39, we’ll return to the nervous system for a more in-depth investigation of its organization and functions.

### Simple Endocrine Pathways

In exploring how endocrine signaling contributes to homeostasis, we’ll begin with a simple endocrine pathway. In such pathways, endocrine cells respond directly to an internal or environmental stimulus by secreting a particular hormone. The hormone travels in the bloodstream to target cells, where it interacts with its specific receptors. Signal transduction within target cells brings about a response.

For an example, we’ll consider the control of pH in the *duodenum*, the first part of the small intestine. During digestion, partially digested food passes to the duodenum from the stomach. The digestive juices of the stomach are extremely acidic and must be neutralized before further steps of digestion can occur. Coordination of this process relies on the endocrine pathway outlined in **Figure 32.10**.

As the contents of the stomach enter the duodenum, the low pH acts as a stimulus for certain endocrine cells, called S cells, in the lining of the duodenum. The stimulated S cells secrete the hormone secretin into the bloodstream. Circulating secretin reaches target cells in the **pancreas**, a gland located behind the stomach. Target cells in the pancreas respond by releasing bicarbonate into ducts leading to the duodenum. This response—the release of bicarbonate—raises the pH in the duodenum, neutralizing the stomach acid.

▲ **Figure 32.10** A simple endocrine pathway.

### Neuroendocrine Pathways

Hormone pathways that respond to stimuli from the external environment typically rely on a sensor in the nervous system. In vertebrates, the hypothalamus plays a central role in integrating the endocrine and nervous systems. The hypothalamus receives information from nerves throughout the body, including the brain. Signals from the hypothalamus travel to a gland located at its base, the **pituitary gland**, which has discrete anterior and posterior parts (**Figure 32.11**, on the next page).

Hormonal signals from the hypothalamus trigger the synthesis and release of hormones from the **anterior pituitary**. These hormones in turn often regulate other endocrine glands. **Figure 32.11** highlights this regulation as part of an exploration of the human endocrine system. You may want to refer back to this figure in later chapters when we return to the topic of endocrine signaling and homeostasis.

The **posterior pituitary** is an extension of the hypothalamus (see **Figure 32.11**). It stores and releases two hormones synthesized by neurosecretory cells of the hypothalamus. One is **oxytocin**, a hormone that regulates milk release during nursing in mammals as part of the *neuroendocrine pathway* shown in **Figure 32.12**. Suckling by an infant stimulates sensory neurons in the nipples, generating nerve impulses that reach the hypothalamus. Nerve impulses from the

▲ **Figure 32.12** A neuroendocrine pathway.

## Major Endocrine Glands and Their Hormones

The endocrine system produces hormones that regulate growth, development, metabolism, homeostasis, and reproduction. Many hormones are secreted by ductless organs called endocrine glands, illustrated below. Others are secreted by isolated endocrine cells in other organs: the thymus, heart, liver, stomach, small intestine, and kidneys. Regardless of where hormones are produced, they reach their target cells via the circulatory system.

**Pineal gland**  
**Melatonin:** Participates in regulation of biological rhythms

**Thyroid gland**  
**Thyroid hormone ( $T_3$  and  $T_4$ ):** Stimulates and maintains metabolic processes  
**Calcitonin:** Lowers blood calcium level

**Parathyroid glands**  
**Parathyroid hormone (PTH):** Raises blood calcium level

**Ovaries (in females)**  
**Estrogens\*:** Stimulate uterine lining growth; promote development and maintenance of female secondary sex characteristics  
**Progesterone\*:** Promotes uterine lining growth

**Testes (in males)**  
**Androgens\*:** Support sperm formation; promote development and maintenance of male secondary sex characteristics

**Hypothalamus**  
Hormones released from posterior pituitary (see below)  
**Releasing and inhibiting hormones:** Regulate anterior pituitary

**Pituitary gland**  
**Anterior pituitary**  
See bottom of page.

**Posterior pituitary**  
**Oxytocin:** Stimulates contraction of uterus and mammary gland cells  
**Vasopressin (also called antidiuretic hormone, ADH):** Promotes retention of water by kidneys; influences social behavior and bonding

**Adrenal glands (atop kidneys)**  
**Adrenal medulla**  
**Epinephrine and norepinephrine:** Raise blood glucose level; increase metabolic activities; constrict certain blood vessels

**Adrenal cortex**  
**Glucocorticoids:** Raise blood glucose level  
**Mineralocorticoids:** Promote reabsorption of  $Na^+$  and excretion of  $K^+$  in kidneys

**Pancreas**  
**Insulin:** Lowers blood glucose level  
**Glucagon:** Raises blood glucose level

\*Found in both males and females, but with a major role in one sex

## Roles of the Hypothalamus and Anterior Pituitary

Hormones produced by the hypothalamus regulate the anterior pituitary. The hypothalamic hormones are secreted near capillaries at the base of the hypothalamus. These capillaries drain into short blood vessels, called portal vessels, which connect directly to a second capillary bed in the anterior pituitary. Hypothalamic hormones thus travel from the hypothalamus to the gland they regulate without first circulating through other body tissues. Upon reaching the anterior pituitary, each hypothalamic hormone either stimulates or inhibits the release of one or more specific hormones.

## Hormone Cascade Pathways

Sets of hormones from the hypothalamus, the anterior pituitary, and a target endocrine gland are often organized into a hormone cascade pathway. Signals to the brain stimulate the hypothalamus to secrete a hormone that regulates the release of an anterior pituitary hormone. The anterior pituitary hormone in turn acts on another endocrine organ, stimulating secretion of yet another hormone, which exerts effects on specific target tissues. Because such pathways in a sense redirect signals from the hypothalamus to other endocrine glands, the anterior pituitary hormones in these pathways are called *tropic hormones* or *tropins*, from the Greek word for bending or turning.

One example of a hormone cascade pathway is the regulation of thyroid hormone levels, shown here.

**Thyroid scan.** Thyroid hormone contains iodine, which is readily obtained from seafood or iodized salt. Because iodine in the body is dedicated to the production of thyroid hormone, physicians can use a radioactive isotope of iodine to detect abnormal patterns of iodine uptake, which may indicate a thyroid disorder. The scan above reveals dramatically different activity in the two lobes of a thyroid gland in a patient with thyroid disease.

hypothalamus then trigger the release of oxytocin, which stimulates the mammary glands to secrete milk. We will discuss **antidiuretic hormone (ADH)**, the other posterior pituitary hormone, later in this chapter.

## Feedback Regulation in Endocrine Pathways

A feedback loop linking the response back to the initial stimulus is characteristic of endocrine pathways. For many hormones, the response pathway involves negative feedback, the same type of control mechanism we saw in Figure 32.4 for a home heating system. In the case of secretin signaling (see Figure 32.10), the release of bicarbonate by the pancreas increases pH in the intestine, eliminating the stimulus and thereby shutting off the pathway. By decreasing or abolishing hormone signaling, negative-feedback regulation prevents excessive pathway activity (see also Figure 32.11).

Whereas negative feedback dampens a stimulus, **positive feedback** reinforces a stimulus, leading to an even greater response. In animals, positive-feedback loops do not play a major role in homeostasis but instead help drive processes to completion. Consider, for instance, the oxytocin pathway outlined in Figure 32.12. In response to the circulating oxytocin, the mammary glands secrete milk. Milk released in response to the oxytocin leads to more suckling and therefore more stimulation. Activation of the pathway continues until the baby stops suckling. Other functions of oxytocin, such as stimulating contractions of the uterus during birthing, also exhibit positive feedback.

## Pathways of Water-Soluble and Lipid-Soluble Hormones

The hormones we have discussed so far are polypeptides and are soluble in water but not soluble in lipids. Unable to pass through the plasma membranes of cells, they bind to cell-surface receptors, triggering events at the plasma membrane that result in a cellular response. The series of changes in cellular proteins that converts the extracellular signal to a specific intracellular response is called *signal transduction*. A signal transduction pathway typically has multiple steps, each involving specific molecular interactions (see Chapter 5).

There are also hormones that are lipid-soluble, including the sex hormones estradiol and testosterone. The major receptors for these steroid hormones are located in the cytosol rather than on the cell surface. When a steroid hormone binds to its cytosolic receptor, a hormone-receptor complex forms, which moves into the

nucleus (see Figure 5.23). There, the receptor portion of the complex alters transcription of particular genes.

## Multiple Effects of Hormones

Many hormones elicit more than one type of response. Consider, for example, **epinephrine**. This hormone, also called *adrenaline*, is secreted by the *adrenal glands*, which lie atop the kidneys (see Figure 32.11). When you are in a stressful situation, perhaps running to catch a bus, the release of epinephrine rapidly triggers responses that help you chase the departing bus: raising blood glucose levels, increasing blood flow to muscles, and decreasing blood flow to the digestive system.

How can one hormone have such different effects? Target cells can vary in their response if they differ in their receptor type or in the molecules that produce the response. In the liver, epinephrine binds to a  $\beta$ -type epinephrine receptor in the plasma membrane of target cells. This receptor activates the enzyme protein kinase A, which regulates enzymes of glycogen metabolism, causing release of glucose into the bloodstream (**Figure 32.13a**). In blood vessels supplying skeletal muscle, the same kinase activated by the same receptor inactivates a muscle-specific enzyme. The result is smooth muscle relaxation, vasodilation, and hence increased blood flow (**Figure 32.13b**). In contrast, intestinal blood vessels have an  $\alpha$ -type epinephrine receptor (**Figure 32.13c**). Rather than activating protein kinase A, the  $\alpha$  receptor triggers a distinct signaling pathway involving different enzymes. The result is smooth muscle contraction, vasoconstriction, and restricted blood flow to the intestines.

**▲ Figure 32.13 One hormone, different effects.** Epinephrine, the primary “fight-or-flight” hormone, produces different responses in different target cells. Target cells with the same receptor exhibit different responses if they have different signal transduction pathways and/or effector proteins; compare (a) with (b). Responses of target cells may also differ if they have different receptors for the hormone; compare (b) with (c).

## A shared system mediates osmoregulation and excretion in many animals

Maintaining the fluid environment of animal tissues requires that the relative concentrations of water and solutes be kept within fairly narrow limits. In addition, ions such as sodium and calcium must be maintained at concentrations that permit normal activity of muscles, neurons, and other body cells. Homeostasis thus requires **osmoregulation**, the general term for the processes by which animals control solute concentrations in the interstitial fluid and balance water gain and loss.

In safeguarding their internal fluid environment, animals must deal with a hazardous metabolite produced by the dismantling of proteins and nucleic acids. Breakdown of *nitrogenous* (nitrogen-containing) molecules releases ammonia, a very toxic compound. Several different mechanisms have evolved for **excretion**, the process that rids the body of nitrogenous metabolites and other metabolic waste products. Because systems for excretion and osmoregulation are structurally and functionally linked in many animals, we will consider both of these processes here.

### Osmosis and Osmolarity

All animals—regardless of their habitat and the type of waste they produce—need to balance water uptake and loss. If animal cells take up too much water, the cells swell and burst; if the cells lose too much water, they shrivel and die (see Figure 5.11). Water enters and leaves cells by osmosis, which occurs whenever two solutions separated by a membrane differ in osmotic pressure, or **osmolarity** (total solute concentration expressed as molarity, that is, moles of solute per liter of solution). The unit of measurement for osmolarity used in this chapter is milliOsmoles per liter (mOsm/L).

If two solutions separated by a selectively permeable membrane have the same osmolarity, they are said to be *isoosmotic*. When two solutions differ in osmolarity, the one with the greater concentration of solutes is said to be *hyperosmotic*, and the more dilute solution is said to be *hypoosmotic*. Water flows by osmosis from a hypoosmotic solution to a hyperosmotic one.

### Osmoregulatory Challenges and Mechanisms

An animal can maintain water balance in two ways. One is to be an **osmoconformer**: to be isoosmotic with its surroundings. All osmoconformers are marine animals. The second way to maintain water balance is to be an **osmoregulator**: to control internal osmolarity independent of the environment. Osmoregulation enables animals to live in environments that are uninhabitable for osmoconformers, such as fresh water and terrestrial habitats.

▲ Tadpole

▲ Adult frog

▲ **Figure 32.14 Specialized role of a hormone in frog metamorphosis.** The hormone thyroxine is responsible for the resorption of the tadpole's tail as the frog develops into its adult form.

### Evolution of Hormone Function

**EVOLUTION** Over the course of evolution, the functions of a given hormone often diverge between species. An example is thyroid hormone, which across many evolutionary lineages plays a role in regulating metabolism (see Figure 32.11). In frogs, however, the thyroid hormone thyroxine ( $T_4$ ) has taken on an apparently unique function: stimulating resorption of the tadpole's tail during metamorphosis (**Figure 32.14**).

Diverse functions have also evolved for many other vertebrate hormones. The hormone *prolactin* has an especially broad range of activities. Prolactin stimulates mammary gland growth and milk synthesis in mammals, regulates fat metabolism and reproduction in birds, delays metamorphosis in amphibians, and regulates salt and water balance in freshwater fishes. These varied roles suggest that prolactin is an ancient hormone with functions that have diversified during the evolution of vertebrate groups.

Now that we have introduced homeostasis and endocrine function, we will explore these topics in more depth by focusing on the processes of osmoregulation and excretion.

#### CONCEPT CHECK 32.2

1. Can cells differ in their response to a hormone if they have the same receptor for that hormone? Explain.
2. **WHAT IF?** If a hormone pathway provides a transient response to a stimulus, how would shortening the stimulus duration affect the need for negative feedback?
3. **MAKE CONNECTIONS** What parallels in properties and effects can you identify between epinephrine and the plant hormone auxin (see Concept 31.1)?

For suggested answers, see Appendix A.

▼ **Figure 32.15** Osmoregulation in marine and freshwater bony fishes: a comparison.

The opposite challenges of marine and freshwater environments are illustrated in **Figure 32.15** for a marine cod and a freshwater perch. For the cod (see Figure 32.15a), the ocean is a strongly dehydrating environment. Constantly losing water by osmosis, such fishes balance the water loss by drinking large amounts of seawater. In ridding themselves of salts, they make use of both their gills and kidneys. In the gills, specialized *chloride cells* actively transport chloride ions ( $\text{Cl}^-$ ) out and allow sodium ions ( $\text{Na}^+$ ) to follow passively. In the kidneys, excess calcium, magnesium, and sulfate ions are excreted with the loss of only small amounts of water.

The freshwater perch (see Figure 32.15b) lives in an environment with a very low osmolarity, so it faces the problem of gaining water by osmosis and losing salts by diffusion. Like many freshwater animals, the perch solves this problem by drinking almost no water and excreting large amounts of very dilute urine. At the same time, salts lost by diffusion and in the urine are replenished by eating. Freshwater fishes such as the perch also replenish salts by uptake across the gills.

For land animals, the threat of dehydration is a major regulatory problem. Although most terrestrial animals have body coverings that help prevent dehydration, they lose water through many routes: in urine and feces, across their skin, and from the surfaces of gas exchange organs. Land animals maintain water balance by drinking and eating moist foods and by producing water metabolically through cellular respiration. In the **Scientific Skills Exercise**, you can examine water balance in one species of desert-dwelling mammal.

## Nitrogenous Wastes

Because most metabolic wastes must be dissolved in water to be excreted from the body, the type and quantity of an animal's waste products may have a large impact on its water balance. In this regard, some of the most significant waste products are the nitrogenous breakdown products of proteins and nucleic acids (**Figure 32.16**). When proteins and nucleic acids are

broken apart for energy or converted to carbohydrates or fats, enzymes remove nitrogen in the form of **ammonia** ( $\text{NH}_3$ ). Ammonia is very toxic, in part because its ion, ammonium ( $\text{NH}_4^+$ ), interferes with oxidative phosphorylation. Although some animals excrete ammonia directly, many species expend energy to convert it to a less toxic compound, either urea or uric acid, prior to excretion.

Animals that excrete nitrogenous wastes as ammonia need access to lots of water because ammonia can be

## Describing and Interpreting Quantitative Data

**How Do Desert Mice Maintain Osmotic Homeostasis?** The sandy inland mouse (*Leggadina hermannsburgensis*) is an Australian desert mammal that can survive indefinitely on a diet of dried seeds without drinking water. To study this species' adaptations to its arid environment, researchers conducted a laboratory experiment in which they controlled access to water. In this exercise, you will analyze some of the data from the experiment.

**How the Experiment Was Done** Nine captured mice were housed in individual cages in an environmentally controlled room. The mice were given birdseed (10% water by weight) to eat. In Part A of the study, the mice also had unlimited access to tap water; in Part B of the study, they were not given any additional water for 35 days, similar to conditions in their natural habitat. For each mouse at the end of each part of the study, the researchers measured the osmolarity and urea concentration of the urine and blood. The researchers also weighed the mice three times a week.

### Data from the Experiment

Condition	Mean Osmolarity (mOsm/L)		Mean Urea Concentration (mM)	
	Urine	Blood	Urine	Blood
Part A: Unlimited access to water	490	350	330	7.6
Part B: No water	4,700	320	2,700	11

When the mice were given unlimited access to water, they drank about 33% of their body weight each day. The change in body weight during the study was negligible for all mice.

### Interpret the Data

- In words, describe how the data differ between the unlimited-water and no-water conditions for the following: (a) osmolarity of urine; (b) osmolarity of blood; (c) urea concentration in urine; (d) urea concentration in blood. (e) Does this data set provide evidence of homeostatic regulation? Explain.
- (a) Calculate the ratio of urine osmolarity to blood osmolarity for mice with unlimited access to water. (b) Calculate this ratio for mice with no access to water. (c) What conclusion would you draw from these ratios?
- If the amount of urine produced were different in the two conditions, how would that affect your calculation? Explain.

**Data from** R. E. MacMillen et al., Water economy and energy metabolism of the sandy inland mouse, *Leggadina hermannsburgensis*, *Journal of Mammalogy* 53:529–539 (1972).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

excrete ammonia. Instead, they mainly excrete a different nitrogenous waste, **urea**. In vertebrates, urea is the product of a metabolic cycle that combines ammonia with carbon dioxide in the liver. The main advantage of urea for nitrogenous waste excretion is its very low toxicity.

Insects, land snails, and many reptiles, including birds, excrete **uric acid** as their primary nitrogenous waste. Uric acid is relatively nontoxic and does not readily dissolve in water. It therefore can be excreted as a semisolid paste with very little water loss. However, uric acid is even more energetically expensive to produce than urea.

## Excretory Processes

In most animals, both osmoregulation and metabolic waste disposal rely on **transport epithelia**, one or more layers of epithelial cells specialized for moving particular solutes in controlled amounts in specific directions. Transport epithelia are typically arranged in complex tubular networks with extensive surface areas. Some transport epithelia face the outside environment directly, while others line channels connected to the outside by an opening on the body surface.

Animals across a wide range of species produce a fluid waste called urine through the basic steps shown in **Figure 32.17**. In

**▲ Figure 32.17 Key steps of excretory system function: an overview.** Most excretory systems produce a filtrate by pressure-filtering body fluids and then modify the filtrate's contents. This diagram is modeled after the vertebrate excretory system.

tolerated only at very low concentrations. Therefore, ammonia excretion is most common in aquatic species. The highly soluble ammonia molecules easily pass through membranes and are readily lost by diffusion to the surrounding water.

Most terrestrial animals and many marine species cannot afford to lose the amount of water necessary to routinely

the first step, body fluid (blood, coelomic fluid, or hemolymph) is brought in contact with the selectively permeable membrane of a transport epithelium. In most cases, hydrostatic pressure (blood pressure in many animals) drives a process of **filtration**. Cells, as well as proteins and other large molecules, cannot cross the epithelial membrane and remain in the body fluid. In contrast, water and small solutes, such as salts, sugars, amino acids, and nitrogenous wastes, cross the membrane, forming a solution called the **filtrate**.

The filtrate is converted to a waste fluid by the specific transport of materials into or out of the filtrate. The process of selective **reabsorption** recovers useful molecules and water from the filtrate and returns them to the body fluids. Valuable solutes—including glucose, certain salts, vitamins, hormones, and amino acids—are reabsorbed by active transport. Non-essential solutes and wastes are left in the filtrate or are added to it by selective **secretion**, which also occurs by active transport. The pumping of various solutes adjusts the osmotic movement of water into or out of the filtrate. In the last step—excretion—the processed filtrate containing nitrogenous wastes is released from the body as urine.

The systems that perform the basic excretory functions vary widely among animal groups. We'll examine examples from invertebrates and vertebrates.

## Invertebrates

Flatworms (phylum Platyhelminthes) have excretory systems called *protonephridia* (singular, *protonephridium*), which form a network of dead-end tubules (**Figure 32.18**). The tubules, which are connected to external openings, branch throughout the flatworm body, which lacks a coelom or body cavity. Cellular units called *flame bulbs* cap the branches of each protonephridium. Consisting of a tubule cell and a cap cell, each flame bulb has a tuft of cilia projecting into the tubule. During filtration, the beating of the cilia draws water and solutes from the interstitial fluid through the flame bulb, releasing filtrate into the tubule network. (The moving cilia resemble a flickering flame, hence the name *flame bulb*.) The processed filtrate then moves outward through the tubules and empties as urine into the external environment. The urine excreted by freshwater flatworms has a low solute concentration, helping to balance the osmotic uptake of water from the environment.

In the freshwater flatworms, protonephridia serve chiefly in osmoregulation. However, in some parasitic flatworms, which are isoosmotic to the surrounding fluids of their host organisms, the main function of protonephridia is the disposal of nitrogenous wastes. Natural selection has thus adapted protonephridia to different tasks in different environments.

In insects and other terrestrial arthropods, the filtration step common to other excretory systems is absent. Instead, the

► **Figure 32.18**  
**Protonephridia: the flame bulb system of a planarian.**  
Protonephridia are branching internal tubules that function mainly in osmoregulation.

transport epithelium of organs called *Malpighian tubules* secretes certain solutes and wastes into the lumen of the tubule. The filtrate passes to the digestive tract, where most solutes are pumped back into the hemolymph, and water reabsorption by osmosis follows. The nitrogenous wastes are eliminated as nearly dry matter along with the feces. Capable of conserving water very effectively, the insect excretory system is a key adaptation contributing to these animals' success on land.

## Vertebrates

In vertebrates and some other chordates, a specialized organ called the **kidney** functions in both osmoregulation and excretion. Like the excretory organs of most animal phyla, kidneys consist of tubules. The numerous tubules of these compact organs are arranged in a highly organized manner and are closely associated with a network of capillaries. The vertebrate excretory system also includes ducts and other structures that carry urine from the tubules out of the kidney and, eventually, the body.

Because kidney organization is integral to kidney function, we begin with **Figure 32.19**, an exploration of the anatomy of the mammalian kidney and associated structures. Familiarizing yourself with the terms and diagrams in this figure will provide you with a solid foundation for learning about filtrate processing in the kidney, the focus of the next section of the chapter.

## ▼ Excretory Organs

In humans, the excretory system consists of a pair of **kidneys**, bean-shaped organs about 10 cm in length, as well as organs for transporting and storing urine. Urine produced by each kidney exits through a duct called the **ureter**; the two ureters drain into a common sac called the **urinary bladder**. During urination, urine is expelled from the bladder through a tube called the **urethra**, which empties to the outside near the vagina in females and through the penis in males. Sphincter muscles near the junction of the urethra and bladder regulate urination.

## ► Nephron Organization

Each nephron consists of a single long tubule and a ball of capillaries called the **glomerulus**. The blind end of the tubule forms a cup-shaped swelling, called **Bowman's capsule**, which surrounds the glomerulus. Filtrate is formed when blood pressure forces fluid from the blood in the glomerulus into the lumen of Bowman's capsule. Processing occurs as the filtrate passes through three major regions of the nephron: the **proximal tubule**, the **loop of Henle** (a hair-pin turn with a descending limb and an ascending limb), and the **distal tubule**. A **collecting duct** receives processed filtrate from many nephrons and transports it to the renal pelvis. Each nephron is supplied with blood by an **afferent arteriole**, an offshoot of the renal artery that branches and forms the capillaries of the glomerulus. The capillaries converge as they leave the glomerulus, forming an **efferent arteriole**. Branches of this vessel form the **peritubular capillaries**, which surround the proximal and distal tubules. Other branches extend downward and form the **vasa recta**, hairpin-shaped capillaries that serve the renal medulla and surround the loop of Henle.

## ► Kidney Structure

Each kidney has an outer **renal cortex** and an inner **renal medulla**. Both regions are supplied with blood by a renal artery and drained by a renal vein. Within the cortex and medulla lie tightly packed excretory tubules and associated blood vessels. The inner **renal pelvis** collects urine from the excretory tubules and passes it to the urinary bladder.

## ► Nephron Types

Weaving back and forth across the renal cortex and medulla are the **nephrons**, the functional units of the vertebrate kidney. Most of these are **cortical nephrons**, which reach only a short distance into the medulla. The remainder, the **juxtamedullary nephrons**, extend deep into the medulla. Juxtamedullary nephrons are essential for production of urine that is hyperosmotic to body fluids.

### CONCEPT CHECK 32.3

1. What is the function of the filtration step in excretory systems?
2. What advantage does uric acid offer as a nitrogenous waste in arid environments?
3. **WHAT IF?** A camel standing in the sun requires much more water when its fur is shaved off, although its body temperature remains the same. What can you conclude about the relationship between osmoregulation and the insulation provided by fur?

For suggested answers, see Appendix A.

## CONCEPT 32.4

### Hormonal circuits link kidney function, water balance, and blood pressure

The nephrons of the mammalian kidney are highly specialized for processing filtrate. As you read how tubules, capillaries, and surrounding tissue work together, note the close relationship between structure and function. Hormones and feedback circuits are the key to managing the complex osmoregulatory activities of the kidney.

The porous capillaries and specialized cells of Bowman's capsule are permeable to water and small solutes, but not to blood cells or large molecules such as plasma proteins. Consequently, the filtrate produced in the capsule contains salts, glucose, amino acids, vitamins, nitrogenous wastes, and other small molecules. Because such molecules pass freely between glomerular capillaries and Bowman's capsule, the concentrations of these substances in the initial filtrate are the same as those in blood plasma.

#### From Blood Filtrate to Urine: A Closer Look

In this section, we will follow the filtrate along its path in the nephron and collecting duct, examining how each region contributes to the stepwise processing of filtrate into urine. Each circled number refers to the processing in a particular region, as illustrated in **Figure 32.20**.

**1 Proximal tubule.** Reabsorption in the proximal tubule is critical for the recapture of ions, water, and valuable nutrients from the huge volume of initial filtrate. NaCl (salt) in the filtrate enters the cells of the transport epithelium by facilitated diffusion and cotransport mechanisms (see Figures 5.13 and 5.17). There Na<sup>+</sup> is actively transported into the interstitial fluid. This transfer of positive charge out of the tubule drives the passive transport of Cl<sup>-</sup>.

As salt moves from the filtrate to the interstitial fluid, water follows by osmosis. The salt and water then diffuse from the interstitial fluid into the peritubular capillaries. Glucose, amino acids, potassium ions (K<sup>+</sup>), and other essential substances are

also actively or passively transported from the filtrate to the interstitial fluid and then into the peritubular capillaries. In contrast, some toxic materials, such as drugs and toxins that have been processed in the liver, are actively secreted into filtrate by the transport epithelium.

**2 Descending limb of the loop of Henle.** Reabsorption of water continues as the filtrate moves into the descending limb of the loop of Henle. Here numerous water channels formed by **aquaporin** proteins make the transport epithelium freely permeable to water. In contrast, there are almost no channels for salt and other small solutes, resulting in very low permeability for these substances.

For water to move out of the tubule by osmosis, the interstitial fluid bathing the tubule must be hyperosmotic to the filtrate. This condition is met along the entire length of the descending limb because the osmolarity of the interstitial fluid increases progressively from the outer cortex to the inner medulla of the kidney. Consequently, the filtrate loses water and increases in solute concentration all along its journey down the descending limb.

**3 Ascending limb of the loop of Henle.** The filtrate reaches the tip of the loop and then returns to the cortex within the ascending limb. Unlike the descending limb, the ascending limb has a transport epithelium that lacks water channels. As a result, in this region the epithelial membrane that faces the filtrate is impermeable to water.

The ascending limb has two specialized regions: a thin segment near the loop tip and a thick segment adjacent to the distal tubule. As filtrate ascends in the thin segment, NaCl, which became concentrated in the descending limb, diffuses out of the permeable tubule into the interstitial fluid. This movement of NaCl out of the tubule helps maintain the osmolarity of the interstitial fluid in the medulla. In the thick segment of the ascending limb, the movement of NaCl out of the filtrate continues. Here, however, the epithelium actively transports NaCl into the interstitial fluid. As a result of losing salt but not water, the filtrate becomes progressively more dilute as it moves up to the cortex in the ascending limb of the loop.

**4 Distal tubule.** The distal tubule plays a key role in regulating the K<sup>+</sup> and NaCl concentrations of body fluids. This regulation involves variation in the amount of K<sup>+</sup> secreted into the filtrate as well as the amount of NaCl reabsorbed from the filtrate. Like the proximal tubule, the distal tubule contributes to pH regulation by the controlled secretion of H<sup>+</sup> and reabsorption of HCO<sub>3</sub><sup>-</sup>.

**5 Collecting duct.** The collecting duct carries the filtrate through the medulla to the renal pelvis (see Figure 32.19). Final processing of the filtrate by the transport epithelium of the collecting duct forms the urine.

Under normal conditions, approximately 1,600 L of blood flows through a pair of human kidneys each day. Processing of this enormous traffic of blood by the nephrons and collecting ducts yields about 180 L of initial filtrate. Of this, about 99% of

▲ **Figure 32.20 The nephron and collecting duct: regional functions of the transport epithelium.**

The numbered regions in this diagram are keyed to the circled numbers in the text discussion of kidney function.

**?** Some cells lining tubules in the kidney synthesize organic solutes to maintain normal cell volume. Where in the kidney would you find these cells? Explain.

the water and nearly all of the sugars, amino acids, vitamins, and other organic nutrients are reabsorbed into the blood, leaving only about 1.5 L of urine to be transported to the bladder.

As filtrate passes along the transport epithelium of the collecting duct, regulation of permeability and transport across the epithelium determines the extent to which the urine becomes concentrated.

When the kidneys are conserving water, aquaporin channels in the collecting duct allow water molecules to cross the epithelium. The filtrate becomes increasingly concentrated, losing more and more water by osmosis to the hyperosmotic interstitial fluid. In the inner medulla, the duct becomes permeable to urea. Because of the high urea concentration in the filtrate at this point, some urea diffuses out of the duct and into the interstitial fluid. The net result is urine that is hyperosmotic to the general body fluids.

When maintaining salt and water balance requires the production of dilute rather than concentrated urine, the kidney

actively absorbs salts without allowing water to follow by osmosis. At these times, the epithelium lacks water channels, and NaCl is actively transported out of filtrate.

As we will see, the state of the collecting duct epithelium is controlled by hormones that together maintain homeostasis for osmolarity, blood pressure, and blood volume.

## Concentrating Urine in the Mammalian Kidney

The mammalian kidney's ability to conserve water is a key terrestrial adaptation. In humans, the osmolarity of blood is about 300 mOsm/L, but the kidney can excrete urine up to four times as concentrated.

To better understand the physiology of the mammalian kidney as a water-conserving organ, let's retrace the flow of filtrate through the excretory tubule. This time, let's focus on how the juxtamedullary nephrons maintain an osmolarity gradient in the tissues that surround the loop of Henle and how they use that

► **Figure 32.21 How the human kidney concentrates urine: the two-solute model.** Two solutes contribute to the osmolarity of the interstitial fluid: NaCl (used as shorthand here to refer collectively to Na<sup>+</sup> and Cl<sup>-</sup>) and urea. The loop of Henle maintains the interstitial gradient of NaCl, which increases continuously in concentration from the cortex to the inner medulla. Urea diffuses into the interstitial fluid of the medulla from the collecting duct (most of the urea in the filtrate remains in the collecting duct and is excreted). The filtrate makes three trips between the cortex and medulla: first down, then up, and then down again in the collecting duct. As the filtrate flows in the collecting duct past interstitial fluid of increasing osmolarity, more water moves out of the duct by osmosis. The loss of water concentrates the solutes, including urea, that will be excreted in the urine.

**WHAT IF?** The drug furosemide blocks the cotransporters for Na<sup>+</sup> and Cl<sup>-</sup> in the ascending limb of the loop of Henle. What effect would you expect this drug to have on urine volume?

gradient to excrete a hyperosmotic urine (**Figure 32.21**). Filtrate passing from Bowman's capsule to the proximal tubule has about the same osmolarity as blood. A large amount of water *and* salt is reabsorbed from the filtrate as it flows through the proximal tubule in the renal cortex. As a result, the filtrate's volume decreases substantially, but its osmolarity remains about the same.

As the filtrate flows from cortex to medulla in the descending limb of the loop of Henle, water leaves the tubule by osmosis. Solutes, including NaCl, become more concentrated, increasing the osmolarity of the filtrate. The highest osmolarity (about 1,200 mOsm/L) occurs at the elbow of the loop of Henle. This maximizes the diffusion of salt out of the tubule as the filtrate rounds the curve and enters the ascending limb, which is permeable to salt but not to water. NaCl diffusing from the ascending limb helps maintain a high osmolarity in the interstitial fluid of the renal medulla.

The loop of Henle and surrounding capillaries act as a type of countercurrent system to generate the steep osmotic gradient between the medulla and cortex. Recall that some endotherms have a countercurrent heat exchanger that reduces heat loss (see Figure 32.7). In that system there is passive movement along a heat gradient. In contrast, the countercurrent system of the loop of Henle involves active transport and thus an expenditure of energy. The active transport of NaCl from the filtrate in the upper part of the ascending limb of the loop maintains a high salt concentration in the interior of the kidney, enabling

the kidney to form concentrated urine. Such a system, which expends energy to create a concentration gradient, is called a **countercurrent multiplier system**.

As a result of active transport of NaCl out of the thick segment of the ascending limb, the filtrate is actually hypoosmotic to body fluids by the time it reaches the distal tubule. Next the filtrate descends again toward the medulla, this time in the collecting duct, which is permeable to water but not to salt. Therefore, osmosis extracts water from the filtrate as it passes from cortex to medulla, concentrating salt, urea, and other solutes in the filtrate.

When the human kidney concentrates urine maximally, the urine reaches an osmolarity of 1,200 mOsm/L. Some mammals can do even better: Australian hopping mice, small marsupials that live in dry desert regions, can produce urine with an osmolarity of 9,300 mOsm/L, 25 times as concentrated as the animal's blood.

## Adaptations of the Vertebrate Kidney to Diverse Environments

**EVOLUTION** Vertebrates occupy habitats ranging from rain forests to deserts and from some of the saltiest bodies of water to the nearly pure waters of high mountain lakes. Variations in nephron structure and function equip the kidneys of different vertebrates for osmoregulation in their various habitats. These adaptations are made apparent by comparing species

that inhabit a range of environments or by comparing the responses of different vertebrates to similar conditions.

Mammals that excrete the most hyperosmotic urine, such as hopping mice, kangaroo rats, and other desert mammals, have loops of Henle that extend deep into the medulla. Long loops maintain steep osmotic gradients in the kidney, resulting in urine becoming very concentrated as it passes from cortex to medulla in the collecting ducts.

Birds have loops of Henle that extend less far into the medulla than those of mammals. Thus, bird kidneys cannot concentrate urine to the high osmolarities achieved by mammalian kidneys. Although birds can produce hyperosmotic urine, their main water conservation adaptation is excreting their nitrogenous waste in the form of uric acid.

In mammals, both the volume and osmolarity of urine are adjusted according to an animal's water and salt balance. In situations of high salt intake and low water availability, a mammal can excrete small volumes of hyperosmotic urine with minimal water loss. If salt is scarce and fluid intake is high, the kidney can instead produce large volumes of hypoosmotic urine, getting rid of the excess water with little salt loss. At such times, the urine can be as dilute as 70 mOsm/L.

The vampire bat shown in **Figure 32.22** illustrates the versatility of the mammalian kidney. This species feeds at night on the blood of large birds and mammals. The bat uses its sharp teeth to make a small incision in the prey's skin and then laps up blood from the wound (the prey animal is typically not seriously harmed). Anticoagulants in the bat's saliva prevent the blood from clotting. Because a vampire bat may fly long distances to locate a suitable victim, when it does find prey it benefits from consuming as much blood as possible—often more than half its body mass. By itself, this blood intake would make the bat too heavy to fly. As the bat feeds, however, its kidneys enable it to excrete large volumes of dilute urine, up to 24% of body mass per hour. Having lost enough weight to take off, the bat can fly back to its roost in a cave or hollow tree, where it spends the day.

▲ **Figure 32.22** A vampire bat (*Desmodus rotundus*), a mammal with a unique excretory challenge.

In the roost, the vampire bat faces a different regulatory problem. Most of the nutrition it derives from blood comes in the form of protein. Digesting proteins generates large quantities of urea, but roosting bats lack access to the drinking water necessary to dilute it. Instead, their kidneys shift to producing small quantities of highly concentrated urine (up to 4,600 mOsm/L), an adjustment that disposes of the urea load while conserving as much water as possible. The bat's ability to alternate rapidly between large amounts of dilute urine and small amounts of very hyperosmotic urine is an essential part of its adaptation to an unusual food source.

## Homeostatic Regulation of the Kidney

A combination of nervous and hormonal inputs regulates the osmoregulatory function of the mammalian kidney. Through their effect on the amount and osmolarity of urine, these inputs contribute to homeostasis for both blood pressure and blood volume.

### Antidiuretic Hormone

One key hormone in the regulatory circuitry of the kidney is antidiuretic hormone (ADH), also called *vasopressin* (**Figure 32.23**). Osmoreceptor cells in the hypothalamus monitor the

▲ **Figure 32.23** Regulation of fluid retention in the kidney by antidiuretic hormone (ADH).

osmolarity of blood and regulate release of ADH from the posterior pituitary. ADH binds to receptor molecules on epithelial cells in the collecting duct, leading to a temporary increase in the number of aquaporin proteins in the plasma membrane. Because aquaporin proteins form water channels, the net effect is an increased permeability of the epithelium to water.

To see how the response to ADH in the kidney contributes to osmoregulation, let's consider first what occurs when blood osmolarity rises, such as after eating salty food or losing water through sweating. When osmolarity rises above the set point (300 mOsm/L), ADH release into the bloodstream is increased. The collecting duct's permeability to water rises, resulting in water reabsorption, which concentrates urine, reduces urine volume, and lowers blood osmolarity back toward the set point. (Only the gain of additional water in food or drink can fully restore osmolarity to 300 mOsm/L.) As the osmolarity of the blood falls, a negative-feedback mechanism reduces the activity of osmoreceptor cells in the hypothalamus, and ADH secretion is reduced.

What happens if, instead of ingesting salt or sweating profusely, you drink a large amount of water? The resulting reduction in blood osmolarity below the set point causes a drop in ADH secretion to a very low level. The number of aquaporin channels decreases, lowering permeability of the collecting ducts. Water reabsorption is reduced, resulting in discharge of large volumes of dilute urine. (A high level of urine production is called diuresis; ADH opposes this state and is therefore called *antidiuretic hormone*.)

### The Renin-Angiotensin-Aldosterone System

A second regulatory mechanism acting on the kidney is the **renin-angiotensin-aldosterone system (RAAS)**. The RAAS involves the **juxtaglomerular apparatus (JGA)**, a specialized tissue consisting of cells of and around the afferent arteriole, which supplies blood to the glomerulus (Figure 32.24). When blood pressure or blood volume in the afferent arteriole drops (for instance, as a result of dehydration), the JGA releases the enzyme renin. Renin initiates a sequence of chemical reactions that cleave a plasma protein called angiotensinogen, ultimately yielding a peptide called **angiotensin II**.

Functioning as a hormone, angiotensin II triggers vasoconstriction, increasing blood pressure and decreasing blood flow to capillaries in the kidney (and elsewhere). Angiotensin II also stimulates the adrenal glands to release a hormone called **aldosterone**. This hormone acts on the nephrons' distal tubules and collecting ducts, making them reabsorb more  $\text{Na}^+$  and water, thus increasing blood volume and pressure.

Because angiotensin II acts in several ways that increase blood pressure, drugs that block angiotensin II production are widely used to treat hypertension (chronic high blood pressure). Many of these drugs are specific inhibitors of angiotensin converting enzyme (ACE), which catalyzes one of the steps in the production of angiotensin II.

▲ **Figure 32.24 Regulation of blood volume and blood pressure by the renin-angiotensin-aldosterone system (RAAS).**

The renin-angiotensin-aldosterone system operates as a feedback circuit. A drop in blood pressure and blood volume triggers renin release. The resulting production of angiotensin II and release of aldosterone cause a rise in blood pressure and volume, reducing the release of renin from the JGA.

### Coordination of ADH and RAAS Activity

The functions of ADH and the RAAS may seem to be redundant, but this is not the case. Both increase water reabsorption in the kidney, but they counter different osmoregulatory problems. The release of ADH is a response to an increase in blood osmolarity, as when the body is dehydrated from excessive water loss or inadequate water intake. However, an excessive loss of both salt and body fluids—caused, for example, by a major wound or severe diarrhea—will reduce blood volume *without* increasing osmolarity. This will not affect ADH release, but the RAAS will respond to the drop in blood volume and pressure by increasing water and  $\text{Na}^+$

reabsorption. Thus, ADH and the RAAS are partners in homeostasis. ADH alone would lower blood  $\text{Na}^+$  concentration by stimulating water reabsorption in the kidney, but the RAAS helps maintain the osmolarity of body fluids at the set point by stimulating  $\text{Na}^+$  reabsorption.

In all animals, certain of the intricate physiological machines we call organs work continuously in maintaining solute and water balance and excreting nitrogenous wastes. The details that we have reviewed in this chapter only hint at the great complexity of the neural and hormonal mechanisms involved in regulating these homeostatic processes.

#### CONCEPT CHECK 32.4

1. Why could it be dangerous to drink a very large amount of water in a short period of time?
2. Many medications make the epithelium of the collecting duct less permeable to water. How would taking such a drug affect kidney output?
3. **WHAT IF?** If blood pressure in the afferent arteriole leading to a glomerulus decreased, how would the rate of blood filtration within Bowman's capsule be affected? Explain.

For suggested answers, see Appendix A.

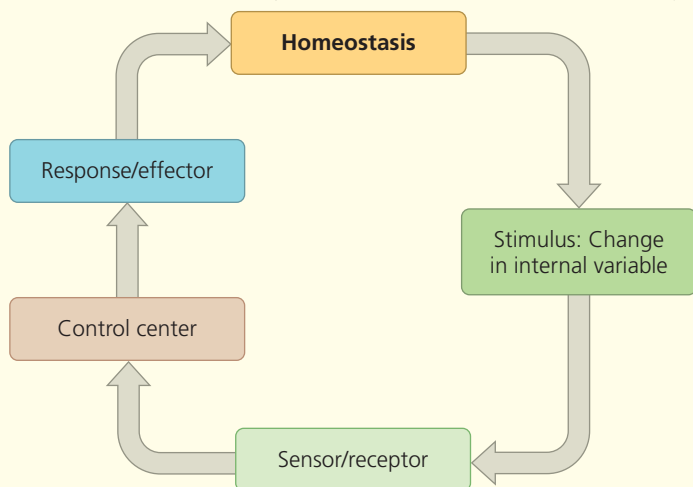

## 32 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 32.1

##### Feedback control maintains the internal environment in many animals (pp. 642–647)

- Animal bodies are based on a hierarchy of cells, **tissues**, **organs**, and **organ systems**. **Epithelial tissue** forms active interfaces on external and internal surfaces; **connective tissue** binds and supports other tissues; **muscle tissue** contracts, moving body parts; and **nervous tissue** transmits nerve impulses throughout the body.
- Animals *regulate* certain internal variables while allowing other internal variables to *conform* to external changes. **Homeostasis** is the maintenance of a steady state despite internal and external changes.

- An animal maintains its internal temperature within a tolerable range by **thermoregulation**. **Endotherms** are warmed mostly by heat generated by metabolism. **Ectotherms** get most of their heat from external sources. The **hypothalamus** acts as the thermostat in mammalian regulation of body temperature.

**?** Given that humans *thermoregulate*, explain why your skin is cooler than your body core.

#### CONCEPT 32.2

##### Endocrine signals trigger homeostatic mechanisms in target tissues (pp. 648–653)

- In communicating between different locations in the body, the **endocrine system** broadcasts signaling molecules called

**hormones** everywhere via the bloodstream. Only certain cells are responsive to each hormone. The **nervous system** uses dedicated cellular circuits involving electrical and chemical signals to send information to specific locations. Hormone pathways may be regulated by **negative feedback**, which damps the stimulus, or **positive feedback**, which amplifies the stimulus and drives the response to completion.

**?** Why would a water-soluble hormone likely have no effect if injected directly into the cytosol of a target cell?

#### CONCEPT 32.3

##### A shared system mediates osmoregulation and excretion in many animals (pp. 653–658)

- Cells balance water gain and loss through **osmoregulation**, a process based on the controlled movement of solutes between internal fluids and the external environment and on the movement of water, which follows by osmosis.
- Protein and nucleic acid metabolism generates **ammonia**, which in many animals is converted to **urea** or **uric acid** for **excretion**. Most excretory systems carry out **filtration**, **reabsorption**, **secretion**, and excretion. Excretory tubules (consisting of **nephrons** and **collecting ducts**) and blood vessels pack the mammalian **kidney**.

**DRAW IT** Construct a table summarizing the three major types of nitrogenous wastes and their relative toxicity, energy content, and associated water loss during excretion.

#### CONCEPT 32.4

##### Hormonal circuits link kidney function, water balance, and blood pressure (pp. 658–663)

- Within the nephron, selective secretion and reabsorption in the **proximal tubule** alter **filtrate** volume and composition. The *descending limb* of the **loop of Henle** is permeable to water but not salt, whereas the *ascending limb* is permeable to salt but not water. The **distal tubule** and collecting duct regulate  $\text{K}^+$  and  $\text{NaCl}$  levels in body fluids.
- In a mammalian kidney, a **countercurrent multiplier system** involving the loop of Henle maintains the gradient of salt concentration in the kidney interior. In response to hormonal signals, urine can be concentrated in the collecting duct.
- Natural selection has shaped the form and function of nephrons in vertebrates to the challenges of the animals' habitats. For example, desert mammals, which excrete the most hyperosmotic urine, have loops of Henle that extend deep into the **renal medulla**.

- When blood **osmolarity** rises, the posterior pituitary releases **antidiuretic hormone (ADH)**, which increases permeability to water in collecting ducts by increasing the number of water channels. When blood pressure or blood volume in the afferent arteriole drops, the **juxtaglomerular apparatus (JGA)** releases renin. **Angiotensin II**, formed in response to renin, constricts arterioles and triggers release of the hormone **aldosterone**, raising blood pressure. This **renin-angiotensin-aldosterone system (RAAS)** has functions that overlap with those of ADH.

**?** How do cortical nephrons and juxtamedullary nephrons differ in reabsorbing nutrients and concentrating urine?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- The body tissue that consists largely of material located outside of cells is
  - epithelial tissue.
  - connective tissue.
  - skeletal muscle.
  - smooth muscle.
  - nervous tissue.
- Which of the following would increase the rate of heat exchange between an animal and its environment?
  - feathers or fur
  - vasoconstriction
  - wind blowing across the body surface
  - countercurrent heat exchanger
  - blubber or fat layer
- Which process in the nephron is *least* selective?
  - filtration
  - reabsorption
  - active transport
  - secretion
  - salt pumping by the loop of Henle

### Level 2: Application/Analysis

- Homeostasis typically relies on negative feedback because positive feedback
  - requires a response but not a stimulus.
  - drives processes to completion rather than to a balance point.
  - acts within, but not beyond, a normal range.
  - can decrease but not increase a variable.
  - involves one location rather than several across the body.
- Which of the following is an accurate statement about thermoregulation?
  - Endotherms are regulators and ectotherms are conformers.
  - Endotherms maintain a constant body temperature and ectotherms do not.
  - Endotherms are warm-blooded and ectotherms are cold-blooded.
  - Endotherms and ectotherms differ in their primary source of heat for thermoregulation.
  - Endothermy has a lower energy cost than ectothermy.

- Natural selection should favor the highest proportion of juxtamedullary nephrons in which of the following species?
  - a river otter
  - a mouse species living in a tropical rain forest
  - a mouse species living in a temperate broadleaf forest
  - a mouse species living in a desert
  - a beaver
- African lungfish, which are often found in small stagnant pools of fresh water, produce urea as a nitrogenous waste. What is the advantage of this adaptation?
  - Urea takes less energy to synthesize than ammonia.
  - Small stagnant pools do not provide enough water to dilute the toxic ammonia.
  - The highly toxic urea makes the pool uninhabitable to potential competitors.
  - Urea forms an insoluble precipitate.
  - Urea makes lungfish tissue hypoosmotic to the pool.

### Level 3: Synthesis/Evaluation

- DRAW IT** Draw a model of the control circuit(s) required for driving an automobile at a fairly constant speed over a hilly road. Indicate each feature that represents a sensor, stimulus, or response.
- SCIENTIFIC INQUIRY**  
You are exploring kidney function in kangaroo rats. You measure urine volume and osmolarity, as well as the amount of chloride ions ( $\text{Cl}^-$ ) and urea in the urine. If the water source provided to the animals were switched from tap water to a 2% NaCl solution, what change in urine osmolarity would you expect? How would you determine if this change was more likely due to a change in the excretion of  $\text{Cl}^-$  or urea?
- FOCUS ON EVOLUTION**  
Merriam's kangaroo rats (*Dipodomys merriami*) live in North American habitats ranging from moist, cool woodlands to hot deserts. Assuming that natural selection has resulted in differences in water conservation between *D. merriami* populations, propose a hypothesis concerning the relative rates of evaporative water loss by populations that live in moist versus dry environments. Using a humidity sensor to detect evaporative water loss by kangaroo rats, how could you test your hypothesis?
- FOCUS ON ORGANIZATION**  
In a short essay (100–150 words), compare how membrane structures in the loop of Henle and collecting duct of the mammalian kidney enable water to be recovered from filtrate in the process of osmoregulation.

For selected answers, see Appendix A.

## MasteringBiology®

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# 33 Animal Nutrition

## KEY CONCEPTS

- 33.1** An animal's diet must supply chemical energy, organic molecules, and essential nutrients
- 33.2** The main stages of food processing are ingestion, digestion, absorption, and elimination
- 33.3** Organs specialized for sequential stages of food processing form the mammalian digestive system
- 33.4** Evolutionary adaptations of vertebrate digestive systems correlate with diet
- 33.5** Feedback circuits regulate digestion, energy allocation, and appetite

## OVERVIEW

### The Need to Feed

**D**innertime has arrived for the Kodiak bear in **Figure 33.1** (and for the salmon, though in quite a different sense). The skin, muscles, and other parts of the fish will be chewed into pieces, broken down by acid and enzymes in the bear's digestive system, and finally absorbed as small molecules into the body of the bear. Such a process is what is meant by animal **nutrition**: food being taken in, taken apart, and taken up.

Although a diet of fish plucked from a waterfall is not common, all animals eat other organisms—dead or alive, piecemeal or whole. Unlike plants, animals must consume food for both energy and the organic molecules used to assemble new molecules, cells, and tissues. Despite this shared need, animals have diverse diets. **Herbivores**, such as cattle, sea slugs, and termites, dine mainly on plants or algae. **Carnivores**, such as sharks, hawks, and spiders, mostly eat other animals. Bears and other **omnivores** (from the Latin *omni*, all) don't in fact eat everything, but they do regularly consume animals as well as plants or algae. We humans are typically omnivores, as are cockroaches and crows.

The terms *herbivore*, *carnivore*, and *omnivore* represent the kinds of food an animal usually eats. Keep in mind, however, that most animals are opportunistic feeders, eating foods outside their standard diet when their usual foods aren't available. For example, deer are herbivores, but in addition to feeding on grass and other plants, they occasionally eat insects, worms, or bird eggs. Note as well that microorganisms are an unavoidable "supplement" in every animal's diet.

Animals must eat. But to survive and reproduce, they must also balance their consumption, storage, and use of food. Bears, for example, store energy, largely in the form of body fat, in preparation for their winter sleep. Eating too little food, too much food, or the wrong mixture of foods can endanger an animal's health. In this chapter, we'll survey the nutritional requirements of animals, explore some of the diverse evolutionary adaptations for obtaining and processing food, and investigate the regulation of energy intake and expenditure.

▼ **Figure 33.1** How does a fish help a bear make fat?

## An animal's diet must supply chemical energy, organic molecules, and essential nutrients

Overall, an adequate diet must satisfy three nutritional needs: chemical energy for cellular processes, organic building blocks for macromolecules, and essential nutrients.

The activities of cells, tissues, organs, and whole animals depend on sources of chemical energy in the diet. This energy is used to produce ATP, which powers processes ranging from DNA replication and cell division to vision and flight. To meet the continuous requirement for ATP, animals ingest and digest nutrients, including carbohydrates, proteins, and lipids, for use in cellular respiration and energy storage.

In addition to providing fuel for ATP production, an animal's diet must supply the raw materials needed for biosynthesis. To build complex molecules, animals need a source of organic carbon (such as sugar) and a source of organic nitrogen (such as protein). Starting with these materials, animals can construct a great variety of organic molecules.

### Essential Nutrients

Some cellular processes require materials that an animal cannot assemble from simpler organic precursors. These materials—preassembled organic molecules and minerals—are called **essential nutrients**. Obtained from an animal's diet, essential nutrients include essential fatty acids and amino acids, vitamins, and minerals. Essential nutrients have key functions in cells, including serving as substrates, coenzymes, and cofactors in biosynthetic reactions (**Figure 33.2**). Needs for particular nutrients vary among species. For instance, ascorbic acid (vitamin C) is an essential nutrient for humans and guinea pigs, but not for many other animals.

### Essential Fatty Acids and Amino Acids

Animals convert fatty acids to a variety of cellular components, including membrane phospholipids, signaling molecules, and storage fats. The **essential fatty acids**, which animals cannot synthesize (but plants can), contain one or more double bonds; an example is linoleic acid (see Figure 33.2). Because seeds, grains, and other plant matter in animal diets generally furnish ample quantities of essential fatty acids, deficiencies in this class of nutrients are rare.

Like fatty acids, amino acids serve as building blocks for biosynthesis. Animals use a set of 20 amino acids to synthesize proteins. Most animals can produce about half of these amino acids, as long as their diet includes sulfur and organic nitrogen. The remaining **essential amino acids** must be obtained from food in prefabricated form. Many animals, including adult humans, require eight amino acids in their diet (infants also need a ninth, histidine).

The proteins in animal products such as meat, eggs, and cheese are “complete,” which means that they provide all the essential amino acids in their proper proportions. In contrast, most plant proteins are “incomplete,” being deficient in one or more essential amino acids. Corn (maize), for example, is deficient in tryptophan and lysine, whereas beans are lacking in methionine. However, vegetarians can easily obtain all of the essential amino acids by eating a varied diet of plant proteins.

### Vitamins

As Albert Szent-Györgyi, the physiologist who discovered vitamin C, once quipped, “A vitamin is a substance that makes you ill if you *don't* eat it.” **Vitamins** are organic molecules that are required in the diet in very small amounts (0.01–100 mg per day, depending on the vitamin). For humans, 13 vitamins have been identified. Some are water-soluble, including the B vitamins, which generally function as coenzymes (see Figure 33.2). Vitamin C, which is required for the production of connective

► **Figure 33.2 Roles of essential nutrients.** This biosynthetic reaction illustrates typical functions for the four classes of essential nutrients (an example of each class is highlighted in blue). Linoleic acid, the substrate, is an essential fatty acid. The enzyme fatty acid desaturase converts it to  $\gamma$ -linoleic acid, a precursor for phospholipids and prostaglandins. Some of the amino acids making up the polypeptide portion of the enzyme are essential, including the five following glutamine (Glu) in the partial sequence shown. In addition, the desaturase requires a mineral (iron) as a cofactor and a vitamin ( $B_3$ ) as a coenzyme.

tissue, is also water-soluble. The remaining vitamins are fat-soluble. These include vitamin A, which is incorporated into visual pigments of the eye, and vitamin D, which aids in calcium absorption and bone formation. The dietary requirement for vitamin D varies because we can actually synthesize this vitamin from other molecules when our skin is exposed to sunlight.

For people with poorly balanced diets, taking vitamin supplements that provide recommended daily levels is reasonable. It is far less clear whether massive doses of vitamins confer any benefits or are in fact even safe. Moderate overdoses of water-soluble vitamins are probably harmless because excess amounts are excreted in urine. However, excesses of fat-soluble vitamins are deposited in body fat, so overconsumption may result in toxic levels of these compounds.

## Minerals

Dietary **minerals** are inorganic nutrients, such as iron and sulfur, that are usually required in small amounts—from less than 1 mg to about 2,500 mg per day. Minerals have diverse functions in animals. Some are assembled into the structure of proteins; iron, for example, is incorporated into the oxygen carrier protein hemoglobin as well as some enzymes (see Figure 33.2). In contrast, sodium, potassium, and chloride are important in the functioning of nerves and muscles and in maintaining osmotic balance between cells and the surrounding body fluid. In vertebrates, the mineral iodine is incorporated into thyroid hormones, which regulate metabolic rate. Vertebrates also require relatively large quantities of calcium and phosphorus for building and maintaining bone.

Ingesting large amounts of some minerals can upset homeostatic balance and impair health. For example, excess salt (sodium chloride) can contribute to high blood pressure. This is a particular problem in the United States, where the typical person consumes about 20 times the required amount of sodium.

## Dietary Deficiencies

A diet that lacks one or more essential nutrients or consistently supplies less chemical energy than the body requires results in *malnutrition*, a failure to obtain adequate nutrition. Malnutrition resulting from either type of dietary deficiency can have negative impacts on health and survival.

### Deficiencies in Essential Nutrients

Insufficient intake of essential nutrients can cause deformities, disease, and even death. For example, cattle, deer, and other herbivores may develop dangerously fragile bones if they graze on plants growing in soil that lacks phosphorus. In such environments, some grazing animals obtain missing nutrients by consuming concentrated sources of salt or other minerals (**Figure 33.3**). Similarly, some birds supplement their diet with snail shells, and certain tortoises ingest stones.

▲ **Figure 33.3 Dietary supplements in nature.** A juvenile chamois (*Rupicapra rupicapra*), an herbivore, licks exposed salts and minerals in its rocky alpine habitat. This behavior is common among herbivores living where soils and plants provide insufficient amounts of essential nutrients, such as sodium, calcium, phosphorus, and iron.

Like other animals, humans sometimes suffer from diets lacking in essential nutrients. A diet that provides insufficient amounts of one or more essential amino acids causes protein deficiency, the most common type of malnutrition among humans. For example, protein deficiency may arise if a child's diet shifts from breast milk to foods that provide almost all of the child's calories in the form of a starch, such as rice. Such children, if they survive infancy, often have impaired physical and mental development.

In populations subsisting on simple rice diets, individuals are often deficient in vitamin A, which can result in blindness or death. To overcome this problem, scientists have engineered a strain of rice that synthesizes beta-carotene, a pigment that is converted to vitamin A in the body (see Chapter 30).

## Undernutrition

A diet that fails to provide adequate sources of chemical energy results in *undernutrition*. When an animal is undernourished, a series of events unfold: The body uses up stored carbohydrates and fat and then begins breaking down its own proteins for fuel; muscles begin to decrease in size; and the brain may become protein-deficient. If energy intake remains less than energy expenditures, the animal will eventually die. Even if a seriously undernourished animal survives, some of the damage may be irreversible.

Human undernutrition is most common when drought, war, or another crisis severely disrupts the food supply. However, undernutrition sometimes occurs within well-fed human populations as a result of eating disorders. For example, anorexia nervosa leads individuals, usually female, to starve themselves compulsively.

## Assessing Nutritional Needs

Determining the ideal diet for the human population is an important but difficult problem for scientists. As objects of study, people present many challenges. Unlike laboratory animals, humans are genetically diverse. They also live in settings far more varied than the stable and uniform environment that scientists use to facilitate comparisons in laboratory experiments. Ethical concerns present an additional barrier. For example, it is not acceptable to investigate the nutritional needs of children in a way that might harm a child's growth or development.

Many insights into human nutrition have come from *epidemiology*, the study of human health and disease at the population level. In the 1970s, for instance, researchers discovered that children born to women of low socioeconomic status were more likely to have neural tube defects, which occur when tissue fails to enclose the developing brain and spinal cord. Hypothesizing that malnutrition among these women was responsible, researchers used dietary studies to show that supplementary folic acid (vitamin B<sub>9</sub>) greatly reduced the risk of neural tube defects. The United States now requires that folic acid be added to enriched grain products used to make bread, cereals, and other foods.

### CONCEPT CHECK 33.1

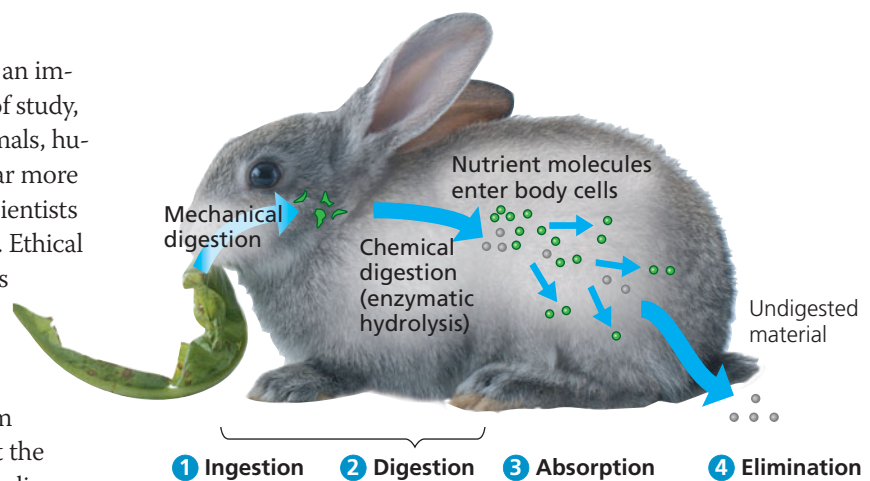

1. All 20 amino acids are needed to make animal proteins. Why aren't they all essential to animal diets?
2. **MAKE CONNECTIONS** Review the role of enzymes in metabolic reactions (see Concept 6.4). Then explain why vitamins are required in very small amounts in the diet.
3. **WHAT IF?** If a zoo animal eating ample food shows signs of malnutrition, how might a researcher determine which nutrient is lacking in its diet?

For suggested answers, see Appendix A.

## CONCEPT 33.2

### The main stages of food processing are ingestion, digestion, absorption, and elimination

In this section, we turn from nutritional requirements to the mechanisms by which animals process food. Food processing can be divided into four distinct stages: ingestion, digestion, absorption, and elimination (**Figure 33.4**). The first stage, **ingestion**, is the act of eating or feeding. **Figure 33.5** surveys and classifies the principal feeding mechanisms that have evolved in animals. Given the variation in food sources among animal species, it is not surprising that strategies for extracting resources from food also differ widely. We will focus, however, on the shared processes, pausing periodi-

▲ **Figure 33.4** The four stages of food processing.

cally to consider some adaptations to particular diets or environments.

In **digestion**, the second stage of food processing, food is broken down into molecules small enough for the body to absorb. Mechanical digestion, such as chewing, typically precedes chemical digestion. Mechanical digestion breaks food into smaller pieces, increasing the surface area available for chemical processes. Chemical digestion is necessary because animals cannot directly use the proteins, carbohydrates, nucleic acids, fats, and phospholipids in food. One problem is that these molecules are too large to pass through membranes and enter the cells of the animal. In addition, the large molecules in food are not all identical to those the animal needs for its particular tissues and functions. When large molecules in food are broken down into their components, however, the animal can use these smaller molecules to assemble the large molecules it needs. For example, although fruit flies and humans have very different diets, both convert proteins in their food to the same 20 amino acids from which they assemble all of the proteins in their bodies.

Recall that a cell makes a macromolecule or fat by linking together smaller components; it does so by removing a molecule of water for each new covalent bond formed. Chemical digestion by enzymes reverses this process by breaking bonds through the addition of water (see Figure 3.6). This splitting process is called *enzymatic hydrolysis*. Polysaccharides and disaccharides are split into simple sugars; proteins are broken down into amino acids; and nucleic acids are cleaved into nucleotides and their components. Enzymatic hydrolysis also releases fatty acids and other components from fats and phospholipids.

The last two stages of food processing occur after the food is digested. In the third stage, **absorption**, the animal's cells take up (absorb) small molecules such as amino acids and simple sugars. **Elimination** completes the process as undigested material passes out of the digestive system.

## Filter Feeders

Many aquatic animals are *filter feeders*, which use a filtration mechanism to strain small organisms or food particles from their surroundings. The humpback whale shown above is one example. The comblike plates attached to the whale's upper jaw, called baleen, strain small invertebrates and fish from enormous volumes of water and sometimes mud. Many other filter feeders are invertebrates, including most sponges, which draw water in through their pores. Filter feeding in water is a type of *suspension feeding*, removing suspended food particles from an animal's surrounding medium. Other types of suspension feeding include capture or trapping mechanisms.

## Bulk Feeders

Most animals, including humans, are *bulk feeders*, which eat relatively large pieces of food. Their adaptations include tentacles, pincers, claws, poisonous fangs, jaws, and teeth that kill their prey or tear off pieces of meat or vegetation. In this amazing scene, a rock python is beginning to ingest a gazelle it has captured and killed. Snakes cannot chew their food into pieces and must

## Substrate Feeders

*Substrate feeders* are animals that live in or on their food source. This leaf miner caterpillar, the larva of a moth, is eating through the soft tissue of an oak leaf, leaving a dark trail of feces in its wake. Some other substrate feeders include maggots (fly larvae), which burrow into animal carcasses.

## Fluid Feeders

*Fluid feeders* suck nutrient-rich fluid from a living host. This mosquito has pierced the skin of its human host with hollow, needlelike mouthparts and is consuming a blood meal (colorized SEM). Similarly, aphids are fluid feeders that tap the phloem sap of plants. In contrast to such parasites, some fluid feeders actually benefit their hosts. For example, hummingbirds and bees move pollen between flowers as they fluid-feed on nectar.

## Digestive Compartments

In our overview of food processing, we have seen that digestive enzymes hydrolyze the same biological materials (such as proteins, fats, and carbohydrates) that make up the bodies of the animals themselves. How, then, are animals able to digest food without digesting their own cells and tissues? The evolutionary adaptation found across a wide range of animal species is the processing of food within specialized compartments. Such compartments can be intracellular, in the form of food vacuoles, or extracellular, as in digestive organs and systems.

### Intracellular Digestion

Food vacuoles—cellular organelles in which hydrolytic enzymes break down food—are the simplest digestive compartments. The hydrolysis of food inside vacuoles, called intracellular digestion, begins after a cell engulfs solid food by phagocytosis or liquid food by pinocytosis (see Figure 5.18). Newly formed food vacuoles fuse with lysosomes, bringing food in contact with hydrolytic enzymes within a compartment enclosed by a protective membrane. A few animals, such as sponges, digest their food entirely by this intracellular mechanism (see Figure 27.3).

### Extracellular Digestion

In most animal species, hydrolysis occurs largely by extracellular digestion, the breakdown of food in compartments that are continuous with the outside of the animal's body. Having one or more extracellular compartments for digestion enables an animal to devour much larger pieces of food than can be ingested by phagocytosis.

Many animals with relatively simple body plans have a digestive compartment with a single opening. This pouch, called a **gastrovascular cavity**, functions in digestion as well as in

▲ **Figure 33.6 Digestion in a hydra.** Digestion begins in the gastrovascular cavity and is completed intracellularly after small food particles are engulfed by specialized cells of the gastrodermis.

the distribution of nutrients throughout the body (hence the *vascular* part of the term). In a hydra, for example, digestion begins when the animal uses its tentacles to stuff captured prey through its mouth into its gastrovascular cavity (**Figure 33.6**). After the hydra has digested its meal, undigested materials that remain in its gastrovascular cavity, such as exoskeletons of small crustaceans, are eliminated through its mouth. Many flatworms also have a gastrovascular cavity.

In contrast with cnidarians and flatworms, most animals have a digestive tube extending between two openings, a mouth and an anus. Such a tube is called a *complete digestive tract* or, more commonly, an **alimentary canal** (**Figure 33.7**). Because

▲ **Figure 33.7 Variation in alimentary canals.** These examples illustrate variation in the organization and structure of compartments that carry out stepwise digestion, storage, and absorption in different species.

food moves along the alimentary canal in a single direction, the tube can be organized into specialized compartments that carry out digestion and nutrient absorption in a stepwise fashion. An animal with an alimentary canal can ingest food while earlier meals are still being digested, a feat that is likely to be difficult or inefficient for an animal with a gastrovascular cavity. In the next section, we'll explore the organization of a mammalian alimentary canal.

### CONCEPT CHECK 33.2

1. Distinguish the overall structure of a gastrovascular cavity from that of an alimentary canal.
2. In what sense are nutrients from a recently ingested meal not really "inside" your body prior to the absorption stage of food processing?
3. **WHAT IF?** Thinking in broad terms, what similarities can you identify between digestion in an animal body and the breakdown of gasoline in an automobile? (You don't have to know about auto mechanics.)

For suggested answers, see Appendix A.

## CONCEPT 33.3

### Organs specialized for sequential stages of food processing form the mammalian digestive system

Because most animals, including mammals, have an alimentary canal, we can use the mammalian digestive system to illustrate the general principles of food processing. In mammals, the digestive system consists of the alimentary canal and

© 2010 Pearson Education, Inc.

various accessory glands that secrete digestive juices through ducts into the canal (**Figure 33.8**). The accessory glands of the mammalian digestive system are three pairs of salivary glands, the pancreas, the liver, and the gallbladder.

Food is pushed along the alimentary canal by **peristalsis**, alternating waves of contraction and relaxation in the smooth muscles lining the canal. At some of the junctions between specialized compartments, the muscular layer forms ringlike valves called **sphincters**. Acting like drawstrings to close off the alimentary canal, sphincters regulate the passage of material between compartments.

Using the human digestive system as a model, let's now follow a meal through the alimentary canal.

### The Oral Cavity, Pharynx, and Esophagus

Ingestion and the initial steps of digestion occur in the mouth, or **oral cavity**. Mechanical digestion begins as teeth of various shapes cut, mash, and grind food, making the food easier to swallow and increasing its surface area. Meanwhile, the presence of food stimulates a nervous reflex that causes the **salivary glands** to deliver saliva through ducts to the oral cavity. Saliva may also be released before food enters the mouth, triggered by a learned association between eating and the time of day, a cooking odor, or another stimulus.

Saliva initiates chemical digestion while also protecting the oral cavity. The enzyme **amylase**, found in saliva, hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose polymer from animals) into smaller polysaccharides and the disaccharide maltose. Much of the protective effect of saliva is provided by **mucus**, which is a viscous mixture of water, salts, cells, and slippery glycoproteins (carbohydrate-protein

**Figure 33.8 The human digestive system.** After food is chewed and swallowed, it takes 5–10 seconds for it to pass down the esophagus and into the stomach, where it spends 2–6 hours being partially digested. Final digestion and nutrient absorption occur in the small intestine over a period of 5–6 hours. In 12–24 hours, any undigested material passes through the large intestine, and feces are expelled through the anus.

© 1996 Cengage Learning, Inc.

complexes). Mucus in saliva protects the lining of the mouth from abrasion and lubricates food for easier swallowing. Additional components of saliva include buffers, which help prevent tooth decay by neutralizing acid, and antimicrobial agents (such as lysozyme; see Figure 3.19), which protect against bacteria that enter the mouth with food.

Much as a doorman screens and assists people entering a fancy hotel, the tongue aids digestive processes by evaluating ingested material and then enabling its further passage. When food arrives at the oral cavity, the tongue plays a critical role in distinguishing which foods should be processed further. (See Chapter 38 for a discussion of the sense of taste.) After food is deemed acceptable and chewing commences, tongue movements manipulate the food, helping shape it into a ball called a **bolus**. During swallowing, the tongue provides further help, pushing the bolus to the back of the oral cavity and into the pharynx.

The **pharynx**, or throat region, opens to two passageways: the esophagus and the trachea (windpipe). The **esophagus** connects to the stomach, whereas the trachea leads to the lungs. Swallowing must therefore be carefully choreographed to keep food from entering and blocking the airway. When you swallow, a flap of cartilage covers your vocal cords and the

opening between them. Guided by movements of the *larynx*, the upper part of the respiratory tract, this swallowing reflex directs each bolus into the entrance of the esophagus. If the swallowing reflex fails, food or liquids can reach the trachea and cause choking, a blockage of the trachea. The resulting lack of airflow into the lungs can be fatal if the material is not dislodged by vigorous coughing, back slaps, or a forced upward thrust of the diaphragm (the Heimlich maneuver).

## Digestion in the Stomach

The **stomach**, which is located just below the diaphragm, stores food and begins digestion of proteins. With accordion-like folds and a very elastic wall, this organ can stretch to accommodate about 2 L of food and fluid. As shown in **Figure 33.9**, the stomach secretes the components of a digestive fluid called **gastric juice**. It then mixes these secretions with the food through a churning action, forming a mixture of ingested food and digestive juice called **chyme**.

### Chemical Digestion in the Stomach

Two components of gastric juice carry out chemical digestion. One is hydrochloric acid (HCl), which disrupts the extracellular matrix that binds cells together in meat and plant material.

► **Figure 33.9 The stomach and its secretions.** The micrograph (colorized SEM) shows a gastric pit on the interior surface of the stomach, through which digestive juices are secreted.

The concentration of HCl is so high that the pH of gastric juice is about 2, acidic enough to dissolve iron nails (and to kill most bacteria). This low pH denatures (unfolds) proteins in food, increasing exposure of their peptide bonds. The exposed bonds are attacked by the second component of gastric juice—a **protease**, or protein-digesting enzyme, called **pepsin**. Unlike most enzymes, pepsin works best in a strongly acidic environment. By breaking peptide bonds, it cleaves proteins into smaller polypeptides. Further digestion to individual amino acids occurs in the small intestine (**Figure 33.10**).

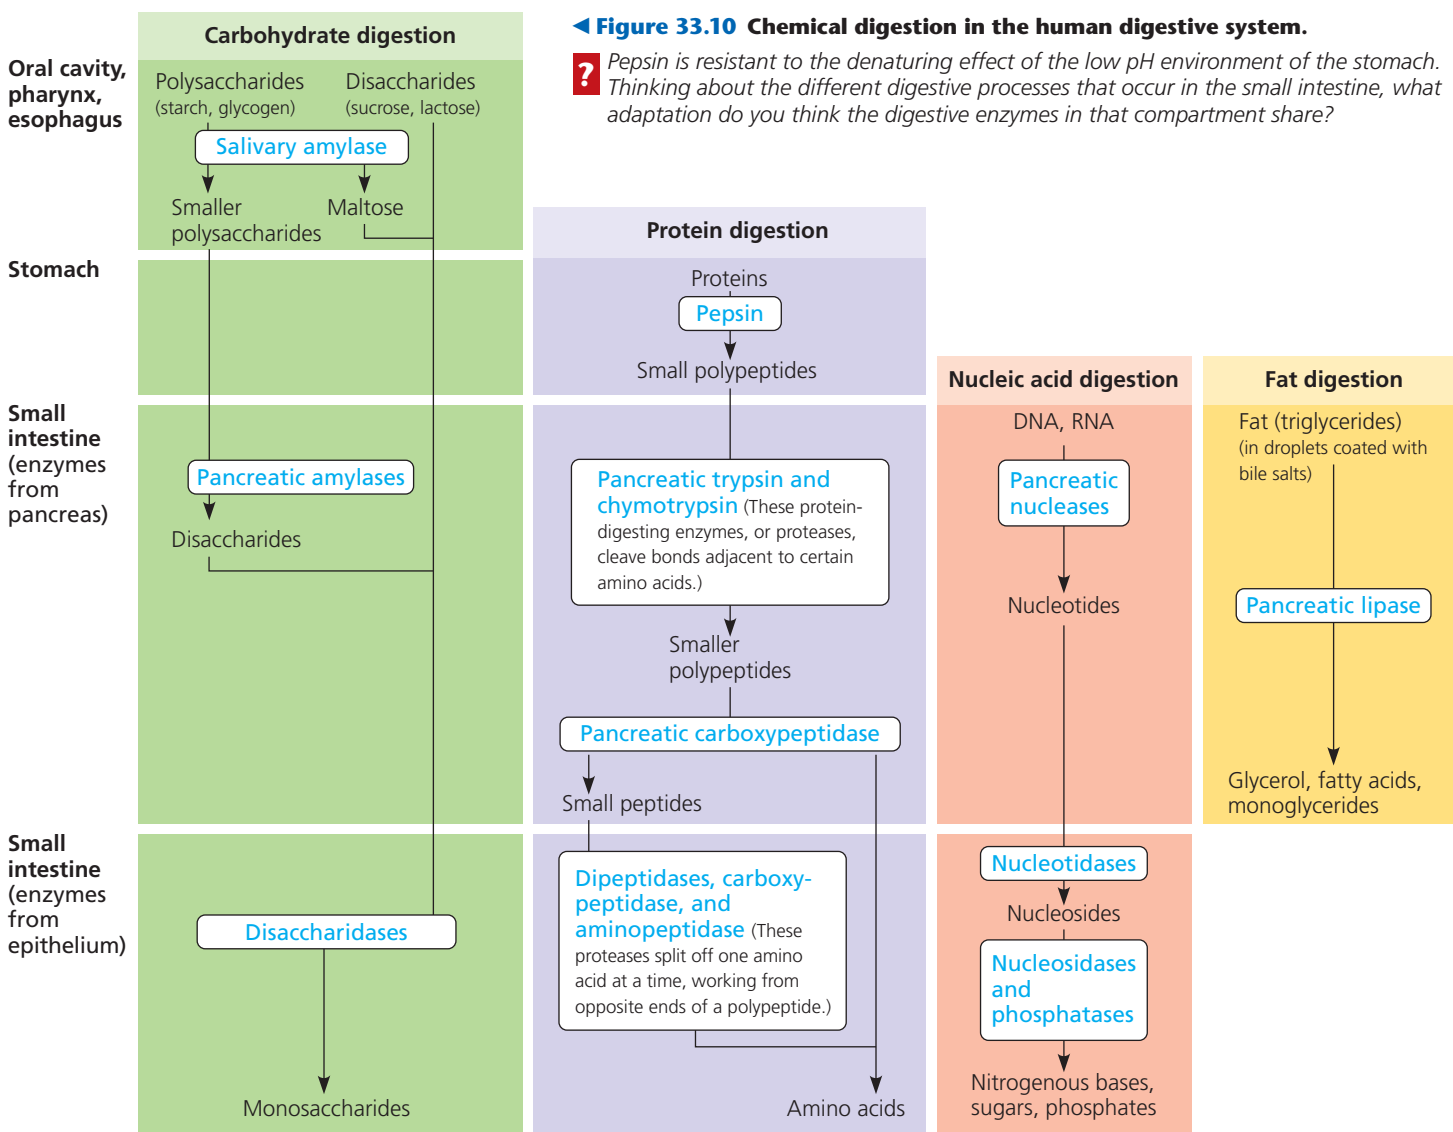

Why doesn't gastric juice destroy the stomach cells that make it? The answer is that the ingredients of gastric juice are kept inactive until they are released into the lumen (cavity) of the stomach. The components of gastric juice are produced by cells in the gastric glands of the stomach. As detailed in Figure 33.9, *parietal cells* and *chief cells* function together to produce HCl and pepsin in the lumen of the stomach, not within the cells themselves.

Why don't HCl and pepsin damage the cells that line the stomach? Actually, these cells are vulnerable to gastric juice as

well as to acid-tolerant pathogens in food or water. However, the stomach lining protects against self-digestion by secreting mucus. In addition, cell division adds a new epithelial layer every three days, replacing cells eroded by digestive juices. Despite these defenses, damaged areas of the stomach lining called gastric ulcers do sometimes appear. For decades, scientists thought that psychological stress and resulting excess acid secretion caused ulcers. In 1982, however, Australian researchers Barry Marshall and Robin Warren reported that infection by the acid-tolerant bacterium *Helicobacter pylori* causes ulcers. They also demonstrated that an antibiotic treatment could cure most gastric ulcers. For these findings, they were awarded the Nobel Prize in 2005.

## Stomach Dynamics

Chemical digestion by gastric juice is facilitated by the churning action of the stomach. This coordinated series of muscle contractions and relaxations mixes the stomach contents about every 20 seconds. As a result of mixing and enzyme action, what begins as a recently swallowed meal becomes the

acidic, nutrient-rich broth known as chyme. Most of the time, sphincters close off the stomach at both ends (see Figure 33.8). The sphincter between the esophagus and the stomach normally opens only when a bolus arrives. Occasionally, however, a person experiences acid reflux, a backflow of chyme from the stomach into the lower end of the esophagus. The resulting irritation of the esophagus is commonly called “heartburn.”

Peristaltic contractions typically move the contents of the stomach into the small intestine within 2–6 hours after a meal. The sphincter located where the stomach opens to the small intestine helps regulate passage into the small intestine, allowing only one squirt of chyme at a time.

## Digestion in the Small Intestine

Although chemical digestion of some nutrients begins in the oral cavity or stomach, most enzymatic hydrolysis of macromolecules from food occurs in the **small intestine**. The small intestine is the alimentary canal’s longest compartment—over 6 m (20 feet) long in humans! Its name refers to its small diameter, compared with that of the large intestine. The first 25 cm or so of the small intestine forms the **duodenum**. It is here that chyme from the stomach mixes with digestive juices from the pancreas, liver, and gallbladder, as well as from gland cells of the intestinal wall itself.

### Pancreatic Secretions

The **pancreas** aids chemical digestion by producing an alkaline solution rich in bicarbonate as well as several enzymes (see Figure 33.10). The bicarbonate neutralizes the acidity of chyme and acts as a buffer. Among the pancreatic enzymes are trypsin and chymotrypsin, proteases secreted into the duodenum in

inactive forms. In a chain reaction similar to activation of pepsin (see Figure 33.9), they are activated when safely located in the lumen within the duodenum.

### Bile Production by the Liver

Digestion of fats and other lipids begins in the small intestine and relies on the production of **bile**, a mixture of substances that is made in the **liver**. Bile contains bile salts, which act as emulsifiers (detergents) that aid in digestion and absorption of lipids. Bile is stored and concentrated in the **gallbladder**.

Bile production is integral to one of the other vital functions of the liver: the destruction of red blood cells that are no longer fully functional. In producing bile, the liver incorporates some pigments that are by-products of red blood cell disassembly. These bile pigments are then eliminated from the body with the feces. In some liver or blood disorders, bile pigments accumulate in the skin, resulting in a characteristic yellowing condition called jaundice.

### Secretions of the Small Intestine

The epithelial lining of the duodenum is the source of several digestive enzymes (see Figure 33.10). Some are secreted into the lumen of the duodenum, whereas others are bound to the surface of epithelial cells.

While enzymatic hydrolysis proceeds, peristalsis moves the mixture of chyme and digestive juices along the small intestine. Most digestion is completed in the duodenum. The remaining regions of the small intestine, the *jejunum* and *ileum*, are the major site for absorption of nutrients, as illustrated in **Figure 33.11** and discussed next.

**▲ Figure 33.11 Nutrient absorption in the small intestine.**

**?** Tapeworms sometimes infect humans, anchoring themselves to the wall of the small intestine. Based on the way digestion is compartmentalized along the mammalian alimentary canal, what digestive functions would you expect these parasites to have?

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Membrane Transport.

## Absorption in the Small Intestine

To reach body tissues, nutrients in the lumen must first cross the lining of the alimentary canal. Most of this absorption occurs across the highly folded surface of the small intestine, as illustrated in Figure 33.11. Large folds in the lining are studded with finger-like projections called **villi**. In turn, each epithelial cell of a villus has many microscopic projections, or **microvilli**, that are exposed to the intestinal lumen. The microvilli give cells of the intestinal epithelium a brush-like appearance that is reflected in the name *brush border*. Together, the folds, villi, and microvilli of the small intestine have a surface area of 200–300 m<sup>2</sup>, roughly the size of a tennis court. This enormous surface area is an evolutionary adaptation that greatly increases the rate of nutrient absorption.

Depending on the nutrient, transport across the epithelial cells can be passive or active (see Chapter 5). The sugar fructose, for example, moves by facilitated diffusion down its concentration gradient from the lumen of the small intestine into the epithelial cells. From there, fructose exits the basal surface and is absorbed into microscopic blood vessels, or capillaries, at the core of each villus. Other nutrients, including amino acids, small peptides, vitamins, and most glucose molecules, are pumped against concentration gradients by the epithelial cells of the villus.

The capillaries and veins that carry nutrient-rich blood away from the villi converge into the **hepatic portal vein**, a blood vessel that leads directly to the liver. From the liver, blood travels to the heart and then to other tissues and organs. This arrangement serves two major functions. First, it allows the liver to regulate the distribution of nutrients to the rest of the body. Because the liver can interconvert many organic molecules, blood that leaves the liver may have a very different nutrient balance than the blood that entered. Second, the arrangement allows the liver to remove toxic substances before the blood circulates broadly. The liver is the primary site for the detoxification of many organic molecules, including drugs, that are foreign to the body.

Although many nutrients leave the small intestine through the bloodstream, some products of fat (triglyceride) digestion take a different path (**Figure 33.12**). Hydrolysis of a fat by lipase generates fatty acids and a monoglyceride (glycerol joined to a fatty acid). These products are absorbed by epithelial cells and recombined into triglycerides. They are then coated with phospholipids, cholesterol, and proteins, forming water-soluble globules called **chylomicrons**.

In exiting the intestine, chylomicrons first enter a **lacteal**, a vessel at the core of each villus (see Figures 33.11 and 33.12). Lacteals are part of the lymphatic system, which is a network of vessels filled with a clear fluid called lymph. Starting at the lacteals, lymph containing the chylomicrons passes into the larger vessels of the lymphatic system and eventually into large veins that return the blood to the heart.

▲ **Figure 33.12 Absorption of fats.** Because fats are insoluble in water, adaptations are needed to digest and absorb them. Bile salts (not shown) break up large fat droplets and maintain a small droplet size in the intestinal lumen, increasing surface area for enzymatic hydrolysis. The fatty acids and monoglycerides released by hydrolysis can diffuse into epithelial cells, where fats are reassembled and incorporated into water-soluble chylomicrons that enter the lymphatic system.

## Absorption in the Large Intestine

The alimentary canal ends with the **large intestine**, which includes the colon, cecum, and rectum. The small intestine connects to the large intestine at a T-shaped junction (**Figure 33.13**). One arm of the T is the 1.5-m-long **colon**, which leads to the rectum and anus. The other arm is a pouch called the **cecum**. The cecum is important for fermenting ingested material, especially in animals that eat large amounts of plant material.

▲ **Figure 33.13 Junction of the small and large intestines.** Compared with many other

mammals, humans have a small cecum. The **appendix**, a finger-like extension of the human cecum, has a minor and dispensable role in immunity.

A major function of the colon is to recover water that has entered the alimentary canal as the solvent of digestive juices. About 7 L of fluid is secreted into the lumen of the alimentary canal each day, and about 90% of that is reabsorbed in the small intestine and colon. There is no mechanism for active transport of water. Instead, water is reabsorbed by osmosis when sodium and other ions are pumped out of the lumen of the colon.

The **feces**, the wastes of the digestive system, become increasingly solid as they are moved along the colon by peristalsis. It takes approximately 12–24 hours for material to travel the length of the colon. If the lining of the colon is irritated—by a viral or bacterial infection, for instance—less water than normal may be reabsorbed, resulting in diarrhea. The opposite problem, constipation, occurs when the feces move along the colon too slowly. Too much water is reabsorbed and the feces become compacted.

A rich community of mostly harmless bacteria lives on unabsorbed organic material in the human colon, contributing approximately one-third of the dry weight of feces. Some bacteria produce vitamins that are absorbed into the blood, supplementing our dietary intake. One bacterial inhabitant, *Escherichia coli*, is so common in the human digestive system that its presence in lakes and streams is a useful indicator of contamination by untreated sewage. As by-products of their metabolism, many colon bacteria generate gases, including methane and hydrogen sulfide, the latter of which has an offensive odor. These gases and ingested air are expelled through the anus.

Besides bacteria, feces contain undigested material, including cellulose fiber. Although it provides no caloric value (energy) to humans, fiber helps move food along the alimentary canal.

The terminal portion of the large intestine is the **rectum**, where feces are stored until they can be eliminated. Between the rectum and the anus are two sphincters, the inner one being involuntary and the outer one being voluntary. Periodically, strong contractions of the colon create an urge to defecate. Because filling of the stomach triggers a reflex that increases the rate of contractions in the colon, the urge to defecate often follows a meal.

We have followed a meal from one opening (the mouth) of the alimentary canal to the other (the anus). Next we'll look at some adaptations of this general digestive plan in different animals.

### CONCEPT CHECK 33.3

1. How does swallowed food reach the stomach of a weightless astronaut in orbit?
2. Explain why a proton pump inhibitor, such as the drug Prilosec, relieves the symptoms of acid reflux.
3. **WHAT IF?** If you mixed gastric juice with crushed food in a test tube, what would happen?

For suggested answers, see Appendix A.

## CONCEPT 33.4

### Evolutionary adaptations of vertebrate digestive systems correlate with diet

**EVOLUTION** The digestive systems of mammals and other vertebrates are variations on a common plan, but there are many intriguing adaptations, often associated with the animal's diet. To highlight how form fits function, we'll examine a few of them.

#### Dental Adaptations

Dentition, an animal's assortment of teeth, is one example of structural variation reflecting diet (**Figure 33.14**). The

▼ **Figure 33.14 Dentition and diet.**

##### Carnivore

Carnivores, such as members of the dog and cat families, generally have large, pointed incisors and canines that can be used to kill prey and rip or cut away pieces of flesh. The jagged premolars and molars crush and shred food.

##### Herbivore

Herbivores, such as horses and deer, usually have premolars and molars with broad, ridged surfaces that grind tough plant material. The incisors and canines are generally modified for biting off pieces of vegetation. In some herbivores, canines are absent.

##### Omnivore

As omnivores, humans are adapted to eating both plants and meat. Adults have 32 teeth. From front to back along either side of the mouth are four blade-like incisors for biting, a pair of pointed canines for tearing, four premolars for grinding, and six molars for crushing (see inset, top view).

**Key** ■ Incisors ■ Canines ■ Premolars ■ Molars

evolutionary adaptation of teeth for processing different kinds of food is one of the major reasons mammals have been so successful. Nonmammalian vertebrates generally have less specialized dentition, but there are interesting exceptions. For example, venomous snakes, such as rattlesnakes, have fangs, modified teeth that inject venom into prey. Some fangs are hollow, like syringes, whereas others drip the toxin along grooves on the surfaces of the teeth.

## Mutualistic Adaptations

Some digestive adaptations involve mutualistic symbiosis, a mutually beneficial interaction between two species (see Chapter 41). For example, microorganisms help herbivores digest plants. Much of the chemical energy in herbivore diets comes from the cellulose of plant cell walls, but animals do not produce enzymes that hydrolyze cellulose. Instead, many vertebrates (as well as termites, whose wooden diets consist largely of cellulose) host mutualistic bacteria and protists in fermentation chambers in their alimentary canals. These microorganisms have enzymes that can digest cellulose to simple sugars and other compounds that the animal can absorb. In many cases, the microorganisms also use the sugars from digested cellulose in the production of a variety of nutrients essential to the animal, such as vitamins and amino acids.

In horses and koalas, symbiotic microorganisms are housed in a large cecum; in rabbits and some rodents, mutualistic bacteria live in the large intestine and cecum. Since most nutrients are absorbed in the small intestine, nourishing by-products of fermentation by bacteria in the large intestine are initially lost with the feces. Rabbits and rodents recover these nutrients by *coprophagy* (from the Greek, meaning “dung eating”), feeding on some of their feces and then passing the food through the alimentary canal a second time. The familiar rabbit “pellets,” which are not reingested, are the feces eliminated after food has passed through the digestive tract twice.

The most elaborate adaptations for an herbivorous diet have evolved in the animals called **ruminants**, which include deer, sheep, and cattle (**Figure 33.15**).

## Stomach and Intestinal Adaptations

Variation in the dimensions of digestive organs also reflects evolutionary adaptation to differences in diet. For example, large, expandable stomachs are common in carnivorous vertebrates, which may wait a long time between meals and must eat as much as they can when they do catch prey. A 200-kg African lion can consume 40 kg of meat in one meal!

Adaptation is likewise apparent in the length of the digestive system in different vertebrates. In general, herbivores and omnivores have longer alimentary canals relative to their body size than do carnivores (**Figure 33.16**). As we have seen, plant

▲ **Figure 33.15 Ruminant digestion.** The stomach of a ruminant has four chambers. Chewed food first enters the rumen and reticulum, where mutualistic microorganisms digest cellulose in the plant material. Periodically, the cow regurgitates and rechews “cud” from the reticulum, further breaking down fibers and thereby enhancing microbial action. The reswallowed cud passes to the omasum, where some water is removed, and then to the abomasum, for digestion by the cow’s enzymes. In this way, the cow obtains significant nutrients from both the grass and the mutualistic microorganisms, which maintain a stable population in the rumen.

▲ **Figure 33.16 The alimentary canals of a carnivore (coyote) and herbivore (koala).** The relatively short digestive tract of the coyote is sufficient for digesting meat and absorbing its nutrients. In contrast, the koala’s long alimentary canal is specialized for digesting eucalyptus leaves. Extensive chewing chops the leaves into tiny pieces, increasing exposure to digestive juices. In the long cecum and the upper portion of the colon, symbiotic bacteria convert the shredded leaves to a more nutritious diet.

matter is more difficult to digest than meat because it contains cell walls. A longer digestive tract furnishes more time for digestion and more surface area for the absorption of nutrients. As an example, consider the koala and coyote in Figure 33.16. Although these two mammals are about the same size, the koala's intestines are much longer, enhancing the processing of fibrous, protein-poor eucalyptus leaves from which the koala obtains nearly all of its food and water.

Having examined how animals optimize their extraction of nutrients from food, we will next turn to the challenge of balancing the use of these nutrients.

#### CONCEPT CHECK 33.4

1. What are two advantages of a longer alimentary canal for processing plant material that is difficult to digest?
2. What features of a mammal's digestive system make it an attractive habitat for mutualistic microorganisms?
3. **WHAT IF?** "Lactose-intolerant" people have a shortage of lactase, the enzyme that breaks down lactose in milk. As a result, they sometimes develop cramps, bloating, or diarrhea after consuming dairy products. Suppose such a person ate yogurt containing bacteria that produce lactase. Why would eating yogurt likely provide at best only temporary relief of the symptoms?

For suggested answers, see Appendix A.

## CONCEPT 33.5

### Feedback circuits regulate digestion, energy allocation, and appetite

The processes that enable an animal to obtain nutrients are matched to the organism's circumstances and need for energy.

#### Regulation of Digestion

Many animals have long intervals between meals and do not need their digestive systems to be active continuously. Instead, each step in processing is activated as food reaches a new compartment in the alimentary canal. The arrival of food triggers the secretion of substances that promote the next stage of chemical digestion, as well as muscular contractions that propel food farther along the canal. For example, you learned earlier that nervous reflexes stimulate the release of saliva when food enters the oral cavity and orchestrate swallowing when a bolus of food reaches the pharynx. Similarly, the arrival of food in the stomach triggers churning and the release of gastric juices. A branch of the nervous system called the *enteric division*, which is dedicated to the digestive organs, regulates these events as well as peristalsis in the small and large intestines.

The endocrine system also plays a critical role in controlling digestion. As described in **Figure 33.17**, a series of hormones released by the stomach and duodenum help ensure that

▲ **Figure 33.17** Hormonal control of digestion.

digestive secretions are present only when needed. Like all hormones, they are transported through the bloodstream. This is true even for the hormone gastrin, whose target (the stomach) is the same organ that secretes it.

## Energy Allocation

Digested food provides animals with chemical energy to fuel metabolism and activity. In turn, the flow and transformation of energy in an animal—its **bioenergetics**—determine nutritional needs (Figure 33.18). Energy extracted from nutrients is converted to ATP by cellular respiration and fermentation. Stores of ATP enable cells, organs, and organ systems to perform the functions that keep an animal alive. ATP is also used in biosynthesis, which is needed for body growth and repair, for energy storage, and for reproduction. The production and use of ATP generate heat, which the animal eventually gives off to its surroundings.

How much of the total energy obtained from food does an animal need just to stay alive? How much energy must be expended to walk, run, swim, or fly from one place to another? What fraction of the energy intake is used for reproduction? Physiologists answer such questions by measuring the rate

▲ **Figure 33.18 Bioenergetics of an animal: an overview.**

**MAKE CONNECTIONS** Review the idea of energy coupling (see Concept 6.3). Then use that idea to explain why heat is produced in the absorption of nutrients, in cellular respiration, and in the synthesis of large biological molecules.

at which an animal uses chemical energy and how this rate changes in different circumstances.

An animal's energy use per unit of time is called its **metabolic rate**. Energy is measured in joules or in calories and kilocalories; 1 kcal = 1,000 cal = 4,184 J. (The unit Calorie, with a capital C, as used by many nutritionists, is actually a kilocalorie.) Because nearly all chemical energy used eventually appears as heat, metabolic rate can be measured by monitoring an animal's rate of heat loss. For this approach, researchers use a calorimeter, which is a recording device in a closed, insulated chamber. Metabolic rate can also be determined from the amount of oxygen consumed or carbon dioxide produced. To calculate metabolic rate over longer periods, researchers record the rate of food consumption, the energy content of the food, and the chemical energy lost in waste products (see Figure 33.18).

## Minimum Metabolic Rate

Animals must maintain a minimum metabolic rate for basic functions such as cell maintenance, breathing, and heart-beat. Researchers measure this minimum metabolic rate differently for endotherms and ectotherms. The minimum metabolic rate of a nongrowing endotherm that is at rest, has an empty stomach, and is not experiencing stress is called the *basal metabolic rate* (BMR). BMR is measured under a “comfortable” temperature range—a range that requires no generation or shedding of heat above the minimum. For ectotherms, the minimum metabolic rate must instead be determined at a specific temperature because changes in the environmental temperature alter body temperature and therefore metabolic rate. The metabolic rate of a fasting, nonstressed ectotherm at rest at a particular temperature is called its *standard metabolic rate* (SMR).

Comparisons of minimum metabolic rates confirm that endothermy and ectothermy have different energy costs. The BMR per day for adult humans averages 1,600–1,800 kcal for males and 1,300–1,500 kcal for females. These BMRs are about equivalent to the rate of energy use by a ceiling fan or an electric blanket. In contrast, the SMR of an American alligator is about 60 kcal per day at 20°C (68°F), less than  $\frac{1}{30}$  the energy used by a comparably sized adult human.

For both ectotherms and endotherms, activity greatly affects metabolic rate. Even a person reading quietly at a desk or an insect twitching its wings consumes energy beyond the BMR or SMR. Maximum metabolic rates (the highest rates of ATP use) occur during peak activity, such as lifting heavy weights, sprinting, or high-speed swimming. In general, the maximum metabolic rate an animal can sustain is inversely related to the duration of activity.

For most terrestrial animals, the average daily rate of energy consumption is 2 to 4 times BMR (for endotherms) or SMR (for ectotherms). People in most developed countries have an unusually low average daily metabolic rate of about 1.5 times BMR—an indication of their relatively sedentary lifestyles.

## Regulation of Energy Storage

When an animal takes in more energy-rich molecules than it needs for metabolism and activity, it stores the excess energy. In humans, the first sites used for energy storage are liver and muscle cells. In these cells, excess energy from the diet is stored in glycogen, a polymer made up of many glucose units. Once glycogen depots are full, any additional excess energy is usually stored in fat in adipose cells.

When fewer calories are taken in than are expended—perhaps because of sustained heavy exercise or lack of food—the human body generally expends liver glycogen first and then draws on muscle glycogen and fat. Fats are especially rich in energy; oxidizing a gram of fat liberates about twice the energy liberated from a gram of carbohydrate or protein. For this reason, adipose tissue provides the most space-efficient way for the body to store large amounts of energy. Most healthy people have enough stored fat to sustain them through several weeks without food.

## Glucose Homeostasis

The synthesis and breakdown of glycogen are central not only to energy storage, but also to maintaining metabolic balance through glucose homeostasis. Tissues throughout the body rely on the generation of ATP by glucose oxidation to fuel cellular processes (see Chapter 7). The pancreatic hormones insulin and glucagon maintain glucose homeostasis by tightly regulating the synthesis and breakdown of glycogen.

The liver is a key site for glucose regulation (**Figure 33.19**). When insulin levels rise after a carbohydrate-rich meal, glucose entering the liver in the hepatic portal vein is used to synthesize glycogen. Between meals, when blood in the hepatic portal vein has a much lower glucose concentration, glucagon stimulates the liver to break down glycogen, releasing glucose into the

blood. Because insulin and glucagon have opposing effects, the combined activity of these two hormones maintains a glucose concentration of 70–110 mg per 100 mL of blood exiting the liver at nearly all times.

Glucagon and insulin are produced in the pancreas. Scattered throughout this organ are clusters of endocrine cells called pancreatic islets. Each pancreatic islet has *alpha cells*, which make glucagon, and *beta cells*, which make insulin. Like all hormones, insulin and glucagon are secreted into the interstitial fluid and from there enter the circulatory system.

## Diabetes Mellitus

A number of disorders can disrupt glucose homeostasis with potentially serious consequences, especially for the heart, blood vessels, eyes, and kidneys. The best known and most prevalent is **diabetes mellitus**, a disease caused by a deficiency of insulin or a decreased response to insulin in target cells. Blood glucose levels rise, but cells are unable to take up enough glucose to meet metabolic needs. Instead, fat becomes the main substrate for cellular respiration. In severe cases, acidic metabolites formed during fat breakdown accumulate in the blood, threatening life by lowering blood pH and depleting sodium and potassium ions from the body.

In people with diabetes mellitus, the level of glucose in the blood may exceed the capacity of the kidneys to reabsorb this nutrient. Glucose that remains in the kidney filtrate is excreted. For this reason, the presence of sugar in urine is one test for this disorder. As glucose is concentrated in the urine, more water is excreted along with it, resulting in excessive volumes of urine. *Diabetes* (from the Greek *diabainein*, to pass through) refers to this copious urination; and *mellitus* (from the Greek *meli*, honey) refers to the presence of sugar in urine.

► **Figure 33.19 Homeostatic regulation of cellular fuel.** After a meal is digested, glucose and other monomers are absorbed into the blood from the digestive tract. The human body regulates the use and storage of glucose, a major cellular fuel.

**MAKE CONNECTIONS** What form of feedback control does each of these regulatory circuits reflect (see Concept 32.1)?

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Homeostasis: Regulating Blood Sugar.

Insulin enhances the transport of glucose into body cells and stimulates liver and muscle cells to store glucose as glycogen. As a result, the blood glucose level drops.

Glucagon promotes the breakdown of glycogen in the liver and the release of glucose into the blood, increasing the blood glucose level.

There are two main types of diabetes mellitus. *Type 1 diabetes*, or insulin-dependent diabetes, is an autoimmune disorder in which the immune system destroys the insulin-producing beta cells of the pancreas. Treatment consists of insulin, typically injected several times daily. *Type 2 diabetes*, or non-insulin-dependent diabetes, is characterized by a failure of target cells to respond normally to insulin. Insulin is produced, but target cells fail to take up glucose from the blood, and blood glucose levels remain elevated. Although heredity can play a role in type 2 diabetes, excess body weight and lack of exercise significantly increase the risk. Type 2 diabetes is the seventh most common cause of death in the United States.

### Regulation of Appetite and Consumption

Consuming more calories than the body needs for normal metabolism, or *overnourishment*, can lead to obesity, the excessive accumulation of fat. Obesity, in turn, contributes to a

number of health problems, including type 2 diabetes, cancer of the colon and breast, and cardiovascular disease that can lead to heart attacks and strokes. Obesity is a factor in an estimated 300,000 deaths per year in the United States.

Researchers have discovered several homeostatic mechanisms that help regulate body weight. Operating as feedback circuits, these mechanisms control the storage and metabolism of fat. Several hormones regulate long-term and short-term appetite by affecting a “satiety center” in the brain. For example, *ghrelin*, a hormone secreted by the stomach wall, triggers feelings of hunger before meals. In contrast, both insulin and *PYY*, a hormone secreted by the small intestine after meals, suppress appetite. *Leptin*, a hormone produced by adipose (fat) tissue, also suppresses appetite and appears to play a major role in regulating body fat levels. In the **Scientific Skills Exercise**, you’ll interpret data from an experiment studying genes that affect leptin production and function in mice.

### Scientific Skills Exercise

#### Interpreting Data from an Experiment with Genetic Mutants

**What Are the Roles of the *ob* and *db* Genes in Appetite Regulation?** A mutation that disrupts a physiological process is often used to study the normal function of the mutated gene. Ideally, researchers use a standard set of conditions and compare animals that differ genetically only in whether a particular gene is mutant (nonfunctional) or wild-type (normal). In this way, a difference in phenotype, the physiological property being measured, can be attributed to a difference in genotype, the presence or absence of the mutation. To study the role of specific genes in regulating appetite, researchers used laboratory animals with known mutations in those genes.

Mice in which recessive mutations inactivate both copies of either the *ob* gene or the *db* gene eat voraciously and grow much more massive than wild-type mice. In the photograph below, the mouse on the right is wild-type, whereas the obese mouse on the left has an inactivating mutation in both copies of the *ob* gene.

One hypothesis for the normal role of the *ob* and *db* genes is that they participate in a hormone pathway that suppresses appetite when caloric intake is sufficient. Before setting out to isolate the potential hormone, researchers explored this hypothesis genetically.

**How the Experiment Was Done** The researchers measured the mass of young subject mice of various genotypes and surgically linked the circulatory system of each one to that of another mouse. This procedure ensured that any factor circulating in the bloodstream of either mouse would be transferred to the other in the pair. After eight weeks, they again measured the mass of each subject mouse.

#### Data from the Experiment

Genotype Pairing (red type indicates mutant genes)			Average Change in Body Mass of Subject (g)
Subject	Paired with		
(a)	<i>ob</i> <sup>+</sup> / <i>ob</i> <sup>+</sup> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	<i>ob</i> <sup>+</sup> / <i>ob</i> <sup>+</sup> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	8.3
(b)	<i>ob</i> / <i>ob</i> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	<i>ob</i> / <i>ob</i> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	38.7
(c)	<i>ob</i> / <i>ob</i> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	<i>ob</i> <sup>+</sup> / <i>ob</i> <sup>+</sup> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	8.2
(d)	<i>ob</i> / <i>ob</i> , <i>db</i> <sup>+</sup> / <i>db</i> <sup>+</sup>	<i>ob</i> <sup>+</sup> / <i>ob</i> <sup>+</sup> , <i>db</i> / <i>db</i>	−14.9*

\* Due to pronounced weight loss and weakening, subjects in this pairing were remeasured after less than eight weeks.

#### Interpret the Data

1. First, practice reading the genotype information given in the data table. For example, pairing (a) joined two mice that each had the wild-type version of both genes. Describe the two mice in pairing (b), in pairing (c), and pairing (d). Explain how each pairing contributed to the experimental design.
2. Compare the results observed for pairing (a) and for pairing (b) in terms of phenotype. If the results had been identical for these two pairings, what would that outcome have implied about the experimental design?
3. Compare the results observed for pairing (c) to those observed for pairing (b). Based on these results, does the *ob*<sup>+</sup> gene product appear to promote or suppress appetite? Explain your answer.
4. Describe the results observed for pairing (d). Note how this result contrasts with the experiment in pairing (b). Suggest a hypothesis to explain this result. How could you test your hypothesis using the kinds of mice in this study?

**Data from** D. L. Coleman, Effects of parabiosis of obese mice with diabetes and normal mice. *Diabetologia* 9:294–298 (1973).

 A version of this Scientific Skills Exercise, as well as a related Experimental Inquiry Tutorial, can be assigned in MasteringBiology.

Our understanding of leptin may lead to treatments for obesity, but questions remain. For one thing, most obese people have a high leptin level that somehow fails to elicit a response from the brain's satiety center. Clearly, there is still much to learn in this important area of human physiology.

The processes of obtaining, digesting, absorbing, and storing nutrients are part of the larger story of how animals fuel their activities. Provisioning the body also involves distributing nutrients (circulation), and using nutrients for metabolism requires exchanging respiratory gases with the environment. The closely related circulatory and respiratory systems are explored in our next chapter.

### CONCEPT CHECK 33.5

1. Explain how people can become obese even if their intake of dietary fat is relatively low compared with carbohydrate intake.
2. The energy required to maintain each gram of body mass is much greater for a mouse than for an elephant. What can you conclude about metabolic rates for the mouse and the elephant?
3. **WHAT IF?** Consider a diabetes patient who has a family history of type 2 diabetes but is active and not obese. To identify genes that might be defective in the patient, which genes would you examine first?

For suggested answers, see Appendix A.

## 33 Chapter Review

### SUMMARY OF KEY CONCEPTS

- Animals have diverse diets. **Herbivores** mainly eat plants; **carnivores** mainly eat other animals; and **omnivores** eat both. Animals must balance consumption, storage, and use of food.

#### CONCEPT 33.1

#### An animal's diet must supply chemical energy, organic molecules, and essential nutrients (pp. 666–668)

- Food provides animals with energy for ATP production, carbon skeletons for biosynthesis, and **essential nutrients**—nutrients that must be supplied in preassembled form. Essential nutrients include certain amino acids and fatty acids that animals cannot synthesize; **vitamins**, which are organic molecules; and **minerals**, which are inorganic substances.
- Animals can suffer from two types of malnutrition: an inadequate intake of essential nutrients and a deficiency in sources of chemical energy. Studies of genetic defects and of disease at the population level help researchers determine human dietary requirements.

**?** How can an enzyme cofactor needed for a process essential to all animals be an essential nutrient (vitamin) for only some?

#### CONCEPT 33.2

#### The main stages of food processing are ingestion, digestion, absorption, and elimination (pp. 668–671)

- Food processing in animals involves **ingestion** (eating), **digestion** (enzymatic breakdown of large molecules), **absorption** (uptake of nutrients by cells), and **elimination** (passage of undigested materials out of the body in feces).
- Animals differ in the ways they obtain and ingest food. Many animals are **bulk feeders**, eating large pieces of food.
- Compartmentalization is necessary to avoid self-digestion. In intracellular digestion, food particles are engulfed by endocytosis and digested within food vacuoles that have fused with lysosomes. In extracellular digestion, which is used by most animals, enzymatic hydrolysis occurs outside cells in a **gastrovascular cavity** or **alimentary canal**.

**?** Propose an artificial diet that would eliminate the need for one of the first three steps in food processing.

#### CONCEPT 33.3

#### Organs specialized for sequential stages of food processing form the mammalian digestive system (pp. 671–676)

- The mammalian digestive system is composed of a tubular alimentary canal and accessory glands that secrete digestive juices into the canal. Food is pushed along the alimentary canal by **peristalsis**. Digestion and absorption occur in specialized portions of the canal.

**?** What structural feature of the small intestine makes it better suited for absorption of nutrients than the stomach?

#### CONCEPT 33.4

#### Evolutionary adaptations of vertebrate digestive systems correlate with diet (pp. 676–678)

- Vertebrate digestive systems display many evolutionary adaptations associated with diet. For example, dentition, which is the assortment of teeth, generally correlates with diet. Many herbivores, including cows, also have fermentation chambers where microorganisms digest cellulose, a form of mutualism. In addition, herbivores usually have longer alimentary canals than carnivores, reflecting the longer time needed to digest vegetation.

**?** How does human anatomy indicate that our ancestors were not strict vegetarians?

## CONCEPT 33.5

### Feedback circuits regulate digestion, energy allocation, and appetite (pp. 678–682)

- Nutrition is regulated at multiple levels. Food in the alimentary canal triggers nervous and hormonal responses that control the secretion of digestive juices and that promote the movement of ingested material through the canal. The availability of glucose for energy production is regulated by the hormones insulin and glucagon, which control the synthesis and breakdown of glycogen.
- Animals obtain chemical energy from food. The total amount used in a unit of time defines an animal's metabolic rate. Animals allocate energy for basal (or standard) metabolism, activity, growth, and reproduction.
- Vertebrates store excess calories in glycogen (in liver and muscle cells) and in fat (in adipose cells). These energy stores can be tapped when an animal expends more calories than it consumes. If, however, an animal consumes more calories than it needs for normal metabolism, the resulting overnourishment can lead to the serious health problem of obesity.
- Several hormones, including leptin and insulin, regulate appetite by affecting the brain's satiety center.

**?** Explain why your stomach might make growling noises when you skip a meal.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. The mammalian trachea and esophagus both connect to the
  - a. large intestine.
  - b. stomach.
  - c. pharynx.
  - d. rectum.
  - e. gastrovascular cavity.
2. Which of the following organs is *incorrectly* paired with its function?
  - a. stomach—protein digestion
  - b. oral cavity—starch digestion
  - c. large intestine—bile production
  - d. small intestine—nutrient absorption
  - e. pancreas—enzyme production
3. Which of the following is *not* a major activity of the stomach?
  - a. mechanical digestion
  - b. HCl secretion
  - c. mucus secretion
  - d. nutrient absorption
  - e. enzyme secretion
4. Fat digestion yields fatty acids and glycerol, whereas protein digestion yields amino acids; both digestive processes
  - a. are catalyzed by the same enzyme.
  - b. occur inside cells in most animals.
  - c. add a water molecule to break bonds.
  - d. require a low pH resulting from HCl production.
  - e. consume ATP.

### Level 2: Application/Analysis

5. After surgical removal of an infected gallbladder, a person must be especially careful to restrict dietary intake of
  - a. starch.
  - b. protein.
  - c. sugar.
  - d. fat.
  - e. water.
6. If you were to jog 1 km a few hours after lunch, which stored fuel would you probably tap?
  - a. muscle proteins
  - b. muscle and liver glycogen
  - c. fat stored in the liver
  - d. fat stored in adipose tissue
  - e. blood proteins

### Level 3: Synthesis/Evaluation

7. **DRAW IT** Make a flowchart of the events that occur after partially digested food leaves the stomach. Use the following terms: bicarbonate secretion, circulation, decrease in acidity, secretin secretion, increase in acidity, signal detection. Next to each term, indicate the compartment(s) involved. You may use terms more than once.
8. **SCIENTIFIC INQUIRY**  
In human populations of northern European origin, the disorder called hemochromatosis causes excess iron uptake from food and affects one in 200 adults. Among adults, men are ten times as likely as women to suffer from iron overload. Taking into account the existence of a menstrual cycle in humans, devise a hypothesis for this difference.
9. **FOCUS ON EVOLUTION**  
The human esophagus and trachea share a passage leading from the mouth and nasal passages, which can cause problems. How does the evolutionary concept of descent with modification explain this “imperfect” anatomy? (See Concept 21.4.)
10. **FOCUS ON ORGANIZATION**  
Hair is largely made up of the protein keratin. In a short essay (100–150 words), explain why a shampoo containing protein is not effective in replacing the protein in damaged hair.

For selected answers, see Appendix A.

# 34

## Circulation and Gas Exchange

▼ **Figure 34.1** How does a feathery fringe help this animal survive?

### KEY CONCEPTS

- 34.1** Circulatory systems link exchange surfaces with cells throughout the body
- 34.2** Coordinated cycles of heart contraction drive double circulation in mammals
- 34.3** Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels
- 34.4** Blood components function in exchange, transport, and defense
- 34.5** Gas exchange occurs across specialized respiratory surfaces
- 34.6** Breathing ventilates the lungs
- 34.7** Adaptations for gas exchange include pigments that bind and transport gases

### OVERVIEW

## Trading Places

The animal in **Figure 34.1** may look like a creature from a science fiction film, but it's actually an axolotl, an amphibian native to shallow ponds in central Mexico. Unlike other amphibians, an axolotl doesn't develop into an air-breathing adult. Instead, it remains in a larval form indefinitely, using feathery gills behind its head to extract oxygen ( $O_2$ ) from water.

Although external gills are uncommon among adult animals, they help the axolotl carry out a process common to all organisms—the exchange of substances between body cells and the environment. The resources that an animal cell requires, such as nutrients and  $O_2$ , enter the cytoplasm by crossing the plasma membrane. Metabolic by-products, such as carbon dioxide ( $CO_2$ ), exit the cell by crossing the same membrane.

In unicellular organisms, exchange occurs directly with the external environment. For most multicellular organisms, however, direct transfer of materials between every cell and the environment is not possible. Instead, these organisms rely on specialized systems that carry out exchange with the environment and that transport materials between sites of exchange and the rest of the body.

The filamentous structure of the axolotl's gills reflects the intimate association between exchange and transport. Oxygen passes from the water into tiny blood vessels near the surface of each gill filament, turning the pigment in the blood cells a bright red. Pumping of the axolotl's heart propels the oxygen-rich blood from the gill filaments to all other tissues of the body. There, more short-range exchange occurs, involving nutrients and  $O_2$  as well as  $CO_2$  and other wastes.

Because internal transport and gas exchange are functionally related in most animals, not just axolotls, circulatory and respiratory systems are discussed together in this chapter. By considering examples of these systems from a range of species, we'll explore the common elements as well as the remarkable variation in form and organization. We'll also highlight the roles of circulatory and respiratory systems in maintaining homeostasis.

## Circulatory systems link exchange surfaces with cells throughout the body

The molecular trade that an animal carries out with its environment—gaining  $O_2$  and nutrients while shedding  $CO_2$  and other waste products—must ultimately involve every cell in the body. Small molecules, including  $O_2$  and  $CO_2$ , can move between cells and their immediate surroundings by **diffusion** (see Chapter 5). When there is a difference in concentration, diffusion can result in net movement. But such movement is very slow for distances of more than a few millimeters. That's because the time it takes for a substance to diffuse from one place to another is proportional to the *square* of the distance. For example, a quantity of glucose that takes 1 second to diffuse 100  $\mu m$  will take 100 seconds to diffuse 1 mm and almost 3 hours to diffuse 1 cm! This relationship between diffusion time and distance places a substantial constraint on the body plan of any animal.

Given that net movement by diffusion is rapid only over very small distances, how does each cell of an animal participate in exchange? Natural selection has resulted in two basic adaptations that allow for effective exchange for all of an animal's cells. One adaptation is a body size and shape that places many or all cells in direct contact with the environment. Each cell can thus exchange materials directly with the surrounding medium. This type of body plan is found only in certain invertebrates, including cnidarians and flatworms. The other adaptation, found in all other animals, is a circulatory system. Such systems move fluid between each cell's immediate surroundings and the body tissues where exchange with the environment occurs.

### Gastrovascular Cavities

Let's begin by looking at some animals whose body shapes put many of their cells into contact with their environment; these animals lack a distinct circulatory system. In hydras and other cnidarians, a central **gastrovascular cavity** functions in the distribution of substances throughout the body and in digestion (see Figure 33.6). Planarians and most other flatworms also survive without a circulatory system. Their combination of a gastrovascular cavity and a flat body is well suited for exchange with the environment (**Figure 34.2**).

► **Figure 34.2**  
**Internal transport in the planarian *Dugesia* (LM).** The mouth, on the ventral (bottom) side, leads to a gastrovascular cavity (here stained red) that branches throughout the body.

## Open and Closed Circulatory Systems

A circulatory system has three basic components: a circulatory fluid, a set of interconnecting vessels, and a muscular pump, the **heart**. The heart powers circulation by using metabolic energy to elevate the hydrostatic pressure of the circulatory fluid, which then flows through the vessels and back to the heart.

Circulatory systems are either open or closed. In an **open circulatory system**, the circulatory fluid, called **hemolymph**, is also the *interstitial fluid* that bathes body cells; arthropods and some molluscs, such as clams, have open systems. Heart contraction pumps the hemolymph through circulatory vessels into sinuses, spaces surrounding the organs (**Figure 34.3a**). There, exchange with body cells occurs. Heart relaxation draws hemolymph back in through pores, which have valves that close when the heart contracts. Body movements periodically squeeze the sinuses, helping circulate the hemolymph.

In a **closed circulatory system**, a circulatory fluid called **blood** is confined to vessels and is distinct from the interstitial fluid (**Figure 34.3b**). This type of circulatory system is

▼ **Figure 34.3** Open and closed circulatory systems.

### (a) An open circulatory system

### (b) A closed circulatory system

found in annelids (including earthworms), most cephalopod molluscs (including squids and octopuses), and all vertebrates. In closed circulatory systems, one or more hearts pump blood into large vessels that branch into smaller ones that infiltrate the organs. Chemical exchange occurs between the blood and the interstitial fluid, as well as between the interstitial fluid and body cells.

The fact that both open and closed circulatory systems are widespread suggests that each system offers evolutionary advantages. The lower hydrostatic pressures typically associated with open circulatory systems make them less costly than closed systems in terms of energy expenditure. In some invertebrates, open circulatory systems serve additional functions. For example, spiders use the hydrostatic pressure generated by their open circulatory system to extend their legs.

The benefits of closed circulatory systems include relatively high blood pressure, which enables the effective delivery of  $O_2$  and nutrients to the cells of larger and more active animals. Among the molluscs, for instance, closed circulatory systems are found in the largest and most active species, the squids and octopuses. Closed systems are also particularly well suited to regulating the distribution of blood to different organs, as you'll learn later in this chapter. In examining closed circulatory systems in more detail, we'll focus on the vertebrates.

## Organization of Vertebrate Circulatory Systems

The closed circulatory system of humans and other vertebrates is often called the **cardiovascular system**. Blood circulates to and from the heart through an amazingly extensive network of vessels: The total length of blood vessels in an average human adult is twice Earth's circumference at the equator!

Arteries, veins, and capillaries are the three main types of blood vessels. Within each type, blood flows in only one direction. **Arteries** carry blood from the heart to organs throughout the body. Within organs, arteries branch into *arterioles*. These small vessels convey blood to **capillaries**, microscopic vessels with very thin, porous walls. Networks of these vessels, called **capillary beds**, infiltrate tissues, passing within a few cell diameters of every cell in the body. Across the thin walls of capillaries, chemicals, including dissolved gases, are exchanged by net diffusion between the blood and the interstitial fluid around the tissue cells. At their "downstream" end, capillaries converge into *venules*, and venules converge into **veins**, the vessels that carry blood back to the heart.

Note that arteries and veins are distinguished by the *direction* in which they carry blood, not by the  $O_2$  content or other characteristics of the blood they contain. Arteries carry blood *away* from the heart toward capillaries, and veins carry blood *toward* the heart from capillaries.

The hearts of all vertebrates contain two or more muscular chambers. The chambers that receive blood entering the heart

are called **atria** (singular, *atrium*). The chambers responsible for pumping blood out of the heart are called **ventricles**. The number of chambers and the extent to which they are separated from one another differ substantially among vertebrate groups, as we'll discuss next. These differences reflect the close fit of form to function that arises from natural selection.

### Single Circulation

In bony fishes, rays, and sharks, the heart consists of two chambers: an atrium and a ventricle (**Figure 34.4a**). The blood passes through the heart once in each complete circuit, an arrangement called **single circulation**. Blood entering the heart collects in the atrium before transfer to the ventricle. Contraction of the ventricle pumps blood to the gills, where there is a net diffusion of  $O_2$  into the blood and of  $CO_2$  out of the blood. As blood leaves the gills, the capillaries converge into a vessel that carries oxygen-rich blood to capillary beds throughout the body. Blood then returns to the heart.

In single circulation, blood that leaves the heart passes through two sets of capillary beds before returning to the heart. When blood flows through a capillary bed, blood pressure drops substantially, for reasons we will explain shortly. The drop in blood pressure in the gills limits the velocity of blood flow in the rest of the animal's body. As the animal swims, however, the contraction and relaxation of its muscles help accelerate the relatively sluggish pace of circulation.

### Double Circulation

The circulatory systems of amphibians, reptiles, and mammals have two circuits, an arrangement called **double circulation** (**Figure 34.4b** and **c**). In animals with double circulation, the pumps for the two circuits are combined into a single organ, the heart. Having both pumps within a single heart simplifies coordination of the pumping cycles. One pump, the right side of the heart, delivers oxygen-poor blood to the capillary beds of the gas exchange tissues, where there is a net movement of  $O_2$  into the blood and of  $CO_2$  out of the blood. This **gas exchange circuit** is called a *pulmonary circuit* if the capillary beds involved are all in the lungs, as in reptiles and mammals. It is called a *pulmocutaneous circuit* if it includes capillaries in both the lungs and the skin, as in many amphibians.

After the oxygen-enriched blood leaves the gas exchange tissues, it enters the other pump, the left side of the heart. Contraction of the heart propels this blood to capillary beds in organs and tissues throughout the body. Following the exchange of  $O_2$  and  $CO_2$ , as well as nutrients and waste products, the now oxygen-poor blood returns to the heart, completing the **systemic circuit**.

Double circulation provides a vigorous flow of blood to the brain, muscles, and other organs because the heart

▼ **Figure 34.4 Generalized circulatory schemes of vertebrates.** (a) Fishes provide an example of single circulation, in which blood passes through the heart once per complete circuit. In contrast, (b) amphibians and (c) mammals offer examples of double circulation, with separate gas exchange and systemic circuits. Comparing (b) and (c) indicates some variations of heart structure and gas exchange tissue types that have evolved in different groups of vertebrates with double circulation. (Note that circulatory systems are shown as if the body were facing you: The right side of the heart is shown on the left, and vice versa.)

repressurizes the blood destined for these tissues after it passes through the capillary beds of the lungs or skin. Indeed, blood pressure is often much higher in the systemic circuit than in the gas exchange circuit. This contrasts sharply with single circulation, in which blood flows under reduced pressure directly from the gas exchange organs to other organs.

### Evolutionary Variation in Double Circulation

**EVOLUTION** Some vertebrates with double circulation are intermittent breathers. For example, amphibians and many reptiles fill their lungs with air periodically, passing long periods of time without gas exchange or relying on another gas exchange tissue, typically the skin. These animals have adaptations that enable the circulatory system to temporarily bypass the lungs in part or in whole:

- Frogs and other amphibians have a heart with three chambers—two atria and one ventricle (see Figure 34.4b). A ridge within the ventricle diverts most (about 90%) of the oxygen-rich blood from the left atrium into the systemic circuit and most of the oxygen-poor blood from the right atrium into the gas exchange (pulmocutaneous) circuit. When a frog is underwater, the incomplete division of the ventricle allows the frog to adjust its circulation, shutting off most blood flow to its temporarily ineffective lungs. Blood

flow continues to the skin, which acts as the sole site of gas exchange while the frog is submerged.

- In the three-chambered heart of turtles, snakes, and lizards, an incomplete septum partially divides the single ventricle into separate right and left chambers. Two major arteries, called aortas, lead to the systemic circulation. As with amphibians, the circulatory system enables control of the relative amount of blood flowing to the lungs and the body.
- In alligators, caimans, and other crocodilians, the ventricles are divided by a complete septum, but the pulmonary and systemic circuits connect where the arteries exit the heart. This connection allows arterial valves to shunt blood flow away from the lungs temporarily, such as when the animal is underwater.

Double circulation in birds and mammals is quite different. As shown for a panda in Figure 34.4c, the heart has two atria and two completely divided ventricles. The left side of the heart receives and pumps only oxygen-rich blood, while the right side receives and pumps only oxygen-poor blood. Unlike amphibians and many reptiles, birds and mammals cannot vary blood flow to the lungs without altering blood flow throughout the body.

How has natural selection shaped the double circulation of birds and mammals? As endotherms, birds and mammals use

about ten times as much energy as equal-sized ectotherms. Their circulatory systems therefore need to deliver about ten times as much fuel and  $O_2$  to their tissues (and remove ten times as much  $CO_2$  and other wastes). This large traffic of substances is made possible by the separate and independently powered systemic and pulmonary circuits and by large hearts that pump the necessary volume of blood. A powerful four-chambered heart arose independently in the different ancestors of birds and mammals and thus reflects convergent evolution (see Chapter 27).

In the next section, we'll restrict our focus to circulation in mammals and to the anatomy and physiology of the key circulatory organ—the heart.

### CONCEPT CHECK 34.1

1. How is the flow of hemolymph through an open circulatory system similar to the flow of water through an outdoor fountain?
2. Three-chambered hearts with incomplete septa were once viewed as being less adapted to circulatory function than mammalian hearts. What advantage of such hearts did this viewpoint overlook?
3. **WHAT IF?** The heart of a normally developing human fetus has a hole between the left and right atria. In some cases, this hole does not close completely before birth. If the hole weren't surgically corrected, how would it affect the  $O_2$  content of the blood entering the systemic circuit?

For suggested answers, see Appendix A.

## CONCEPT 34.2

### Coordinated cycles of heart contraction drive double circulation in mammals

Timely delivery of  $O_2$  to body organs is critical: Some brain cells, for example, die if their  $O_2$  supply is interrupted for even a few minutes. How does the mammalian cardiovascular system meet the body's continuous (although variable) demand for  $O_2$ ? To answer this question, we need to consider how the parts of the system are arranged and how each part functions.

#### Mammalian Circulation

Let's first examine the overall organization of the mammalian cardiovascular system, beginning with the pulmonary circuit. (The circled numbers refer to corresponding locations in **Figure 34.5**.) Contraction of **1** the right ventricle pumps blood to the lungs via **2** the pulmonary arteries. As the blood flows through **3** capillary beds in the left and right lungs, it loads  $O_2$  and unloads  $CO_2$ . Oxygen-rich blood returns from the lungs via the pulmonary veins to **4** the left atrium of the heart. Next, the oxygen-rich blood flows into **5** the heart's left ventricle, which pumps the oxygen-rich blood out to body tissues through the systemic circuit. Blood leaves the left ventricle via **6** the aorta,

**▲ Figure 34.5 The mammalian cardiovascular system: an overview.** Note that the dual circuits operate simultaneously, not in the serial fashion that the numbering in the diagram suggests. The two ventricles pump almost in unison; while some blood is traveling in the pulmonary circuit, the rest of the blood is flowing in the systemic circuit.

which conveys blood to arteries leading throughout the body. The first branches leading from the aorta are the coronary arteries (not shown), which supply blood to the heart muscle itself. Then branches lead to **7** capillary beds in the head and arms (forelimbs). The aorta then descends into the abdomen, supplying oxygen-rich blood to arteries leading to **8** capillary beds in the abdominal organs and legs (hind limbs). Within the capillaries, there is a net diffusion of  $O_2$  from the blood to the tissues and of  $CO_2$  (produced by cellular respiration) into the blood. Capillaries rejoin, forming venules, which convey blood to veins. Oxygen-poor blood from the head, neck, and forelimbs is channeled into a large vein, **9** the superior vena cava. Another large vein, **10** the inferior vena cava, drains blood from the trunk and hind limbs. The two venae cavae empty their blood into **11** the right atrium, from which the oxygen-poor blood flows into the right ventricle.

#### The Mammalian Heart: A Closer Look

Located behind the sternum (breastbone), the human heart is about the size of a clenched fist and consists mostly of cardiac muscle. The two atria have relatively thin walls and serve as collection chambers for blood returning to the heart from the lungs or other body tissues (**Figure 34.6**). Much of the blood that enters the atria flows into the ventricles while all

▲ **Figure 34.6 The mammalian heart: a closer look.** Notice the locations of the valves, which prevent backflow of blood within the heart. Also notice how the atria and left and right ventricles differ in the thickness of their muscular walls.

heart chambers are relaxed. The remainder is transferred by contraction of the atria before the ventricles begin to contract. Compared to the atria, the ventricles have thicker walls and contract much more forcefully—especially the left ventricle, which pumps blood to all body organs through the systemic circuit. Although the left ventricle contracts with greater force than the right ventricle, it pumps the same volume of blood as the right ventricle during each contraction.

The heart contracts and relaxes in a rhythmic cycle. When it contracts, it pumps blood; when it relaxes, its chambers fill with blood. One complete sequence of pumping and filling is referred to as the **cardiac cycle** (**Figure 34.7**). The contraction phase of the cycle is called **systole**, and the relaxation phase is called **diastole**.

The volume of blood each ventricle pumps per minute is the cardiac output. Two factors determine cardiac output: the rate of contraction, or heart rate (number of beats per minute), and the *stroke volume*, the amount of blood pumped by a ventricle in a single contraction. The average stroke volume in humans is about 70 mL. Multiplying this stroke volume by a resting heart rate of 72 beats per minute yields a cardiac output of 5 L/min—about equal to the total volume of blood in the human body. During heavy exercise, cardiac output increases as much as fivefold.

Four valves in the heart prevent backflow and keep blood moving in the correct direction (see Figures 34.6 and 34.7). Made of flaps of connective tissue, the valves open when pushed from one side and close when pushed from the other. An **atrioventricular (AV) valve** lies between each atrium and ventricle. The AV valves are anchored by strong fibers that prevent them from turning inside out. Pressure generated by the powerful contraction of the ventricles closes the AV valves, keeping blood from flowing back into the atria. **Semilunar valves** are located at

▲ **Figure 34.7 The cardiac cycle.** Note that during all but 0.1 second of the cardiac cycle, the atria are relaxed and are filling with blood returning via the veins.

the two exits of the heart: where the aorta leaves the left ventricle and where the pulmonary artery leaves the right ventricle. These valves are pushed open by the pressure generated during contraction of the ventricles. When the ventricles relax, blood pressure built up in the aorta and pulmonary artery closes the semilunar valves and prevents significant backflow.

You can follow the closing of the two sets of heart valves either with a stethoscope or by pressing your ear tightly against the chest of a friend (or a friendly dog). The sound pattern is “lub-dup, lub-dup, lub-dup.” The first heart sound (“lub”) is created by the recoil of blood against the closed AV valves. The second sound (“dup”) is due to the vibrations caused by closing of the semilunar valves.

If blood squirts backward through a defective valve, it may produce an abnormal sound called a heart murmur. Some people are born with heart murmurs; in others, the valves may be damaged by infection (from rheumatic fever, for instance). When a valve defect is severe enough to endanger health, surgeons may implant a mechanical replacement valve. However, not all heart murmurs are caused by a defect, and most valve defects do not reduce the efficiency of blood flow enough to warrant surgery.

**▲ Figure 34.8 The control of heart rhythm.** Electrical signals follow a set path through the heart in establishing the heart rhythm. The diagrams at the top trace the movement of electrical signals (yellow) during the cardiac cycle; specialized cells involved in electrical control of the rhythm are indicated in orange. Under each step, the corresponding portion of an electrocardiogram (ECG) is highlighted in yellow. In step 4, the portion of the ECG to the right of the “spike” represents electrical activity that reprimed the ventricles for the next round of contraction.

**WHAT IF?** If your doctor gave you a copy of your ECG recording, how could you determine what your heart rate had been during the test?

## Maintaining the Heart’s Rhythmic Beat

In vertebrates, the heartbeat originates in the heart itself. Some cardiac muscle cells are autorhythmic, meaning they contract and relax repeatedly without any signal from the nervous system. A group of such cells forms the **sinoatrial (SA) node**, or **pacemaker**, which sets the rate and timing at which all other cardiac muscle cells contract. (In contrast, some arthropods have pacemakers located in the nervous system, outside the heart.)

The SA node produces electrical impulses that spread rapidly within heart tissue. Because body fluids can conduct electricity, currents generated by those impulses can be detected at the surface of the body in an **electrocardiogram (ECG or, often, EKG, from the German spelling)**. The resulting graph of current against time has a characteristic shape that represents the stages in the cardiac cycle (**Figure 34.8**).

Impulses from the SA node first spread rapidly through the walls of the atria, causing both atria to contract in unison. During atrial contraction, the impulses originating at the SA node reach other autorhythmic cells located in the wall between the left and right atria. These cells form a relay point called the **atrioventricular (AV) node**. Here the impulses are delayed for about 0.1 second before spreading to the heart apex. This delay allows the atria to empty completely before the ventricles contract. Then the signals from the AV node are conducted to the heart apex and throughout the ventricular walls.

Physiological cues alter heart tempo by regulating the pacemaker function of the SA node. For example, when you stand up and start walking, the nervous system speeds up your pacemaker. The resulting increase in heart rate provides the additional  $O_2$  needed by the muscles that are powering

your activity. If you then sit down and relax, the nervous system slows down your pacemaker, decreasing your heart rate and thus conserving energy. Hormones and temperature also influence the pacemaker. For instance, epinephrine, the “fight-or-flight” hormone secreted by the adrenal glands, causes the heart rate to increase, as does an increase in body temperature.

Having examined the operation of the circulatory pump, we turn in the next section to the forces and structures that influence blood flow in the vessels of each circuit.

### CONCEPT CHECK 34.2

1. Explain why blood in the pulmonary veins has a higher  $O_2$  concentration than in the venae cavae, which are also veins.
2. Why is it important that the AV node delay the electrical impulse moving from the SA node and the atria to the ventricles?
3. **WHAT IF?** After you exercise regularly for several months, your resting heart rate decreases, but your cardiac output at rest is unchanged. What change in the function of your heart at rest could explain these findings?

For suggested answers, see Appendix A.

## CONCEPT 34.3

### Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels

The vertebrate circulatory system enables blood to deliver oxygen and nutrients and remove wastes throughout the body. In doing so, the circulatory system relies on a branching network

of vessels much like the plumbing system that delivers fresh water to a city and removes its wastes. In fact, the same physical principles that govern the operation of plumbing systems apply to the functioning of blood vessels.

## Blood Vessel Structure and Function

Blood vessels contain a central lumen (cavity) lined with an **endothelium**, a single layer of flattened epithelial cells. The smooth surface of the endothelium minimizes resistance to the flow of blood. Surrounding the endothelium are layers of tissue that differ in capillaries, arteries, and veins, reflecting the specialized functions of these vessels.

Capillaries are the smallest blood vessels, having a diameter only slightly greater than that of a red blood cell (**Figure 34.9**). Capillaries also have very thin walls, which consist of just the endothelium and its basal lamina. The exchange of substances between the blood and interstitial fluid occurs in capillaries because only there are blood vessel walls thin enough to permit this transfer.

The walls of other blood vessels have a more complex organization than those of capillaries. Both arteries and veins have two layers of tissue surrounding the endothelium. The outer layer is formed by connective tissue that contains elastic fibers, which allow the vessel to stretch and recoil, and collagen, which provides strength. The layer next to the endothelium contains smooth muscle and more elastic fibers.

While similar in organization, the walls of arteries and veins differ, reflecting adaptations to distinct functions. The walls of arteries are thick and strong, accommodating blood pumped at high pressure by the heart. Arterial walls also have an elastic recoil that helps maintain blood pressure and flow to capillaries when the heart relaxes between contractions. Nervous system signals and hormones in the blood act on the smooth muscle in arteries and arterioles, dilating or constricting these vessels and thus controlling blood flow to different body parts.

Because veins convey blood back to the heart at a lower pressure, they do not require thick walls. For a given blood vessel diameter, a vein has a wall only about a third as thick as that of an artery. Unlike arteries, veins contain valves, which maintain a unidirectional flow of blood despite the low blood pressure in these vessels.

We consider next how blood vessel diameter, vessel number, and pressure influence the velocity at which blood flows in different locations within the body.

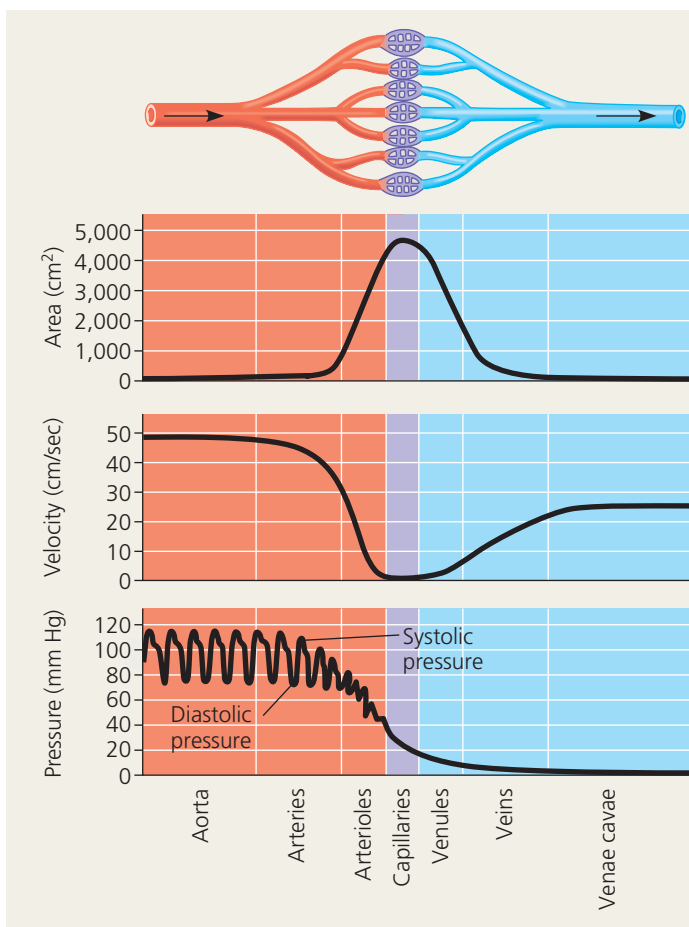

▲ **Figure 34.9** The structure of blood vessels.

## Blood Flow Velocity

To understand how blood vessel diameter influences blood flow, consider how water flows through a thick hose connected to a faucet. When the faucet is turned on, water flows at the same velocity at each point along the hose. However, if a narrow nozzle is attached to the end of the hose, the water will exit the nozzle at a much greater velocity. Because water doesn't compress under pressure, the volume of water moving through the nozzle in a given time must be the same as the volume moving through the rest of the hose. The cross-sectional area of the nozzle is smaller than that of the hose, so the water speeds up in the nozzle.

An analogous situation exists in the circulatory system, but blood *slows* as it moves from arteries to arterioles to the much narrower capillaries. Why? The reason is that the number of capillaries is enormous, roughly 7 billion in a human body. Each artery conveys blood to so many capillaries that the *total* cross-sectional area is much greater in

▲ **Figure 34.10** The interrelationship of cross-sectional area of blood vessels, blood flow velocity, and blood pressure.

Because total cross-sectional area increases in the arterioles and in the capillaries, blood flow velocity decreases markedly. Blood pressure, the main force driving blood from the heart to the capillaries, is highest in the aorta and other arteries.

capillary beds than in the arteries or any other part of the circulatory system (**Figure 34.10**). The result is a dramatic decrease in velocity from the arteries to the capillaries: Blood travels 500 times more slowly in the capillaries (about 0.1 cm/sec) than in the aorta (about 48 cm/sec). After passing through the capillaries, the blood speeds up as it enters the venules and veins, which have smaller *total* cross-sectional areas than the capillaries.

## Blood Pressure

Blood, like all fluids, flows from areas of higher pressure to areas of lower pressure. Contraction of a heart ventricle generates blood pressure, which exerts force in all directions. The force directed lengthwise in an artery causes the blood to flow away from the heart, the site of highest pressure. The force exerted sideways against the wall of an artery stretches the wall. Following ventricular contraction, the recoil of the elastic arterial walls plays a critical role in maintaining blood pressure, and hence

blood flow, throughout the cardiac cycle. Once the blood enters the millions of tiny arterioles and capillaries, the narrow diameter of these vessels generates substantial resistance to flow. By the time the blood enters the veins, resistance dissipates much of the pressure generated by the pumping heart.

## Changes in Blood Pressure During the Cardiac Cycle

Arterial blood pressure is highest during systole, the contraction phase of the cardiac cycle. The pressure at the time the ventricles contract is called *systolic pressure* (see **Figure 34.10**). Each spike in blood pressure caused by a contraction of a ventricle stretches the arteries. By placing your fingers on the inside of your wrist, you can feel a **pulse**—the rhythmic bulging of the artery walls with each heartbeat. The pressure surge is partly due to the narrow openings of arterioles impeding the exit of blood from the arteries. When the heart contracts, blood enters the arteries faster than it can leave, and the vessels stretch from the rise in pressure.

During diastole, the relaxation phase, the elastic walls of the arteries snap back. As a consequence, there is a lower but still substantial arterial blood pressure when the ventricles are relaxed (*diastolic pressure*). Before enough blood has flowed into the arterioles to completely relieve pressure in the arteries, the heart contracts again. Because the arteries remain pressurized throughout the cardiac cycle (see **Figure 34.10**), blood continuously flows into arterioles and capillaries.

To measure blood pressure, doctors or nurses often use an inflatable cuff attached to a pressure gauge. The cuff is wrapped around the upper arm and inflated until the pressure closes the artery; the cuff is then deflated gradually. When the cuff pressure drops just below that in the artery, blood begins to pulse past the cuff, making sounds that can be heard with a stethoscope. The pressure measured at this point equals the systolic pressure. As deflation continues, the cuff pressure at some point no longer constricts blood movement. The reading on the gauge when the blood begins to flow freely and silently equals the diastolic pressure. For a healthy 20-year-old human at rest, arterial blood pressure in the systemic circuit is typically about 120 millimeters of mercury (mm Hg) at systole and 70 mm Hg at diastole, expressed as 120/70. (Arterial blood pressure in the pulmonary circuit is six to ten times lower.)

## Maintenance of Blood Pressure

Homeostatic mechanisms regulate arterial blood pressure by altering the diameter of arterioles. As the smooth muscles in arteriole walls contract, the arterioles narrow, a process called **vasoconstriction**. Narrowing of the arterioles increases blood pressure upstream in the arteries. When the smooth muscles relax, the arterioles undergo **vasodilation**, an increase in diameter that causes blood pressure in the arteries to fall.

Researchers have identified nitric oxide (NO), a gas, as a major inducer of vasodilation and endothelin, a peptide, as the most potent inducer of vasoconstriction. Cues from the nervous and endocrine systems regulate production of NO and endothelin in blood vessels, where their activities regulate blood pressure.

Gravity also has a significant effect on blood pressure. When you are standing, for example, your head is roughly 0.35 m higher than your chest, and the arterial blood pressure in your brain is about 27 mm Hg less than that near your heart. If the blood pressure in your brain is too low to provide adequate blood flow, you will likely faint. By causing your body to collapse to the ground, fainting effectively places your head at the level of your heart, quickly increasing blood flow to your brain.

For animals with very long necks, the blood pressure required to overcome gravity is particularly high. A giraffe, for example, requires a systolic pressure of more than 250 mm Hg near the heart to get blood to its head. When a giraffe lowers its head to drink, one-way valves and sinuses, along with feedback mechanisms that reduce cardiac output, prevent this high pressure from damaging its brain.

Gravity is also a consideration for blood flow in veins, especially those in the legs. Although blood pressure in veins is relatively low, the valves inside the veins maintain a unidirectional flow of blood. The return of blood to the heart is further enhanced by rhythmic contractions of smooth muscles in the walls of venules and veins and by the contraction of skeletal muscles during exercise (**Figure 34.11**).

▲ **Figure 34.11 Blood flow in veins.** Skeletal muscle contraction squeezes and constricts veins. Flaps of tissue within the veins act as one-way valves that keep blood moving only toward the heart. If you sit or stand too long, the lack of muscular activity may cause your feet to swell as blood pools in your veins.

## Capillary Function

At any given time, only about 5–10% of the body's capillaries have blood flowing through them. Capillaries in the brain, heart, kidneys, and liver are usually filled to capacity, but at many other sites the blood supply varies over time as blood is diverted from one destination to another. For example, blood flow to the skin is regulated to help control body temperature, and blood supply to the digestive tract increases after a meal. During strenuous exercise, blood is diverted from the digestive tract and supplied more generously to skeletal muscles and skin. This is one reason why exercising heavily immediately after eating a big meal may cause indigestion.

Given that capillaries lack smooth muscle, how is blood flow in capillary beds altered? One mechanism for altering blood flow is vasoconstriction or vasodilation of the arteriole that supplies a capillary bed. A second mechanism involves rings of smooth muscle located at the entrance to capillary beds. Opening and closing these muscular rings regulates and redirects the passage of blood into particular sets of capillaries.

As you have read, the critical exchange of substances between the blood and interstitial fluid takes place across the thin endothelial walls of the capillaries. Some substances are carried across the endothelium in vesicles that form on one side by endocytosis and release their contents on the opposite side by exocytosis. Small molecules, such as  $O_2$  and  $CO_2$ , simply diffuse across the endothelial cells or, in some tissues, through microscopic pores in the capillary wall. These openings also provide the route for transport of small solutes such as sugars, salts, and urea, as well as for bulk flow of fluid into tissues driven by blood pressure within the capillary.

Two opposing forces control the movement of fluid between the capillaries and the surrounding tissues: Blood pressure tends to drive fluid out of the capillaries, and the presence of blood proteins tends to pull fluid back. Many blood proteins (and all blood cells) are too large to pass readily through the endothelium, and they remain in the capillaries. These dissolved proteins are responsible for much of the blood's *osmotic pressure* (the pressure produced by the difference in solute concentration across a membrane). The difference in osmotic pressure between the blood and the interstitial fluid opposes fluid movement out of the capillaries. On average, blood pressure is greater than the opposing forces, leading to a net loss of fluid from capillaries. The net loss is generally greatest at the arterial end of these vessels, where blood pressure is highest.

## Fluid Return by the Lymphatic System

Each day, the adult human body loses approximately 4–8 L of fluid from capillaries to the surrounding tissues. There is also some leakage of blood proteins, even though the capillary wall is not very permeable to large molecules. The lost fluid and proteins return to the blood via the **lymphatic system**,

© 2010 Pearson Education, Inc.

**▲ Figure 34.12 The human lymphatic system.** Lymph flows through lymphatic vessels (shown in green). Foreign substances carried by the lymph are trapped in lymph nodes (orange) and lymphoid organs (yellow): the adenoids, tonsils, spleen, Peyer's patches, and appendix. Steps 1–4 trace the flow of lymph and illustrate the critical role of lymph nodes in activating immune responses.

which includes a network of tiny vessels intermingled among capillaries of the cardiovascular system (**Figure 34.12**).

After entering the lymphatic system by diffusion, the fluid lost by capillaries is called **lymph**; its composition is about the same as that of interstitial fluid. The lymphatic system drains into large veins of the circulatory system at the base of the neck. This joining of the lymphatic and circulatory systems enables lipids to be transferred from the small intestine to the blood (see Chapter 33).

The movement of lymph from peripheral tissues to the heart relies on much the same mechanisms that assist blood flow in veins. Lymph vessels, like veins, have valves that prevent the backflow of fluid. Rhythmic contractions of the vessel walls help draw fluid into the small lymphatic vessels. In addition, skeletal muscle contractions play a role in moving lymph.

Disorders that interfere with the lymphatic system highlight its role in maintaining proper fluid distribution in the body. Disruptions in the movement of lymph often cause edema, swelling that results from the excessive accumulation of fluid in tissues. Severe blockage of lymph flow, as occurs when certain parasitic worms lodge in lymph vessels, results in extremely swollen limbs or other body parts, a condition known as elephantiasis.

Along a lymph vessel are organs called **lymph nodes**. By filtering the lymph and by housing cells that attack viruses and bacteria, lymph nodes play an important role in

the body's defense. When the body is fighting an infection, the white cells in lymph nodes multiply rapidly, causing swelling and tenderness (which is why your doctor may check for swollen lymph nodes in your neck, armpits, or groin when you feel sick). Because lymph nodes have filtering and surveillance functions, doctors may examine the lymph nodes of cancer patients to detect the spread of diseased cells.

In recent years, evidence has surfaced demonstrating that the lymphatic system also plays a role in harmful immune responses, such as those responsible for asthma. Because of these and other findings, the lymphatic system, given limited attention until the 1990s, has become a very active and promising area of biomedical research.

### CONCEPT CHECK 34.3

1. What is the primary cause of the low velocity of blood flow in capillaries?
2. What short-term changes in cardiovascular function might best enable skeletal muscles to help an animal escape from a dangerous situation?
3. **WHAT IF?** If you had additional hearts distributed throughout your body, what would be one likely advantage and one likely disadvantage?

For suggested answers, see Appendix A.

## CONCEPT 34.4

# Blood components function in exchange, transport, and defense

As you read in Concept 34.1, the fluid transported by an open circulatory system is continuous with the fluid that surrounds all of the body cells and therefore has the same composition. In contrast, the fluid in a closed circulatory system can be more highly specialized, as is the case for the blood of vertebrates.

## Blood Composition and Function

Vertebrate blood is a connective tissue consisting of cells suspended in a liquid matrix called **plasma**. Separating the components of blood using a centrifuge reveals that cellular elements (cells and cell fragments) occupy about 45% of the volume of blood (**Figure 34.13**). The remainder is plasma. Dissolved in the plasma are ions and proteins that, together with the blood cells, function in osmotic regulation, transport, and defense.

### Plasma

Among the many solutes in plasma are inorganic salts in the form of dissolved ions, sometimes referred to as blood

electrolytes. Although plasma is about 90% water, the dissolved salts are an essential component of the blood. Some of these ions buffer the blood, which in humans normally has a pH of 7.4. Salts are also important in maintaining the osmotic balance of the blood. In addition, the concentration of ions in plasma directly affects the composition of the interstitial fluid, where many of these ions have a vital role in muscle and nerve activity. Serving all of these functions necessitates keeping plasma electrolytes within narrow concentration ranges via homeostatic mechanisms.

Plasma proteins act as buffers against pH changes and help maintain the osmotic balance between blood and interstitial fluid. Particular plasma proteins have additional functions. The immunoglobulins, or antibodies, help combat viruses and other foreign agents that invade the body (see Chapter 35). Other plasma proteins serve as escorts for lipids, which are insoluble in water and can travel in blood only when bound to proteins. Still other plasma proteins are clotting factors that help plug leaks when blood vessels are injured. (The term *serum* refers to blood plasma from which these clotting factors have been removed.)

Plasma also contains a wide variety of other substances in transit from one part of the body to another, including nutrients, metabolic wastes, respiratory gases, and hormones.

▲ **Figure 34.13** The composition of mammalian blood.

▲ **Figure 34.14 Differentiation of blood cells.** Some of the multipotent stem cells differentiate into lymphoid stem cells, which then develop into B cells and T cells, two types of lymphocytes that function in immunity (see Chapter 35). All other blood cells and platelets arise from myeloid stem cells.

### Cellular Elements

Blood contains two classes of cells: red blood cells, which transport  $O_2$ , and white blood cells, which function in defense. Also suspended in blood plasma are **platelets**, cell fragments that are involved in the clotting process. All these cellular elements develop from multipotent **stem cells** that are dedicated to replenishing the body's blood cell populations (**Figure 34.14**). The stem cells that produce blood cells and platelets are located in the red marrow inside bones, particularly the ribs, vertebrae, sternum, and pelvis.

**Erythrocytes** Red blood cells, or **erythrocytes**, are by far the most numerous blood cells. Each microliter ( $\mu L$ , or  $mm^3$ ) of human blood contains 5–6 million red cells, and there are about 25 trillion of these cells in the body's 5 L of blood. Their main function is  $O_2$  transport, and their structure is closely related to this function. Human erythrocytes are small disks (7–8  $\mu m$  in diameter) that are biconcave—thinner in the center than at the edges. This shape increases surface area, enhancing the rate of diffusion of  $O_2$  across the plasma membrane. Mature mammalian erythrocytes lack nuclei. This unusual characteristic leaves more space in these tiny cells for **hemoglobin**, the iron-containing protein that transports  $O_2$  (see Figure 3.21).

Despite its small size, an erythrocyte contains about 250 million molecules of hemoglobin (Hb). Because each molecule of hemoglobin binds up to four molecules of  $O_2$ , one erythrocyte can transport about one billion  $O_2$  molecules. As erythrocytes pass through the capillary beds of lungs, gills, or

other respiratory organs,  $O_2$  diffuses into the erythrocytes and binds to hemoglobin. In the systemic capillaries,  $O_2$  dissociates from hemoglobin and diffuses into body cells.

In **sickle-cell disease**, an abnormal form of hemoglobin (Hb<sup>S</sup>) polymerizes into aggregates. Because the concentration of hemoglobin in erythrocytes is so high, these aggregates are large enough to distort the erythrocyte into an elongated, curved shape that resembles a sickle. This abnormality results from an alteration in the amino acid sequence of hemoglobin at a single position (see Figure 3.22).

Throughout a person's life, stem cells replace the worn-out cellular elements of blood. Erythrocytes are the shortest lived, circulating for only 120 days on average before being replaced. A negative-feedback mechanism, sensitive to the amount of  $O_2$  reaching the body's tissues via the blood, controls erythrocyte production. If the tissues do not receive enough  $O_2$ , the kidneys synthesize and secrete *erythropoietin* (EPO), a hormone that stimulates erythrocyte production. Today, EPO produced by recombinant DNA technology is used to treat health problems such as *anemia*, a condition of lower-than-normal erythrocyte or hemoglobin levels. Some athletes inject themselves with EPO to increase their erythrocyte levels, although this practice, a form of blood doping, has been banned by major sports organizations.

**Leukocytes** The blood contains five major types of white blood cells, or **leukocytes**. Their function is to fight infections. Some are phagocytic, engulfing and digesting microorganisms as well as debris from the body's own dead cells. Other leukocytes, called lymphocytes, develop into specialized B cells and T cells that mount immune responses against foreign substances (as will be discussed in Chapter 35). Normally, 1  $\mu L$  of human blood contains about 5,000–10,000 leukocytes; their numbers increase temporarily whenever the body is fighting an infection. Unlike erythrocytes, leukocytes are also found outside the circulatory system, patrolling both interstitial fluid and the lymphatic system.

**Platelets** Platelets are pinched-off cytoplasmic fragments of specialized bone marrow cells. They are about 2–3  $\mu m$  in diameter and have no nuclei. Platelets serve both structural and molecular functions in blood clotting.

### Blood Clotting

The occasional cut or scrape is not life-threatening because blood components seal the broken blood vessels. A break in a blood vessel wall exposes proteins that attract platelets and initiate coagulation, the conversion of liquid components of blood to a solid clot. The coagulant, or sealant, circulates in an inactive form called fibrinogen. In response to a broken blood vessel, platelets release clotting factors that trigger reactions leading to the formation of thrombin, an enzyme that converts fibrinogen to fibrin. Newly formed fibrin aggregates into threads that form the framework of the clot. Thrombin also

1 The clotting process begins when the endothelium of a vessel is damaged, exposing connective tissue in the vessel wall to blood. Platelets adhere to collagen fibers in the connective tissue and release a substance that makes nearby platelets sticky.

2 The platelets form a plug that provides immediate protection against blood loss.

3 Unless the break is very small, this plug is reinforced by a fibrin clot.

◀ **Figure 34.15 Blood clotting.**

activates a factor that catalyzes the formation of more thrombin, driving clotting to completion through positive feedback (see Chapter 32). The steps in the production of a blood clot are diagrammed in **Figure 34.15**. Any genetic mutation that blocks a step in the clotting process can cause hemophilia, a disease characterized by excessive bleeding and bruising from even minor cuts and bumps (see Chapter 12).

Anticlotting factors in the blood normally prevent spontaneous clotting in the absence of injury. Sometimes, however, clots form within a blood vessel, blocking the flow of blood. Such a clot is called a **thrombus**. We'll explore how a thrombus forms and the danger that it poses later in this chapter.

## Cardiovascular Disease

Cardiovascular diseases—disorders of the heart and blood vessels—cause more than 750,000 human deaths each year in the United States. These diseases range from a minor disturbance of vein or heart valve function to a life-threatening disruption of blood flow to the heart or brain.

Cholesterol metabolism has a central role in cardiovascular disease. In animal cell membranes this steroid is important for maintaining normal membrane fluidity (see Figure 5.5). Cholesterol travels in plasma in particles that consist of thousands of cholesterol molecules and other lipids bound

to a protein. One type of particle—**low-density lipoprotein (LDL)**—delivers cholesterol to cells for membrane production. Another type—**high-density lipoprotein (HDL)**—scavenges excess cholesterol for return to the liver. A high ratio of LDL to HDL substantially increases the risk for atherosclerosis, a form of heart disease discussed below.

Another factor in cardiovascular disease is *inflammation*, the body's reaction to injury. Tissue damage leads to recruitment of two types of circulating immune cells, macrophages and leukocytes. Signals released by these cells trigger a flow of fluid out of blood vessels at the site of injury, resulting in the tissue swelling characteristic of inflammation (see Figure 35.5). Although inflammation is often a normal and healthy response to injury, it sometimes significantly disrupts circulatory function, as explained in the next section.

## Atherosclerosis, Heart Attacks, and Stroke

Circulating cholesterol and inflammation can act together to produce a cardiovascular disease called **atherosclerosis**, the hardening of the arteries by fatty deposits. Healthy arteries have a smooth inner lining that reduces resistance to blood flow. Damage or infection can roughen the lining and lead to inflammation. Leukocytes are attracted to the damaged lining and begin to take up lipids, including cholesterol from LDL.

▲ **Figure 34.16 Atherosclerosis.** In atherosclerosis, thickening of an arterial wall by plaque formation can restrict blood flow through the artery. Fragments of ruptured plaque can travel via the bloodstream and become lodged in other arteries. If the blockage is in an artery that supplies the heart or brain, the result could be a heart attack or stroke, respectively.

A fatty deposit called a plaque, grows steadily, incorporating fibrous connective tissue and additional cholesterol. As the plaque grows, the walls of the artery become thick and stiff, and the obstruction of the artery increases, reducing the diameter available for blood flow (**Figure 34.16**).

Untreated atherosclerosis often results in a heart attack or a stroke. A **heart attack**, also called a *myocardial infarction*, is the damage or death of cardiac muscle tissue resulting from blockage of one or more coronary arteries, which supply  $O_2$ -rich blood to the heart muscle. Because the coronary arteries are small in diameter, they are especially vulnerable to obstruction. Such blockage can destroy cardiac muscle quickly because the constantly beating heart muscle cannot survive long without  $O_2$ . If the heart stops beating, the victim may nevertheless survive if a heartbeat is restored within a few minutes by cardiopulmonary resuscitation (CPR) or some other emergency procedure.

A **stroke** is the death of nervous tissue in the brain due to a lack of  $O_2$ . Strokes usually result from rupture or blockage of arteries in the neck or head. The effects of a stroke and the individual's chance of survival depend on the extent and location of the damaged brain tissue. If a stroke results from a blocked artery, rapid administration of a clot-dissolving drug may help limit the damage.

Although atherosclerosis often isn't detected until critical blood flow is disrupted, there can be warning signs. Partial blockage of the coronary arteries may cause occasional chest pain, a condition known as angina pectoris, or more commonly angina. The pain is most likely to be felt when the heart is laboring hard during physical or emotional stress, and it signals that part of the heart is not receiving enough  $O_2$ . An obstructed coronary artery may be treated surgically, either by inserting a metal mesh tube called a stent to expand the artery or by transplanting a healthy blood vessel from the chest or a limb to bypass the blockage.

## Risk Factors and Treatment of Cardiovascular Disease

Although the tendency to develop particular cardiovascular diseases is inherited, it is also strongly influenced by lifestyle. For example, exercise decreases the LDL/HDL ratio. In contrast, smoking, as well as consuming certain processed vegetable oils called *trans fats*, increases the ratio of LDL to HDL, raising the risk of cardiovascular disease. For many individuals at high risk, treatment with drugs called statins can lower LDL levels and thereby reduce the likelihood of heart attacks. In the **Scientific Skills Exercise**, you can interpret the effect of a genetic mutation on blood LDL levels.

The recognition that inflammation plays a central role in atherosclerosis and thrombus formation is also shaping the treatment of cardiovascular disease. For example, aspirin, which inhibits the inflammatory response, has been found to help prevent the recurrence of heart attacks and stroke. Researchers have also focused on C-reactive protein (CRP), which is produced by the liver and found in the blood during episodes of acute inflammation. Like a high level of LDL cholesterol, the presence of significant amounts of CRP in blood is a useful risk indicator for cardiovascular disease.

**Hypertension** (high blood pressure) is yet another contributor to heart attack and stroke as well as other health problems. According to one hypothesis, chronic high blood pressure damages the endothelium that lines the arteries, promoting plaque formation. The usual definition of hypertension in adults is a systolic pressure above 140 mm Hg or a diastolic pressure above 90 mm Hg. Fortunately, hypertension is simple to diagnose and can usually be controlled by dietary changes, exercise, medication, or a combination of these approaches.

### CONCEPT CHECK 34.4

1. Explain why a physician might order a white cell count for a patient with symptoms of an infection.
2. Clots in arteries can cause heart attacks and strokes. Why, then, does it make sense to treat people with hemophilia by introducing clotting factors into their blood?
3. **WHAT IF?** Nitroglycerin (the key ingredient in dynamite) is sometimes prescribed for heart disease patients. Within the body, the nitroglycerin is converted to nitric oxide. Why would you expect nitroglycerin to relieve chest pain in these patients?

For suggested answers, see Appendix A.

## CONCEPT 34.5

### Gas exchange occurs across specialized respiratory surfaces

In the remainder of this chapter, we will focus on the process of **gas exchange**. Although this process is often called respiratory exchange or respiration, it should not be confused

## Interpreting Data in Histograms

**Does Inactivating the PCSK9 Enzyme Lower LDL Levels in Humans?** Researchers interested in genetic factors affecting susceptibility to cardiovascular disease examined the DNA of 15,000 individuals. This screening revealed that 3% of the population sample had a mutation that inactivated one copy (allele) of the gene for PCSK9, a human liver enzyme. Because mutations that *increase* PCSK9 activity *increase* levels of LDL cholesterol in the blood, the researchers hypothesized that *inactivating* mutations in this gene would *lower* LDL levels. In this exercise, you will interpret the results of an experiment they carried out to test this hypothesis.

**How the Experiment Was Done** Researchers measured LDL cholesterol levels in blood plasma from 85 individuals with one copy of the *PCSK9* gene inactivated (the study group) and from 3,278 wild-type individuals (the control group).

### Data from the Experiment

Individuals with an inactivating mutation in one copy of *PCSK9* gene (study group)

Individuals with two functional copies of *PCSK9* gene (control group)

### Interpret the Data

- The results are presented using a variant of bar graph called a *histogram*. In a histogram, the variable on the x-axis is grouped into ranges. The height of each bar in this histogram reflects the percentage of samples that fall into the range specified on the x-axis for that bar. For example, in the top histogram, about 4% of individuals studied had plasma LDL cholesterol levels in the 25–50 mg/dL (milligrams per deciliter) range. Add the percentages for the relevant bars to calculate the percentage of individuals in the study group and the control group with an LDL level below 100 mg/dL. (For additional information about histograms, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
- Given the differences between these two histograms, what conclusion can you draw?
- Based on what you know about LDL cholesterol, would you predict that the individuals in the study group have an increased, unchanged, or reduced risk for cardiovascular disease relative to wild-type individuals? Explain.
- Propose an explanation for the fact that the two histograms overlap as much as they do.
- Comparing these two histograms allowed researchers to draw a conclusion regarding the effect of PCSK9 mutations on LDL cholesterol levels in blood. Suppose you now consider two individuals with a plasma LDL level of 160 mg/dL, one from the study group and one from the control group. What do you predict regarding their relative risk of cardiovascular disease? Explain how you arrived at your prediction. What role did the histograms play in making your prediction in this case?

**Data from** J. C. Cohen et al., Sequence variations in PCSK9, low LDL, and protection against coronary heart disease, *New England Journal of Medicine* 354:1264–1272 (2006).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

with the energy transformations of cellular respiration. Gas exchange is the uptake of molecular  $O_2$  from the environment and the discharge of  $CO_2$  to the environment. The respiratory medium—the source of oxygen in the environment—is either water or air.

## Partial Pressure Gradients in Gas Exchange

To understand the driving forces for gas exchange, we must calculate **partial pressure**, which is simply the pressure exerted by a particular gas in a mixture of gases. To do so, we need to know the pressure that the mixture exerts and the

fraction of the mixture represented by a particular gas. Let's consider  $O_2$  as an example. At sea level, the atmosphere exerts a downward force equal to that of a column of mercury (Hg) 760 mm high. Atmospheric pressure at sea level is thus 760 mm Hg. Since the atmosphere is 21%  $O_2$  by volume, the partial pressure of  $O_2$  is  $0.21 \times 760$ , or about 160 mm Hg. This value is called the *partial pressure* of  $O_2$  (abbreviated  $P_{O_2}$ ) because it is the part of atmospheric pressure contributed by  $O_2$ . The partial pressure of  $CO_2$  (abbreviated  $P_{CO_2}$ ) is much less, only 0.29 mm Hg at sea level.

Partial pressures also apply to gases dissolved in a liquid, such as water. When water is exposed to air, an equilibrium is reached in which the partial pressure of each gas in the water equals the partial pressure of that gas in the air. Thus, water exposed to air at sea level has a  $P_{O_2}$  of 160 mm Hg, the same as in the atmosphere. However, the *concentrations* of  $O_2$  in the air and water differ substantially because  $O_2$  is much less soluble in water than in air.

Once we have calculated partial pressures, we can readily predict the net result of diffusion at gas exchange surfaces: A gas always undergoes net diffusion from a region of higher partial pressure to a region of lower partial pressure.

## Respiratory Media

The conditions for gas exchange vary considerably, depending on whether the respiratory medium—the source of  $O_2$ —is air or water. As already noted,  $O_2$  is plentiful in air, making up about 21% of Earth's atmosphere by volume. Compared to water, air is much less dense and less viscous, so it is easier to move and to force through small passageways. As a result, breathing air is relatively easy and need not be particularly efficient. Humans, for example, extract only about 25% of the  $O_2$  in inhaled air.

Gas exchange with water as the respiratory medium is much more demanding. The amount of  $O_2$  dissolved in a given volume of water varies but is always less than in an equivalent volume of air: Water in many marine and freshwater habitats contains only 4–8 mL of dissolved  $O_2$  per liter, a concentration roughly 40 times less than in air. The warmer and saltier the water is, the less dissolved  $O_2$  it can hold. Water's lower  $O_2$  content, greater density, and greater viscosity mean that aquatic animals such as fishes and lobsters must expend considerable energy to carry out gas exchange. In the context of these challenges, adaptations have evolved that enable most aquatic animals to be very efficient in gas exchange. Many of these adaptations involve the organization of

the surfaces dedicated to exchange, as illustrated in a marine worm and a sea star (**Figure 34.17**).

## Respiratory Surfaces

Specialization for gas exchange is apparent in the structure of the respiratory surface, the part of an animal's body where gas exchange occurs. Like all living cells, the cells that carry out gas exchange have a plasma membrane that must be in contact with an aqueous solution. Respiratory surfaces are therefore always moist.

The movement of  $O_2$  and  $CO_2$  across respiratory surfaces takes place by diffusion. The rate of diffusion is proportional to the surface area across which it occurs and inversely proportional to the square of the distance through which molecules must move. In other words, gas exchange is fast when the area for diffusion is large and the path for diffusion is short. As a result, respiratory surfaces tend to be large and thin.

In some relatively simple animals, such as sponges, cnidarians, and flatworms, every cell in the body is close enough to the external environment that gases can diffuse quickly between any cell and the environment. In many animals, however, the bulk of the body's cells lack immediate access to the environment. The respiratory surface in these animals is a thin, moist epithelium that constitutes a respiratory organ.

**(a) Marine worm.** Many polychaetes (marine worms of the phylum Annelida) have a pair of flattened appendages called parapodia (singular, *parapodium*) on each body segment. The parapodia serve as gills and also function in crawling and swimming.

**(b) Sea star.** The gills of a sea star are simple tubular projections of the skin. The hollow core of each gill is an extension of the coelom (body cavity). Gas exchange occurs by diffusion across the gill surfaces, and fluid in the coelom circulates in and out of the gills, aiding gas transport. The surfaces of a sea star's tube feet also function in gas exchange.

**▲ Figure 34.17** Diversity in the structure of gills, external body surfaces that function in gas exchange.

In some animals, including earthworms and some amphibians, the skin serves as a respiratory organ. A dense network of capillaries just below the surface facilitates the exchange of gases between the circulatory system and the environment. For most animals, however, the general body surface lacks sufficient area to exchange gases for the whole organism. The evolutionary solution to this limitation is a respiratory organ that is extensively folded or branched, thereby enlarging the available surface area for gas exchange. Gills, tracheae, and lungs are three such organs.

## Gills in Aquatic Animals

Gills are outfoldings of the body surface that are suspended in the water. They can be localized to specialized structures, as in an axolotl (see Figure 34.1), or distributed across the body, as in a sea star or marine worm (see Figure 34.17). Movement of the respiratory medium over the respiratory surface, a process called **ventilation**, maintains the partial pressure gradients of  $O_2$  and  $CO_2$  across the gill that are necessary for gas exchange.

To promote ventilation, most gill-bearing animals move their gills through the water or move water over their gills. For example, crayfish and lobsters have paddle-like appendages that drive a current of water over the gills, whereas mussels and clams move water with cilia. Octopuses and squids ventilate their gills by taking in and ejecting water, with the side benefit of locomotion by jet propulsion. Fishes use the motion

of swimming or movements of the mouth and gill covers to ventilate their gills. In both cases, a water current enters the mouth of the fish, passes through slits in the pharynx, flows over the gills, and exits the body (**Figure 34.18**).

In fishes, the efficiency of gas exchange is maximized by **countercurrent exchange**, the exchange of a substance or heat between two fluids flowing in opposite directions. (Recall from Chapter 32 that countercurrent exchange also contributes to temperature regulation and kidney function.) Because blood flows in the direction opposite to that of water passing over the gills, blood is less saturated with  $O_2$  at each point in its travel than the water it meets (see Figure 34.18). As blood enters a gill capillary, it encounters water that is completing its passage through the gill. Depleted of much of its dissolved  $O_2$ , this water nevertheless has a higher  $P_{O_2}$  than the incoming blood, and  $O_2$  transfer takes place. As the blood continues its passage, its  $P_{O_2}$  steadily increases, but so does that of the water it encounters, since each successive position in the blood's travel corresponds to an earlier position in the water's passage over the gills. Thus, a partial pressure gradient favoring the diffusion of  $O_2$  from water to blood exists along the entire length of the capillary.

Countercurrent exchange mechanisms are remarkably efficient. More than 80% of the  $O_2$  dissolved in the water entering the mouth and gills of the fish is removed as it passes over the respiratory surface.

▲ **Figure 34.19** The insect tracheal system.

## Tracheal Systems in Insects

In most terrestrial animals, respiratory surfaces are enclosed within the body, exposed to the atmosphere only through narrow tubes. Although the most familiar such structure is the lung, the most common is the insect **tracheal system**, a network of air tubes that branch throughout the body. The largest tubes, called tracheae, open to the outside (**Figure 34.19a**). The finest branches extend close to the surface of nearly every cell, where gas is exchanged by diffusion across the moist epithelium that lines the tips of the tracheal branches (**Figure 34.19b**). Because the tracheal system brings air within a very short distance of virtually every body cell in an insect, it can transport  $O_2$  and  $CO_2$  without the participation of the animal's open circulatory system.

For small insects, diffusion through the tracheae brings in enough  $O_2$  and removes enough  $CO_2$  to support cellular respiration. Larger insects meet their higher energy demands by ventilating their tracheal systems with rhythmic body movements that compress and expand the air tubes like bellows. Insects in flight, which have a particularly high metabolic rate, have flight muscle cells that are packed with mitochondria. Tracheal tubes distributed throughout the flight muscles supply these ATP-generating organelles with ample  $O_2$  (**Figure 34.19c**).

## Lungs

Unlike tracheal systems, which branch throughout the insect body, **lungs** are localized respiratory organs. Representing an infolding of the body surface, they are typically subdivided into numerous pockets. Because the respiratory surface of a lung is not in direct contact with all other parts of the body, the gap must be bridged by the circulatory system, which transports gases between the lungs and the rest of the body. Lungs have

evolved in organisms with open circulatory systems, such as spiders and land snails, as well as in vertebrates.

Among vertebrates that lack gills, the use of lungs for gas exchange varies. Amphibians rely heavily on diffusion across body surfaces, such as the skin, to carry out gas exchange; lungs, if present, are relatively small. In contrast, most reptiles (including all birds) and all mammals depend entirely on lungs for gas exchange. Lungs and air breathing have evolved in a few aquatic vertebrates as adaptations to living in oxygen-poor water or to spending part of their time exposed to air (for instance, when the water in a pond recedes).

## Mammalian Respiratory Systems: A Closer Look

In mammals, a system of branching ducts conveys air to the lungs, which are located in the thoracic cavity (**Figure 34.20**). Air enters through the nostrils and is then filtered by hairs, warmed, humidified, and sampled for odors as it flows through a maze of spaces in the nasal cavity. The nasal cavity leads to the pharynx, an intersection where the paths for air and food cross. When food is swallowed, the **larynx** (the upper part of the respiratory tract) moves upward and tips a flap of cartilage over the opening of the **trachea**, or windpipe. This allows food to go down the esophagus to the stomach. The rest of the time, the airway is open, enabling breathing.

From the larynx, air passes into the trachea. Cartilage reinforcing the walls of both the larynx and the trachea keeps this part of the airway open. Within the larynx of most mammals, exhaled air rushes by a pair of elastic bands of muscle called vocal folds, or, in humans, vocal cords. Sounds are produced when muscles in the larynx are tensed, stretching the cords so they vibrate. High-pitched sounds result from tightly stretched cords vibrating rapidly; low-pitched sounds come from less tense cords vibrating slowly.

▲ **Figure 34.20 The mammalian respiratory system.** From the nasal cavity and pharynx, inhaled air passes through the larynx, trachea, and bronchi to the bronchioles, which end in microscopic alveoli lined by a thin, moist epithelium. Branches of the pulmonary arteries convey oxygen-poor blood to the alveoli; branches of the pulmonary veins transport oxygen-rich blood from the alveoli back to the heart.

The trachea branches into two **bronchi** (singular, *bronchus*), one leading to each lung. Within the lung, the bronchi branch repeatedly into finer and finer tubes called *bronchioles*. The entire system of air ducts has the appearance of an inverted tree, the trunk being the trachea. The epithelium lining the major branches of this respiratory tree is covered by cilia and a thin film of mucus. The mucus traps dust, pollen, and other particulate contaminants, and the beating cilia move the mucus upward to the pharynx, where it can be swallowed into the esophagus. This process, sometimes referred to as the “mucus escalator,” plays a crucial role in cleansing the respiratory system.

Gas exchange in mammals occurs in **alveoli** (singular, *alveolus*; see Figure 34.20), air sacs clustered at the tips of the tiniest bronchioles. Human lungs contain millions of alveoli, which together have a surface area of about  $100 \text{ m}^2$ —50 times that of the skin. Oxygen in the air entering the alveoli dissolves in the moist film lining their inner surfaces and rapidly undergoes net diffusion across the epithelium into a web of capillaries that surrounds each alveolus. Net diffusion of carbon dioxide occurs in the opposite direction, from the capillaries across the epithelium of the alveolus and into the air space.

Lacking cilia or significant air currents to remove particles from their surface, alveoli are highly susceptible to

contamination. White blood cells patrol the alveoli, engulfing foreign particles. However, if too much particulate matter reaches the alveoli, the defenses can be overwhelmed, leading to inflammation and irreversible damage. For example, particulates from cigarette smoke that enter alveoli can cause a permanent reduction in lung capacity. For coal miners, inhalation of large amounts of coal dust can lead to silicosis, a disabling, irreversible, and sometimes fatal lung disease.

The film of liquid that lines alveoli is subject to surface tension, an attractive force that has the effect of minimizing a liquid’s surface area (see Chapter 2). Given their tiny diameter (about  $0.25 \text{ mm}$ ), why don’t alveoli collapse under high surface tension? Researchers reasoned that alveoli must be coated with a material that reduces surface tension. In 1955, English biophysicist Richard Pattle obtained experimental evidence for such a material, now called a **surfactant**, for *surface-active* agent. In addition, he proposed that the absence of surfactant might cause respiratory distress syndrome (RDS), a disease common among preterm infants born 6 weeks or more before their due dates. In the 1950s, RDS killed 10,000 infants annually in the United States alone.

In the late 1950s, Mary Ellen Avery carried out the first experiment linking RDS to a surfactant deficiency

## What causes respiratory distress syndrome?

**Experiment** Mary Ellen Avery, a research fellow at Harvard University, hypothesized that a lack of surfactant caused respiratory distress syndrome (RDS) in preterm infants. To test this idea, she obtained autopsy samples of lungs from infants that had died of RDS or from other causes. She extracted material from the samples and let it form a film on water. Avery then measured the tension (in dynes per centimeter) across the water surface and recorded the lowest surface tension observed for each sample.

**Results** In analyzing the data, Avery noted a pattern when she grouped the samples from infants with a body mass of less than 1,200 g (2.7 lbs) and those who had grown larger.

**Conclusion** For infants 1,200 g and above, the samples from those that had died of causes other than RDS exhibited much lower surface tension than samples from those that had died of RDS. Avery inferred that infants' lungs normally contain a surface-tension reducing material (now called surfactant), and that a lack of this material was a likely cause of RDS. The results from infants less than 1,200 g were similar to those of infants who had died from RDS, suggesting that surfactant is not normally produced until a fetus reaches this size.

**Source** M. E. Avery and J. Mead, Surface properties in relation to atelectasis and hyaline membrane disease, *American Journal of Diseases of Children* 97:517–523 (1959).

**WHAT IF?** Suppose researchers had measured the amount of surfactant in lung samples. Describe the graph you would expect if the amount of surfactant were plotted against infant weight.

**(Figure 34.21).** Subsequent studies revealed that surfactant contains a mixture of phospholipids and proteins and in a full-term (38-week) pregnancy appears in the lungs about five weeks before birth. Artificial surfactants are now used routinely to treat early preterm infants. For her contributions, Avery received the National Medal of Science in 1991.

## CONCEPT CHECK 34.5

1. Why is the position of lung tissues *within* the body an advantage for terrestrial animals?
2. After a heavy rain, earthworms come to the surface. How would you explain this behavior in terms of an earthworm's requirements for gas exchange?
3. **MAKE CONNECTIONS** Describe the role of countercurrent exchange in facilitating both thermoregulation (see Concept 32.1) and respiration.

For suggested answers, see Appendix A.

## CONCEPT 34.6

## Breathing ventilates the lungs

Having surveyed the route that air follows when we breathe, we turn now to the process of breathing itself. Like fishes, terrestrial vertebrates rely on ventilation to maintain high  $O_2$  and low  $CO_2$  concentrations at the gas exchange surface. The process that ventilates lungs is **breathing**, the alternating inhalation and exhalation of air. A variety of mechanisms for moving air in and out of lungs have evolved, as we will see by considering amphibians, birds, and mammals.

An amphibian such as a frog ventilates its lungs by **positive pressure breathing**, filling the lungs with forced airflow. During each cycle of ventilation, fresh air is first drawn through the nostrils into a specialized oral cavity. Next, this air-filled cavity is closed off while elastic recoil of the lungs directs stale air out through the mouth and nostrils. Finally, with the nostrils and mouth closed and the oral cavity open to the trachea, the floor of the oral cavity rises, forcing air into the lungs.

To bring fresh air to their lungs, birds use eight or nine air sacs situated on either side of the lungs. The air sacs do not function directly in gas exchange but act as bellows that keep air flowing through the lungs. Instead of alveoli, the sites of gas exchange in bird lungs are tiny channels called *parabronchi*. Passage of air through the entire system—lungs and air sacs—requires two cycles of inhalation and exhalation.

Two features of ventilation in birds make it highly efficient. First, when birds breathe, air passes over the gas exchange surface in only one direction. Second, incoming fresh air does not mix with air that has already carried out gas exchange.

## How a Mammal Breathes

Mammals employ **negative pressure breathing**—pulling, rather than pushing, air into their lungs (**Figure 34.22**). Using muscle contraction to actively expand their thoracic cavity, mammals lower air pressure in their lungs below that of the outside air. Because gas flows from a region of higher pressure to a region of lower pressure, air rushes through the nostrils and mouth and down the breathing tubes to the alveoli. During exhalation, the muscles controlling the thoracic cavity relax, and the cavity's volume is reduced. The increased air pressure in the alveoli forces air up the breathing tubes and out of the body. Thus, inhalation is always active and requires work, whereas exhalation is usually passive.

Expanding the thoracic cavity during inhalation involves rib muscles and the **diaphragm**, a sheet of skeletal muscle that forms the bottom wall of the cavity. Contracting one set of rib muscles expands the rib cage, the front wall of the thoracic cavity, by pulling the ribs upward and the sternum outward. At the same time, the diaphragm contracts, expanding the thoracic cavity downward. The effect of the descending diaphragm is similar to that of a plunger being drawn out of a syringe.

▲ **Figure 34.22 Negative pressure breathing.** A mammal breathes by changing the air pressure within its lungs relative to the pressure of the outside atmosphere.

Within the thoracic cavity, a double membrane surrounds the lungs. The inner layer of this membrane adheres to the outside of the lungs, and the outer layer adheres to the wall of the thoracic cavity. A thin space filled with fluid separates the two layers. Surface tension in the fluid causes the two layers to stick together like two plates of glass separated by a film of water: The layers can slide smoothly past each other, but they cannot be pulled apart easily. Consequently, the volume of the thoracic cavity and the volume of the lungs change in unison.

The volume of air inhaled and exhaled with each breath is called **tidal volume**. It averages about 500 mL in resting adult humans. The tidal volume during maximal inhalation and exhalation is the **vital capacity**, which is about 3.4 L and 4.8 L for college-age women and men, respectively. The air that remains after a forced exhalation is called the **residual volume**. As humans age, our lungs lose their resilience, and residual volume increases at the expense of vital capacity.

Because the lungs in mammals do not completely empty with each breath, and because inhalation occurs through the same airways as exhalation, each inhalation mixes fresh air with oxygen-depleted residual air. As a result, the maximum  $P_{O_2}$  in alveoli is always considerably less than in the atmosphere. This is one reason mammals don't function as well as birds at high altitude. For example, humans have great difficulty obtaining enough  $O_2$  when climbing Earth's highest peaks, such as Mount Everest (8,850 m) in the Himalayas. However, bar-headed geese and several other bird species easily fly through high Himalayan passes during their migrations.

## Control of Breathing in Humans

Although you can voluntarily hold your breath or breathe faster and deeper, most of the time your breathing is regulated by involuntary mechanisms. These control mechanisms ensure

that gas exchange is coordinated with blood circulation and with metabolic demand.

The neurons mainly responsible for regulating breathing are in the medulla oblongata, near the base of the brain (**Figure 34.23**). Neural circuits in the medulla form a breathing control center that establishes the breathing rhythm. When you breathe deeply, a negative-feedback mechanism prevents the lungs from overexpanding: During inhalation, sensors that detect stretching of the lung tissue send nerve impulses to the control circuits in the medulla, inhibiting further inhalation.

In regulating breathing, the medulla uses the pH of the surrounding tissue fluid as an indicator of blood  $CO_2$  concentration. The reason pH can be used in this way is that blood  $CO_2$  is the main determinant of the pH of cerebrospinal fluid, the fluid surrounding the brain and spinal cord. Carbon dioxide diffuses from the blood to the cerebrospinal fluid, where it reacts with water and forms carbonic acid ( $H_2CO_3$ ). The

▲ **Figure 34.23 Homeostatic control of breathing.**

**WHAT IF?** Suppose a person began breathing very rapidly while resting. Describe the effect on blood  $CO_2$  levels and the steps by which the negative-feedback circuit would restore homeostasis.

$\text{H}_2\text{CO}_3$  can then dissociate into a bicarbonate ion ( $\text{HCO}_3^-$ ) and a hydrogen ion ( $\text{H}^+$ ):

Increased metabolic activity, such as occurs during exercise, increases the concentration of  $\text{CO}_2$  in the blood, and lowers pH through the reaction shown above. Sensors in the medulla as well as in major blood vessels detect this pH change. In response, the medulla's control circuits increase the depth and rate of breathing (see Figure 34.23). Both remain high until the excess  $\text{CO}_2$  is eliminated in exhaled air and pH returns to a normal value.

The blood  $\text{O}_2$  level usually has little effect on the breathing control centers. However, when the  $\text{O}_2$  level drops very low (at high altitudes, for instance),  $\text{O}_2$  sensors in the aorta and the carotid arteries in the neck send signals to the breathing control centers, which respond by increasing the breathing rate.

Breathing control is effective only if ventilation is matched to blood flow through the capillaries in the alveoli. During exercise, for instance, such coordination couples an increased breathing rate, which enhances  $\text{O}_2$  uptake and  $\text{CO}_2$  removal, with an increase in cardiac output.

#### CONCEPT CHECK 34.6

1. How does an increase in the  $\text{CO}_2$  concentration in the blood affect the pH of cerebrospinal fluid?
2. A drop in blood pH causes an increase in heart rate. What is the function of this control mechanism?
3. **WHAT IF?** If an injury tore a small hole in the membranes surrounding your lungs, what effect on lung function would you expect?

For suggested answers, see Appendix A.

## CONCEPT 34.7

### Adaptations for gas exchange include pigments that bind and transport gases

The high metabolic demands of many animals necessitate the exchange of large quantities of  $\text{O}_2$  and  $\text{CO}_2$ . Blood molecules called respiratory pigments facilitate this exchange through their interaction with  $\text{O}_2$  and  $\text{CO}_2$ . Before exploring how respiratory pigments function, let's summarize the basic gas exchange circuit in humans.

### Coordination of Circulation and Gas Exchange

The partial pressures of  $\text{O}_2$  and  $\text{CO}_2$  in the blood vary at different points in the circulatory system, as shown in **Figure 34.24**. Blood flowing through the alveolar capillaries has a lower  $P_{\text{O}_2}$

and a higher  $P_{\text{CO}_2}$  than the air in the alveoli. As a result,  $\text{CO}_2$  diffuses down its partial pressure gradient from the blood to the air in the alveoli. Meanwhile,  $\text{O}_2$  in the air dissolves in the fluid that coats the alveolar epithelium and undergoes net diffusion into the blood. By the time the blood leaves the lungs in the pulmonary veins, its  $P_{\text{O}_2}$  has been raised and its  $P_{\text{CO}_2}$  has been lowered. After returning to the heart, this blood is pumped through the systemic circuit.

In the tissue capillaries, gradients of partial pressure favor the net diffusion of  $\text{O}_2$  out of the blood and  $\text{CO}_2$  into the blood. These gradients exist because cellular respiration in the mitochondria of cells near each capillary removes  $\text{O}_2$  from and adds  $\text{CO}_2$  to the surrounding interstitial fluid. After the blood unloads  $\text{O}_2$  and loads  $\text{CO}_2$ , it is returned to the heart and pumped to the lungs again.

Having characterized the driving forces for gas exchange in different tissues, we will now introduce the critical role of the specialized carrier proteins—the respiratory pigments.

### Respiratory Pigments

The low solubility of  $\text{O}_2$  in water (and thus in blood) poses a problem for animals that rely on the circulatory system to deliver  $\text{O}_2$ . For example, a person requires almost 2 L of  $\text{O}_2$  per minute during intense exercise, and all of it must be carried in the blood from the lungs to the active tissues. At normal body temperature and air pressure, however, only 4.5 mL of  $\text{O}_2$  can dissolve into a

© 1998 Pearson Education, Inc.

**▲ Figure 34.24 Loading and unloading of respiratory gases.** The colored bars indicate the partial pressures (in mm Hg) of  $\text{O}_2$  ( $P_{\text{O}_2}$ ) and  $\text{CO}_2$  ( $P_{\text{CO}_2}$ ) in different locations.

**WHAT IF?** If you consciously forced more air out of your lungs each time you exhaled, how would that affect the values shown above?

liter of blood in the lungs. Even if 80% of the dissolved  $O_2$  were delivered to the tissues (an unrealistically high percentage), the heart would still need to pump 555 L of blood per minute!

In fact, animals transport most of their  $O_2$  bound to proteins called **respiratory pigments**. Respiratory pigments circulate with the blood or hemolymph and are often contained within specialized cells. The pigments greatly increase the amount of  $O_2$  that can be carried in the circulatory fluid (to about 200 mL of  $O_2$  per liter in mammalian blood). In our example of an exercising human with an  $O_2$  delivery rate of 80%, the presence of a respiratory pigment reduces the cardiac output necessary for  $O_2$  transport to a manageable 12.5 L of blood per minute.

A variety of respiratory pigments have evolved among the animal taxa. With a few exceptions, these molecules have a distinctive color (hence the term *pigment*) and consist of a metal bound to a protein. One example is the blue pigment hemocyanin, which has copper as its oxygen-binding component and is found in arthropods and many molluscs. The respiratory pigment of many invertebrates and almost all vertebrates is hemoglobin.

In vertebrates, hemoglobin is contained in the erythrocytes and consists of four subunits (polypeptide chains), each with a cofactor called a heme group that has an iron atom at its center. Each iron atom binds one molecule of  $O_2$ ; hence, a single hemoglobin molecule can carry four molecules of  $O_2$ . Like all respiratory pigments, hemoglobin binds  $O_2$  reversibly, loading  $O_2$  in the lungs or gills and unloading it in other parts of the body. This process depends on cooperativity between the hemoglobin subunits (see Concept 6.5). When  $O_2$  binds to one subunit, the others change shape slightly, increasing their affinity for  $O_2$ . Similarly, when four  $O_2$  molecules are bound and one subunit unloads its  $O_2$ , the other three subunits more readily unload  $O_2$ , as an associated shape change lowers their affinity for  $O_2$ .

The cooperativity in both  $O_2$  binding and release is evident in the dissociation curve for hemoglobin (**Figure 34.25a**). Over the range of  $P_{O_2}$  where the dissociation curve has a steep slope, even a slight change in  $P_{O_2}$  causes hemoglobin to load or unload a substantial amount of  $O_2$ . Notice that the steep part of the curve corresponds to the range of  $P_{O_2}$  found in body tissues. When cells in a particular location begin working harder—during exercise, for instance— $P_{O_2}$  dips in their vicinity as the  $O_2$  is consumed in cellular respiration. Because of the effect of subunit cooperativity, a slight drop in  $P_{O_2}$  causes a relatively large increase in the amount of  $O_2$  the blood unloads.

The production of  $CO_2$  during cellular respiration promotes the unloading of  $O_2$  by hemoglobin in active tissues. As we have seen,  $CO_2$  reacts with water, forming carbonic acid, which lowers the pH of its surroundings. Low pH, in turn,

**(a)  $P_{O_2}$  and hemoglobin dissociation at pH 7.4.** The curve shows the relative amounts of  $O_2$  bound to hemoglobin exposed to solutions with different  $P_{O_2}$ . At a  $P_{O_2}$  of 100 mm Hg, typical in the lungs, hemoglobin is about 98% saturated with  $O_2$ . At a  $P_{O_2}$  of 40 mm Hg, common in the vicinity of tissues at rest, hemoglobin is about 70% saturated, having unloaded nearly a third of its  $O_2$ . As shown in the above graph, hemoglobin can release much more  $O_2$  to metabolically very active tissues, such as muscle tissue during exercise.

**(b) pH and hemoglobin dissociation.** Because hydrogen ions affect the shape of hemoglobin, a drop in pH shifts the  $O_2$  dissociation curve toward the right (the Bohr shift). At a given  $P_{O_2}$ , say 40 mm Hg, hemoglobin gives up more  $O_2$  at pH 7.2 than at pH 7.4, the normal pH of human blood. The pH is lower in very active tissues because the  $CO_2$  produced by cellular respiration reacts with water, forming carbonic acid. There, hemoglobin releases more  $O_2$ , which supports the increased cellular respiration in the active tissues.

▲ **Figure 34.25 Dissociation curves for hemoglobin at 37°C.**

decreases the affinity of hemoglobin for  $O_2$ , an effect called the **Bohr shift** (**Figure 34.25b**). Thus, where  $CO_2$  production is greater, hemoglobin releases more  $O_2$ , which can then be used to support more cellular respiration.

In addition to its role in O<sub>2</sub> transport, hemoglobin assists in buffering the blood—that is, preventing harmful changes in pH. It also has a minor role in CO<sub>2</sub> transport, the topic we will explore next.

## Carbon Dioxide Transport

Only about 7% of the CO<sub>2</sub> released by respiring cells is transported in solution in blood plasma. The remainder diffuses from the plasma into erythrocytes and reacts with water (assisted by the enzyme carbonic anhydrase), forming H<sub>2</sub>CO<sub>3</sub>. The H<sub>2</sub>CO<sub>3</sub> readily dissociates into H<sup>+</sup> and HCO<sub>3</sub><sup>−</sup>. Most of the H<sup>+</sup> binds to hemoglobin and other proteins, minimizing the change in blood pH. Most of the HCO<sub>3</sub><sup>−</sup> diffuses out of the erythrocyte and is transported to the lungs in the plasma. The remainder, about 5% of the overall CO<sub>2</sub>, binds to hemoglobin and is transported in erythrocytes.

When blood flows through the lungs, the relative partial pressures of CO<sub>2</sub> favor the diffusion of CO<sub>2</sub> out of the blood. As CO<sub>2</sub> diffuses from blood into alveoli, the amount of CO<sub>2</sub> in the blood decreases. This decrease shifts the chemical equilibrium in favor of the conversion of HCO<sub>3</sub><sup>−</sup> to CO<sub>2</sub>, enabling further net diffusion of CO<sub>2</sub> into alveoli. Overall, the P<sub>CO<sub>2</sub></sub> gradient is sufficient to reduce P<sub>CO<sub>2</sub></sub> by about 15% during passage of blood through the lungs.

## Respiratory Adaptations of Diving Mammals

**EVOLUTION** Animals vary greatly in their ability to temporarily inhabit environments in which there is no access to their normal respiratory medium—for example, when an air-breathing mammal swims underwater. Whereas most humans, even well-trained divers, cannot hold their breath longer than 2 or 3 minutes or swim deeper than 20 m, the Weddell seal of Antarctica routinely plunges to 200–500 m and remains there for about 20 minutes (and sometimes for more than an hour). Another diving mammal, the elephant seal, can reach depths

of 1,500 m—almost a mile—and stay submerged for as long as 2 hours! What evolutionary adaptations enable these animals to perform such amazing feats?

One adaptation of diving mammals to prolonged stays underwater is an ability to store large amounts of O<sub>2</sub>. The Weddell seal has a greater volume of blood per kilogram of body mass than a human and has a high concentration of an oxygen-storing protein called **myoglobin** in its muscles. As a result, the Weddell seal can store about twice as much O<sub>2</sub> per kilogram of body mass as can a human.

Diving mammals not only have a relatively large O<sub>2</sub> stockpile but also have adaptations that conserve O<sub>2</sub>. They swim with little muscular effort and glide passively upward or downward by changing their buoyancy. During a dive, most blood is routed to the brain, spinal cord, eyes, adrenal glands, and, in pregnant seals, the placenta. Blood supply to the muscles is restricted or, during the longest dives, shut off altogether. During dives of more than about 20 minutes, a Weddell seal's muscles deplete the O<sub>2</sub> stored in myoglobin and then derive their ATP from fermentation instead of respiration.

The unusual abilities of the Weddell seal and other air-breathing divers to power their bodies during long dives showcase two related themes in our study of organisms—the response to environmental challenges over the short term by physiological adjustments and over the long term as a result of natural selection.

### CONCEPT CHECK 34.7

1. What determines whether the net diffusion of O<sub>2</sub> and CO<sub>2</sub> is into or out of the capillaries? Explain.
2. How does the Bohr shift help deliver O<sub>2</sub> to very active tissues?
3. **WHAT IF?** A doctor might give bicarbonate (HCO<sub>3</sub><sup>−</sup>) to a patient who is breathing very rapidly. What assumption is the doctor making about the blood chemistry of the patient?

For suggested answers, see Appendix A.

# 34 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 34.1

**Circulatory systems link exchange surfaces with cells throughout the body (pp. 685–688)**

- In animals with simple body plans, a **gastrovascular cavity** mediates exchange between the environment and body cells. Because net diffusion is slow over long distances, most complex animals have a circulatory system that moves fluid between cells and the organs that carry out exchange with the environment. Arthropods and most molluscs have an **open circulatory system**, in which **hemolymph** bathes organs directly.

Vertebrates have a **closed circulatory system**, in which **blood** circulates in a closed network of pumps and vessels.

- The closed circulatory system of vertebrates consists of blood, blood vessels, and a two- to four-chambered **heart**. Blood pumped by a heart **ventricle** passes to **arteries** and then to **capillaries**, the sites of chemical exchange between blood and interstitial fluid. **Veins** return blood from capillaries to an **atrium**, which passes blood to a ventricle.
- Fishes, rays, and sharks have a single pump in their circulatory systems, whereas air-breathing vertebrates have two pumps combined in a single heart. Variations between different species in ventricle number and divisions reflect adaptations to different environments and metabolic needs.

**?** How does the flow of a fluid in a closed circulatory system differ from the movement of molecules between cells and their environment with regard to distance traveled, direction traveled, and driving force?

## CONCEPT 34.2

### Coordinated cycles of heart contraction drive double circulation in mammals (pp. 689–690)

- The right ventricle pumps blood to the lungs, where it loads  $O_2$  and unloads  $CO_2$ . Oxygen-rich blood from the lungs enters the heart at the left atrium and is pumped to the body tissues by the left ventricle. Blood returns to the heart through the right atrium.

© 1998 Pearson Education, Inc.

- The **cardiac cycle**, one complete sequence of the heart's pumping and filling, consists of a period of contraction, called **systole**, and a period of relaxation, called **diastole**. The heartbeat originates with impulses at the **sinoatrial (SA) node** (pacemaker) of the right atrium. The impulses trigger atrial contraction, are delayed at the **atrioventricular (AV) node**, and then cause ventricular contraction. The nervous system, hormones, and body temperature influence pacemaker activity.

**?** What changes in cardiac function might you expect after surgical replacement of a defective heart valve?

## CONCEPT 34.3

### Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels (pp. 690–694)

- Blood vessels have structures well adapted to function. Capillaries have narrow diameters and thin walls that facilitate exchange. Arteries contain thick elastic walls that maintain blood pressure. Veins contain one-way valves that contribute to the return of blood to the heart. Blood pressure is altered by changes in cardiac output and by variable constriction of arterioles.
- The velocity of blood flow is lowest in the capillary beds as a result of their large total cross-section area. Fluid leaks out of capillaries and is returned to blood by the **lymphatic system**, which also plays a vital role in defense against infection.

**?** If you rest your forearm on the top of your head rather than by your side, how, if at all, is blood pressure in that arm affected? Explain.

## CONCEPT 34.4

### Blood components function in exchange, transport, and defense (pp. 695–698)

- Whole blood consists of cells and cell fragments (**platelets**) suspended in a liquid matrix called **plasma**. Plasma proteins influence blood pH, osmotic pressure, and viscosity, and they function in lipid transport, immunity (antibodies), and blood clotting (fibrinogen). Red blood cells, or **erythrocytes**, transport  $O_2$ . White blood cells, or **leukocytes**, function in defense against microbes and foreign substances. Platelets function in blood clotting.
- A variety of diseases impair function of the circulatory system. In **sickle-cell disease**, an aberrant form of **hemoglobin** disrupts erythrocyte shape and function. In cardiovascular disease, inflammation of the arterial lining enhances deposition of lipids and cells, resulting in the potential for life-threatening damage to the heart or brain.

**?** In the absence of infection, what percentage of cells in human blood are leukocytes?

## CONCEPT 34.5

### Gas exchange occurs across specialized respiratory surfaces (pp. 698–704)

- At all sites of **gas exchange**, a gas undergoes net diffusion from where its **partial pressure** is higher to where it is lower. Air is more conducive to gas exchange than water because air has a higher  $O_2$  content, lower density, and lower viscosity.
- Gills are outfoldings of the body specialized for gas exchange in water. The effectiveness of gas exchange in some gills, including those of fishes, is increased by **ventilation** and **countercurrent exchange** between blood and water. Gas exchange in insects relies on a **tracheal system**, a branched network of tubes that brings  $O_2$  directly to cells. Spiders, land snails, and most terrestrial vertebrates have **lungs**. In mammals, inhaled air passes through the pharynx into the **trachea**, **bronchi**, bronchioles, and dead-end **alveoli**, where gas exchange occurs.

**?** Why does altitude have almost no effect on an animal's ability to rid itself of  $CO_2$  through gas exchange?

## CONCEPT 34.6

### Breathing ventilates the lungs (pp. 704–706)

- Breathing mechanisms vary substantially among vertebrates. An amphibian ventilates its lungs by **positive pressure breathing**, which forces air down the trachea. Birds use a system of air sacs as bellows to keep air flowing through the lungs in one direction only. Mammals ventilate their lungs by **negative pressure breathing**, which pulls air into the lungs. Lung volume increases as the rib muscles and **diaphragm** contract. Incoming and outgoing air mix, decreasing the efficiency of ventilation.
- Control centers in the brain regulate the rate and depth of breathing. Sensors detect the pH of cerebrospinal fluid (reflecting  $CO_2$  concentration in the blood), and the medulla adjusts breathing rate and depth to match metabolic demands. Secondary control is exerted by sensors in the aorta and carotid arteries that monitor blood levels of  $O_2$  as well as  $CO_2$  (via blood pH).

**?** How does air in the lungs differ from the fresh air that enters the body during inspiration?

## CONCEPT 34.7

### Adaptations for gas exchange include pigments that bind and transport gases (pp. 706–708)

- In the lungs, gradients of partial pressure favor the net diffusion of  $O_2$  into the blood and  $CO_2$  out of the blood. The opposite situation exists in the rest of the body. **Respiratory pigments**, such as hemoglobin, bind  $O_2$ , greatly increasing the amount of  $O_2$  transported by the circulatory system.
- Evolutionary adaptations enable some animals to satisfy extraordinary  $O_2$  demands. Deep-diving air-breathers stockpile  $O_2$  in blood and other tissues and deplete it slowly.

**?** In what way is the role of a respiratory pigment like that of an enzyme?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. Which of the following respiratory systems is not closely associated with a blood supply?
  - a. the lungs of a vertebrate
  - b. the gills of a fish
  - c. the tracheal system of an insect
  - d. the skin of an earthworm
  - e. the parapodia of a polychaete worm
2. Blood returning to the mammalian heart in a pulmonary vein drains first into the
  - a. vena cava.
  - b. left atrium.
  - c. right atrium.
  - d. left ventricle.
  - e. right ventricle.
3. Pulse is a direct measure of
  - a. blood pressure.
  - b. stroke volume.
  - c. cardiac output.
  - d. heart rate.
  - e. breathing rate.
4. When you hold your breath, which of the following blood gas changes first leads to the urge to breathe?
  - a. rising  $O_2$
  - b. falling  $O_2$
  - c. rising  $CO_2$
  - d. falling  $CO_2$
  - e. rising  $CO_2$  and falling  $O_2$

### Level 2: Application/Analysis

5. If a molecule of  $CO_2$  released into the blood in your left toe is exhaled from your nose, it must pass through all of the following *except*
  - a. the pulmonary vein.
  - b. an alveolus.
  - c. the trachea.
  - d. the right atrium.
  - e. the right ventricle.
6. Compared with the interstitial fluid that bathes active muscle cells, blood reaching these cells in arteries has a
  - a. higher  $P_{O_2}$ .
  - b. higher  $P_{CO_2}$ .
  - c. greater bicarbonate concentration.
  - d. lower pH.
  - e. lower osmotic pressure.

7. Which of the following would *increase* the amount of oxygen undergoing net diffusion from the lungs into the blood?
  - a. increasing the binding of oxygen to hemoglobin
  - b. increasing the water vapor content of air in the lungs
  - c. increasing the partial pressure of oxygen in the blood
  - d. decreasing the red blood cell count of the blood
  - e. decreasing the partial pressure of oxygen in the lung

### Level 3: Synthesis/Evaluation

8. **DRAW IT** Plot blood pressure against time for one cardiac cycle in humans, drawing separate lines for the pressure in the aorta, the left ventricle, and the right ventricle. Below the time axis, add a vertical arrow pointing to the time when you expect a peak in atrial blood pressure.

9. **SCIENTIFIC INQUIRY**

The hemoglobin of a human fetus differs from adult hemoglobin. Compare the dissociation curves of the two hemoglobins in the graph at right. Propose a hypothesis to explain the benefit of this difference between these two hemoglobins.

10. **FOCUS ON EVOLUTION**

One of the many mutant opponents of the movie monster Godzilla is Mothra, a giant mothlike creature with a wingspan of several dozen meters. However, the largest known insects were Paleozoic dragonflies with half-meter wingspans. Focusing on respiration and gas exchange, explain why truly giant insects are improbable.

11. **FOCUS ON INTERACTIONS**

Some athletes prepare for competition at sea level by sleeping in a tent in which  $P_{O_2}$  is kept artificially low. When climbing very high peaks, some mountaineers breathe from bottles of pure  $O_2$ . Relate these behaviors to humans' physiological interactions with our gaseous environment and control mechanisms governing oxygen delivery within the body.

For selected answers, see Appendix A.

# The Immune System

▼ **Figure 35.1** What triggered this attack by an immune cell on a clump of rod-shaped bacteria?

## KEY CONCEPTS

- 35.1** In innate immunity, recognition and response rely on traits common to groups of pathogens
- 35.2** In adaptive immunity, receptors provide pathogen-specific recognition
- 35.3** Adaptive immunity defends against infection of body fluids and body cells

## OVERVIEW

### Recognition and Response

For a **pathogen**—a bacterium, fungus, virus, or other disease-causing agent—the internal environment of an animal is a nearly ideal habitat. The animal body offers a ready source of nutrients, a protected setting for growth and reproduction, and a means of transport to new environments. From the perspective of a cold or flu virus, we are wonderful hosts. From our vantage point, the situation is not so ideal. Fortunately, adaptations have arisen over the course of evolution that protect animals against many invaders.

Dedicated immune cells in the body fluids and tissues of most animals specifically interact with and destroy pathogens. For example, **Figure 35.1** shows an immune cell called a macrophage (brown) surrounding and engulfing a clump of bacteria (green). Immune cells also release defense molecules into body fluids, including proteins that punch holes in bacterial membranes or block viruses from entering body cells. Together, the body's defenses make up the **immune system**, which enables an animal to avoid or limit many infections. A foreign molecule or cell doesn't have to be pathogenic (disease-causing) to elicit an immune response, but we'll focus in this chapter on the immune system's role in defending against pathogens.

The first lines of defense offered by immune systems help prevent pathogens from gaining entrance to the body. For example, an outer covering, such as a shell or skin, blocks entry by many microbes. Sealing off the entire body surface is impossible, however, because gas exchange, nutrition, and reproduction require openings to the environment. Secretions that trap or kill microbes guard the body's entrances and exits, while the linings of the digestive tract, airway, and other exchange surfaces provide additional barriers to infection.

If a pathogen breaches barrier defenses and enters the body, the problem of how to fend off attack changes substantially. Housed within body fluids and tissues, the invader is no longer an outsider. To fight infections, an animal's immune system must detect foreign particles and cells within the body. In other words, a properly functioning immune system distinguishes nonself from self. How is this accomplished? Immune cells produce receptor molecules that bind specifically

to molecules from foreign cells or viruses and activate defense responses. The specific binding of immune receptors to foreign molecules is a type of *molecular recognition* and is the central event in identifying nonself particles and cells.

## CONCEPT 35.1

### In innate immunity, recognition and response rely on traits common to groups of pathogens

Innate immunity is found in all animals (as well as in plants). In exploring innate immunity, we'll begin with invertebrates, which repel and fight infection with only this type of immunity. We'll then turn to vertebrates, in which innate immunity serves both as an immediate defense against infection and as the foundation for adaptive immune defenses.

#### Innate Immunity of Invertebrates

The great success of insects in terrestrial and freshwater habitats teeming with diverse microbes highlights the effectiveness of invertebrate innate immunity. In each of these environments, insects rely on their exoskeleton as a first line of defense against infection. Within the digestive system, **lysozyme**, an enzyme that breaks down bacterial cell walls, acts as a chemical barrier against pathogens ingested with food.

Any pathogen that breaches an insect's barrier defenses encounters a number of internal immune defenses. Immune cells called *hemocytes* travel throughout the body in the hemolymph, the insect circulatory fluid. Some hemocytes ingest and break down bacteria and other foreign substances, a process known as **phagocytosis** (Figure 35.3). Other hemocytes

**▲ Figure 35.3 Phagocytosis.** This schematic depicts events in the ingestion and destruction of a microbe by a typical phagocytic cell.

**▲ Figure 35.2 Overview of animal immunity.** Immune responses can be divided into innate and adaptive immunity. Some components of innate immunity help activate adaptive immune defenses.

Animal immune systems rely on either one or two major components for molecular recognition and defense. All animals have the component called **innate immunity**, which includes barrier defenses. Besides innate immunity, an additional component, called **adaptive immunity**, is found only in vertebrates.

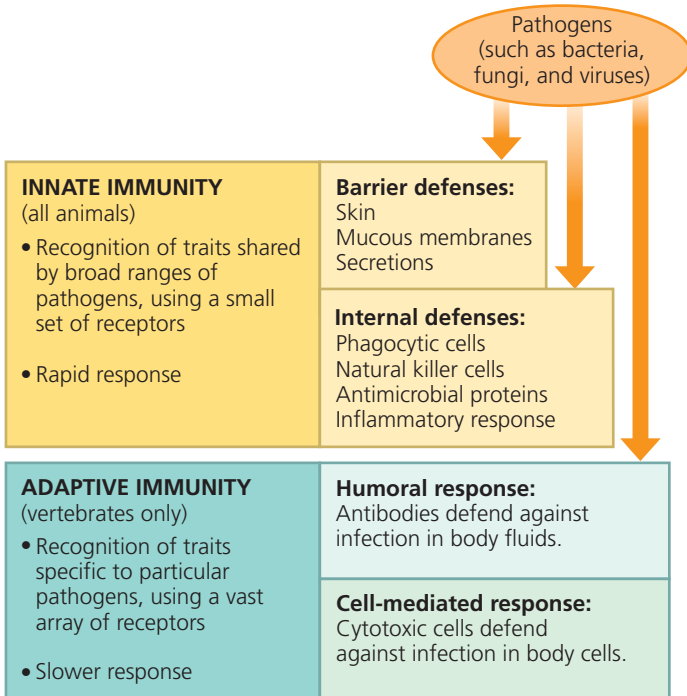

Figure 35.2 provides an overview of the basic components of both innate and adaptive immunity.

Molecular recognition in innate immunity relies on a small set of receptors that bind to molecules or structures that are absent from animal bodies but common to a group of viruses, bacteria, or other microbes. Binding of an innate immune receptor to a foreign molecule activates internal defenses, enabling responses to a very broad range of pathogens.

In adaptive immunity, molecular recognition relies on a vast arsenal of receptors, each of which recognizes a feature typically found only on a particular part of a particular molecule in a particular pathogen. As a result, recognition and response in adaptive immunity occur with tremendous specificity.

The adaptive immune response, also known as the acquired immune response, is activated after the innate immune response and develops more slowly. The names *adaptive* and *acquired* reflect the fact that this immune response is enhanced by previous exposure to the infecting pathogen. Examples of adaptive responses include the synthesis of proteins that inactivate a bacterial toxin and the targeted killing of a virus-infected body cell.

In this chapter, we'll examine how each type of immunity protects animals from disease. You'll also learn how pathogens can avoid or overwhelm the immune system and how defects in the immune system can imperil an animal's health.

release chemicals that kill pathogens and help entrap large invaders, such as *Plasmodium*, the parasite of mosquitoes that causes malaria in humans. One major class of defense molecules consists of antimicrobial peptides, which circulate throughout the body and inactivate or kill fungi and bacteria by disrupting their plasma membranes.

Immune cells of insects bind to molecules found only in the outer layers of fungi or bacteria. Fungal cell walls contain certain unique polysaccharides, whereas bacterial cell walls have polymers containing combinations of sugars and amino acids not found in animal cells. Such macromolecules serve as “identity tags” in the process of pathogen recognition. Insect immune cells secrete recognition proteins, each of which binds to a macromolecule characteristic of a broad class of bacteria or fungi. Once bound to a macromolecule, the recognition protein triggers an innate immune response specific for that class.

## Innate Immunity of Vertebrates

Among jawed vertebrates, innate immune defenses coexist with the more recently evolved system of adaptive immunity. Because most of the recent discoveries regarding vertebrate innate immunity have come from studies of mice and humans, we’ll focus here on mammals. We’ll consider first the innate defenses that are similar to those found among invertebrates: barrier defenses, phagocytosis, and antimicrobial peptides. We’ll then examine some unique aspects of vertebrate innate immunity, such as natural killer cells, interferons, and the inflammatory response.

### Barrier Defenses

In mammals, barrier defenses block the entry of many pathogens. These defenses include the skin and the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts. The mucous membranes produce *mucus*, a viscous fluid that traps microbes and other particles. In the airway, ciliated epithelial cells sweep mucus and any entrapped microbes upward, helping prevent infection of the lungs.

Beyond their physical role in inhibiting microbial entry, body secretions create an environment that is hostile to many microbes. Lysozyme in tears, saliva, and mucous secretions destroys the cell walls of susceptible bacteria as they enter the openings around the eyes or the upper respiratory tract. Microbes in food or water and those in swallowed mucus must also contend with the acidic environment of the stomach, which kills most of them before they can enter the intestines. Similarly, secretions from oil and sweat glands give human skin a pH ranging from 3 to 5, acidic enough to prevent the growth of many bacteria.

### Cellular Innate Defenses

Pathogens entering the mammalian body are engulfed by phagocytic cells that detect fungal or bacterial components using several types of receptors. Some mammalian receptors are

very similar to Toll, a key activator of innate immunity in insects. Each mammalian **Toll-like receptor (TLR)** binds to fragments of molecules characteristic of a set of pathogens (**Figure 35.4**). For example, TLR3 binds to double-stranded RNA, a form of nucleic acid characteristic of certain viruses. Similarly, TLR4 recognizes lipopolysaccharide, a molecule found on the surface of many bacteria, and TLR5 recognizes flagellin, the main protein of bacterial flagella. In each case, the recognized macromolecule is normally absent from the vertebrate body and is an essential component of certain groups of pathogens.

As in invertebrates, detection of invading pathogens in mammals triggers phagocytosis and destruction. The two main types of phagocytic cells in the mammalian body are neutrophils and macrophages. **Neutrophils**, which circulate in the blood, are attracted by signals from infected tissues. **Macrophages** (“big eaters”) are larger phagocytic cells. Some migrate throughout the body, whereas others reside in organs and tissues where they are likely to encounter pathogens. For example, some macrophages are located in the spleen, where pathogens in the blood become trapped.

**▲ Figure 35.4 TLR signaling.** Each mammalian Toll-like receptor (TLR) recognizes a molecular pattern characteristic of a group of pathogens. Lipopolysaccharide, flagellin, CpG DNA (DNA containing unmethylated CG sequences), and double-stranded RNA (dsRNA) are all found in bacteria, fungi, or viruses, but not in animal cells. Together with other recognition and response factors, TLR proteins trigger internal innate immune defenses.

**?** Some TLR proteins are on the cell surface, whereas others are inside vesicles. Suggest a possible benefit of this distribution.

Two other types of cells—dendritic cells and eosinophils—provide additional functions in innate defense. *Dendritic cells* mainly populate tissues, such as skin, that contact the environment. They stimulate adaptive immunity against pathogens they encounter and engulf, as we'll explore shortly. *Eosinophils*, often found beneath mucous membranes, are important in defending against multicellular invaders, such as parasitic worms. Upon encountering such parasites, eosinophils discharge destructive enzymes.

Cellular innate defenses in vertebrates also involve **natural killer cells**. These cells circulate through the body and detect the abnormal array of surface proteins characteristic of some virus-infected and cancerous cells. Natural killer cells do not engulf stricken cells. Instead, they release chemicals that lead to cell death, inhibiting further spread of the virus or cancer.

Many cellular innate defenses in vertebrates involve the lymphatic system (see Figure 34.12). Some macrophages reside in lymph nodes, where they engulf pathogens that have entered the lymph from the interstitial fluid. Dendritic cells reside outside the lymphatic system but migrate to the lymph nodes after interacting with pathogens. Within the lymph nodes, dendritic cells interact with other immune cells, stimulating adaptive immunity.

### Antimicrobial Peptides and Proteins

In mammals, pathogen recognition triggers the production and release of a variety of peptides and proteins that attack pathogens or impede their reproduction. Some of these defense molecules function like the antimicrobial peptides of insects, damaging broad groups of pathogens by disrupting membrane integrity. Others, including the interferons and complement proteins, are unique to vertebrate immune systems.

**Interferons** are proteins that provide innate defense by interfering with viral infections. Virus-infected body cells secrete interferons, which induce nearby uninfected cells to produce substances that inhibit viral reproduction. In this way, interferons limit the cell-to-cell spread of viruses in the body, helping control viral infections such as colds and influenza. Some white blood cells secrete a different type of interferon that helps activate macrophages, enhancing their phagocytic ability. Pharmaceutical companies now use recombinant DNA technology to mass-produce interferons to help treat certain viral infections, such as hepatitis C.

The infection-fighting **complement system** consists of roughly 30 proteins in blood plasma. These proteins circulate in an inactive state and are activated by substances on the surface of many microbes. Activation results in a cascade of biochemical reactions that can lead to lysis (bursting) of invading cells. The complement system also functions in the inflammatory response, our next topic, as well as in the adaptive defenses discussed later in the chapter.

### Inflammatory Response

The pain and swelling that alert you to a splinter under your skin are the result of a local **inflammatory response**, the changes brought about by signaling molecules released upon injury or infection (**Figure 35.5**). One important inflammatory signaling molecule is **histamine**, which is stored in the granules (vesicles) of **mast cells**, found in connective tissue. Histamine released at sites of damage triggers nearby blood vessels to dilate and become more permeable. Activated macrophages and neutrophils discharge **cytokines**, signaling molecules that in an immune response promote blood flow to the site of injury or infection. The increase in local blood supply causes the

© 1998 Pearson Education, Inc.

▲ **Figure 35.5** Major events in a local inflammatory response.

redness and increased skin temperature typical of the inflammatory response (from the Latin *inflammare*, to set on fire). Blood-engorged capillaries leak fluid into neighboring tissues, causing swelling.

During inflammation, cycles of signaling and response transform the site. Activated complement proteins promote further release of histamine, attracting more phagocytic cells that enter injured tissues (see Figure 35.5) and carry out additional phagocytosis. At the same time, enhanced blood flow to the site helps deliver antimicrobial peptides. The result is an accumulation of pus, a fluid rich in white blood cells, dead pathogens, and cell debris from damaged tissue.

A minor injury or infection causes a local inflammatory response, but severe tissue damage or infection may lead to a response that is systemic (throughout the body). Cells in injured or infected tissue often secrete molecules that stimulate the release of additional neutrophils from the bone marrow. In a severe infection, such as meningitis or appendicitis, the number of white blood cells in the blood may increase several-fold within a few hours.

Another systemic inflammatory response is fever. In response to certain pathogens, substances released by activated macrophages cause the body's thermostat to reset to a higher temperature (see Concept 32.1). The benefits of the resulting fever are still a subject of debate. One hypothesis is that an elevated body temperature may enhance phagocytosis and, by speeding up chemical reactions, accelerate tissue repair.

Certain bacterial infections can induce an overwhelming systemic inflammatory response, leading to a life-threatening condition called *septic shock*. Characterized by very high fever, low blood pressure, and poor blood flow through capillaries, septic shock occurs most often in the very old and the very young. It is fatal in more than one-third of cases and kills more than 90,000 people each year in the United States alone.

Chronic (ongoing) inflammation can also threaten human health. For example, millions of individuals worldwide suffer from Crohn's disease and ulcerative colitis, often debilitating disorders in which an unregulated inflammatory response disrupts intestinal function.

## Evasion of Innate Immunity by Pathogens

Adaptations have evolved in some pathogens that enable them to avoid destruction by phagocytic cells. For example, the outer capsule that surrounds certain bacteria interferes with molecular recognition and phagocytosis. One such bacterium, *Streptococcus pneumoniae*, played a critical role in the discovery that DNA can convey genetic information (see Figure 13.2). Other bacteria, after being engulfed by a host cell, resist breakdown within lysosomes. An example is the bacterium that causes tuberculosis (TB). Rather than being destroyed within host cells, this bacterium grows and reproduces, effectively hidden from the body's innate immune defenses. These and other mechanisms that prevent destruction by the innate immune system make certain fungi and

bacteria substantial pathogenic threats. Indeed, TB kills more than a million people a year worldwide.

### CONCEPT CHECK 35.1

1. Although pus is often seen simply as a sign of infection, it is also an indicator of immune defenses in action. Explain.
2. **MAKE CONNECTIONS** How do the molecules that activate the vertebrate TLR signal transduction pathway differ from the ligands in most other signaling pathways (see Concept 5.6)?
3. **WHAT IF?** Suppose humans were the major host for a bacterial species. What temperature would you predict would be optimal for growth of this species? Explain.

For suggested answers, see Appendix A.

## CONCEPT 35.2

### In adaptive immunity, receptors provide pathogen-specific recognition

Vertebrates are unique in having adaptive immunity in addition to innate immunity. The adaptive response relies on T cells and B cells, which are types of white blood cells called **lymphocytes**. Like all blood cells, lymphocytes originate from stem cells in the bone marrow. Some lymphocytes migrate from the bone marrow to the **thymus**, an organ in the thoracic cavity above the heart (see Figure 34.12). These lymphocytes mature into **T cells**. Lymphocytes that remain and mature in the bone marrow develop as **B cells**.

Any substance that elicits a response from a B cell or T cell is called an **antigen**. In adaptive immunity, recognition occurs when a B cell or T cell binds to an antigen, such as a bacterial or viral protein, via a protein called an **antigen receptor**. An antigen receptor is specific enough to bind to just one part of one molecule from a particular pathogen, such as a species of bacteria or strain of virus. Although the cells of the immune system produce millions of different antigen receptors, all of the antigen receptors made by a single B or T cell are identical. Infection by a virus, bacterium, or other pathogen triggers activation of B and T cells with antigen receptors specific for parts of that pathogen. B and T cells are shown in this text with only a few antigen receptors, but there are actually about 100,000 antigen receptors on the surface of a single B or T cell.

Antigens are usually foreign and are typically large molecules, either proteins or polysaccharides. The small, accessible portion of an antigen that binds to an antigen receptor is called an **epitope**, or *antigenic determinant*. An example is a group of amino acids in a particular protein. A single antigen usually has several different epitopes, each of which binds to a receptor with a different specificity. Because all antigen receptors

produced by a single B cell or T cell are identical, they bind to the same epitope. Each B or T cell thus displays *specificity* for a particular epitope, enabling it to respond to any pathogen that produces molecules containing that same epitope.

The antigen receptors of B cells and T cells have similar components, but they encounter antigens in different ways. We'll consider the two processes in turn.

## Antigen Recognition by B Cells and Antibodies

Each B cell antigen receptor is a Y-shaped molecule consisting of four polypeptide chains: two identical **heavy chains** and two identical **light chains**, with disulfide bridges linking the chains together (**Figure 35.6**). A transmembrane region near one end of each heavy chain anchors the receptor in the cell's plasma membrane. A short tail region at the end of the heavy chain extends into the cytoplasm.

The light and heavy chains each have a *constant (C) region*, where amino acid sequences vary little among the receptors on different B cells. Within the two tips of the Y shape (see Figure 35.6), each chain has a *variable (V) region*, so named because its amino acid sequence varies extensively from one B cell to another. Together, parts of a heavy-chain V region and a light-chain V region form an asymmetric binding site for an antigen. As shown in Figure 35.6, each B cell antigen receptor has two identical antigen-binding sites.

The binding of a B cell antigen receptor to an antigen is an early step in B cell activation, leading eventually to formation of cells that secrete a soluble form of the receptor (**Figure 35.7a**). This secreted protein is called an **antibody**, or **immunoglobulin (Ig)**. Antibodies have the same Y-shaped organization as B cell antigen receptors, but they are secreted rather than membrane-bound. It is the antibodies, rather than the B cells themselves, that actually help defend against pathogens.

▲ **Figure 35.6** The structure of a B cell antigen receptor.

(a) **B cell antigen receptors and antibodies.** An antigen receptor of a B cell binds to an epitope, a particular part of an antigen. Following binding, the B cell gives rise to cells that secrete a soluble form of the antigen receptor. This soluble receptor, called an antibody, is specific for the same epitope as the original B cell.

(b) **Antigen receptor specificity.** Different antibodies can recognize distinct epitopes on the same antigen. Furthermore, antibodies can recognize free antigens as well as antigens on a pathogen's surface.

▲ **Figure 35.7** Antigen recognition by B cells and antibodies.

**MAKE CONNECTIONS** The interactions depicted here involve a highly specific binding between antigen and receptor. How is antigen-antibody binding similar to an enzyme-substrate interaction (see Figures 3.20 and 6.14)?

The antigen-binding site of a membrane-bound receptor or antibody has a unique shape that provides a lock-and-key fit for a particular epitope. Many noncovalent bonds between an epitope and the binding surface provide a stable and specific interaction. Differences in the amino acid sequences of variable regions provide the variation in binding surfaces that enables this highly specific binding.

B cell antigen receptors and antibodies bind to intact antigens in the blood and lymph. As illustrated in **Figure 35.7b** for antibodies, they can bind to antigens on the surface of pathogens or free in body fluids.

## Antigen Recognition by T Cells

For a T cell, the antigen receptor consists of two different polypeptide chains, an  $\alpha$  chain and a  $\beta$  chain, linked by a disulfide bridge (**Figure 35.8**). Near the base of the T cell antigen receptor

▲ **Figure 35.8** The structure of a T cell antigen receptor.

(often called simply a T cell receptor) is a transmembrane region that anchors the molecule in the cell's plasma membrane. At the outer tip of the molecule, the variable (V) regions of  $\alpha$  and  $\beta$  chains together form a single antigen-binding site. The remainder of the molecule is made up of the constant (C) regions.

Whereas the antigen receptors of B cells bind to epitopes of intact antigens on pathogens or circulating in body fluids, those of T cells bind only to fragments of antigens that are displayed, or presented, on the surface of host cells. The host protein that displays the antigen fragment on the cell surface is called a **major histocompatibility complex (MHC) molecule**.

Recognition of protein antigens by T cells begins when a pathogen or part of a pathogen either infects or is taken in by a host cell (**Figure 35.9**). Inside the host cell, enzymes in the cell

cleave the antigen into smaller peptides. Each peptide, called an *antigen fragment*, then binds to an MHC molecule inside the cell. Movement of the MHC molecule and bound antigen fragment to the cell surface results in **antigen presentation**, the display of the antigen fragment in an exposed groove of the MHC protein.

In effect, antigen presentation advertises the fact that a host cell contains a foreign substance. If the cell displaying an antigen fragment encounters a T cell with the right specificity, the antigen receptor on the T cell can bind to both the antigen fragment and the MHC molecule. This interaction of an MHC molecule, an antigen fragment, and an antigen receptor is necessary for a T cell to participate in an adaptive immune response, as you'll see later.

## B Cell and T Cell Development

Now that you know how B cells and T cells recognize antigens, let's consider four major characteristics of adaptive immunity. First, there is an immense diversity of lymphocytes and receptors, enabling the immune system to detect pathogens never before encountered. Second, adaptive immunity normally has self-tolerance, the lack of reactivity against an animal's own molecules and cells. Third, cell proliferation triggered by activation greatly increases the number of B and T cells specific for an antigen. Fourth, there is a stronger and more rapid response to an antigen encountered previously, due to a feature known as immunological memory.

Receptor diversity and self-tolerance arise as a lymphocyte matures. Cell proliferation and the formation of immunological memory occur later, after a mature lymphocyte encounters and binds to a specific antigen. We'll consider these four characteristics in the order in which they develop.

### Generation of B Cell and T Cell Diversity

Each person makes more than 1 million different B cell antigen receptors and 10 million different T cell antigen receptors. Yet there are only about 20,000 protein-coding genes in the human genome. How, then, do we generate such remarkable diversity in antigen receptors? The answer lies in combinations. Think of selecting a car with a choice of three interior colors and six exterior colors. There are 18 ( $3 \times 6$ ) color combinations to consider. Similarly, by combining variable elements, the immune system assembles many different receptors from a much smaller collection of parts.

To understand the origin of receptor diversity, let's consider an immunoglobulin (Ig) gene that encodes the light chain of both secreted antibodies (immunoglobulins) and membrane-bound B cell antigen receptors. Although we'll analyze only a single Ig light-chain gene, all B and T cell antigen receptor genes undergo very similar transformations.

The capacity to generate diversity is built into the structure of Ig genes. A receptor light chain is encoded by three gene segments: a variable (V) segment, a joining (J) segment, and a

▲ **Figure 35.9** Antigen recognition by T cells. Inside the host cell, an antigen fragment from a pathogen binds to an MHC molecule and is brought up to the cell surface, where it is displayed. The combination of MHC molecule and antigen fragment is recognized by a T cell.

constant (*C*) segment. The *V* and *J* segments together encode the variable region of the receptor chain, while the *C* segment encodes the constant region. The light-chain gene contains a single *C* segment, 40 different *V* segments, and 5 different *J* segments. These alternative copies of the *V* and *J* segments are arranged within the gene in a series (**Figure 35.10**). Because a functional gene is built from one copy of each type of segment, the pieces can be combined in 200 different ways ( $40\ V \times 5\ J \times 1\ C$ ). The number of different heavy-chain combinations is even greater, resulting in even more diversity.

Assembling a functional Ig gene requires rearranging the DNA. Early in B cell development, an enzyme complex called *recombinase* links one light-chain *V* gene segment to one *J* gene segment. This recombination event eliminates the long stretch of DNA between the segments, forming a single exon that is part *V* and part *J*. Because there is only an intron between the *J* and *C* DNA segments, no further DNA rearrangement is required. Instead, the *J* and *C* segments of the RNA transcript will be joined when splicing removes the intervening RNA (see Figure 14.12 to review RNA splicing).

Recombinase acts randomly, linking any one of the 40 *V* gene segments to any one of the 5 *J* gene segments. Heavy-chain genes undergo a similar rearrangement. In any given cell, however, only one allele of a light-chain gene and one allele of a heavy-chain gene are rearranged. Furthermore, the rearrangements are permanent and are passed on to the daughter cells when the lymphocyte divides.

After both a light-chain and a heavy-chain gene have rearranged, antigen receptors can be synthesized. The rearranged genes are transcribed, and the transcripts are processed for translation. Following translation, the light chain and heavy chain assemble together, forming an antigen receptor (see Figure 35.10). Each pair of randomly rearranged heavy and light chains results in a different antigen-binding site. For the total population of B cells in a human body, the number of such combinations has been calculated as  $3.5 \times 10^6$ . Furthermore, mutations introduced during *VJ* recombination add additional variation, making the number of possible antigen-binding specificities even greater.

### Origin of Self-Tolerance

In adaptive immunity, how does the body distinguish self from nonself? Because antigen receptor genes are randomly rearranged, some immature lymphocytes produce receptors specific for epitopes on the organism's own molecules. If these self-reactive lymphocytes were not eliminated or inactivated, the immune system could not distinguish self from nonself and would attack body proteins, cells, and tissues. Instead, as lymphocytes mature in the bone marrow or thymus, their antigen receptors are tested for self-reactivity. Some B and T cells with receptors specific for the body's own molecules are destroyed by programmed cell death. The remaining self-reactive lymphocytes are typically rendered nonfunctional, leaving only those lymphocytes that react to foreign molecules. Since the

**► Figure 35.10**  
**Immunoglobulin (antibody) gene rearrangement.** The joining of randomly selected *V* and *J* gene segments (*V*<sub>39</sub> and *J*<sub>5</sub> in this example) results in a functional gene that encodes the light-chain polypeptide of a B cell antigen receptor. Transcription, splicing, and translation result in a light chain that combines with a polypeptide produced from an independently rearranged heavy-chain gene to form a functional receptor. Mature B cells (and T cells) are exceptions to the generalization that all nucleated cells in the body have exactly the same DNA.

#### MAKE CONNECTIONS

Both *alternative splicing* and *joining of V and J segments by recombination* generate diverse gene products from a limited set of gene segments. How do these processes differ (see Figure 15.12)?

body normally lacks mature lymphocytes that can react against its own components, the immune system is said to exhibit self-tolerance.

### Proliferation of B Cells and T Cells

Despite the enormous variety of antigen receptors, only a tiny fraction are specific for a given epitope. How, then, does an effective adaptive response develop? To begin with, an antigen is presented to a steady stream of lymphocytes in the lymph nodes (see Figure 34.12) until a match is made. A successful match then triggers changes in cell number and activity for the lymphocyte to which an antigen has bound.

The binding of an antigen receptor to an epitope initiates events that activate the lymphocyte. Once activated, a B cell or T cell undergoes multiple cell divisions. For each activated cell, the result of this proliferation is a clone, a population of cells that are identical to the original cell. Some cells from this clone become **effector cells**, short-lived cells that take effect immediately against the antigen and any pathogens producing that antigen. The effector forms of B cells are **plasma cells**, which secrete antibodies. The effector forms of T cells are helper T cells and cytotoxic T cells, whose roles we'll explore in Concept 35.3. The remaining cells in the clone become **memory cells**, long-lived cells that can give rise to effector cells if the same antigen is encountered later in the animal's life.

**Figure 35.11** summarizes the proliferation of a lymphocyte into a clone of cells in response to binding to an antigen, using B cells as an example. This process is called **clonal selection** because an encounter with an antigen *selects* which lymphocyte will divide to produce a *clonal* population of thousands of cells specific for a particular epitope.

### Immunological Memory

Immunological memory is responsible for the long-term protection that a prior infection provides against many diseases, such as chickenpox. This type of protection was noted almost 2,400 years ago by the Greek historian Thucydides. He observed that individuals who had recovered from the plague could safely care for those who were sick or dying, “for the same man was never attacked twice—never at least fatally.”

Prior exposure to an antigen alters the speed, strength, and duration of the immune response. The production of effector cells from a clone of lymphocytes during the first exposure to an antigen is the basis for the **primary immune response**. The primary response peaks about 10–17 days after the initial exposure. During this time, selected B cells and T cells give rise to their effector forms. If an individual is exposed again to the same antigen, the response is faster (typically peaking only 2–7 days after exposure), of greater magnitude, and more prolonged. This is the **secondary immune response**, a hallmark of adaptive, or acquired, immunity. Because selected

▲ **Figure 35.11 Clonal selection.** This figure illustrates clonal selection, using B cells as an example. In response to a specific antigen and to immune cell signals (not shown), one B cell divides and forms a clone of cells. The remaining B cells, which have antigen receptors specific for other antigens, do not respond. The clone of cells formed by the selected B cell gives rise to memory B cells and antibody-secreting plasma cells. T cells also undergo clonal selection, generating memory T cells and effector T cells (cytotoxic T cells and helper T cells).

**Primary immune response** to antigen A produces antibodies to A.

**Secondary immune response** to antigen A produces antibodies to A; **primary immune response** to antigen B produces antibodies to B.

**▲ Figure 35.12 The specificity of immunological memory.** Long-lived memory cells generated in the primary response to antigen A give rise to a heightened secondary response to the same antigen, but do not affect the response to a different antigen (B).

B cells give rise to antibody-secreting effector cells, measuring the concentrations of specific antibodies in blood over time distinguishes the primary and secondary immune responses (**Figure 35.12**).

The secondary immune response relies on the reservoir of T and B memory cells generated following initial exposure to an antigen. Because these cells are long-lived, they provide the basis for immunological memory, which can span many decades. (Effector cells have much shorter life spans, which is why the immune response diminishes after an infection is overcome.) If an antigen is encountered again, memory cells specific for that antigen enable the rapid formation of clones of thousands of effector cells also specific for that antigen, thus generating a greatly enhanced immune defense.

Although the processes for antigen recognition, clonal selection, and immunological memory are similar for B cells and T cells, these two classes of lymphocytes fight infection in different ways and in different settings, as we'll explore next.

### CONCEPT CHECK 35.2

- DRAW IT** Sketch a B cell antigen receptor. Label the V and C regions of the light and heavy chains. Label the antigen-binding sites, disulfide bridges, and transmembrane region. Where are these features located relative to the V and C regions?
- Explain two advantages of having memory cells when a pathogen is encountered for a second time.
- WHAT IF?** If both copies of a light-chain gene and a heavy-chain gene recombined in each (diploid) B cell, how would this affect B cell development and function?

For suggested answers, see Appendix A.

## CONCEPT 35.3

### Adaptive immunity defends against infection of body fluids and body cells

Having considered how clones of lymphocytes arise, we now explore how these cells help fight infections and minimize damage by pathogens. The defenses provided by B and T lymphocytes can be divided into a humoral immune response and a cell-mediated immune response. The **humoral immune response** occurs in the blood and lymph (once called body humors, or fluids). In the humoral response, antibodies help neutralize or eliminate toxins and pathogens in the blood and lymph. In the **cell-mediated immune response**, specialized T cells destroy infected host cells. Both responses include a primary immune response and a secondary immune response, with memory cells enabling the secondary response.

### Helper T Cells: A Response to Nearly All Antigens

A type of T cell called a **helper T cell** triggers both the humoral and cell-mediated immune responses. Helper T cells themselves do not carry out those responses. Instead, signals from helper T cells initiate production of antibodies that neutralize pathogens and activate T cells that kill infected cells.

Two requirements must be met for a helper T cell to activate adaptive immune responses. First, a foreign molecule must be present that can bind specifically to the antigen receptor of the T cell. Second, this antigen must be displayed on the surface of an **antigen-presenting cell**. The antigen-presenting cell can be a dendritic cell, macrophage, or B cell.

When host cells are infected, they, too, display antigens on their surface. What, then, distinguishes an antigen-presenting cell? The answer lies in the existence of two classes of MHC molecules. Most body cells have only class I MHC molecules, but antigen-presenting cells have both class I and class II MHC molecules. The class II molecules provide a molecular signature by which an antigen-presenting cell is recognized.

A helper T cell and the antigen-presenting cell displaying its specific epitope have a complex interaction (**Figure 35.13**). The antigen receptors on the surface of the helper T cell bind to the antigen fragment and to the class II MHC molecule displaying that fragment on the antigen-presenting cell. At the same time, an accessory protein called CD4 on the helper T cell surface binds to the class II MHC molecule, helping keep the cells joined. As the two cells interact, signals in the form of cytokines are exchanged.

Antigen-presenting cells interact with helper T cells in several different contexts. Antigen presentation by a dendritic cell or macrophage activates a helper T cell, which then proliferates, forming a clone of activated cells. B cells present antigens

**▲ Figure 35.13 The central role of helper T cells in humoral and cell-mediated immune responses.**

In this example, a helper T cell responds to a dendritic cell displaying a microbial antigen.

to *already* activated helper T cells, which in turn activate the B cells themselves. Activated helper T cells also help stimulate cytotoxic T cells, as we'll discuss next.

## Cytotoxic T Cells: A Response to Infected Cells

In the cell-mediated immune response, **cytotoxic T cells** use toxic proteins to kill cells infected by viruses or other intracellular pathogens. To become active, cytotoxic T cells require signals from helper T cells and interaction with an antigen-presenting cell. Fragments of foreign proteins produced in infected host cells associate with class I MHC

molecules and are displayed on the cell surface, where they can be recognized by activated cytotoxic T cells (**Figure 35.14**). As with helper T cells, cytotoxic T cells have an accessory protein that binds to the MHC molecule. This accessory protein, called CD8, helps keep the two cells in contact while the cytotoxic T cell is activated.

The targeted destruction of an infected host cell by a cytotoxic T cell involves the secretion of proteins that disrupt membrane integrity and trigger cell death (see Figure 35.14). The death of the infected cell not only deprives the pathogen of a place to reproduce, but also exposes cell contents to circulating antibodies, which mark released antigens for disposal.

**▲ Figure 35.14 The killing action of cytotoxic T cells on an infected host cell.** An activated cytotoxic T cell releases molecules that make pores in an infected cell's membrane and enzymes that break down proteins, promoting the cell's death.

**1** After an antigen-presenting cell engulfs and degrades a pathogen, it displays an antigen fragment complexed with a class II MHC molecule. A helper T cell that recognizes the complex is activated with the aid of cytokines secreted from the antigen-presenting cell.

**2** When a B cell with receptors for the same epitope internalizes the antigen, it displays an antigen fragment on the cell surface in a complex with a class II MHC molecule. An activated helper T cell bearing receptors specific for the displayed fragment binds to and activates the B cell.

**3** The activated B cell proliferates and differentiates into memory B cells and antibody-secreting plasma cells. The secreted antibodies are specific for the same antigen that initiated the response.

**▲ Figure 35.15 Activation of a B cell in the humoral immune response.** Most protein antigens require activated helper T cells to trigger a humoral response. A macrophage (shown here) or a dendritic cell can activate a helper T cell, which in turn can activate a B cell to give rise to antibody-secreting plasma cells.

**?** What function do cell-surface antigen receptors play for memory B cells?

## B Cells and Antibodies: A Response to Extracellular Pathogens

The secretion of antibodies by clonally selected B cells is the hallmark of the humoral immune response. As illustrated in **Figure 35.15**, activation of B cells involves both helper T cells and proteins on the surface of pathogens. Stimulated by both an antigen and cytokines, the B cell proliferates and differentiates into memory B cells and antibody-secreting plasma cells.

A single activated B cell gives rise to thousands of identical plasma cells. Each plasma cell secretes approximately 2,000 antibodies every second during its 4- to 5-day life span. The antibodies do not kill pathogens, but by binding to antigens, they mark pathogens in various ways for inactivation or destruction. In the simplest of these activities, *neutralization*, antibodies bind to proteins on the surface of a virus (see **Figure 35.7b**). The bound antibodies prevent infection of a host cell, thus neutralizing the virus. Similarly, antibodies sometimes bind to toxins released in body fluids, preventing the toxins from entering body cells. Because each antibody has two antigen-binding sites, antibodies can also facilitate phagocytosis by linking bacterial cells, viruses, or other foreign substances into aggregates.

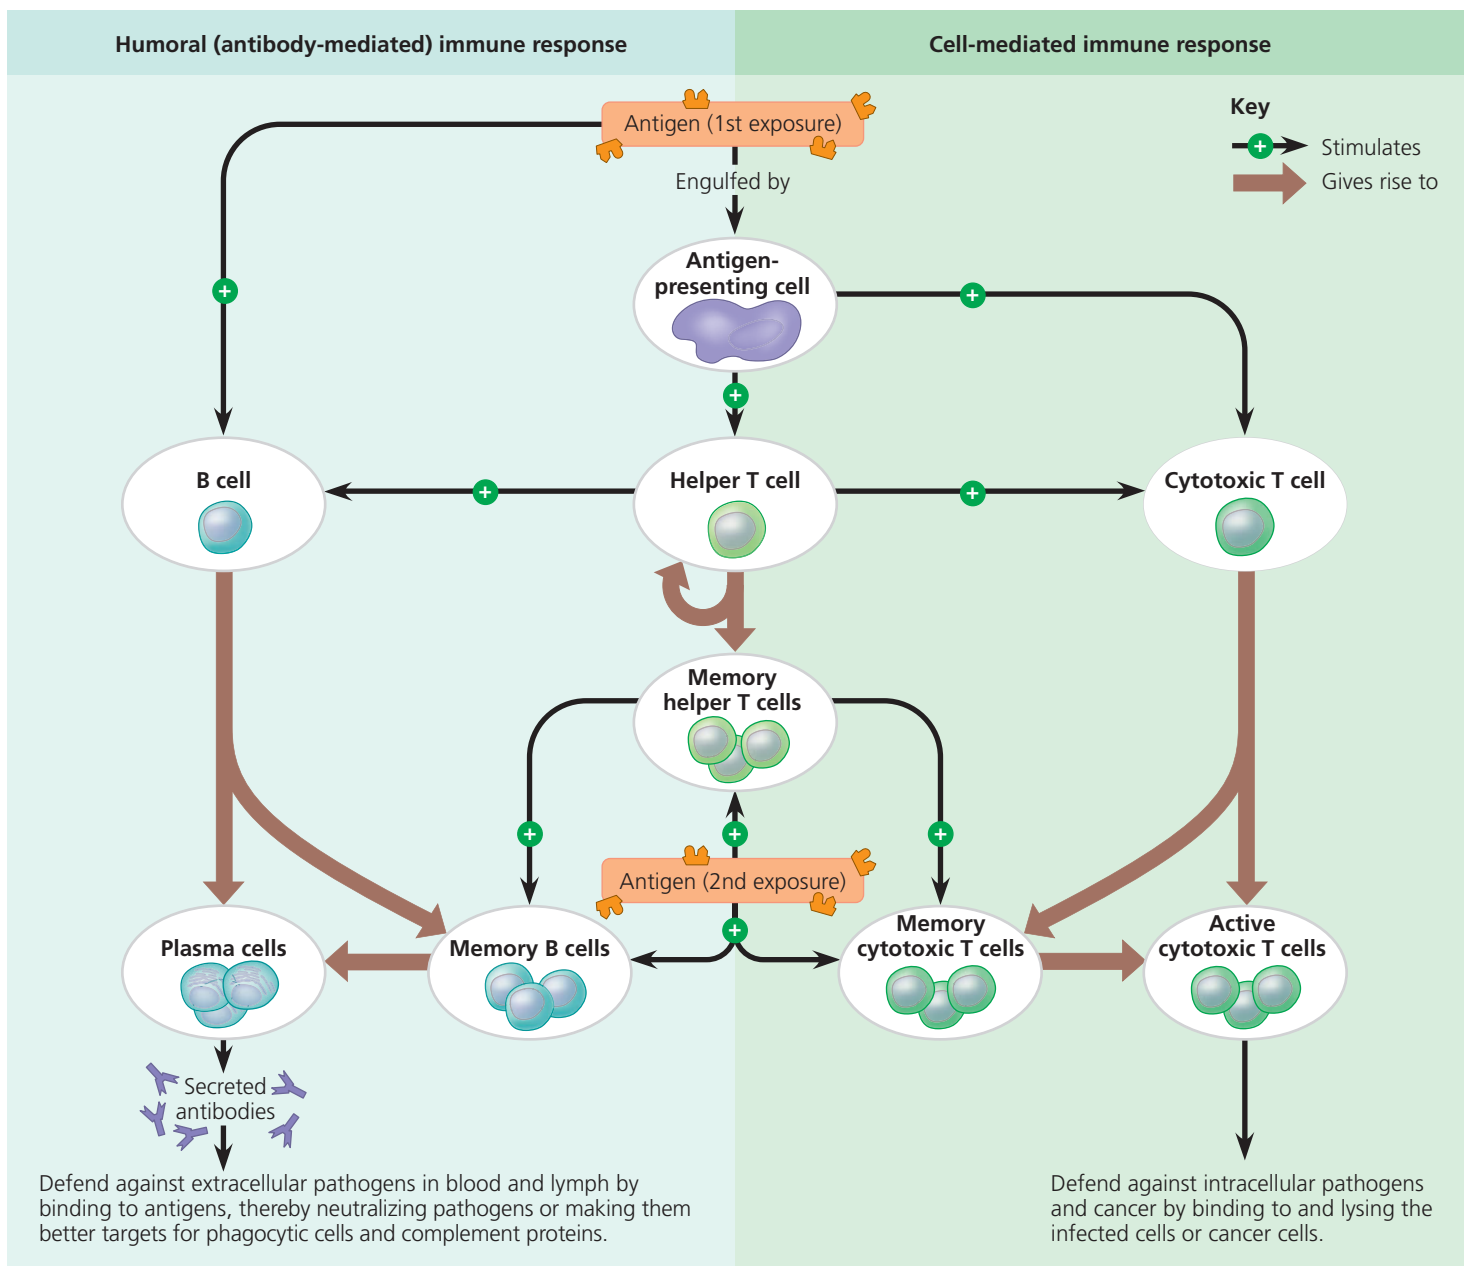

Antibodies sometimes work together with the proteins of the complement system. (The name *complement* reflects the

fact that these proteins increase the effectiveness of antibody-directed attacks on bacteria.) Binding of a complement protein to an antigen-antibody complex on a foreign cell triggers events leading to formation of a pore in the membrane of the cell. Ions and water rush into the cell, causing it to swell and lyse.

B cells can express five different types of immunoglobulin. For a given B cell, each type has an identical antigen-binding specificity but a distinct heavy-chain C region. One type of B cell Ig, the B cell antigen receptor, is membrane bound. The other four Ig types consist of soluble antibodies, including those found in blood, tears, saliva, and breast milk.

## Summary of the Humoral and Cell-Mediated Immune Responses

As noted earlier, both the humoral and cell-mediated responses can include primary as well as secondary immune responses. Memory cells of each type—helper T cell, B cell, and cytotoxic T cell—enable the secondary response. For example, when body fluids are reinfected by a pathogen encountered previously, memory B cells and memory helper T cells initiate a secondary humoral response. **Figure 35.16** reviews the events that initiate humoral and cell-mediated immune responses, highlights the central role of the helper T cell, and serves as a helpful summary of adaptive immunity.

▲ **Figure 35.16** An overview of the adaptive immune response.

? Identify each black or brown arrow as representing part of the primary or secondary response.

Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Immunology.

## Active and Passive Immunization

Our discussion of adaptive immunity has focused to this point on **active immunity**, the defenses that arise when a pathogen infects the body. A different type of immunity results when, for example, antibodies in the blood of a pregnant female cross the placenta to her fetus. This protection is called **passive immunity** because the antibodies in the recipient (in this case, the fetus) are produced by another individual (the mother). Antibodies present in breast milk provide additional passive immunity to the infant's digestive tract while the infant's immune system develops. Because passive immunity does not involve the recipient's B and T

cells, it persists only as long as the transferred antibodies last (a few weeks to a few months).

Both active immunity and passive immunity can be induced artificially. Active immunity is induced when antigens are introduced into the body in **vaccines**, which may be made from inactivated bacterial toxins, killed or weakened pathogens, or even genes encoding microbial proteins. This process, called **immunization** (or vaccination), induces a primary immune response and immunological memory. As a result, any subsequent encounter with the pathogen from which the vaccine was derived triggers a rapid and strong secondary immune response (see Figure 35.12).

Misinformation about vaccine safety and disease risk has led to a substantial and growing public health problem. Consider measles as just one example. Side effects of immunization are remarkably rare, with fewer than one in a million children suffering a significant allergic reaction to the measles vaccine. The disease, however, is quite dangerous, killing more than 200,000 people each year. Declining vaccination rates in parts of the United Kingdom, Russia, and the United States have resulted in a number of recent measles outbreaks and many preventable deaths.

In artificial passive immunization, antibodies from an immune animal are injected into a nonimmune animal. For example, humans bitten by venomous snakes are sometimes treated with antivenin, serum from sheep or horses that have been immunized against a snake venom. When injected immediately after a snakebite occurs, the antibodies in antivenin can neutralize toxins in the venom before the toxins do massive damage.

## Antibodies as Tools

Antibodies produced after exposure to an antigen are *polyclonal*: They are the products of many different clones of plasma cells, each specific for a different epitope. Antibodies can also be prepared from a clone of B cells grown in culture. The **monoclonal antibodies** produced by such a culture are identical and specific for the same epitope on an antigen.

Monoclonal antibodies have provided the basis for many recent advances in medical diagnosis and treatment. For example, home pregnancy test kits use monoclonal antibodies to detect human chorionic gonadotropin (hCG). Because hCG is produced as soon as an embryo implants in the uterus (see Chapter 36), the presence of this hormone in a woman's urine is a reliable indicator for a very early stage of pregnancy. Monoclonal antibodies are also produced in large amounts and injected as a therapy for a number of human diseases.

## Immune Rejection

Like pathogens, cells from another person can be recognized as foreign and attacked by immune defenses. For example, skin transplanted from one person to a genetically nonidentical person will look healthy for a week or so but will then be destroyed (rejected) by the recipient's immune response. Carbohydrates on the surface of transfused blood cells can also be recognized as foreign by the recipient's immune system, triggering an immediate and devastating reaction. To avoid this danger, the so-called ABO blood groups of the donor and recipient must be taken into account.

In the case of tissue and organ transplants, or grafts, MHC molecules stimulate

the immune response that leads to rejection. Each vertebrate species has many alleles for each MHC gene, enabling presentation of antigen fragments that vary in shape and net electrical charge. This diversity of MHC molecules almost guarantees that no two people, except identical twins, will have exactly the same set. Thus, in the vast majority of graft and transplant recipients, some MHC molecules on the donated tissue are foreign to the recipient. To minimize rejection, physicians use donor tissue bearing MHC molecules that match those of the recipient as closely as possible. In addition, the recipient takes medicines that suppress immune responses (but as a result leave the recipient more susceptible to infections).

## Disruptions in Immune System Function

Although adaptive immunity offers significant protection against a wide range of pathogens, it is not fail-safe. Here we'll examine some of the ways the adaptive immune system fails to protect the host organism.

### Allergies

Allergies are exaggerated (hypersensitive) responses to certain antigens called **allergens**. Hay fever, for instance, occurs when plasma cells secrete antibodies specific for antigens on the surface of pollen grains, as illustrated in **Figure 35.17**. The interaction of pollen grains and these antibodies triggers immune cells in connective tissue to release histamine and other inflammatory chemicals. The results can include sneezing, teary eyes, and smooth muscle contractions in the lungs that inhibit effective breathing. Drugs called antihistamines block receptors for histamine, diminishing allergy symptoms (and inflammation).

In some instances, an acute allergic response leads to a life-threatening reaction called *anaphylactic shock*. Inflammatory chemicals trigger abrupt dilation of peripheral blood vessels, causing a precipitous drop in blood pressure, as well as constriction of bronchioles. Death may occur within minutes due to lack of blood

**▲ Figure 35.17 Mast cells and the allergic response.** In this example, pollen grains act as the allergen, and the immunoglobulins that mediate the response are of a type called IgE.

► **Figure 35.18** Colored X-ray of hands deformed by rheumatoid arthritis.

flow and the inability to breathe. Substances that can cause anaphylactic shock in allergic individuals include bee venom, penicillin, peanuts, and shellfish. People with severe hypersensitivities often carry syringes containing the hormone epinephrine, which counteracts this allergic response.

### Autoimmune Diseases

In some people, the immune system is active against particular molecules of the body, causing an **autoimmune disease**. In systemic lupus erythematosus, commonly called lupus, the immune system generates antibodies against histones and DNA. Other targets of autoimmunity are the insulin-producing beta cells of the pancreas (in type 1 diabetes) and the myelin sheaths that encase many neurons (in multiple sclerosis).

Gender, genetics, and environment all influence susceptibility to autoimmune disorders. For example, many autoimmune diseases afflict females more often than males. Women are nine times as likely as men to suffer from lupus and two to three times as likely to develop rheumatoid arthritis, a damaging and painful inflammation of the cartilage and bone in joints (**Figure 35.18**). The cause of this sex bias, as well as the rise in autoimmune disease frequency in industrialized countries, are areas of active research and debate.

### Immune System Avoidance

**EVOLUTION** Just as immune systems that ward off pathogens have evolved in animals, mechanisms that thwart immune responses have evolved in pathogens. In one such mechanism, a pathogen alters how it appears to the immune system. If a pathogen changes the epitopes it expresses to ones that a host has not previously encountered, it can reinfect or remain in the host without triggering the rapid and robust response mediated by memory cells. Such changes in epitope expression are called *antigenic variation*. The parasite that causes sleeping sickness provides an extreme example, periodically switching at random among 1,000 different versions of the protein found over its entire surface. In the **Scientific Skills Exercise**, you will interpret data related to this example of antigenic variation and the body's response.

Antigenic variation is the major reason the influenza, or “flu,” virus remains a major public health problem. As it replicates in one human host after another, the human flu virus undergoes frequent mutations. Because any change that lessens recognition by the immune system provides a selective advantage, the virus steadily accumulates such alterations. These changes are the reason that a new flu vaccine must be distributed each year. In addition, the human flu virus occasionally exchanges genes with influenza viruses that infect domesticated animals, such as pigs or chickens. If the new strain expresses surface epitopes of the animal rather than the human virus, it may not be recognized by any of the memory cells in the human population. The resulting outbreak can be deadly: The 1918–1919 influenza outbreak killed more than 20 million people.

Some viruses avoid an immune response by infecting cells and then entering a largely inactive state called *latency*. The viral genome integrates into the chromosome of the host cell, which ceases making most viral proteins and typically releases no free viruses. Latency typically persists until conditions arise that are favorable for viral transmission or unfavorable for host survival.

Herpes simplex viruses provide a good example of latency. The type 1 virus causes most oral herpes infections, whereas the sexually transmitted type 2 virus is responsible for most cases of genital herpes. These viruses remain latent in sensory neurons until a stimulus such as fever, emotional stress, or menstruation reactivates the viruses. Activation of the type 1 virus can result in blisters around the mouth that are inaccurately called “cold” sores. Infections of the type 2 virus pose a serious threat to the babies of infected mothers and can increase transmission of HIV.

The **human immunodeficiency virus (HIV)**, the pathogen that causes AIDS (acquired immune deficiency syndrome), both escapes and attacks the adaptive immune response. Once introduced into the body, HIV infects helper T cells with high efficiency. Although the body responds to HIV with an immune response sufficient to eliminate most viral infections, some HIV invariably escapes. One reason HIV persists is that it has a very high mutation rate. Altered proteins on the surface of some mutated viruses reduce interaction with antibodies and cytotoxic T cells. Such viruses survive, proliferate, and mutate further. The virus thus evolves within the body. The continued presence of HIV is also helped by latency.

Over time, an untreated HIV infection not only avoids the adaptive immune response but also abolishes it. Viral reproduction and cell death triggered by the virus lead to loss of helper T cells, impairing both humoral and cell-mediated immune responses. The result is a progression to AIDS, characterized by susceptibility to infections and cancers that a healthy immune system would usually defeat. For example, *Pneumocystis carinii*, a common fungus that does not cause disease in healthy individuals, can result in severe pneumonia in people with AIDS. Such opportunistic diseases, as well as nerve damage and wasting, are the primary causes of death from AIDS, not HIV itself.

## Comparing Two Variables on a Common x-Axis

### How Does the Immune System Respond to a Changing Pathogen?

Natural selection favors parasites that are able to maintain a low-level infection in a host for a long time. *Trypanosoma*, the unicellular parasite that causes sleeping sickness, is one example (see Figure 25.12). The glycoproteins covering a trypanosome's surface are encoded by a gene that is duplicated more than a thousand times in the organism's genome. Each copy is slightly different. By periodically switching among these genes, the trypanosome can change the molecular structure of its surface glycoproteins. In this exercise, you will interpret two data sets to explore hypotheses about the benefits of the trypanosome's ever-shifting surface glycoproteins and the host's immune response.

**Part A: Data from a Study of Parasite Levels** This study measured the abundance of parasites in the blood of one human patient during the first few weeks of a chronic infection.

Day	Number of Parasites (in millions) per mL of Blood
4	0.1
6	0.3
8	1.2
10	0.2
12	0.2
14	0.9
16	0.6
18	0.1
20	0.7
22	1.2
24	0.2

### Part A: Interpret the Data

- Plot the data in the above table as a line graph. Which column is the independent variable, and which is the dependent variable? Put the independent variable on the x-axis. (For additional information about graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
- Visually displaying data in a graph can help make patterns in the data more noticeable. Describe any patterns revealed by your graph.
- Assume that a drop in parasite abundance reflects an effective immune response by the host. Formulate a hypothesis to explain the pattern you described in question 2.

**Part B: Data from a Study of Antibody Levels** Many decades after scientists first observed the pattern of *Trypanosoma* abundance over the course of infection, researchers identified antibodies specific to different forms of the parasite's surface glycoprotein. The table below lists the relative abundance of two such antibodies during the early period of chronic infection, using an index ranging from 0 to 1.

Day	Antibody Specific to Glycoprotein Variant A	Antibody Specific to Glycoprotein Variant B
4	0	0
6	0	0
8	0.2	0
10	0.5	0
12	1	0
14	1	0.1
16	1	0.3
18	1	0.9
20	1	1
22	1	1
24	1	1

### Part B: Interpret the Data

- Note that these data were collected over the same period of infection (days 4–24) as the parasite abundance data you graphed in Part A. Therefore, you can incorporate these new data into your first graph, using the same x-axis. However, since the antibody level data are measured in a different way than the parasite abundance data, add a second set of y-axis labels on the right side of your graph. Then, using different colors or sets of symbols, add the data for the two antibody types. Labeling the y-axis two different ways enables you to compare how two dependent variables change relative to a shared independent variable.
- Describe any patterns you observe by comparing the two data sets over the same period. Do these patterns support your hypothesis from Part A? Do they prove that hypothesis? Explain.
- Scientists can now also distinguish the abundance of trypanosomes recognized specifically by antibodies type A and type B. How would incorporating such information change your graph?

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

HIV transmission requires the transfer of virus particles or infected cells via body fluids such as semen, blood, or breast milk. Unprotected sex (that is, without a condom) and transmission via HIV-contaminated needles (often among intravenous drug users) account for the vast majority of HIV infections. People infected with HIV can transmit the disease in the first few weeks of infection, *before* they express HIV-specific antibodies that can be detected in a blood test. Although HIV infection cannot be cured, drugs have been developed that can significantly slow HIV replication and the progression to AIDS. New drugs continue to be needed as HIV's high mutation rate results in the frequent appearance of drug-resistant strains.

## Cancer and Immunity

When adaptive immunity is inactivated, the frequency of certain cancers increases dramatically. For example, the risk of developing Kaposi's sarcoma is 20,000 times greater for untreated AIDS patients than for healthy people. This observation was unanticipated. If the immune system recognizes only nonself, it should fail to recognize the uncontrolled growth of self cells that is the hallmark of cancer. It turns out, however, that viruses are involved in about 15–20% of all human cancers. Because the immune system can recognize viral proteins as foreign, it can act as a defense against viruses that can cause cancer and against cancer cells that harbor viruses.

Scientists have identified six viruses that can cause cancer in humans. The Kaposi's sarcoma herpesvirus is one such virus. Hepatitis B virus, which can trigger liver cancer, is another. A vaccine introduced in 1986 for hepatitis B virus was the first vaccine shown to help prevent a specific human cancer. Rapid progress on developing vaccines for virus-induced cancers continues. In 2006, the release of a vaccine against cervical cancer, specifically human papillomavirus (HPV), marked a major victory against a disease that afflicts more than half a million women worldwide every year.

### CONCEPT CHECK 35.3

1. In the condition known as myasthenia gravis, antibodies bind to and block certain receptors on muscle cells, preventing muscle contraction. What type of disorder does this reflect?
2. If a child were born without a thymus, what cells and functions would be deficient? Explain.
3. **WHAT IF?** Suppose that a snake handler bitten by a particular venomous snake species was treated with antivenin. Why might the same treatment for a second such bite a year later have different results?

For suggested answers, see Appendix A.

## 35 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 35.1

**In innate immunity, recognition and response rely on traits common to groups of pathogens (pp. 712–715)**

- In both invertebrates and vertebrates, **innate immunity** is mediated by physical and chemical barriers as well as cell-based defenses. Activation of innate immune responses relies on recognition proteins specific for broad classes of pathogens. Microbes that penetrate barrier defenses are ingested by phagocytic cells, which in vertebrates include **macrophages** and **dendritic cells**. In the **inflammatory response**, **histamine** and other chemicals released at the injury site promote changes in blood vessels that enhance immune cell access and action.

**?** *In what ways does innate immunity protect the mammalian digestive tract?*

#### CONCEPT 35.2

**In adaptive immunity, receptors provide pathogen-specific recognition (pp. 715–720)**

- **Adaptive immunity** relies on two types of **lymphocytes** that arise from stem cells in the bone marrow: **T cells** and **B cells**. Lymphocytes have cell-surface **antigen receptors** for foreign molecules (**antigens**). Some T cells help other lymphocytes; others kill infected host cells. B cells called **plasma cells** produce soluble receptor proteins called **antibodies**, which bind to foreign molecules and cells. Activated T and B lymphocytes called **memory cells** defend against future infections by the same pathogen.
- Recognition of foreign molecules involves the binding of variable regions of receptors to an **epitope**, a small region of an antigen. B cells and antibodies recognize epitopes on the surface of antigens. T cells recognize protein epitopes in small antigen fragments (peptides) that are presented on the surface of host cells by proteins called **major histocompatibility complex (MHC) molecules**.
- The four major characteristics of B and T cell development are the generation of cell diversity, self-tolerance, proliferation, and immunological memory. Proliferation and memory are both based on **clonal selection**, illustrated here for B cells.

**?** *Why is the adaptive immune response to an initial infection slower than the innate response?*

#### CONCEPT 35.3

**Adaptive immunity defends against infection of body fluids and body cells (pp. 720–727)**

- **Helper T cells** interact with antigen fragments displayed by class II MHC molecules on the surface of **antigen-presenting cells**: dendritic cells, macrophages, and B cells. Activated helper T cells secrete **cytokines** that stimulate other lymphocytes. In the **cell-mediated immune response**, activated **cytotoxic T cells** trigger destruction of infected cells. In the **humoral immune response**, antibodies help eliminate antigens by phagocytosis and complement-mediated lysis.

- **Active immunity** develops in response to infection or to **immunization**. The transfer of antibodies in **passive immunity** provides immediate, short-term protection.
- In tissue grafts and organ transplants, MHC molecules stimulate immune rejection.
- In allergies, such as hay fever, the interaction of antibodies and **allergens** triggers immune cells to release histamine and other mediators that cause vascular changes and allergic symptoms. Loss of self-tolerance can lead to **autoimmune diseases**, such as multiple sclerosis.
- Antigenic variation, latency, and direct assault on the immune system allow some pathogens to thwart immune responses. **HIV** infection destroys helper T cells, leaving the patient prone to disease. Immune defense against cancer appears to primarily involve action against viruses that can cause cancer and cancer cells that harbor viruses.

**?** *Do natural infection and immunization result in different types of immunological memory? Explain.*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. Which of these is not part of insect immunity?
  - a. activation of microbe-killing chemicals
  - b. activation of natural killer cells
  - c. phagocytosis by hemocytes
  - d. production of antimicrobial peptides
  - e. a protective exoskeleton
2. An epitope associates with which part of an antigen receptor or antibody?
  - a. the disulfide bridge
  - b. the heavy-chain constant regions only
  - c. variable regions of a heavy chain and light chain combined
  - d. the light-chain constant regions only
  - e. the tail
3. Which statement best describes the difference in responses of effector B cells (plasma cells) and cytotoxic T cells?
  - a. B cells confer active immunity; cytotoxic T cells confer passive immunity.
  - b. B cells kill pathogens directly; cytotoxic T cells kill host cells.
  - c. B cells secrete antibodies against a pathogen; cytotoxic T cells kill pathogen-infected host cells.
  - d. B cells carry out the cell-mediated response; cytotoxic T cells carry out the humoral response.
  - e. B cells respond the first time a pathogen is present; cytotoxic T cells respond subsequent times.

### Level 2: Application/Analysis

4. Which of the following statements is *not* true?
  - a. An antibody has more than one antigen-binding site.
  - b. An antigen can have different epitopes.
  - c. A pathogen makes more than one antigen.
  - d. A lymphocyte has receptors for multiple different antigens.
  - e. A liver cell makes one class of MHC molecule.
5. Which of the following should be the same in identical twins?
  - a. the set of antibodies produced
  - b. the set of MHC molecules produced
  - c. the set of T cell antigen receptors produced
  - d. the susceptibility to a particular virus
  - e. the set of immune cells eliminated as self-reactive

### Level 3: Synthesis/Evaluation

6. Vaccination increases the number of
  - a. different receptors that recognize a pathogen.
  - b. lymphocytes with receptors that can bind to the pathogen.
  - c. epitopes that the immune system can recognize.
  - d. macrophages specific for a pathogen.
  - e. MHC molecules that can present an antigen.
7. Which of the following would *not* help a virus avoid triggering an adaptive immune response?
  - a. having frequent mutations in genes for surface proteins
  - b. infecting cells that produce very few MHC molecules
  - c. producing proteins very similar to those of other viruses
  - d. infecting and killing helper T cells
  - e. building the viral shell from host proteins
8. **DRAW IT** Consider a pencil-shaped protein with two epitopes, Y (the “eraser” end) and Z (the “point” end). They are recognized by antibodies A1 and A2, respectively. Draw and label a picture showing the antibodies linking proteins into a complex that could trigger endocytosis by a macrophage.
9. **MAKE CONNECTIONS** Contrast the clonal selection of lymphocytes with Lamarck’s idea for the inheritance of acquired characteristics (see Concept 19.1).
10. **SCIENTIFIC INQUIRY** A diagnostic test for tuberculosis (TB) involves injecting antigen (from the bacterium that causes TB) under the skin and then waiting a few days for a reaction to appear. This test is *not* useful for diagnosing TB in AIDS patients. Why?
11. **FOCUS ON EVOLUTION** Describe one invertebrate defense mechanism and discuss how it is an evolutionary adaptation retained in vertebrates.
12. **FOCUS ON INFORMATION** Among all nucleated body cells, only B and T cells lose DNA during their development and maturation. In a short essay (100–150 words), discuss the relationship between this loss and the theme of DNA as heritable biological information, focusing on similarities between cellular and organismal generations.

For selected answers, see Appendix A.

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# Reproduction and Development

▼ **Figure 36.1** How can each of these sea slugs be both male and female?

## KEY CONCEPTS

- 36.1** Both asexual and sexual reproduction occur in the animal kingdom
- 36.2** Reproductive organs produce and transport gametes
- 36.3** The interplay of tropic and sex hormones regulates reproduction in mammals
- 36.4** Fertilization, cleavage, and gastrulation initiate embryonic development

## OVERVIEW

### Pairing Up for Sexual Reproduction

**T**he sea slugs, or nudibranchs (*Nembrotha chamberlaini*), in **Figure 36.1** are mating. If not disturbed, these marine molluscs may remain joined for hours as sperm are transferred and eggs are fertilized. A few weeks later, new individuals will hatch, and sexual reproduction will be complete—but which parent is the mother of these offspring? The answer is simple yet probably unexpected: both. In fact, each sea slug produces eggs *and* sperm, and so is both a mother and a father to the next generation.

As humans, we tend to think of reproduction in terms of the mating of males and females and the fusion of sperm and eggs. Across the animal kingdom, however, reproduction takes many forms. In some species, individuals change their sex during their lifetime; in other species, such as sea slugs, an individual is both male and female. There are animals that can fertilize their own eggs, as well as others that can reproduce without any form of sex. In certain species, such as honeybees, only a few members of a large population reproduce.

A population outlives its members only by reproduction, the generation of new individuals from existing ones. In this chapter, we'll compare the diverse reproductive mechanisms that have evolved in the animal kingdom. Then we'll examine details of reproduction in mammals, with particular emphasis on the intensively studied example of humans. Lastly, we'll explore fundamental events in the earliest stages of an animal's development.

## CONCEPT 36.1

### Both asexual and sexual reproduction occur in the animal kingdom

There are two modes of animal reproduction—sexual and asexual. In **sexual reproduction**, the fusion of haploid gametes forms a diploid cell, the **zygote**. The animal that develops from a zygote can in turn give rise to gametes by meiosis (see Figure 10.8). The female gamete, the **egg**, is large and nonmotile, whereas the male gamete, the **sperm**, is generally much smaller and motile. In contrast, in **asexual reproduction**, new individuals are generated without the

▲ **Figure 36.2 Asexual reproduction of a sea anemone (*Anthopleura elegantissima*).** The large individual in the center of this photograph is undergoing fission, a type of asexual reproduction. Two smaller individuals will form as the parent divides approximately in half. Each offspring will be a genetic copy of the parent.

fusion of egg and sperm. For most asexual animals, reproduction relies entirely on mitotic cell division.

## Mechanisms of Asexual Reproduction

Several simple forms of asexual reproduction are found only among invertebrates. One of these is *budding*, in which new individuals arise from outgrowths of existing ones (see Figure 10.2). In stony corals, for example, buds form and remain attached to the parent. The eventual result is a colony more than 1 m across, consisting of thousands of connected individuals. Also common among invertebrates is *fission*, the separation of a parent organism into two individuals of approximately equal size (**Figure 36.2**).

Asexual reproduction can also be a two-step process: *fragmentation*, the breaking of the body into several pieces, followed by *regeneration*, the regrowth of lost body parts. If more than one piece grows and develops into a complete animal, the net effect is reproduction. For example, certain annelid worms can split their body into several fragments, each regenerating a complete worm in less than a week. Many sponges, cnidarians, bristle worms, and sea squirts also reproduce by fragmentation and regeneration.

A particularly intriguing form of asexual reproduction is **parthenogenesis**, in which an egg develops without being fertilized. Among invertebrates, parthenogenesis occurs in certain species of bees, wasps, and ants. The progeny can be either haploid or diploid. If haploid, the offspring develop into adults that produce eggs or sperm without meiosis. Among vertebrates,

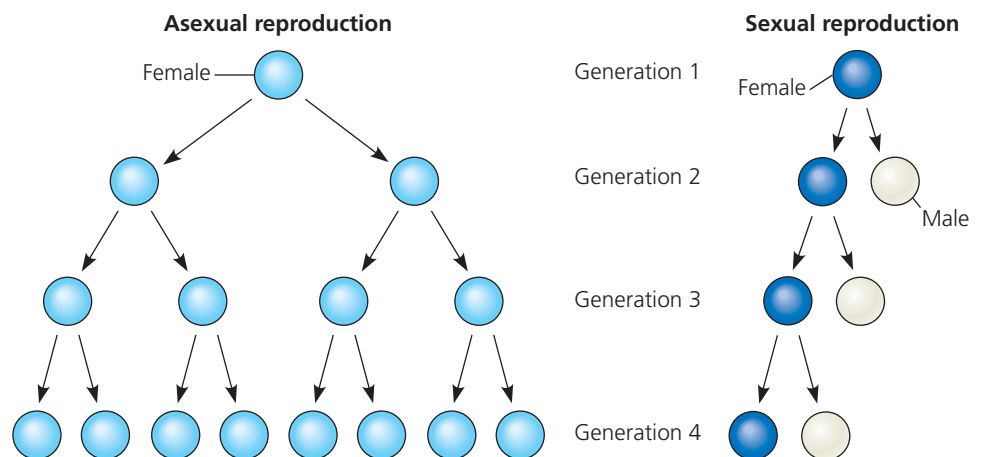

parthenogenesis has been observed in about one in every thousand species. Recently, zookeepers discovered evidence of parthenogenesis in Komodo dragons and in a species of hammerhead shark: In both cases, females had been kept completely isolated from males of their species but nevertheless produced offspring.

The rest of this chapter focuses on sexual reproduction, the existence of which is in fact puzzling, at least from an evolutionary perspective.

## Sexual Reproduction: An Evolutionary Enigma

**EVOLUTION** Sex must enhance reproductive success or survival because it would otherwise rapidly disappear. To see why, consider an animal population in which half the females reproduce sexually and half reproduce asexually (**Figure 36.3**). We'll assume that the number of offspring per female is a constant, two in this case. The two offspring of an asexual female will both be daughters that will each give birth to two more daughters that can reproduce. In contrast, on average, half of a sexual female's offspring will be male. The number of sexual offspring will remain the same at each generation, because both a male and a female are required to reproduce. Thus, the asexual condition will increase in frequency at each generation. Yet despite this "twofold cost," sex is maintained even in animal species that can also reproduce asexually.

What advantage does sex provide? The answer remains elusive. Most hypotheses focus on the unique combinations of parental genes formed during meiotic recombination and fertilization. By producing offspring of varied genotypes, sexual reproduction may enhance the reproductive success of parents when environmental factors, such as pathogens, change relatively rapidly. In contrast, we would expect asexual reproduction to be most advantageous in stable, favorable environments because it perpetuates successful genotypes precisely.

▲ **Figure 36.3 The “reproductive handicap” of sex.** These diagrams contrast the reproductive output of females (blue spheres) over four generations for asexual versus sexual reproduction, assuming two surviving offspring per female. The asexual portion of the population rapidly outgrows the sexual one.

▲ **Figure 36.4 Caribou (*Rangifer tarandus*) mother and calf.** As a result of warming due to global climate change, the number of caribou offspring in a West Greenland study site has fallen fourfold.

## Reproductive Cycles

Most animals exhibit cycles in reproductive activity, often related to changing seasons. These cycles are controlled by hormones, whose secretion in turn is regulated by environmental cues. In this way, animals conserve resources, reproducing only when sufficient energy sources or stores are available and when environmental conditions favor the survival of offspring.

Because seasonal temperature is often an important cue for reproduction, climate change can decrease reproductive success. Researchers have demonstrated just such an effect on caribou (wild reindeer) in Greenland. In spring, caribou migrate to calving grounds to eat sprouting green plants, give birth, and care for their calves (**Figure 36.4**). Prior to 1993, the arrival of caribou at the calving grounds coincided with the brief period during which the plants were nutritious and digestible. From 1993 to 2006, however, average spring temperatures in the calving grounds increased by more than 4°C, and the plants now sprout two weeks earlier. Because caribou migration is triggered by day length, not temperature, there is a mismatch between the timing of new plant growth and caribou birthing. Without adequate nutrition for the nursing females, production of caribou offspring has declined by 75% since 1993.

A different kind of reproductive cycle occurs in some species of whiptail lizards in the genus *Aspidoscelis*, in which members of breeding pairs alternate roles. In these species, reproduction is exclusively asexual, and there are no males. Nevertheless, these lizards have courtship and mating behaviors very similar to those of sexual species of *Aspidoscelis*. During the breeding season, one female of each mating pair mimics a male (**Figure 36.5a**). Each member of the pair alternates roles two or three times during the season. An individual adopts female behavior prior to ovulation, when the level of the female sex hormone estradiol is high, and then switches to male-like behavior after ovulation, when the level of progesterone is

(a) Both lizards in this photograph are *A. uniparens* females. The one on top is playing the role of a male. Every two or three weeks during the breeding season, individuals switch sex roles.

(b) The sexual behavior of *A. uniparens* is correlated with the cycle of ovulation mediated by sex hormones. As the blood level of estradiol rises, the ovaries grow, and the lizard behaves as a female. After ovulation, the estradiol level drops abruptly, and the progesterone level rises; these hormone levels correlate with male-like behavior.

▲ **Figure 36.5 Sexual behavior in parthenogenetic lizards.** The desert-grassland whiptail lizard (*Aspidoscelis uniparens*) is an all-female species. These reptiles reproduce by parthenogenesis, the development of an unfertilized egg. Nevertheless, ovulation is stimulated by mating behavior.

high (**Figure 36.5b**). Ovulation is more likely to occur if the individual is mounted during the critical time of the hormone cycle; isolated lizards lay fewer eggs than those that go through the motions of sex. These observations support the hypothesis that these parthenogenetic lizards evolved from species having two sexes and still require certain sexual stimuli for maximum reproductive success.

## Variation in Patterns of Sexual Reproduction

For many animals, finding a partner for sexual reproduction can be challenging. Adaptations that arose during the evolution of some species meet this challenge in a novel way—by blurring the strict distinction between male and female. One

such adaptation arose among sessile (stationary) animals, such as barnacles; burrowing animals, such as clams; and some parasites, including tapeworms. Largely lacking mobility, these animals have little opportunity to find a mate. The evolutionary solution in this case is **hermaphroditism**, in which each individual has both male and female reproductive systems (the term *hermaphrodite* merges the names Hermes and Aphrodite, a Greek god and goddess). Because each hermaphrodite reproduces as both a male and a female, *any* two individuals can mate. Each animal donates and receives sperm during mating, as the sea slugs in Figure 36.1 are doing. In some species, hermaphrodites are also capable of self-fertilization, allowing a form of sexual reproduction that doesn't require any partner.

The bluehead wrasse (*Thalassoma bifasciatum*) provides an example of a quite different variation in sexual reproduction. These coral reef fish live in harems, each consisting of a single male and several females. When the lone male dies, the opportunity for sexual reproduction would appear lost. Instead, the largest female in the harem transforms into a male and within a week begins to produce sperm instead of eggs. What selective pressure in the evolution of the bluehead wrasse resulted in sex reversal for that female with the largest body? Because it is the male wrasse that defends a harem against intruders, a larger size may be particularly important for a male in ensuring successful reproduction.

## External and Internal Fertilization

Sexual reproduction requires **fertilization**, the union of sperm and egg. In species with **external fertilization**, the female releases eggs into the environment, where the male then fertilizes them. Other species have **internal fertilization**: Sperm are deposited in or near the female reproductive tract, and fertilization occurs within the tract.

A moist habitat is almost always required for external fertilization, both to prevent the gametes from drying out and to allow the sperm to swim to the eggs. Many aquatic invertebrates simply shed their eggs and sperm into the surroundings, and fertilization occurs without the parents making physical contact. However, timing is crucial to ensure that mature sperm and eggs encounter one another.

Among some species with external fertilization, individuals clustered in the same area release their gametes into the water at the same time, a process known as *spawning*. In some cases, chemical signals generated by one individual as it releases gametes trigger other individuals to release gametes. In other cases, environmental cues, such as temperature or day length, cause a whole population to release gametes at one time. For example, the palolo worm, native to coral reefs of the South Pacific, coordinates its spawning to both the season and the lunar cycle. Sometime in spring when the moon is in its last quarter, palolo worms break in half, releasing tail segments engorged with sperm or eggs. These packets rise to the ocean surface and burst in such vast numbers that the sea appears milky with gametes.

▲ **Figure 36.6 External fertilization.** Many species of amphibians reproduce by external fertilization. In most of these species, behavioral adaptations ensure that a male is present when the female releases eggs. Here, a female frog (on bottom) has released a mass of eggs in response to being clasped by a male. The male released sperm (not visible) at the same time, and external fertilization has already occurred in the water.

The sperm quickly fertilize the floating eggs, and within hours, the palolo's once-a-year reproductive frenzy is complete.

When external fertilization is not synchronous across a population, individuals may exhibit specific "courtship" behaviors leading to the fertilization of the eggs of one female by one male (**Figure 36.6**). By triggering the release of both sperm and eggs, these behaviors increase the probability of successful fertilization.

Internal fertilization is an adaptation that enables sperm to reach an egg efficiently, even when the environment is dry. It typically requires cooperative behavior that leads to copulation, as well as sophisticated and compatible reproductive systems. The male copulatory organ delivers sperm, and the female reproductive tract often has receptacles for storage and delivery of sperm to mature eggs.

No matter how fertilization occurs, the mating animals may make use of *pheromones*, chemicals released by one organism that can influence the physiology and behavior of other individuals of the same species. Pheromones are small, volatile or water-soluble molecules that disperse into the environment and, like hormones, are active in tiny amounts. Many pheromones function as mate attractants, enabling some female insects to be detected by males more than a kilometer away.

## Ensuring the Survival of Offspring

Internal fertilization typically is associated with the production of fewer gametes than external fertilization but results in the survival of a higher fraction of zygotes. Better zygote survival is due in part to the fact that eggs fertilized internally are sheltered from potential predators. However, internal fertilization is also more often associated with mechanisms that provide

## Reproductive organs produce and transport gametes

Sexual reproduction in animals relies on sets of cells that are precursors for eggs and sperm. A group of cells dedicated to this function is often established early in the formation of the embryo and remains inactive while the body takes shape. Cycles of growth and mitosis then increase, or *amplify*, the number of cells available for making eggs or sperm.

### Variation in Reproductive Systems

In producing gametes and making them available for fertilization, animals employ a variety of reproductive systems.

**Gonads**, organs that produce gametes, are found in many but not all animals. Exceptions include the palolo worm, discussed earlier. The palolo and most other polychaete worms (phylum Annelida; see Figure 27.11) have separate sexes but lack distinct gonads; rather, the eggs and sperm develop from undifferentiated cells lining the coelom (body cavity). As the gametes mature, they are released from the body wall and fill the coelom. Depending on the species, mature gametes in these worms may be shed through the excretory opening, or the swelling mass of eggs may split a portion of the body open, spilling the eggs into the environment.

More elaborate reproductive systems include sets of accessory tubes and glands that carry, nourish, and protect the gametes and sometimes the developing embryos. Most insects, for example, have separate sexes with complex reproductive systems. In many insect species, the female reproductive system includes one or more *spermathecae*, sacs in which sperm may be stored for extended periods, a year or more in some species. Because the female releases male gametes from the spermathecae only in response to the appropriate stimuli, fertilization occurs under conditions likely to be well suited to embryonic development.

Vertebrate reproductive systems display limited but significant variations. In many nonmammalian vertebrates, the digestive, excretory, and reproductive systems have a common opening to the outside, the **cloaca**, a structure probably present in the ancestors of all vertebrates. Males of these species lack a well-developed penis and release sperm by turning the cloaca inside out.

In contrast, mammals generally lack a cloaca and have a separate opening for the digestive tract. Most female mammals also have separate openings for the excretory and reproductive systems. In some vertebrates, the uterus is divided into two chambers; in others, including humans and birds, it is a single structure.

Having surveyed some general features of animal reproduction, we turn now to human reproduction, beginning with the reproductive anatomy of males.

▲ **Figure 36.7 Parental care in an invertebrate.** Compared with many other insects, giant water bugs of the genera *Abedus* and *Belostoma* produce relatively few offspring, but offer much greater parental protection. Following internal fertilization, the female glues her fertilized eggs to the back of the male (shown here). The male carries them for days, frequently fanning water over them to keep the eggs moist, aerated, and free of parasites.

greater protection of the embryos and parental care of the young. For example, the eggs of birds and other reptiles have calcium- and protein-containing shells and internal membranes that protect against water loss and physical damage (see Figure 27.25). In contrast, the eggs of fishes and amphibians have only a gelatinous coat and lack internal membranes.

Rather than secreting a protective eggshell, some animals retain the embryo for a portion of its development within the female's reproductive tract. Embryos of marsupial mammals, such as kangaroos and opossums, spend only a short period in the uterus; the embryos then crawl out and complete fetal development attached to a mammary gland in the mother's pouch. Embryos of eutherian (placental) mammals, such as humans, remain in the uterus throughout fetal development. There they are nourished by the mother's blood supply through a temporary organ, the placenta. The embryos of some fishes and sharks also complete development internally.

When an eagle hatches out of an egg or when a human is born, the newborn is not yet capable of independent existence. Instead, adult birds feed their young and adult mammals nurse their offspring. Parental care is in fact widespread among animals, including invertebrate species (**Figure 36.7**).

#### CONCEPT CHECK 36.1

1. How does internal fertilization facilitate life on land?
2. **WHAT IF?** If a hermaphrodite self-fertilizes, will the offspring be identical to the parent? Explain.
3. **MAKE CONNECTIONS** What examples of plant reproduction are most similar to asexual reproduction in animals? (See Concept 30.2.)

For suggested answers, see Appendix A.

► **Figure 36.8**  
**Reproductive anatomy**  
**of the human male.** Some  
nonreproductive structures are labeled in  
parentheses for orientation purposes.

## Human Male Reproductive Anatomy

The human male's external reproductive organs are the scrotum and penis. The internal reproductive organs consist of gonads that produce both sperm and reproductive hormones, accessory glands that secrete products essential to sperm movement, and ducts that carry the sperm and glandular secretions (**Figure 36.8**).

### Testes

The male gonads, or **testes** (singular, *testis*), produce sperm in highly coiled tubes called **seminiferous tubules**. Most mammals produce sperm properly only when the testes are cooler than the rest of the body. In humans and many other mammals, the **scrotum**, a fold of the body wall, maintains testis temperature about 2°C below the core body temperature.

The testes develop in the abdominal cavity and descend into the scrotum just before birth (a testis within a scrotum is a *testicle*). In many rodents, the testes are drawn back into the cavity between breeding seasons, interrupting sperm maturation. Some mammals whose body temperature is low enough to allow sperm maturation—such as whales and elephants—retain the testes in the abdominal cavity at all times.

### Ducts

From the seminiferous tubules of a testis, the sperm pass into the coiled duct of an **epididymis**. In humans, it takes 3 weeks for sperm to travel the 6 m length of this duct, during which time the sperm complete maturation and become motile. During **ejaculation**, the sperm are propelled from each epididymis through a muscular duct, the **vas deferens**. Each vas deferens (one from each epididymis) extends around and behind the urinary bladder, where it joins a duct from the seminal vesicle, forming a short **ejaculatory duct**. The ejaculatory ducts open into the **urethra**, the outlet tube for both the excretory system and the reproductive system. The urethra runs through the penis and opens to the outside at the tip of the penis.

### Accessory Glands

Three sets of accessory glands—the seminal vesicles, the prostate gland, and the bulbourethral glands—produce secretions that combine with sperm to form **semen**, the fluid that is ejaculated. Two **seminal vesicles** contribute about 60% of the volume of semen. The fluid from the seminal vesicles is thick, yellowish, and alkaline. It contains mucus, the sugar fructose (which provides most of the sperm's energy), a coagulating enzyme, ascorbic acid, and local regulators called prostaglandins.

The **prostate gland** secretes its products into the urethra through small ducts. This fluid is thin and milky; it contains anticoagulant enzymes and citrate (a sperm nutrient). This gland undergoes benign (noncancerous) enlargement in more than half of all men over age 40 and in almost all men over 70. In addition, prostate cancer, which most often afflicts men 65 and older, is one of the most common human cancers.

The **bulbourethral glands** are a pair of small glands along the urethra below the prostate. Before ejaculation, they secrete clear mucus that neutralizes any acidic urine remaining in the urethra. Bulbourethral fluid also carries some sperm released before ejaculation, which is one reason for the high failure rate of the withdrawal method of birth control (coitus interruptus).

### Penis

The human **penis** contains the urethra as well as three cylinders of spongy erectile tissue. During sexual arousal, the erectile tissue, which is derived from modified veins and capillaries, fills with blood from the arteries. As this tissue fills, the increasing pressure seals off the veins that drain the penis, causing it to engorge with blood. The resulting erection enables the penis to be inserted into the vagina. Alcohol consumption, certain drugs, emotional issues, and aging all can cause an inability to achieve an erection (erectile dysfunction). For individuals with long-term erectile dysfunction, drugs such as Viagra promote the vasodilating action of nitric oxide; the resulting relaxation of smooth muscles in the blood

vessels of the penis enhances blood flow into the erectile tissues. Although all mammals rely on penile erection for mating, the penis of rodents, raccoons, walruses, whales, and several other mammals also contains a bone, the baculum, which is thought to further stiffen the penis for mating.

The main shaft of the penis is covered by relatively thick skin. The head, or **glans**, of the penis has a much thinner covering and is consequently more sensitive to stimulation. The human glans is covered by a fold of skin called the **prepuce**, or foreskin, which is removed when a male is circumcised.

## Human Female Reproductive Anatomy

The human female's external reproductive structures are the clitoris and two sets of labia, which surround the clitoris and vaginal opening. The internal organs are the gonads, which produce both eggs and reproductive hormones, and a system of ducts and chambers, which receive and carry gametes and house the embryo and fetus (**Figure 36.9**).

### Ovaries

The female gonads are a pair of **ovaries** that flank the uterus and are held in place in the abdominal cavity by ligaments. The outer layer of each ovary is packed with **follicles**, each consisting of an **oocyte**, a partially developed egg, surrounded by support cells. The surrounding cells nourish and protect the oocyte during much of its formation and development.

### Oviducts and Uterus

An **oviduct**, or fallopian tube, extends from the uterus toward a funnel-like opening at each ovary. The dimensions of this tube vary along its length, with the inside diameter near the uterus being as narrow as a human hair. Upon **ovulation**, the release of a mature egg, cilia on the epithelial lining of the oviduct help collect the egg by drawing fluid from the body cavity

into the oviduct. Together with wavelike contractions of the oviduct, the cilia convey the egg down the duct to the **uterus**, also known as the womb. The uterus is a thick, muscular organ that can expand during pregnancy to accommodate a 4-kg fetus. The inner lining of the uterus, the **endometrium**, is richly supplied with blood vessels. The neck of the uterus, called the **cervix**, opens into the vagina.

### Vagina and Vulva

The **vagina** is a muscular but elastic chamber that is the site for insertion of the penis and deposition of sperm during copulation. The vagina, which also serves as the birth canal through which a baby is born, opens to the outside at the **vulva**, the collective term for the external female genitalia.

A pair of thick, fatty ridges, the **labia majora**, encloses and protects the rest of the vulva. The vaginal opening and the separate opening of the urethra are located within a cavity bordered by a pair of slender skin folds, the **labia minora**. A thin piece of tissue called the **hymen** partly covers the vaginal opening in humans at birth and usually until sexual intercourse or vigorous physical activity ruptures it. Located at the top of the labia minora, the **clitoris** consists of erectile tissue supporting a rounded glans, or head, covered by a small hood of skin, the prepuce. During sexual arousal, the clitoris, vagina, and labia minora all engorge with blood and enlarge. Richly supplied with nerve endings, the clitoris is one of the most sensitive points of sexual stimulation. Sexual arousal also induces the vestibular glands near the vaginal opening to secrete lubricating mucus, thereby facilitating intercourse.

### Mammary Glands

The **mammary glands** are present in both sexes, but they normally produce milk only in females. Though not part of the reproductive system, the female mammary glands are important to reproduction. Within the glands, small sacs of epithelial tissue secrete milk, which drains into a series of ducts that open at the nipple. The breasts contain connective and fatty (adipose) tissue in addition to the mammary glands. Because the low level of the hormone estradiol in males limits the development of the fat deposits, male breasts usually remain small.

## Gametogenesis

With this overview of reproductive anatomy in mind, we turn now to **gametogenesis**, the production of gametes. **Figure 36.10** compares this process in human males and females, highlighting the close relationship between the gonads' structure and their function.

**Spermatogenesis**, the formation and development of sperm, is continuous and

▲ **Figure 36.9** Reproductive anatomy of the human female. Some nonreproductive structures are labeled in parentheses for orientation purposes.

## Spermatogenesis

These drawings correlate the mitotic and meiotic divisions in sperm development with the microscopic structure of seminiferous tubules.

The initial, or *primordial*, germ cells of the embryonic testes divide and differentiate into stem cells that divide by mitosis to form **spermatogonia**, which in turn generate spermatocytes, also by mitosis. Each spermatocyte gives rise to four spermatids through meiosis, reducing the chromosome number from diploid ( $2n = 46$  in humans) to haploid ( $n = 23$ ). Spermatids undergo extensive changes in cell shape and organization in differentiating into sperm.

Within the seminiferous tubules, there is a concentric organization of the steps of spermatogenesis. Stem cells are situated near the outer edge of the tubules. As spermatogenesis proceeds, cells move steadily inward as they pass through the spermatocyte stage and the spermatid stage. In the last step, mature sperm are released into the lumen (fluid-filled cavity) of the tubule. The sperm travel along the tubule into the epididymis, where they become motile.

The structure of a sperm cell fits its function. In humans, as in most species, a head containing the haploid nucleus is tipped with a specialized vesicle, the **acrosome**, which contains enzymes that help the sperm penetrate an egg. Behind the head, many mitochondria (or one large mitochondrion in some species) provide ATP for movement of the flagellar tail.

## Oogenesis

Oogenesis begins in the female embryo with the production of **oogonia** from primordial germ cells. The oogonia divide by mitosis to form cells that begin meiosis, but stop the process at prophase I before birth. These developmentally arrested cells, called **primary oocytes**, each reside within a small follicle, a cavity lined with protective cells. Beginning at puberty, follicle-stimulating hormone (FSH) periodically stimulates a small group of follicles to resume growth and development. Cells of the follicle produce the primary female sex hormone, estradiol (a type of estrogen). Typically, only one follicle fully matures each month, with its primary oocyte completing meiosis I. The second meiotic division begins, but stops at metaphase. Thus arrested in meiosis II,

the **secondary oocyte** is released at ovulation, when its follicle breaks open. Only if a sperm penetrates the oocyte does meiosis II resume. (In other animal species, the sperm may enter the oocyte at the same stage, earlier, or later.) Each of the two meiotic divisions involves unequal cytokinesis, with the smaller cells becoming polar bodies that eventually degenerate (the first polar body may or may not divide again). Thus, the functional product of complete oogenesis is a single mature egg already containing a sperm head; fertilization is defined strictly as the fusion of the haploid nuclei of the sperm and secondary oocyte, although we often use it loosely to mean the entry of the sperm head into the egg.

The ruptured follicle left behind after ovulation develops into a mass called the **corpus luteum** ("yellow body"). The corpus luteum secretes additional estradiol as well as progesterone, a hormone that helps maintain the uterine lining during pregnancy. If the egg is not fertilized, the corpus luteum degenerates, and a new follicle matures during the next cycle.

At birth, the ovaries together contain 1–2 million primary oocytes, of which about 500 fully mature between puberty and menopause. To the best of our current knowledge, women are born with all the primary oocytes they will ever have. It is worth noting, however, that a similar conclusion regarding most other mammals was overturned in 2004 when researchers discovered that the ovaries of adult mice contain multiplying oogonia that develop into oocytes. If the same is true of humans, then the marked decline in fertility that occurs as women age might result from both a depletion of oogonia and the degeneration of aging oocytes.

**WHAT IF?** Suppose you are analyzing the DNA from the polar bodies formed during human oogenesis. If the mother has a mutation in a known disease gene, would analyzing the polar body DNA allow you to infer whether the mutation is present in the mature oocyte? Explain.

prolific in adult males. To produce hundreds of millions of sperm each day, cell division and maturation occur throughout the seminiferous tubules coiled within the two testes. For a single sperm, the process takes about 7 weeks from start to finish.

**Oogenesis**, the development of mature oocytes (eggs), is a prolonged process in the human female. Immature eggs form in the ovary of the female embryo but do not complete their development until years, and often decades, later.

Spermatogenesis differs from oogenesis in three significant ways:

- Only in spermatogenesis do all four products of meiosis develop into mature gametes. In oogenesis, cytokinesis during meiosis is unequal, with almost all the cytoplasm segregated to a single daughter cell. This large cell is destined to become the egg; the other products of meiosis, smaller cells called polar bodies, degenerate.
- Spermatogenesis occurs throughout adolescence and adulthood. In contrast, the mitotic divisions of oogenesis in human females are thought to be complete before birth, and the production of mature gametes ceases at about age 50.
- Spermatogenesis produces mature sperm from precursor cells in a continuous sequence, whereas oogenesis has long interruptions.

#### CONCEPT CHECK 36.2

1. In what ways are a second polar body and an early spermatid similar? In what ways are they dissimilar?
2. Why might using a hot tub frequently make it harder for a couple to conceive a child?
3. **MAKE CONNECTIONS** How are the uterus of an insect and the ovary of a flowering plant similar in function? How are they different? (See Figure 30.7.)
4. **WHAT IF?** If each vas deferens in a male was surgically sealed off, what changes would you expect in sexual response and ejaculate composition?

For suggested answers, see Appendix A.

## CONCEPT 36.3

### The interplay of tropic and sex hormones regulates reproduction in mammals

In both male and female humans, the coordinated actions of hormones from the hypothalamus, anterior pituitary, and gonads govern reproduction. The hypothalamus secretes *gonadotropin-releasing hormone* (*GnRH*), which directs the anterior pituitary to secrete **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**). FSH and LH are **tropic hormones**, meaning that they act on endocrine tissues to trigger the release of other hormones. They are called *gonadotropins* because the endocrine tissues they act on are in the gonads.

▲ **Figure 36.11 Androgen-dependent male anatomy and behavior in a lizard.** A male anole (*Norops ortoni*) extends his dewlap, a brightly colored skinflap beneath the throat. Testosterone is required in the male both for the dewlap to develop and for the anole to display it to attract mates and guard his territory.

FSH and LH regulate gametogenesis by targeting tissues in the gonads and by regulating sex hormone production.

The principal sex hormones are steroid hormones that include *androgens*, *estrogens*, and **progesterone**. The major androgen is **testosterone**; the major estrogen is **estradiol**. Males and females both produce androgens and estrogens, but differ in their blood concentrations of particular hormones. Testosterone levels are about 10 times higher in males than in females, whereas estradiol levels are about 10 times higher in females than in males. The gonads are the major source of sex hormones, with much smaller amounts being produced by the adrenal gland.

Like gonadotropins, the sex hormones regulate gametogenesis both directly and indirectly, but they have other actions as well. For example, androgens are responsible for the male vocalizations of many vertebrates, such as the territorial songs of birds and the courtship displays of lizards (**Figure 36.11**). In human embryos, androgens promote the appearance of the primary sex characteristics of males, the structures directly involved in reproduction. These include the seminal vesicles and associated ducts, as well as external reproductive structures. In the **Scientific Skills Exercise**, you can interpret the results of an experiment investigating the development of reproductive structures in mammals.

At puberty, sex hormones in both male and female humans induce formation of secondary sex characteristics, the physical and behavioral features that are not directly related to the reproductive system. In males, androgens cause the voice to deepen, facial and pubic hair to develop, and muscles to grow (by stimulating protein synthesis). Androgens also promote specific sexual behaviors and sex drive, as well as an increase in general aggressiveness. Estrogens similarly have multiple effects in females. At puberty, estradiol stimulates breast and pubic hair development. Estradiol also influences female sexual behavior; induces fat deposition in the breasts and hips, increases water retention, and alters calcium metabolism.

# Making Inferences and Designing an Experiment

**What Role Do Hormones Play in Making a Mammal Male or Female?** In non-egg-laying mammals, females have two X chromosomes, whereas males have one X chromosome and one Y chromosome. In the 1940s, French physiologist Alfred Jost wondered whether development of mammalian embryos as female or male in accord with their chromosome set requires instructions in the form of hormones produced by the gonads. In this exercise, you will interpret the results of an experiment that Jost performed to answer this question.

**How the Experiment Was Done** Working with rabbit embryos still in the mother's uterus at a stage before sex differences are observable, Jost surgically removed the portion of each embryo that would form the ovaries or testes. When the baby rabbits were born, he made note of their chromosomal sex and whether their genital structures were male or female.

## Data from the Experiment

Chromosome Set	Appearance of Genitalia	
	No Surgery	Embryonic Gonad Removed
XY (male)	Male	Female
XX (female)	Female	Female

## Interpret the Data

1. This experiment is an example of a research approach in which scientists infer how something works normally based on what happens when the normal process is blocked. What normal process was blocked in Jost's experiment? From the results, what inference can you make about the role of the gonads in controlling the development of mammalian genitalia?
2. The data in Jost's experiment could be explained if some aspect of the surgery other than gonad removal caused female genitalia to develop. If you were to repeat Jost's experiment, how might you test the validity of such an explanation?
3. What result would Jost have obtained if female development also required a signal from the gonad?
4. Design another experiment to determine whether the signal that controls male development is a hormone. Make sure to identify your hypothesis, prediction, data collection plan, and controls.

**Data from** A. Jost, Recherches sur la differentiation sexuelle de l'embryon de lapin (Studies on the sexual differentiation of the rabbit embryo), *Archives d'Anatomie Microscopique et de Morphologie Experimentale* 36:271–316 (1947).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

▲ **Figure 36.12** Hormonal control of the testes.

We turn now to the role of gonadotropins and sex hormones in gametogenesis, beginning with males.

## Hormonal Control of the Male Reproductive System

FSH and LH, released by the anterior pituitary in response to GnRH secretion by the hypothalamus, act on different types

of cells in the testes to direct spermatogenesis (**Figure 36.12**). **Sertoli cells**, located within the seminiferous tubules, respond to FSH by nourishing developing sperm (see Figure 36.10). **Leydig cells**, scattered in connective tissue between the tubules, respond to LH by producing testosterone and other androgens, which promote spermatogenesis in the tubules.

Two negative-feedback mechanisms control sex hormone production in males (see Figure 36.12). Testosterone regulates blood levels of GnRH, FSH, and LH through inhibitory effects on the hypothalamus and anterior pituitary. In addition, *inhibin*, a hormone that in males is produced by Sertoli cells, acts on the anterior pituitary gland to reduce FSH secretion. Together, these negative-feedback circuits maintain androgen production at optimal levels.

## Hormonal Control of Female Reproductive Cycles

Whereas human males produce sperm continuously, human females produce eggs in cycles. Ovulation occurs only after the endometrium (lining of the uterus) has started to thicken and develop a rich blood supply, preparing the uterus for the possible implantation of an embryo. If pregnancy does not occur, the uterine lining is sloughed off, and another cycle begins. The cyclic shedding of the blood-rich endometrium from the uterus, a process that occurs in a flow through the cervix and vagina, is called **menstruation**.

There are two closely linked reproductive cycles in human females. Changes in the uterus define the **menstrual cycle**, also called the **uterine cycle**. Menstrual cycles average 28 days (although cycles vary, ranging from about 20 to 40 days). The cyclic events in the ovaries define the **ovarian cycle**. Hormone activity links the two cycles to each other, synchronizing ovarian follicle growth and ovulation with the establishment of a uterine lining that can support embryonic development.

**Figure 36.13** outlines the major events of the female reproductive cycles, illustrating the close coordination across different tissues in the body.

### The Ovarian Cycle

The ovarian cycle begins **1** with the release from the hypothalamus of GnRH, which stimulates the anterior pituitary to **2** secrete small amounts of FSH and LH. **3** Follicle-stimulating hormone (as its name implies) stimulates follicle growth, aided by LH, and **4** the cells of the growing follicles start to make estradiol. There is a slow rise in estradiol secreted during most of the **follicular phase**, the part of the ovarian cycle during which follicles grow and oocytes mature. (Several follicles begin to grow with each cycle, but usually only one matures; the others disintegrate.) The low levels of estradiol inhibit secretion of the pituitary hormones, keeping the levels of FSH and LH relatively low. During this portion of the cycle, regulation of the hormones controlling reproduction closely parallels the regulation observed in males.

**5** When estradiol secretion by the growing follicle begins to rise steeply, **6** the FSH and LH levels increase markedly. Whereas a low level of estradiol inhibits the secretion of pituitary gonadotropins, a high concentration has the opposite effect: It stimulates gonadotropin secretion by acting on the hypothalamus to increase its output of GnRH. The effect is greater for LH because the high concentration of estradiol increases the GnRH sensitivity of LH-releasing cells in the pituitary. In addition, follicles respond more

**▲ Figure 36.13 The reproductive cycles of the human female.** This figure shows how **(c)** the ovarian cycle and **(e)** the uterine (menstrual) cycle are regulated by changing hormone levels in the blood, depicted in parts **(a)**, **(b)**, and **(d)**. The time scale at the bottom of the figure applies to parts **(b)**–**(e)**.

strongly to LH at this stage because more of their cells have receptors for this hormone.

The increase in LH concentration caused by increased estradiol secretion from the growing follicle is an example of positive feedback. The result is final maturation of the follicle. **7** The maturing follicle, containing a fluid-filled cavity, enlarges, forming a bulge near the surface of the ovary. The follicular phase ends at ovulation, about a day after the LH surge. In response to the peak in LH levels, the follicle and adjacent wall of the ovary rupture, releasing the secondary oocyte. There is sometimes a distinctive pain in the lower abdomen at or near the time of ovulation; this pain is felt on the left or right side, corresponding to whichever ovary has matured a follicle during that cycle.

The *luteal phase* of the ovarian cycle follows ovulation.

**8** LH stimulates the follicular tissue left behind in the ovary to transform into a corpus luteum, a glandular structure. Under continued stimulation by LH, the corpus luteum secretes progesterone and estradiol, which in combination exert negative feedback on the hypothalamus and pituitary. This feedback reduces the secretion of LH and FSH to very low levels, preventing another egg from maturing when a pregnancy may already be under way.

Near the end of the luteal phase, low gonadotropin levels cause the corpus luteum to disintegrate, triggering a sharp decline in estradiol and progesterone concentrations. The decreasing levels of ovarian steroid hormones liberate the hypothalamus and pituitary from the negative-feedback effect of these hormones. The pituitary can then begin to secrete enough FSH to stimulate the growth of new follicles in the ovary, initiating the next ovarian cycle.

### The Uterine (Menstrual) Cycle

Prior to ovulation, ovarian steroid hormones stimulate the uterus to prepare for support of an embryo. Estradiol secreted in increasing amounts by growing follicles signals the endometrium to thicken. In this way, the follicular phase of the ovarian cycle is coordinated with the *proliferative phase* of the uterine cycle. After ovulation, **9** the estradiol and progesterone secreted by the corpus luteum stimulate maintenance of the uterine lining, as well as further development, including enlargement of arteries and growth of endometrial glands. These glands secrete a nutrient fluid that can sustain an early embryo even before it implants in the uterine lining. Thus, the luteal phase of the ovarian cycle is coordinated with what is called the *secretory phase* of the uterine cycle.

Once the corpus luteum has disintegrated, **10** the rapid drop in ovarian hormone levels causes arteries in the endometrium to constrict. Deprived of its circulation, the uterine lining largely disintegrates, and the uterus, in response to prostaglandin secretion, contracts. Small endometrial blood vessels constrict, releasing blood that is shed along with endometrial tissue and fluid. The result is menstruation—the *menstrual flow phase* of the uterine cycle. During this phase, which

usually lasts a few days, a new group of ovarian follicles begin to grow. By convention, the first day of flow is designated day 1 of the new uterine (and ovarian) cycle.

Overall, the hormonal cycles in females coordinate egg maturation and release with changes in the uterus, the organ that must accommodate an embryo if the egg cell is fertilized. If an embryo has not implanted in the endometrium by the end of the secretory phase, a new menstrual flow commences, marking the start of the next cycle. Later in the chapter, you'll learn about override mechanisms that prevent disintegration of the endometrium in pregnancy.

### Menopause

After about 500 cycles, a woman undergoes **menopause**, the cessation of ovulation and menstruation. Menopause usually occurs between the ages of 46 and 54. During this interval, the ovaries lose their responsiveness to FSH and LH, resulting in a decline in estradiol production.

Menopause is an unusual phenomenon. In most other species, females and males retain their reproductive capacity throughout life. Is there an evolutionary explanation for menopause? One intriguing hypothesis proposes that during early human evolution, undergoing menopause after bearing several children allowed a mother to provide better care for her children and grandchildren, thereby increasing the survival of individuals who share much of her genetic makeup.

### Menstrual Versus Estrous Cycles

In all female mammals, the endometrium thickens before ovulation, but only humans and some other primates have menstrual cycles. Other mammals have **estrous cycles**, in which in the absence of a pregnancy, the uterus reabsorbs the endometrium and no extensive fluid flow occurs. Whereas human females may engage in sexual activity throughout the menstrual cycle, mammals with estrous cycles usually copulate only during the period surrounding ovulation. This period, called estrus (from the Latin *oestrus*, frenzy, passion), is the only time the female is receptive to mating. It is often called “heat,” and the female’s temperature does increase slightly.

The length and frequency of estrous cycles vary widely among mammals. Bears and wolves have one estrous cycle per year; elephants typically have multiple cycles lasting 14–16 weeks each. Rats have estrous cycles throughout the year, each lasting only 5 days.

### Human Sexual Response

In humans, the arousal of sexual interest is complex, involving a variety of psychological as well as physical factors. Although many reproductive structures in the male and female are quite different in appearance, they often serve similar functions in arousal, reflecting their shared developmental origin. For example, the same embryonic tissues give rise to the glans of the penis and the clitoris, to the scrotum and the labia majora, and

to the skin on the penis and the labia minora. Furthermore, the general pattern of human sexual response is similar in males and females. Two types of physiological reactions predominate in both sexes: *vasocongestion*, the filling of a tissue with blood, and *myotonia*, increased muscle tension.

The sexual response cycle can be divided into four phases: excitement, plateau, orgasm, and resolution. An important function of the excitement phase is to prepare the vagina and penis for *coitus* (sexual intercourse). During this phase, vasocongestion is particularly evident in erection of the penis and clitoris; and in enlargement of the testicles, labia, and breasts. The vagina becomes lubricated and myotonia may occur, resulting in nipple erection or tension of the arms and legs.

In the plateau phase, these responses continue as a result of direct stimulation of the genitalia. In females, the outer third of the vagina becomes vasocongested, while the inner two-thirds slightly expands. This change, coupled with the elevation of the uterus, forms a depression for receiving sperm at the back of the vagina. Breathing increases and heart rate rises, sometimes to 150 beats per minute—not only in response to the physical effort of sexual activity, but also as an involuntary response to stimulation of the autonomic nervous system (see Chapter 38).

**Orgasm** is characterized by rhythmic, involuntary contractions of the reproductive structures in both sexes. Male orgasm has two stages. The first, emission, occurs when the glands and ducts of the reproductive tract contract, forcing semen into the urethra. Expulsion, or ejaculation, occurs when the urethra contracts and the semen is expelled. During female orgasm, the uterus and outer vagina contract, but the inner two-thirds of the vagina does not. Orgasm is the shortest phase of the sexual response cycle, usually lasting only a few seconds. In both sexes, contractions occur at about 0.8-second intervals and may also involve the anal sphincter and several abdominal muscles.

The resolution phase completes the cycle and reverses the responses of the earlier stages. Vasocongested organs return to their normal size and color, and muscles relax. Most of the changes of resolution are completed within 5 minutes, but some may take as long as an hour. Following orgasm, the male typically enters a refractory period, lasting anywhere from a few minutes to hours, during which erection and orgasm cannot be achieved. Females do not have a refractory period, making possible multiple orgasms within a short period of time.

### CONCEPT CHECK 36.3

1. FSH and LH get their names from events of the female reproductive cycle, but they also function in males. How are their functions in females and males similar?
2. How does an estrous cycle differ from a menstrual cycle, and in what animals are the two types of cycles found?
3. **WHAT IF?** If a human female were to take estradiol and progesterone immediately after the start of a new menstrual cycle, how would ovulation be affected? Explain.

For suggested answers, see Appendix A.

## CONCEPT 36.4

### Fertilization, cleavage, and gastrulation initiate embryonic development

Having explored gamete production and mating, we turn our attention now to development. Across a range of animal species, embryonic development involves common stages that occur in a set order. As shown in **Figure 36.14**, the first is fertilization, which forms a zygote. Development proceeds with the cleavage stage, during which a series of mitoses divide, or cleave, the zygote into a many-celled embryo. These cleavage divisions, which typically are rapid and lack accompanying cell growth, convert the embryo to a hollow ball of cells called a blastula. Next, the blastula folds in on itself, rearranging into a three-layered embryo, the gastrula, in a process called gastrulation. During organogenesis, the last major stage of embryonic development, local changes in cell shape and large-scale changes in cell location generate the rudimentary organs from which adult structures grow.

With this overview of embryonic development in mind, let's take a brief look at the early events of development—fertilization, cleavage, and gastrulation—in sea urchins (phylum Echinodermata; see Figure 27.11). Why sea urchins? Their gametes are easy to collect, and they have external fertilization; as a result, researchers can observe fertilization and subsequent events simply by combining eggs and sperm in seawater. Sea urchins are one example of a model organism, a species chosen for in-depth research in part because it is easy to study in the laboratory.

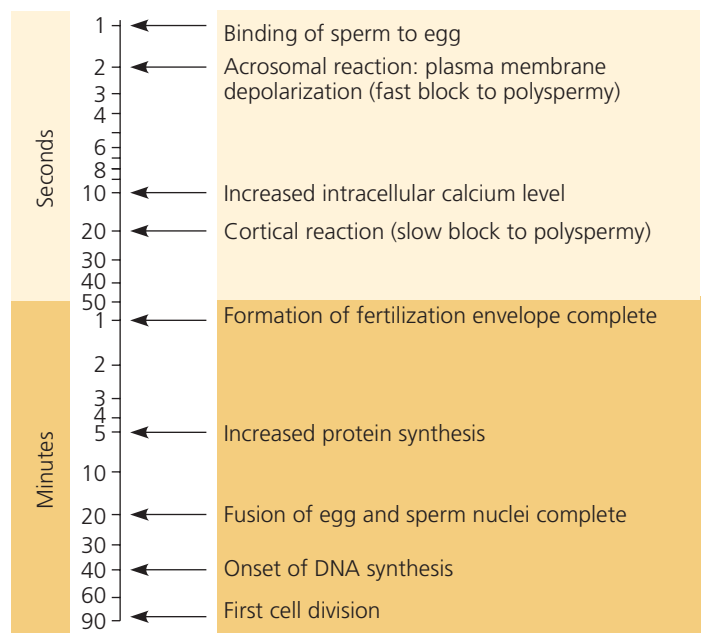

**▲ Figure 36.14** Developmental events in the life cycle of a frog.

## Fertilization

Molecules and events at the egg surface play a crucial role in each step of fertilization. First, sperm dissolve or penetrate any protective layer surrounding the egg to reach the plasma membrane. Next, molecules on the sperm surface bind to receptors on the egg, helping ensure that a sperm of the same species fertilizes the egg. Finally, changes at the surface of the egg prevent **polyspermy**, the entry of multiple sperm nuclei into the egg. If polyspermy were to occur, the resulting abnormal number of chromosomes in the embryo would be lethal. **Figure 36.15** illustrates the events that provide a fast and slow block to polyspermy in sea urchins, ensuring that only one sperm nucleus crosses the egg plasma membrane.

A major function of fertilization is combining haploid sets of chromosomes from two individuals into a single diploid cell, the zygote. However, the events of fertilization also initiate metabolic reactions that trigger the onset of embryonic development, thus “activating” the egg. As shown in **Figure 36.16**, activation leads to a number of events, such as an increase in protein synthesis, that precede the formation of a diploid nucleus.

What triggers egg activation? Studies show that sperm entry triggers release of internal  $\text{Ca}^{2+}$  stores into the egg cytoplasm and that injecting  $\text{Ca}^{2+}$  into an unfertilized egg activates

▲ **Figure 36.16** **Timeline for the fertilization of sea urchin eggs.** The process begins when a sperm cell binds the egg (top of chart). Notice that the scale is logarithmic.

▲ **Figure 36.15** **The acrosomal and cortical reactions during sea urchin fertilization.** The events following contact of a single sperm and egg ensure that the nucleus of only one sperm enters the egg cytoplasm.

egg metabolism. Other experiments indicate that the rise in  $\text{Ca}^{2+}$  concentration also causes the cortical reaction that provides the slow block to polyspermy (see Figure 36.15).

Fertilization in other species shares many features with the process in sea urchins. However, the timing of events differs, as does the stage of meiosis the egg has reached by the time it is fertilized. Sea urchin eggs have already completed meiosis when they are released from the female. In other species, eggs are arrested at a specific stage of meiosis and do not complete the meiotic divisions until fertilization occurs. Human eggs, for example, are arrested at metaphase of meiosis II prior to fertilization (see Figure 36.10).

## Cleavage and Gastrulation

Once fertilization is complete, many animal species undergo a succession of rapid cell divisions that characterize the **cleavage** stage of early development. During cleavage, the cell cycle consists primarily of the S (DNA synthesis) and M (mitosis) phases (for a review of the cell cycle, see Figure 9.6). Cells essentially skip the  $G_1$  and  $G_2$  (gap) phases, and little or no protein synthesis occurs. As a result, cleavage partitions the cytoplasm of the large fertilized egg into many smaller cells. The first five to seven cleavage divisions produce a hollow ball of cells, the **blastula**, surrounding a fluid-filled cavity called the **blastocoel** (Figure 36.17).

After cleavage, the rate of cell division slows considerably as the normal cell cycle is restored. The remaining stages of embryonic development are responsible for **morphogenesis**, the cellular and tissue-based processes by which the animal body takes shape.

During **gastrulation**, a set of cells at or near the surface of the blastula moves to an interior location, cell layers are

established, and a primitive digestive tube is formed. Gastrulation reorganizes the hollow blastula into a two-layered or three-layered embryo called a **gastrula**. The cell layers produced by gastrulation are collectively called the embryonic *germ layers* (from the Latin *germen*, to sprout or germinate). In the late gastrula, **ectoderm** forms the outer layer and **endoderm** lines the embryonic digestive compartment or tract. In vertebrates and other animals with bilateral symmetry, a third germ layer, the **mesoderm**, forms between the ectoderm and the endoderm.

Gastrulation in the sea urchin begins at the vegetal pole of the blastula (Figure 36.18). There, *mesenchyme cells* individually detach from the blastocoel wall and enter the blastocoel. The remaining cells near the vegetal pole flatten slightly and cause that end of the embryo to buckle inward. This process—the infolding of a sheet of cells into the embryo—is called *invagination*. Extensive rearrangement of cells transforms the shallow depression into a deeper, narrower, blind-ended tube called the *archenteron*. The open end of the archenteron, which will become the anus, is called the *blastopore*. A second opening, which will become the mouth, forms when the opposite end of the archenteron touches the inside of the ectoderm and the two layers fuse, producing a rudimentary digestive tube.

The cell movements and interactions that form the germ layers vary considerably among species. One basic distinction is whether the mouth develops from the first opening that forms in the embryo (protostomes) or the second (deuterostomes). Sea urchins and other echinoderms are deuterostomes, as are chordates like ourselves and other vertebrates.

Each germ layer contributes to a distinct set of structures in the adult animal, as shown for vertebrates in Figure 36.19. Note that some organs and many organ systems of the adult

(a) **Fertilized egg.** Shown here is the zygote shortly before the first cleavage division, surrounded by the fertilization envelope.

(b) **Four-cell stage.** Remnants of the mitotic spindle can be seen between the two pairs of cells that have just completed the second cleavage division.

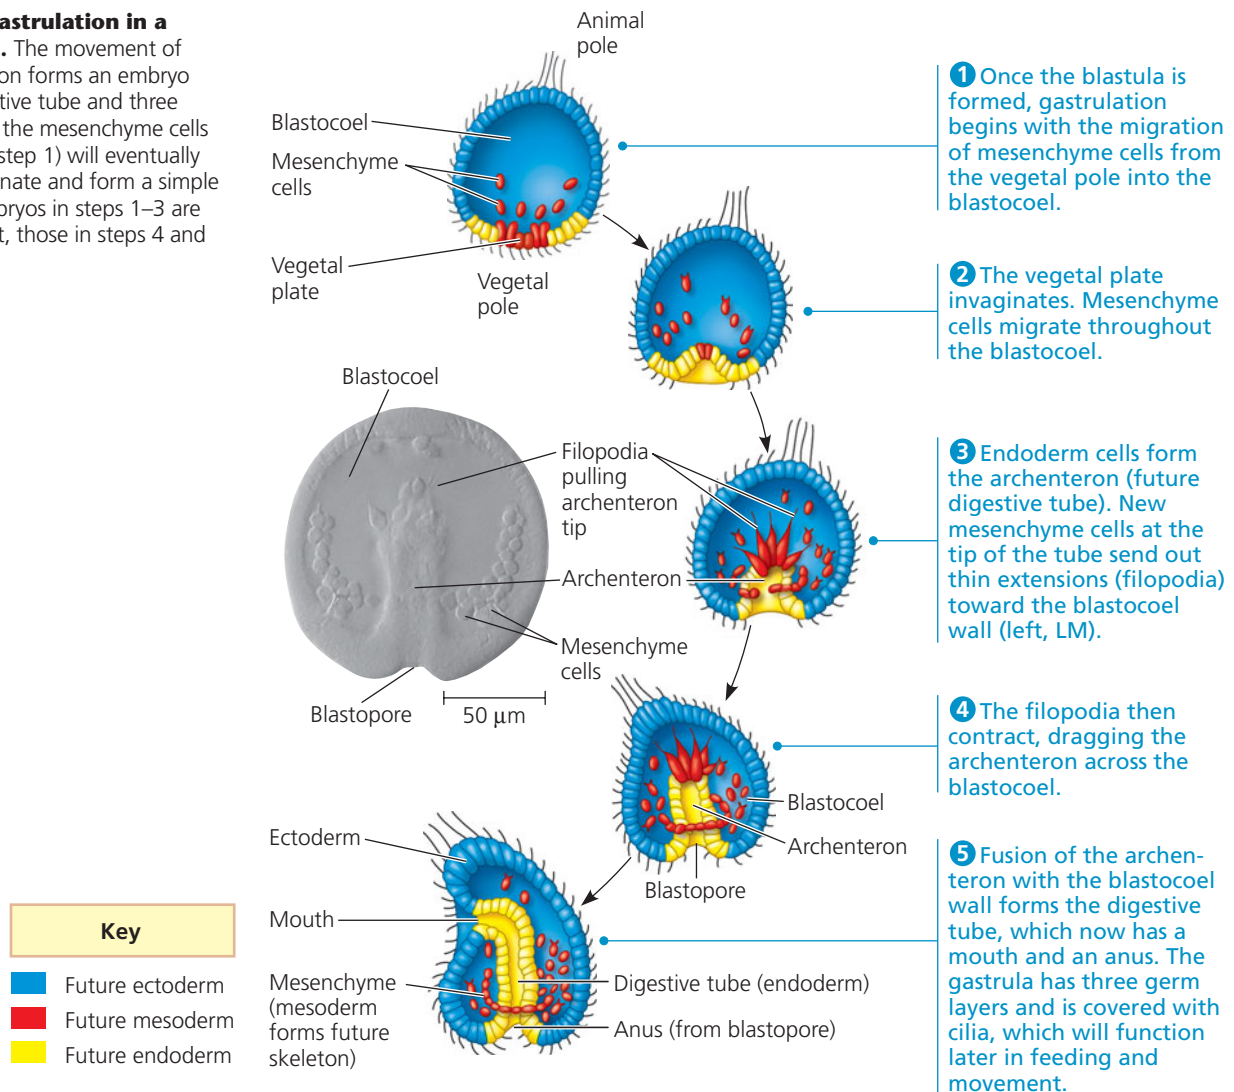

(c) **Early blastula.** After further cleavage divisions, the embryo is a multicellular ball that is still surrounded by the fertilization envelope. The blastocoel has begun to form in the center.

(d) **Later blastula.** A single layer of cells surrounds a large blastocoel. Although not visible here, the fertilization envelope is still present; the embryo will soon hatch from it and begin swimming.

▲ **Figure 36.17 Cleavage in an echinoderm embryo.** Cleavage is a series of mitotic cell divisions that transform the zygote into a blastula, a hollow ball of cells called blastomeres. These light micrographs show the embryonic stages of a sand dollar, which are virtually identical to those of a sea urchin.

► **Figure 36.18 Gastrulation in a sea urchin embryo.** The movement of cells during gastrulation forms an embryo with a primitive digestive tube and three germ layers. Some of the mesenchyme cells that migrate inward (step 1) will eventually secrete calcium carbonate and form a simple internal skeleton. Embryos in steps 1–3 are viewed from the front, those in steps 4 and 5 from the side.

▲ **Figure 36.19 Major derivatives of the three embryonic germ layers in vertebrates.**

derive from more than one germ layer. For example, the adrenal glands have both ectodermal and mesoderm tissue, and many other endocrine glands contain endodermal tissue.

Having introduced the developmental stages of fertilization, cleavage, and gastrulation, using the sea urchin as the primary example, we now return to our consideration of human reproduction.

## Human Conception, Embryonic Development, and Birth

During human copulation, the male delivers 2–5 mL of semen containing hundreds of millions of sperm. When first ejaculated, the semen coagulates, which may serve to keep the ejaculate in place until sperm reach the cervix. Soon after, anti-coagulants liquefy the semen, and the sperm begin swimming through the uterus and oviducts. Fertilization—also called **conception** in humans—occurs when a sperm fuses with an

egg (mature oocyte) in the oviduct (**Figure 36.20a**). As in sea urchin fertilization, sperm binding triggers a cortical reaction, which results in a slow block to polyspermy. (No fast block to polyspermy has been identified in mammals.)

The zygote begins cleavage about 24 hours after fertilization and produces a blastocyst after an additional 4 days. A few days later, the embryo implants into the endometrium of the uterus (**Figure 36.20b**). The condition of carrying one or more embryos in the uterus is called *pregnancy*, or **gestation**. Human pregnancy averages 266 days (38 weeks) from fertilization of the egg, or 40 weeks from the start of the last menstrual cycle. In comparison, gestation averages 21 days in many rodents, 270 days in cows, and more than 600 days in elephants.

Human gestation can be divided for convenience into three *trimesters* of about three months each. During the first trimester, the implanted embryo secretes hormones that signal its presence and regulate the mother's reproductive system. One embryonic hormone, *human chorionic gonadotropin* (*hCG*), acts like LH in maintaining secretion of progesterone and estrogens by the corpus luteum through the

first few months of pregnancy. Some hCG passes from the maternal blood to the urine; detecting hCG in the urine is the basis of the most common early pregnancy test.

Occasionally, the embryo splits during the first month of development, resulting in identical, or *monozygotic* (one-egg), twins. Fraternal, or *dizygotic*, twins arise in a very different way: Two follicles mature in a single cycle, are independently fertilized, and implant as two genetically distinct embryos.

Not all embryos are capable of completing development. Many spontaneously stop developing as a result of chromosomal or developmental abnormalities. Such spontaneous abortion, or *miscarriage*, occurs in as many as one-third of all pregnancies, often before the woman is even aware she is pregnant.

During its first 2–4 weeks of development, the embryo obtains nutrients directly from the endometrium. Meanwhile, the outer layer, called the **trophoblast**, grows outward and mingles with the endometrium, eventually helping form the **placenta**. This disk-shaped organ, containing both embryonic and maternal blood vessels, can weigh close to 1 kg. Material diffusing between the maternal and embryonic circulatory systems supplies nutrients, provides immune protection,

**▲ Figure 36.20** Formation of a human zygote and early postfertilization events.

**(a) 5 weeks.** Limb buds, eyes, the heart, the liver, and rudiments of all other organs have started to develop in the embryo, which is only about 1 cm long.

**(b) 14 weeks.** Growth and development of the offspring, now called a fetus, continue during the second trimester. This fetus is about 6 cm long.

**(c) 20 weeks.** Growth to nearly 20 cm in length requires adoption of the fetal position (head at knees) due to the limited space available.

▲ **Figure 36.21 Human fetal development.**

exchanges respiratory gases, and disposes of metabolic wastes for the embryo.

The first trimester is the main period of **organogenesis**, the development of the body organs. During organogenesis, the embryo is particularly susceptible to damage. For example, alcohol that passes through the placenta and reaches the developing central nervous system of the embryo can cause fetal alcohol syndrome, a disorder that can result in mental retardation and other serious birth defects. At 8 weeks, all the major structures of the adult are present in rudimentary form, and the embryo is called a **fetus**. The heart begins beating by the fourth week; a heartbeat can be detected at 8–10 weeks. At the end of the first trimester, the fetus, although well differentiated, is only 5 cm long (**Figure 36.21**).

During the second trimester, the fetus grows to about 30 cm in length and is very active. The mother may feel fetal movements as early as one month into the second trimester. During the third trimester, the fetus grows to about 3–4 kg in weight and 50 cm in length. Fetal activity may decrease as the fetus fills the available space.

Childbirth begins with *labor*, a series of strong, rhythmic uterine contractions that push the fetus and placenta out of the body. Once labor begins, local regulators (prostaglandins) and hormones (chiefly estradiol and oxytocin) induce and regulate further contractions of the uterus. A positive-feedback loop (see Chapter 32) is central to this regulation: Uterine contractions stimulate secretion of oxytocin, which in turn stimulates further contractions.

One aspect of postnatal care unique to mammals is *lactation*, the production of mother's milk. In response to suckling by the newborn, as well as changes in estradiol levels after birth, the hypothalamus signals the anterior pituitary to secrete prolactin, which stimulates the mammary glands to produce milk. Suckling also stimulates the secretion of oxytocin from

the posterior pituitary, which triggers milk release from the mammary glands (see Figure 32.12).

## Contraception

**Contraception**, the deliberate prevention of pregnancy, can be achieved in a number of ways. Some contraceptive methods prevent gamete development or release from female or male gonads; others prevent fertilization by keeping sperm and egg apart; and still others prevent implantation of an embryo. For complete information on contraceptive methods, you should consult a health-care provider. The following brief introduction to the biology of the most common methods and the corresponding diagram in **Figure 36.22** make no pretense of being a contraception manual.

Fertilization can be prevented by abstinence from sexual intercourse or by any of several barriers that keep live sperm from contacting the egg. Temporary abstinence, often called the *rhythm method* of birth control or *natural family planning*, depends on refraining from intercourse when conception is most likely. Because the egg can survive in the oviduct for 24–48 hours and sperm for up to 5 days, a couple practicing temporary abstinence should not engage in intercourse for a significant number of days before and after ovulation. Contraceptive methods based on fertility awareness require that the couple be knowledgeable about physiological indicators associated with ovulation, such as changes in cervical mucus. Note that a pregnancy rate of 10–20% is typically reported for couples practicing natural family planning. (Pregnancy rate is the average number of women who become pregnant during a year for every 100 women using a particular pregnancy prevention method, expressed as a percentage.)

As a method of preventing fertilization, *coitus interruptus*, or withdrawal (removal of the penis from the vagina before

▲ **Figure 36.22 Mechanisms of several contraceptive methods.** Red arrows indicate where these methods, devices, or products interfere with events from the production of sperm and primary oocytes to an implanted, developing embryo.

ejaculation), is unreliable. Sperm from a previous ejaculate may be transferred in secretions that precede ejaculation. Furthermore, a split-second lapse in timing or willpower can result in tens of millions of sperm being transferred before withdrawal.

Used properly, several barrier methods of contraception that block the sperm from meeting the egg have pregnancy rates of less than 10%. The *condom* is a thin, latex rubber or natural membrane sheath that fits over the penis to collect the semen. For sexually active individuals, latex condoms are the only contraceptives that are highly effective in preventing the

spread of sexually transmitted diseases, including AIDS. (This protection is, however, not absolute.) Another common barrier device is the *diaphragm*, a dome-shaped rubber cap inserted into the upper portion of the vagina before intercourse. Both devices have lower pregnancy rates when used in conjunction with a spermicidal (sperm-killing) foam or jelly. Other barrier devices include the vaginal pouch, or “female condom.”

Except for complete abstinence from sexual intercourse, the most effective means of birth control are sterilization, intra-uterine devices (IUDs), and hormonal contraceptives. Sterilization (vasectomy in males or tubal ligation in females) is almost 100% effective. The IUD has a pregnancy rate of 1% or less and is the most commonly used reversible method of birth control outside the United States. Placed in the uterus by a doctor, the IUD interferes with fertilization and implantation. Hormonal contraceptives, most often in the form of *birth control pills*, also have pregnancy rates of 1% or less.

The most commonly prescribed hormonal contraceptives are a combination of a synthetic estrogen and a synthetic progestin (progesterone-like hormone). This combination mimics negative feedback in the ovarian cycle, stopping the release of GnRH by the hypothalamus and thus of FSH and LH by the pituitary. The prevention of LH release blocks ovulation. In addition, the inhibition of FSH secretion by the low dose of estrogens in the pills prevents follicles from developing. Such combination birth control pills can also act as “morning-after” pills. Taken within 3 days after unprotected intercourse, they prevent fertilization or implantation with an effectiveness of about 75%.

A different type of hormonal contraceptive contains only progestin. Progestin causes a woman’s cervical mucus to thicken so that it blocks sperm from entering the uterus. Progestin also decreases the frequency of ovulation and causes changes in the endometrium that may interfere with implantation if fertilization occurs. Progestin can be administered as injections that last for three months or as a tablet (“minipill”) taken daily. Pregnancy rates for progestin treatment are very low.

Hormonal contraceptives have both beneficial and harmful side effects. Women who regularly smoke cigarettes face a three to ten times greater risk of dying from cardiovascular disease if they also use oral contraceptives. Among nonsmokers, birth control pills slightly raise a woman’s risk of abnormal blood clotting, high blood pressure, heart attack, and stroke. Although oral contraceptives increase the risk for these cardiovascular disorders, they eliminate the dangers of pregnancy; women on birth control pills have mortality rates about one-half those of pregnant women. Also, the pill decreases the risk of ovarian and endometrial cancers.

### Infertility and *In Vitro* Fertilization

Infertility—an inability to conceive offspring—is quite common, affecting about one in ten couples both in the United States and worldwide. The causes of infertility are varied, and the likelihood of a reproductive defect is nearly the same for

men and women. Among preventable causes of infertility, the most significant is *sexually transmitted disease (STD)*. In women 15–24 years old, approximately 700,000 cases of chlamydia and gonorrhea are reported annually in the United States. The actual number infected is considerably higher because most women with these STDs have no symptoms and are therefore unaware of their infection. Up to 40% of women who remain untreated for chlamydia or gonorrhea develop an inflammatory disorder that can lead to infertility or to potentially fatal complications during pregnancy.

Some forms of infertility are treatable. Hormone therapy can sometimes increase sperm or egg production, and surgery can often correct ducts that have failed to form properly or have become blocked. In some cases, doctors recommend *in vitro fertilization (IVF)*, which involves mixing oocytes and

sperm in culture dishes. Fertilized eggs are incubated until they have formed at least eight cells and are then transferred to the woman's uterus for implantation. If mature sperm are defective or low in number, a sperm nucleus is sometimes injected directly into an oocyte. Though costly, IVF procedures have enabled more than a million couples to conceive children.

#### CONCEPT CHECK 36.4

1. Where does fertilization occur in the human female?
2. Which of the three germ layers contributes least to tissues lining the interior or exterior of the body?
3. **WHAT IF?** If an STD led to complete blockage of both oviducts, what effect would you expect on the menstrual cycle and on fertility?

For suggested answers, see Appendix A.

## 36 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 36.1

**Both asexual and sexual reproduction occur in the animal kingdom (pp. 729–733)**

- **Sexual reproduction** requires the fusion of male and female gametes, forming a diploid **zygote**. **Asexual reproduction** is the production of offspring without gamete fusion. Mechanisms of asexual reproduction include budding, fission, and fragmentation with regeneration. Variations on the mode of reproduction are achieved through **parthenogenesis**, **hermaphroditism**, and sex reversal. Hormones and environmental cues control reproductive cycles.
- **Fertilization**, whether external or internal, requires coordinated timing, which may be mediated by environmental cues, pheromones, or courtship behavior. **Internal fertilization** is typically often associated both with fewer offspring and with greater protection of offspring by the parents.

**?** Would a pair of haploid offspring produced by parthenogenesis be genetically identical? Explain.

#### CONCEPT 36.2

**Reproductive organs produce and transport gametes (pp. 733–738)**

- Systems for gamete production and delivery range from undifferentiated cells in the body cavity to complex **gonads** with accessory tubes and glands that carry and protect gametes and embryos. In human males, **sperm** are produced in **testes**, which are suspended outside the body in the **scrotum**. Ducts connect the testes to internal accessory glands and to the **penis**. The reproductive system of the human female consists principally of the **ovaries**, **oviducts**, **uterus**, and **vagina** internally and the **labia** and the **glans** of the **clitoris** externally. **Eggs** are produced in the ovaries and upon fertilization develop in the uterus.
- **Gametogenesis**, or gamete production, consists of **spermatogenesis** in males and **oogenesis** in females. Meiosis generates one large egg in oogenesis, but four sperm in spermatogenesis. In humans, sperm develop continuously, whereas oocyte maturation is discontinuous and cyclic.

**?** How does the difference in size and cellular contents between sperm and eggs relate to their specific functions?

#### CONCEPT 36.3

**The interplay of tropic and sex hormones regulates reproduction in mammals (pp. 738–742)**

- In mammals, GnRH from the hypothalamus regulates the release of **FSH** and **LH** from the anterior pituitary, which in turn orchestrates gametogenesis. In males, secretion of androgens (chiefly

**testosterone**) and sperm production are both controlled by FSH and LH. In the female **menstrual cycle**, cyclic secretion of FSH and LH brings about changes in the ovary and uterus via estrogens, primarily **estradiol**, and **progesterone**. The follicle and corpus luteum also secrete hormones, with positive and negative feedback coordinating the uterine and ovarian cycles.

- In **estrous cycles**, the endometrial lining is reabsorbed, and sexual receptivity is limited to a heat period.

**?** *Why do anabolic steroids lead to reduced sperm count?*

## CONCEPT 36.4

### Fertilization, cleavage, and gastrulation initiate embryonic development (pp. 742–749)

- Fertilization brings together the nuclei of sperm and egg, forming a diploid zygote, and activates the egg, initiating embryonic development. Changes at the egg surface triggered by sperm entry help block **polyspermy** in many animals.
- Fertilization is followed by **cleavage**, a period of rapid cell division without growth, which results in the production of a large number of cells. In many species, cleavage creates a multicellular ball called the **blastula**, which contains a fluid-filled cavity, the **blastocoel**.
- **Gastrulation** converts the blastula to a **gastrula**, which has a primitive digestive cavity and three germ layers: **ectoderm**, **mesoderm**, and **endoderm**.
- The mammalian zygote develops into a blastocyst before implantation in the **endometrium**. All major organs start developing by 8 weeks.
- **Contraception** may prevent release of gametes from the gonads, fertilization, or embryo implantation. Infertile couples may be helped by hormonal methods or **in vitro fertilization**.

**?** *How does the fertilization envelope form in sea urchins? What is its function?*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- Which of the following characterizes parthenogenesis?
  - An individual may change its sex during its lifetime.
  - Specialized groups of cells grow into new individuals.
  - An organism is first a male and then a female.
  - An egg develops without being fertilized.
  - Both mates have male and female reproductive organs.
- The cortical reaction of sea urchin eggs functions directly in
  - the formation of a fertilization envelope.
  - the production of a fast block to polyspermy.
  - the release of hydrolytic enzymes from the sperm.
  - the generation of an electrical impulse by the egg.
  - the fusion of egg and sperm nuclei.
- Which of the following is *not* properly paired?
  - seminiferous tubule—cervix
  - Sertoli cells—follicle cells
  - testosterone—estradiol
  - scrotum—labia majora
  - vas deferens—oviduct
- Peaks of LH and FSH production occur during
  - the menstrual flow phase of the uterine cycle.
  - the beginning of the follicular phase of the ovarian cycle.
  - the period just before ovulation.
  - the end of the luteal phase of the ovarian cycle.
  - the secretory phase of the menstrual cycle.

- During human gestation, rudiments of all organs develop
  - in the first trimester.
  - in the second trimester.
  - in the third trimester.
  - while the embryo is in the oviduct.
  - during the blastocyst stage.

### Level 2: Application/Analysis

- Which of the following is a true statement?
  - All mammals have menstrual cycles.
  - The endometrial lining is shed in menstrual cycles but reabsorbed in estrous cycles.
  - Estrous cycles are more frequent than menstrual cycles.
  - Estrous cycles are not controlled by hormones.
  - Ovulation occurs before the endometrium thickens in estrous cycles.
- For which is the number the same in males and females?
  - interruptions in meiotic divisions
  - functional gametes produced by meiosis
  - meiotic divisions required to produce each gamete
  - gametes produced in a given time period
  - different cell types produced by meiosis
- Which statement about human reproduction is false?
  - Fertilization occurs in the oviduct.
  - Effective hormonal contraceptives are currently available only for females.
  - An oocyte completes meiosis after a sperm penetrates it.
  - The earliest stages of spermatogenesis occur closest to the lumen of the seminiferous tubules.
  - Spermatogenesis and oogenesis require different temperatures.

### Level 3: Synthesis/Evaluation

- DRAW IT** In human spermatogenesis, mitosis of a stem cell gives rise to one cell that remains a stem cell and one cell that becomes a spermatogonium. (a) Draw four rounds of mitosis for a stem cell, and label the daughter cells. (b) For one spermatogonium, draw the cells it would produce from one round of mitosis followed by meiosis. Label the cells, and label mitosis and meiosis. (c) What would happen if stem cells divided like spermatogonia?
- SCIENTIFIC INQUIRY**  
Suppose that you discover a new egg-laying worm species. You dissect four adults and find both oocytes and sperm in each. Cells outside the gonad contain five chromosome pairs. Lacking genetic variants, how would you determine whether the worms can self-fertilize?
- FOCUS ON EVOLUTION**  
Hermaphroditism is often found in animals that are fixed to a surface. Motile species are less often hermaphroditic. Why?
- FOCUS ON ENERGY AND MATTER**  
In a short essay (100–150 words), discuss how investments of energy by females contribute to the reproductive success of a frog (see Figure 36.6) and of a human.

For selected answers, see Appendix A.

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# 37 Neurons, Synapses, and Signaling

▼ **Figure 37.1** What makes this snail such a deadly predator?

## KEY CONCEPTS

**37.1** Neuron structure and organization reflect function in information transfer

**37.2** Ion pumps and ion channels establish the resting potential of a neuron

**37.3** Action potentials are the signals conducted by axons

**37.4** Neurons communicate with other cells at synapses

## OVERVIEW

### Lines of Communication

**T**he tropical cone snail (*Conus geographus*) in **Figure 37.1** is both beautiful and dangerous. A carnivore, this marine snail hunts, kills, and dines on fish. Injecting venom with a hollow, harpoon-like tooth, the cone snail paralyzes its free-swimming prey in seconds. The venom is so deadly that unlucky scuba divers have died from just a single injection. What makes cone snail venom so fast acting and lethal? The answer is its mixture of toxins, each with a specific mechanism of disabling **neurons**, the nerve cells that transfer information within the body. Because the venom almost instantaneously disrupts neuronal control of locomotion and respiration, an animal attacked by the cone snail cannot escape, defend itself, or otherwise survive.

Communication by neurons largely consists of long-distance electrical signals and short-distance chemical signals. The specialized structure of neurons allows them to use pulses of electrical current to receive, transmit, and regulate the flow of information over long distances within the body. In transferring information from one cell to another, neurons often rely on chemical signals that act over very short distances. The mixture of molecules in a cone snail's venom is particularly potent because it interferes with both electrical signaling and chemical signaling by neurons.

All neurons transmit electrical signals within the cell in an identical manner. Thus a neuron transmitting sensory input encodes information in the same way as a neuron involved in processing information or coordinating movement. What distinguishes the type of information being transmitted is the connections made by the active neuron. Interpreting signals in the nervous system therefore involves sorting those signals according to neuronal paths and connections. In more complex animals, this higher-order processing is carried out largely in groups of neurons organized into a **brain** or into simpler clusters called **ganglia**.

In this chapter, we'll examine the structure of a neuron and explore the molecules and physical principles that govern signaling by neurons. In Chapter 38, we'll examine how nervous systems are organized for processing information, as well as how organisms

gather information through receptors that are sensitive to stimuli such as light or sound. Then, in Chapter 39, we'll study how organisms respond to stimuli through movement and other forms of behavior.

## Neuron structure and organization reflect function in information transfer

Our starting point for exploring the nervous system is the neuron, a cell type exemplifying the close fit of form and function that often arises over the course of evolution.

### Neuron Structure and Function

The ability of a neuron to receive and transmit information is based on a highly specialized cellular organization (**Figure 37.2**). Most of a neuron's organelles, including its nucleus, are located in the **cell body**. A typical neuron has numerous highly branched extensions called **dendrites** (from the Greek *dendron*, tree). Together with the cell body, the dendrites *receive* signals from other neurons. A neuron also has a single **axon**, an extension that *transmits* signals to other cells. Axons are often much longer than dendrites, and some, such as those that reach from the spinal cord of a giraffe to the muscle cells in its feet, are over a meter long. The cone-shaped base of an axon, called the axon hillock, is typically where signals that travel down the axon are generated. Near its other end, an axon usually divides into many branches.

▲ **Figure 37.2** Neuron structure.

▲ **Figure 37.3** Glia in the mammalian brain. This micrograph (a fluorescently labeled laser confocal image) shows a region of the rat brain packed with glia and interneurons. Glia are labeled red, DNA in nuclei is labeled blue, and dendrites of neurons are labeled green.

Each branched end of an axon transmits information to another cell at a junction called a **synapse** (see Figure 37.2). The part of each axon branch that forms this specialized junction is a *synaptic terminal*. At most synapses, chemical messengers called **neurotransmitters** pass information from the transmitting neuron to the receiving cell. In describing a synapse, we refer to the transmitting neuron as the *presynaptic cell* and the neuron, muscle, or gland cell that receives the signal as the *postsynaptic cell*.

The neurons of vertebrates and most invertebrates require supporting cells called *glial cells*, or **glia** (from a Greek word meaning “glue”) (**Figure 37.3**). Overall, glia outnumber neurons in the mammalian brain 10- to 50-fold. Glia nourish neurons, insulate the axons of neurons, and regulate the extracellular fluid surrounding neurons. In addition, glia sometimes function in replenishing certain groups of neurons and in transmitting information (as we’ll discuss in Chapter 38).

## Introduction to Information Processing

Information processing by a nervous system occurs in three stages: sensory input, integration, and motor output. As an example, let's consider how a cone snail like the one in Figure 37.1 identifies and attacks its prey (**Figure 37.4**). Sensory input is generated as the snail surveys its environment with its tube-like siphon, sampling scents that might reveal a nearby fish. During the integration stage, the snail's nervous system processes this information to determine if a fish is in fact present and, if so, where the fish is located. Motor output then initiates attack, activating neurons that trigger release of the harpoon-like tooth toward the prey.

In all but the simplest animals, specialized populations of neurons handle each stage of information processing.

- **Sensory neurons**, like those in the snail's siphon, transmit information to processing centers in the brain or ganglia. Some sensors detect external stimuli such as light, sound, touch, or smell, whereas others monitor internal conditions such as blood pressure or muscle tension.
- Neurons in the brain or ganglia integrate (analyze and interpret) the sensory input, taking into account the immediate context and the animal's experience. The vast majority of

▲ **Figure 37.4 Summary of information processing.** The cone snail's siphon (highlighted in gold in the top left panel) acts as a sensor and transfers sensory information to neuronal circuits in the snail's head (right panel). If the scent of prey is detected, these circuits issue motor commands that trigger release of a harpoon-like tooth from the proboscis (in gold in the lower left panel).

▲ **Figure 37.5 Structural diversity of neurons.** In these drawings of neurons, cell bodies and dendrites are black and axons are red.

neurons in the brain are **interneurons**, which form the local circuits connecting neurons in the brain.

- Neurons that extend out of the processing centers trigger output in the form of muscle or gland activity. For example, **motor neurons** transmit signals to muscle cells, causing them to contract.

In many animals, the neurons that carry out integration are organized in a **central nervous system (CNS)**, which includes the brain and a longitudinal nerve cord. The neurons that carry information into and out of the CNS constitute the **peripheral nervous system (PNS)**. When bundled together, such neurons form **nerves**.

Depending on its role in information processing, the shape of a neuron can vary from simple to quite complex (**Figure 37.5**). Neurons that transmit information to many target cells have highly branched axons. Similarly, neurons with highly branched dendrites can receive input through large numbers of synapses, as many as 100,000 in the case of some interneurons.

### CONCEPT CHECK 37.1

1. Compare and contrast the structure and function of axons and dendrites.
2. Describe the basic pathway of information flow through neurons that causes you to turn your head when someone calls your name.
3. **WHAT IF?** How might increased branching of an axon help coordinate responses to signals communicated by the nervous system?

For suggested answers, see Appendix A.

## CONCEPT 37.2

### Ion pumps and ion channels establish the resting potential of a neuron

In continuing our exploration of neuron function, we turn now to the essential role of ions in neuronal signaling. In a neuron, as in other cells, ions are unequally distributed between the cell interior and the surrounding extracellular fluid (see Chapter 5). As a result, the inside of a cell is negatively charged relative to the outside. Because the attraction of opposite charges across the plasma membrane is a source of potential energy, this charge difference, or voltage, is called the **membrane potential**. For a resting neuron—one that is not sending a signal—the membrane potential is called the **resting potential** and is typically between  $-60$  and  $-80$  mV (millivolts).

Inputs from other neurons or specific stimuli cause changes in the neuron's membrane potential that act as signals, transmitting information. Fundamentally, rapid changes in membrane potential are what enable us to see the intricate structure of a spiderweb, read a biology textbook, or ride a bicycle. Thus, to understand how neurons function, we first need to examine how chemical and electrical forces form, maintain, and alter membrane potentials.

#### Formation of the Resting Potential

Potassium ions ( $K^+$ ) and sodium ions ( $Na^+$ ) play an essential role in the formation of the resting potential. Each type of ion has a concentration gradient across the plasma membrane of a neuron (Table 37.1). For most neurons, the concentration of  $K^+$  is higher inside the cell, while the concentration of  $Na^+$  is higher outside. These  $Na^+$  and  $K^+$  gradients are maintained by the **sodium-potassium pump** (see Chapter 5). This ion pump uses the energy of ATP hydrolysis to actively transport  $Na^+$  out of the cell and  $K^+$  into the cell (Figure 37.6). There are also concentration gradients for chloride ions ( $Cl^-$ ) and other anions, as shown in Table 37.1, but we can ignore these for the moment.

**Table 37.1** Ion Concentrations Inside and Outside of Mammalian Neurons

Ion	Intracellular Concentration (mM)	Extracellular Concentration (mM)
Potassium ( $K^+$ )	140	5
Sodium ( $Na^+$ )	15	150
Chloride ( $Cl^-$ )	10	120
Large anions ( $A^-$ ) inside cell, such as proteins	100	(not applicable)

#### Key

**▲ Figure 37.6 The basis of the membrane potential.** The sodium-potassium pump generates and maintains the ionic gradients of  $Na^+$  and  $K^+$  shown in Table 37.1. (Many such pump molecules are located in the plasma membrane of each cell.) Although there is a substantial concentration gradient of sodium across the membrane, very little net diffusion of  $Na^+$  occurs because there are very few open sodium channels. In contrast, the large number of open potassium channels allow a significant net outflow of  $K^+$ . Because the membrane is only weakly permeable to chloride and other anions, this outflow of  $K^+$  results in a net negative charge inside the cell.

The sodium-potassium pump transports three  $Na^+$  out of the cell for every two  $K^+$  that it transports in. Although this pumping generates a net export of positive charge, the resulting voltage difference is only a few millivolts. Why, then, is there a voltage difference of 60 to 80 mV in a resting neuron? The answer lies in ion movement through **ion channels**, pores formed by clusters of specialized proteins that span the membrane. Ion channels allow ions to diffuse back and forth across the membrane. As ions diffuse through channels, they carry with them units of electrical charge. Any resulting *net* movement of positive or negative charge will generate a membrane potential, or voltage across the membrane.

The concentration gradients of  $K^+$  and  $Na^+$  across the plasma membrane represent a chemical form of potential energy. The ion channels that convert this chemical potential energy to electrical potential energy can do so because they have *selective permeability*—they allow only certain ions to pass.

For example, a potassium channel allows  $K^+$  to diffuse freely across the membrane, but not other ions, such as  $Na^+$ .

Diffusion of  $K^+$  through potassium channels that are always open (sometimes called leak channels) is critical for establishing the resting potential. The  $K^+$  concentration is 140 mM inside the cell, but only 5 mM outside. The chemical concentration gradient thus favors a net outflow of  $K^+$ . Furthermore, a resting neuron has many open potassium channels, but very few open sodium channels (see Figure 37.6). Because  $Na^+$  and other ions can't readily cross the membrane,  $K^+$  outflow leads to a net negative charge inside the cell. This buildup of negative charge within the neuron is the major source of the membrane potential.

What stops the buildup of negative charge? The excess negative charges inside the cell exert an attractive force that opposes the flow of additional positively charged potassium ions out of the cell. The separation of charge (voltage) thus results in an electrical gradient that counterbalances the chemical concentration gradient of  $K^+$ .

## Modeling the Resting Potential

The net flow of  $K^+$  out of a neuron proceeds until the chemical and electrical forces are in balance. How well do these two forces account for the resting potential in a mammalian neuron? Consider a simple model consisting of two chambers separated by an artificial membrane (Figure 37.7a). To begin, imagine that the membrane contains many open ion channels, all of which allow only  $K^+$  to diffuse across. To produce a  $K^+$  concentration gradient like that of a mammalian neuron, we place a solution of 140 mM potassium chloride (KCl) in the inner chamber and 5 mM KCl in the outer chamber. The  $K^+$  will diffuse down its concentration gradient into the outer chamber. But because the chloride ions ( $Cl^-$ ) lack a means of cross-

ing the membrane, there will be an excess of negative charge in the inner chamber.

When our model neuron reaches equilibrium, the electrical gradient will exactly balance the chemical gradient, so that no further net diffusion of  $K^+$  occurs across the membrane. The magnitude of the membrane voltage at equilibrium for a particular ion is called that ion's **equilibrium potential** ( $E_{ion}$ ). For a membrane permeable to a single type of ion,  $E_{ion}$  can be calculated using a formula called the Nernst equation. At human body temperature (37°C) and for an ion with a net charge of 1+, such as  $K^+$  or  $Na^+$ , the Nernst equation is

$$E_{ion} = 62 \text{ mV} \left( \log \frac{[ion]_{outside}}{[ion]_{inside}} \right)$$

Plugging in the  $K^+$  concentrations reveals that the equilibrium potential for  $K^+$  ( $E_K$ ) is  $-90 \text{ mV}$  (see Figure 37.7a). The minus sign indicates that  $K^+$  is at equilibrium when the inside of the membrane is 90 mV more negative than the outside.

Whereas the equilibrium potential for  $K^+$  is  $-90 \text{ mV}$ , the resting potential of a mammalian neuron is somewhat less negative. This difference reflects the small but steady movement of  $Na^+$  across the few open sodium channels in a resting neuron. The concentration gradient of  $Na^+$  has a direction opposite to that of  $K^+$  (see Table 37.1).  $Na^+$  therefore diffuses into the cell, making the inside of the cell less negative. If we model a membrane in which the only open channels are selectively permeable to  $Na^+$ , we find that a tenfold higher concentration of  $Na^+$  in the outer chamber results in an equilibrium potential ( $E_{Na}$ ) of  $+62 \text{ mV}$  (Figure 37.7b). In an actual neuron, the resting potential ( $-60$  to  $-80 \text{ mV}$ ) is much closer to  $E_K$  than to  $E_{Na}$  because there are many open potassium channels but only a small number of open sodium channels.

**► Figure 37.7 Modeling a mammalian neuron.** Each container is divided into two chambers by an artificial membrane. Ion channels allow free diffusion for particular ions, resulting in the net ion flow represented by arrows.

- (a) The presence of open potassium channels makes the membrane selectively permeable to  $K^+$ , and the inner chamber contains a 28-fold higher concentration of  $K^+$  than the outer chamber; at equilibrium, the inside of the membrane is  $-90 \text{ mV}$  relative to the outside.
- (b) The membrane is selectively permeable to  $Na^+$ , and the inner chamber contains a tenfold lower concentration of  $Na^+$  than the outer chamber; at equilibrium, the inside of the membrane is  $+62 \text{ mV}$  relative to the outside.

**WHAT IF?** Consider the effect of adding potassium or chloride channels to the membrane in (b) in place of sodium channels. How would the membrane potential be affected in each case?

**(a) Membrane selectively permeable to  $K^+$**

Nernst equation for  $K^+$  equilibrium potential at 37°C:

$$E_K = 62 \text{ mV} \left( \log \frac{5 \text{ mM}}{140 \text{ mM}} \right) = -90 \text{ mV}$$

**(b) Membrane selectively permeable to  $Na^+$**

Nernst equation for  $Na^+$  equilibrium potential at 37°C:

$$E_{Na} = 62 \text{ mV} \left( \log \frac{150 \text{ mM}}{15 \text{ mM}} \right) = +62 \text{ mV}$$

Because neither  $K^+$  nor  $Na^+$  is at equilibrium in a resting neuron, there is a net flow of each ion (a current) across the membrane. The resting potential remains steady, which means that the  $K^+$  and  $Na^+$  currents are equal and opposite. Ion concentrations on either side of the membrane also remain steady. Why? The resting potential arises from the net movement of far fewer ions than would be required to alter the concentration gradients.

Under conditions that allow  $Na^+$  to cross the membrane more readily, the membrane potential will move toward  $E_{Na}$  and away from  $E_K$ . As you'll see in the next section, this is precisely what happens during the generation of a nerve impulse.

### CONCEPT CHECK 37.2

1. Under what circumstances could ions flow through an ion channel from a region of lower concentration to a region of higher ion concentration?
2. **WHAT IF?** Suppose a cell's membrane potential shifts from  $-70$  mV to  $-50$  mV. What changes in the cell's permeability to  $K^+$  or  $Na^+$  could cause such a shift?
3. **MAKE CONNECTIONS** Figure 5.9 illustrates diffusion by dye molecules. Could diffusion eliminate the concentration gradient of a dye that has a net charge? Explain.

For suggested answers, see Appendix A.

**▲ Figure 37.9 Voltage-gated ion channel.** A change in the membrane potential in one direction (indicated by the right-pointing arrow) opens the channel. The opposite change (left-pointing arrow) closes the channel.

researchers can record these changes as a function of time. Changes in the membrane potential occur because neurons contain **gated ion channels**, ion channels that open or close in response to stimuli. The opening or closing of gated ion channels alters the membrane's permeability to particular ions (**Figure 37.9**), which in turn alters the membrane potential.

## Hyperpolarization and Depolarization

To explore how the membrane potential changes, let's consider what happens when gated potassium channels that are closed in a resting neuron are stimulated to open. Opening these potassium channels increases the membrane's permeability to  $K^+$ . Net diffusion of  $K^+$  out of the neuron increases, shifting the membrane potential toward  $E_K$  ( $-90$  mV at  $37^\circ\text{C}$ ). This increase in the magnitude of the membrane potential, called a **hyperpolarization**, makes the inside of the membrane more negative (**Figure 37.10a**). In a resting neuron, hyperpolarization results from any stimulus that increases the outflow of positive ions or the inflow of negative ions.

Although opening potassium channels in a resting neuron causes hyperpolarization, opening some other types of ion channels has an opposite effect, making the inside of the membrane less negative (**Figure 37.10b**). A reduction in the magnitude of the membrane potential is called a **depolarization**. Depolarization in neurons often involves gated sodium channels. If a stimulus causes the gated sodium channels in a resting neuron to open, the membrane's permeability to  $Na^+$  increases.  $Na^+$  diffuses into the cell along its concentration gradient, causing a depolarization as the membrane potential shifts toward  $E_{Na}$  ( $+62$  mV at  $37^\circ\text{C}$ ).

## Graded Potentials and Action Potentials

Sometimes, the response to hyperpolarization or depolarization is simply a shift in the membrane potential. This shift, called a **graded potential**, has a magnitude that varies with

## CONCEPT 37.3

### Action potentials are the signals conducted by axons

When a neuron responds to a stimulus, the membrane potential changes. Using intracellular recording (**Figure 37.8**),

#### ▼ Figure 37.8 Research Method

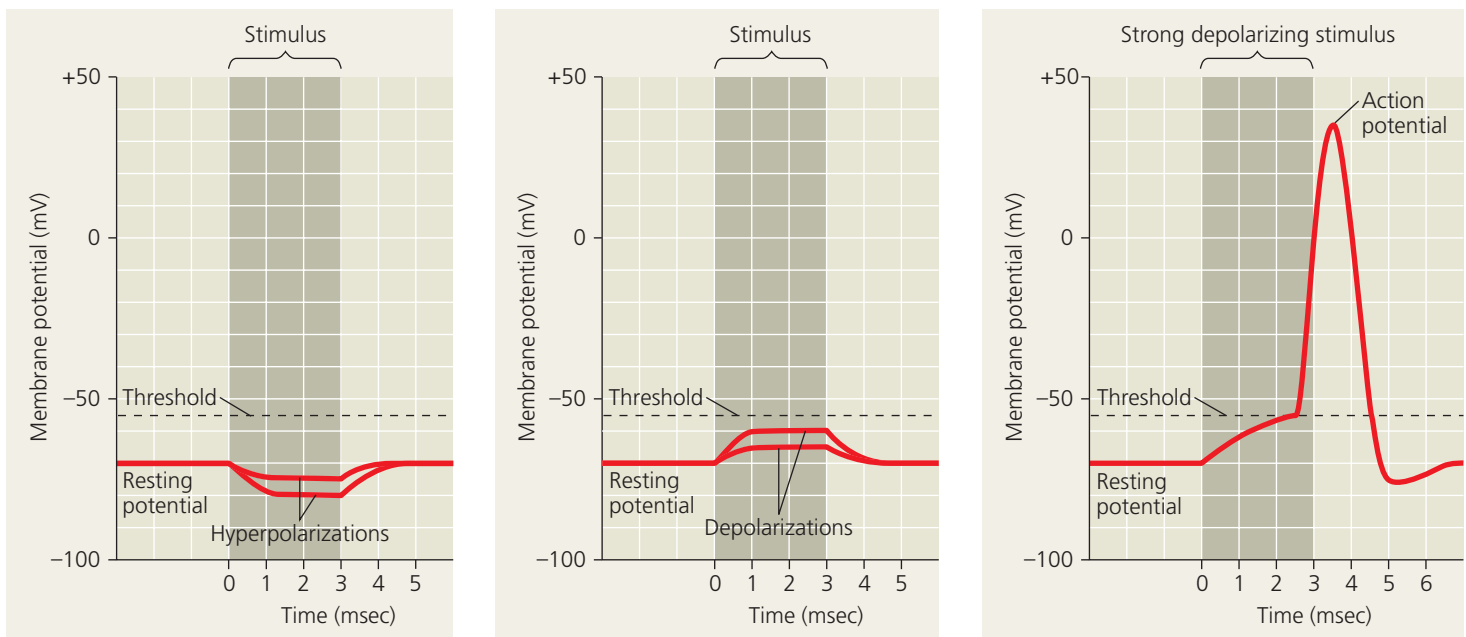

##### Intracellular Recording

**Application** Electrophysiologists use intracellular recording to measure the membrane potential of neurons and other cells.

**Technique** A microelectrode is made from a glass capillary tube filled with an electrically conductive salt solution. One end of the tube tapers to an extremely fine tip (diameter  $< 1 \mu\text{m}$ ). While looking through a microscope, the experimenter uses a micropositioner to insert the tip of the microelectrode into a cell. A voltage recorder (usually an oscilloscope or a computer-based system) measures the voltage between the microelectrode tip inside the cell and a reference electrode placed in the solution outside the cell.

**(a) Graded hyperpolarizations produced by two stimuli that increase membrane permeability to  $K^+$ .** The larger stimulus produces a larger hyperpolarization.

**(b) Graded depolarizations produced by two stimuli that increase membrane permeability to  $Na^+$ .** The larger stimulus produces a larger depolarization.

**(c) Action potential triggered by a depolarization that reaches the threshold.**

**▲ Figure 37.10 Graded potentials and an action potential in a neuron.**

**DRAW IT** Redraw the graph in part (c), extending the y-axis. Then label the positions of  $E_K$  and  $E_{Na}$ .

the strength of the stimulus: A larger stimulus causes a greater change in the membrane potential. Graded potentials induce a small electrical current that leaks out of the neuron as it flows along the membrane. Graded potentials thus decay with distance from their source.

If a depolarization shifts the membrane potential sufficiently, the result is a massive change in membrane voltage called an **action potential**. Unlike graded potentials, action potentials have a constant magnitude and can regenerate in adjacent regions of the membrane. Action potentials can therefore spread along axons, making them well suited for transmitting a signal over long distances.

Action potentials arise because some of the ion channels in neurons are **voltage-gated ion channels**, opening or closing when the membrane potential passes a particular level (see Figure 37.9). If a depolarization opens voltage-gated sodium channels, the resulting flow of  $Na^+$  into the neuron results in further depolarization. Because the sodium channels are voltage gated, the increased depolarization causes more sodium channels to open, leading to an even greater flow of current. The result is a process of positive feedback that triggers a very rapid opening of many voltage-gated sodium channels and the marked temporary change in membrane potential that defines an action potential (**Figure 37.10c**).

Action potentials occur whenever a depolarization increases the membrane voltage to a particular value, called the **threshold**. For many mammalian neurons, the threshold is

a membrane potential of about  $-55$  mV. Once initiated, the action potential has a magnitude that is independent of the strength of the triggering stimulus. Because action potentials either occur fully or do not occur at all, they represent an *all-or-none* response to stimuli. This all-or-none property reflects the fact that depolarization opens voltage-gated sodium channels, and the opening of sodium channels causes further depolarization. The positive-feedback loop of depolarization and channel opening triggers an action potential whenever the membrane potential reaches threshold.

## Generation of Action Potentials: A Closer Look

The characteristic shape of the graph of an action potential (see Figure 37.10c) reflects the large change in membrane potential resulting from ion movement through voltage-gated sodium and potassium channels. Membrane depolarization opens both types of channels, but they respond independently and sequentially. Sodium channels open first, initiating the action potential. As the action potential proceeds, the sodium channels become inactivated: A loop of the channel protein moves, blocking ion flow through the opening. Sodium channels remain inactivated until after the membrane returns to the resting potential and the channels close. In contrast, potassium channels open more slowly than sodium channels, but remain open and functional until the end of the action potential.

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on How Neurons Work.

To understand further how voltage-gated channels shape the action potential, consider the process as a series of stages, as depicted in **Figure 37.11**. **1** When the membrane of the axon is at the resting potential, most voltage-gated sodium channels are closed. Some potassium channels are open, but most voltage-gated potassium channels are closed. **2** When a stimulus depolarizes the membrane, some gated sodium channels open, allowing more  $\text{Na}^+$  to diffuse into the cell. The  $\text{Na}^+$  inflow causes further depolarization, which opens still more gated sodium channels, allowing even more  $\text{Na}^+$  to diffuse into the cell. **3** Once the threshold is crossed, the positive-feedback cycle rapidly brings the membrane potential close to

$E_{\text{Na}}$ . This stage of the action potential is called the *rising phase*.

**4** Two events prevent the membrane potential from actually reaching  $E_{\text{Na}}$ : Voltage-gated sodium channels inactivate soon after opening, halting  $\text{Na}^+$  inflow; and most voltage-gated potassium channels open, causing a rapid outflow of  $\text{K}^+$ . Both events quickly bring the membrane potential back toward  $E_{\text{K}}$ . This stage is called the *falling phase*. **5** In the final phase of an action potential, called the *undershoot*, the membrane's permeability to  $\text{K}^+$  is higher than at rest, so the membrane potential is closer to  $E_{\text{K}}$  than it is at the resting potential. The gated potassium channels eventually close, and the membrane potential returns to the resting potential.

The sodium channels remain inactivated during the falling phase and the early part of the undershoot. As a result, if a second depolarizing stimulus occurs during this period, it will be unable to trigger an action potential. The “downtime” when a second action potential cannot be initiated is called the **refractory period**. One consequence of the refractory period is to limit the maximum frequency at which action potentials can be generated. As we will discuss shortly, the refractory period also ensures that all signals in an axon travel in one direction, from the cell body to the axon terminals.

Note that the refractory period is due to the inactivation of sodium channels, not to a change in the ion gradients across the plasma membrane. The flow of charged particles during an action potential involves far too few ions to change the concentration on either side of the membrane significantly.

For most neurons, the interval between the onset of an action potential and the end of the refractory period is only 1–2 milliseconds (msec). Because action potentials are so brief, a neuron can produce them as rapidly as several hundred per second. Furthermore, the rate at which action potentials are produced conveys information about the strength of the input signal. In hearing, for example, louder sounds result in more frequent action potentials in neurons connecting the ear to the brain. Differences in the number of action potentials in a given time are in fact the only variable in how information is encoded and transmitted along an axon.

Gated ion channels and action potentials have a central role in nervous system activity. As a consequence, mutations in genes that encode ion channel proteins can cause disorders affecting the nerves or brain—or the muscles or heart, depending largely on where in the body the gene for the ion channel protein is expressed. For example, mutations affecting sodium channels in skeletal muscle can cause periodic muscle spasms, or myotonia. Mutations affecting sodium channels in the brain can cause epilepsy, in which groups of nerve cells fire simultaneously and excessively, producing seizures.

## Conduction of Action Potentials

Now that we’ve described the events that occur in a single action potential, we’ll look at how a series of action potentials moves a signal along an axon. At the site where an action potential is initiated (usually the axon hillock),  $\text{Na}^+$  inflow during the rising phase creates an electrical current that depolarizes the neighboring region of the axon membrane (**Figure 37.12**). The depolarization is large enough to reach threshold, causing an action potential in the neighboring region. This process is repeated many times along the length of the axon. Because an action potential is an all-or-none event, the magnitude and duration of the action potential are the same at each position along the axon. The net result is the movement of a nerve impulse from the cell body to the synaptic terminals, much like the cascade of events triggered by knocking over the first domino in a line.

An action potential that starts at the axon hillock moves along the axon only toward the synaptic terminals. Why? Immediately behind the traveling zone of depolarization caused by  $\text{Na}^+$  inflow is a zone of repolarization caused by  $\text{K}^+$  outflow. In the repolarized zone, the sodium channels remain inactivated. Consequently, the inward current that depolarizes the axon membrane *ahead* of the action potential cannot produce another action potential *behind* it. This prevents action potentials from traveling back toward the cell body.

▲ **Figure 37.12 Conduction of an action potential.** This figure shows events at three successive times as an action potential passes from left to right. At each point along the axon, voltage-gated ion channels go through the sequence of changes depicted in Figure 37.11. Membrane colors correspond to the action potential phases in Figure 37.11.

▲ **Figure 37.13 Schwann cells and the myelin sheath.** In the PNS, glia called Schwann cells wrap themselves around axons, forming layers of myelin. Gaps between adjacent Schwann cells are called nodes of Ranvier. The TEM shows a cross section through a myelinated axon.

## Evolutionary Adaptations of Axon Structure

**EVOLUTION** The rate at which the axons within nerves conduct action potentials governs how rapidly an animal can react to danger or opportunity. As a consequence, natural selection often results in anatomical adaptations that increase conduction speed. One such adaptation is a wider axon. Axon width matters because resistance to electrical current flow is inversely proportional to the cross-sectional area of a conductor (such as a wire or an axon). In the same way that a wide hose offers less resistance to the flow of water than does a narrow hose, a wide axon provides less resistance to the current associated with an action potential than does a narrow axon.

In invertebrates, conduction speed varies from several centimeters per second in very narrow axons to approximately 30 m/sec in the giant axons of some arthropods and molluscs. These giant axons (up to 1 mm wide) function in rapid behavioral responses, such as the muscle contraction that propels a hunting squid toward its prey.

Vertebrate axons have narrow diameters but can still conduct action potentials at high speed. How is this possible? The evolutionary adaptation that enables fast conduction in vertebrate axons is electrical insulation, analogous to the plastic insulation that encases many electrical wires. Insulation causes the depolarizing current associated with an action potential to spread farther along the axon interior, bringing more distant regions to the threshold sooner.

The electrical insulation that surrounds vertebrate axons is called a **myelin sheath** (Figure 37.13). Myelin sheaths are produced by two types of glia—**oligodendrocytes** in the CNS

and **Schwann cells** in the PNS. During development, these specialized glia wrap axons in many layers of membrane. The membranes forming these layers are mostly lipid, which is a poor conductor of electrical current.

In myelinated axons, voltage-gated sodium channels are restricted to gaps in the myelin sheath called **nodes of Ranvier** (see Figure 37.13). The extracellular fluid is in contact with the axon membrane only at the nodes. As a result, action potentials are not generated in the regions between the nodes. Rather, the inward current produced during the rising phase of the action potential at a node travels all the way to the next node, where it depolarizes the membrane and regenerates the action potential (Figure 37.14). Thus, the time-consuming process of opening and closing ion channels occurs at only a limited number of positions along the axon. This mechanism for propagating action potentials is called **saltatory conduction** (from the Latin *saltare*, to leap) because the action potential appears to jump along the axon from node to node.

The major selective advantage of myelination is its space efficiency. A myelinated axon 20 μm in diameter has a conduction speed faster than that of a squid giant axon with a diameter 40 times greater. Furthermore, more than 2,000 of those myelinated axons can be packed into the space occupied by just one giant axon.

For any axon, myelinated or not, the conduction of an action potential to the end of the axon sets the stage for the next step in neuronal signaling—the transfer of information to another cell. This information handoff occurs at synapses, the topic of the next section.

► **Figure 37.14 Saltatory conduction.** In a myelinated axon, the depolarizing current during an action potential at one node of Ranvier spreads along the interior of the axon to the next node (blue arrows), where voltage-gated sodium channels enable reinitiation. Thus, the action potential appears to jump from node to node as it travels along the axon (red arrows).

### CONCEPT CHECK 37.3

1. How do action potentials and graded potentials differ?
2. In multiple sclerosis (from the Greek *skleros*, hard), a person's myelin sheaths harden and deteriorate. How would this affect nervous system function?
3. **WHAT IF?** Suppose a mutation caused gated sodium channels to remain inactivated longer after an action potential. How would this affect the frequency at which action potentials could be generated? Explain.

For suggested answers, see Appendix A.

## CONCEPT 37.4

### Neurons communicate with other cells at synapses

In most cases, action potentials are not transmitted from neurons to other cells. However, information is transmitted, and this transmission occurs at the synapses. Some synapses, called electrical synapses, contain gap junctions (see Figure 4.27),

which *do* allow electrical current to flow directly from one neuron to another. In both vertebrates and invertebrates, electrical synapses synchronize the activity of neurons responsible for certain rapid, unvarying behaviors. For example, electrical synapses associated with the giant axons of squids and lobsters facilitate swift escapes from danger. There are also many electrical synapses in the vertebrate brain.

The majority of synapses are chemical synapses, which involve the release of a chemical neurotransmitter by the presynaptic neuron. At each terminal, the presynaptic neuron synthesizes the neurotransmitter and packages it in multiple membrane-enclosed compartments called *synaptic vesicles*. The arrival of an action potential at a synaptic terminal depolarizes the plasma membrane, opening voltage-gated channels that allow  $\text{Ca}^{2+}$  to diffuse into the terminal (**Figure 37.15**). The resulting rise in  $\text{Ca}^{2+}$  concentration in the terminal causes some of the synaptic vesicles to fuse with the terminal membrane, releasing the neurotransmitter.

Once released, the neurotransmitter diffuses across the *synaptic cleft*, the gap that separates the presynaptic neuron

**1** An action potential arrives, depolarizing the presynaptic membrane.

**2** The depolarization opens voltage-gated channels, triggering an influx of  $\text{Ca}^{2+}$ .

**3** The elevated  $\text{Ca}^{2+}$  concentration causes synaptic vesicles to fuse with the presynaptic membrane, releasing neurotransmitter into the synaptic cleft.

**4** The neurotransmitter binds to ligand-gated ion channels in the postsynaptic membrane. In this example, binding triggers opening, allowing  $\text{Na}^+$  and  $\text{K}^+$  to diffuse through.

**Figure 37.15 A chemical synapse.** This figure illustrates the sequence of events that transmits a signal across a chemical synapse. In response to binding of neurotransmitter, ligand-gated ion channels in the postsynaptic membrane open (as shown here) or, less commonly, close. Synaptic transmission ends when the neurotransmitter diffuses out of the synaptic cleft, is taken up by the synaptic terminal or by another cell, or is degraded by an enzyme.

**WHAT IF?** If all the  $\text{Ca}^{2+}$  in the fluid surrounding a neuron were removed, how would this affect the transmission of information within and between neurons?

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on How Synapses Work.

from the postsynaptic cell. Diffusion time is very short because the gap is less than 50 nm across. Upon reaching the postsynaptic membrane, the neurotransmitter binds to and activates a specific receptor in the membrane, which in turn triggers a response in the postsynaptic cell.

Information transfer is much more readily modified at chemical synapses than at electrical synapses. A variety of factors can affect the amount of neurotransmitter that is released or the responsiveness of the postsynaptic cell. Such modifications underlie an animal's ability to alter its behavior in response to change and form the basis for learning and memory (as we will discuss in Chapter 38).

## Generation of Postsynaptic Potentials

At many chemical synapses, the receptor protein that binds and responds to neurotransmitters is a **ligand-gated ion channel**, often called an *ionotropic receptor*. These receptors are clustered in the membrane of the postsynaptic cell, directly opposite the synaptic terminal. Binding of the neurotransmitter (the receptor's ligand) to a particular part of the receptor opens the channel and allows specific ions to diffuse across the postsynaptic membrane. The result is a *postsynaptic potential*, a graded potential in the postsynaptic cell.

At some synapses, the ligand-gated ion channel is permeable to both  $K^+$  and  $Na^+$  (see Figure 37.15). When this channel opens, the membrane potential depolarizes toward a value roughly midway between  $E_K$  and  $E_{Na}$ . Because such a depolarization brings the membrane potential toward threshold, it is called an **excitatory postsynaptic potential (EPSP)**.

At other synapses, the ligand-gated ion channel is selectively permeable for only  $K^+$  or  $Cl^-$ . When such a channel opens, the postsynaptic membrane hyperpolarizes. A hyperpolarization produced in this manner is an **inhibitory postsynaptic potential (IPSP)** because it moves the membrane potential further from threshold.

Various mechanisms limit the duration of postsynaptic potentials by rapidly clearing neurotransmitter molecules from the synaptic cleft. Some neurotransmitters are recaptured into presynaptic neurons, to be repackaged into synaptic vesicles, or into glia, to be metabolized as fuel or recycled to neurons. Other neurotransmitters are removed from the synaptic cleft by simple diffusion or by an enzyme that catalyzes hydrolysis of the neurotransmitter.

## Summation of Postsynaptic Potentials

The cell body and dendrites of one postsynaptic neuron may receive inputs from chemical synapses formed with hundreds or even thousands of synaptic terminals (Figure 37.16). The magnitude of the postsynaptic potential at any one synapse varies with a number of factors, including the amount of neurotransmitter released by the presynaptic neuron. As a graded potential, a postsynaptic potential becomes smaller with distance from the synapse. Therefore, by the time a single EPSP

▲ **Figure 37.16** Synaptic terminals on the cell body of a postsynaptic neuron (colorized SEM).

reaches the axon hillock, it is usually too small to trigger an action potential in a postsynaptic neuron (Figure 37.17a).

On some occasions, two EPSPs occur at a single synapse in such rapid succession that the postsynaptic neuron's membrane potential has not returned to the resting potential before the arrival of the second EPSP. When that happens, the EPSPs add together, an effect called **temporal summation** (Figure 37.17b). Moreover, EPSPs produced nearly simultaneously by *different* synapses on the same postsynaptic neuron can also add together, an effect called **spatial summation** (Figure 37.17c). Through spatial and temporal summation, several EPSPs can combine to depolarize the membrane at the axon hillock to threshold, causing the postsynaptic neuron to produce an action potential. Summation applies as well to IPSPs: Two or more IPSPs occurring nearly simultaneously at synapses in the same region or in rapid succession at the same synapse have a larger hyperpolarizing effect than a single IPSP. Through summation, an IPSP can also counter the effect of an EPSP (Figure 37.17d).

The interplay between multiple excitatory and inhibitory inputs is the essence of integration in the nervous system. The axon hillock is the neuron's integrating center, the region where the membrane potential at any instant represents the summed effect of all EPSPs and IPSPs. Whenever the membrane potential at the axon hillock reaches threshold, an action potential is generated and travels along the axon to its synaptic terminals. After the refractory period, the neuron may produce another action potential, provided the membrane potential at the axon hillock once again reaches threshold.

## Modulated Signaling at Synapses

So far, we have focused on synapses where a neurotransmitter binds directly to an ion channel, causing the channel to open. However, there are also synapses in which the receptor for the neurotransmitter is *not* part of an ion channel. At these synapses, the neurotransmitter binds to a *metabotropic receptor*, so called because the resulting opening or closing of ion channels depends on one or more metabolic steps. Binding of a neurotransmitter

**▲ Figure 37.17 Summation of postsynaptic potentials.** These graphs trace changes in the membrane potential at a postsynaptic neuron's axon hillock. The arrows indicate times when postsynaptic potentials occur at two excitatory synapses ( $E_1$  and  $E_2$ , green in the diagrams above the graphs) and at one inhibitory synapse ( $I$ , red). Like most EPSPs, those produced at  $E_1$  or  $E_2$  do not reach the threshold at the axon hillock without summation.

to a metabotropic receptor activates a signal transduction pathway in the postsynaptic cell involving a second messenger (see Chapter 5). Compared with the postsynaptic potentials produced by ligand-gated channels, the effects of these second-messenger systems have a slower onset but last longer (minutes or even hours). Second messengers modulate the responsiveness of postsynaptic neurons to inputs in diverse ways, such as by altering the number of open potassium channels.

A variety of signal transduction pathways play a role in modulating synaptic transmission. One of the best-studied pathways involves cyclic AMP (cAMP) as a second messenger. For example, when the neurotransmitter norepinephrine binds to its metabotropic receptor, the neurotransmitter-receptor complex activates a G protein, which in turn activates adenylyl cyclase, the enzyme that converts ATP to cAMP (see Figure 5.25). Cyclic AMP activates protein kinase A, which phosphorylates specific ion channel proteins in the postsynaptic membrane, causing them to open or close. Because of the amplifying effect of the signal transduction pathway, the binding of a neurotransmitter molecule to a metabotropic receptor can open or close many channels.

## Neurotransmitters

Signaling at a synapse brings about a response that depends on both the neurotransmitter released from the presynaptic membrane and the receptor produced at the postsynaptic membrane. A single neurotransmitter may bind specifically to more than a dozen different receptors, including ionotropic and metabotropic types. Indeed, a particular neurotransmitter can excite postsynaptic cells expressing one receptor and

inhibit postsynaptic cells expressing a different receptor. As an example, let's examine **acetylcholine**, a common neurotransmitter in both invertebrates and vertebrates.

### Acetylcholine

Acetylcholine is vital for nervous system functions that include muscle stimulation, memory formation, and learning. In vertebrates, there are two major classes of acetylcholine receptor. One type is a ligand-gated ion channel. We know the most about its function at the vertebrate *neuromuscular junction*, the site where a motor neuron forms a synapse with a skeletal muscle cell. When acetylcholine released by motor neurons binds this receptor, the ion channel opens, producing an EPSP. This excitatory activity is soon terminated by acetylcholinesterase, an enzyme in the synaptic cleft that hydrolyzes the neurotransmitter into an inactive form.

The acetylcholine receptor active at the neuromuscular junction is also found elsewhere in the PNS, as well as in the CNS. There this ionotropic receptor can bind nicotine, a chemical found in tobacco and tobacco smoke. Nicotine's effects as a physiological and psychological stimulant result from its binding to this receptor.

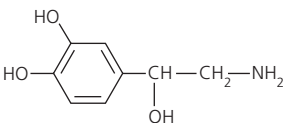

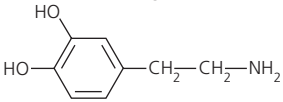

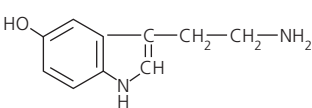

A metabotropic acetylcholine receptor is found at locations that include the vertebrate CNS and heart. In heart muscle, acetylcholine released by neurons activates a signal transduction pathway. The G proteins in the pathway inhibit adenylyl cyclase and open potassium channels in the muscle cell membrane. Both effects reduce the rate at which the heart pumps. Thus, the effect of acetylcholine in heart muscle is inhibitory rather than excitatory.

A number of toxins disrupt neurotransmission by acetylcholine. For example, the nerve gas sarin inhibits acetylcholinesterase, causing a buildup of acetylcholine to levels that trigger paralysis and typically death. In contrast, certain bacteria produce a toxin that inhibits presynaptic release of acetylcholine. This toxin causes a rare but often fatal form of food poisoning called botulism. Today, injections of the botulinum toxin, known by the trade name Botox, are used cosmetically to minimize wrinkles around the eyes or mouth by blocking transmission at synapses that control particular facial muscles.

Although acetylcholine has many roles, it is just one of more than 100 known neurotransmitters. As shown by the examples in [Table 37.2](#), the rest fall into four classes: amino acids, biogenic amines, neuropeptides, and gases.

### Amino Acids

**Glutamate** is one of several amino acids that can act as a neurotransmitter. In invertebrates, glutamate, rather than acetylcholine, is the neurotransmitter at the neuromuscular junction. In vertebrates, glutamate is the most common neurotransmitter in the CNS. Synapses at which glutamate is the neurotransmitter have a key role in the formation of long-term memory (as we'll discuss in Chapter 38).

Table 37.2 Major Neurotransmitters	
Neurotransmitter	Structure
Acetylcholine	$\text{H}_3\text{C}-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}^+(\text{CH}_3)_2$
Amino Acids	
Glutamate	$\begin{array}{c} \text{H}_2\text{N}-\text{CH}-\text{CH}_2-\text{CH}_2-\text{COOH} \\   \\ \text{COOH} \end{array}$
GABA (gamma-aminobutyric acid)	$\text{H}_2\text{N}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{COOH}$
Glycine	$\text{H}_2\text{N}-\text{CH}_2-\text{COOH}$
Biogenic Amines	
Norepinephrine	
Dopamine	
Serotonin	
Neuropeptides (a very diverse group, only two of which are shown)	
Substance P	Arg—Pro—Lys—Pro—Gln—Gln—Phe—Phe—Gly—Leu—Met
Met-enkephalin (an endorphin)	Tyr—Gly—Gly—Phe—Met
Gases	
Nitric oxide	N=O

The amino acid **gamma-aminobutyric acid (GABA)** is the neurotransmitter at most inhibitory synapses in the brain. Binding of GABA to receptors in postsynaptic cells increases membrane permeability to Cl<sup>−</sup>, resulting in an IPSP. The widely prescribed drug diazepam (Valium) reduces anxiety through binding to a site on a GABA receptor.

A third amino acid, glycine, acts at inhibitory synapses in parts of the CNS that lie outside of the brain. There, glycine binds to an ionotropic receptor that is inhibited by strychnine, a chemical often used as a rat poison.

### Biogenic Amines

The neurotransmitters grouped as **biogenic amines** are synthesized from amino acids and include **norepinephrine**, which is made from tyrosine. Norepinephrine is an excitatory neurotransmitter in the autonomic nervous system, a branch of the PNS. Outside the nervous system, norepinephrine has distinct but related functions as a hormone, as does the chemically similar biogenic amine *epinephrine* (see Chapter 32).

The biogenic amines **dopamine**, made from tyrosine, and **serotonin**, made from tryptophan, are released at many sites in the brain and affect sleep, mood, attention, and learning. Some psychoactive drugs, including LSD and mescaline, apparently produce their hallucinatory effects by binding to brain receptors for these neurotransmitters.

Biogenic amines have a central role in a number of nervous system disorders and treatments (see Chapter 38). The degenerative illness Parkinson's disease is associated with a lack of dopamine in the brain. In addition, depression is often treated with drugs that increase the brain concentrations of biogenic amines. Prozac, for instance, enhances the effect of serotonin by inhibiting its reuptake after release.

### Neuropeptides

Several **neuropeptides**, relatively short chains of amino acids, serve as neurotransmitters that operate via metabotropic receptors. Such peptides are typically produced by cleavage of much larger protein precursors. The neuropeptide *substance P* is a key excitatory neurotransmitter that mediates our perception of pain. Other neuropeptides, called **endorphins**, function as natural analgesics, decreasing pain perception.

Endorphins are produced in the brain during times of physical or emotional stress, such as childbirth. In addition to relieving pain, they reduce urine output, decrease respiration, and produce euphoria, as well as other emotional effects. Opiates (drugs such as morphine and heroin) mimic endorphins and produce many of the same physiological effects (see Figure 2.14). In the [Scientific Skills Exercise](#), you can interpret data from an experiment designed to search for opiate receptors in the brain.

### Gases

In common with many other types of cells, some vertebrate neurons release dissolved gases, notably nitric oxide (NO), that act as local regulators (see Concept 5.6). In human males, for example, certain neurons release NO into the erectile tissue

## Interpreting Data Values Expressed in Scientific Notation

### Does the Brain Have Specific Protein Receptors for Opiates?

A team of researchers were looking for opiate receptors in the mammalian brain. Knowing that the drug naloxone blocks the analgesic effect of opiates, they hypothesized that naloxone acts by binding tightly to brain opiate receptors without activating them. In this exercise, you will interpret the results of an experiment that the researchers conducted to test their hypothesis.

**How the Experiment Was Done** The researchers added radioactive naloxone to a protein mixture prepared from rodent brains. If the mixture contained opiate receptors or other proteins that could bind naloxone, the radioactivity would stably associate with the mixture. To determine whether the binding was due to specific opiate receptors, they tested other drugs, opiate and non-opiate, for their ability to block naloxone binding.

### Data from the Experiment

Drug	Opiate	Lowest Concentration That Blocked Naloxone Binding
Morphine	Yes	$6 \times 10^{-9} M$
Methadone	Yes	$2 \times 10^{-8} M$
Levorphanol	Yes	$2 \times 10^{-9} M$
Phenobarbital	No	No effect at $10^{-4} M$
Atropine	No	No effect at $10^{-4} M$
Serotonin	No	No effect at $10^{-4} M$

©1973 AAAS

### Interpret the Data

- The data from this experiment are expressed using scientific notation: a numerical factor times a power of 10. Remember that a negative power of 10 means a number less than 1. For example, the concentration  $10^{-1} M$  (molar) can also be written as  $0.1 M$ . Write the concentrations in the table above for morphine and atropine in this alternative format.
- Compare the concentrations listed in the table for methadone and phenobarbital. Which concentration is higher? By how much?
- Would phenobarbital, atropine, or serotonin have blocked naloxone binding at a concentration of  $10^{-5} M$ ? Explain why or why not.
- Which drugs blocked naloxone binding in this experiment? What do these results indicate about the brain receptors for naloxone?
- When the researchers repeated the experiment using tissue from mammalian intestinal muscles rather than brains, they found no naloxone binding. What does that suggest about opiate receptors in mammalian muscle tissue?

**Data from** C. B. Pert and S. H. Snyder, Opiate receptor: Demonstration in nervous tissue, *Science*, 179:1011–1014 (1973).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

of the penis during sexual arousal. The resulting relaxation of smooth muscle in the blood vessel walls allows the spongy erectile tissue to fill with blood, producing an erection. The erectile dysfunction drug Viagra works by inhibiting an enzyme that terminates the action of NO.

Unlike most neurotransmitters, NO is not stored in cytoplasmic vesicles but is instead synthesized on demand. NO diffuses into neighboring target cells, produces a change, and is broken down—all within a few seconds. In many of its targets, including smooth muscle cells, NO works like many hormones, stimulating an enzyme to synthesize a second messenger that directly affects cellular metabolism.

Although inhaling air containing the gas carbon monoxide (CO) can be deadly, the vertebrate body produces small amounts of CO, some of which acts as a neurotransmitter. Carbon monoxide is generated by the enzyme heme oxygenase, one form of which is found in certain populations of neurons in the brain and PNS. In the brain, CO regulates the

release of hypothalamic hormones. In the PNS, it acts as an inhibitory neurotransmitter that hyperpolarizes the plasma membrane of intestinal smooth muscle cells.

In the next chapter, we'll consider how the cellular and biochemical mechanisms we have discussed contribute to nervous system function on the system level.

### CONCEPT CHECK 37.4

- How is it possible for a particular neurotransmitter to produce opposite effects in different tissues?
- Organophosphate pesticides work by inhibiting acetylcholinesterase, the enzyme that breaks down the neurotransmitter acetylcholine. Explain how these toxins would affect EPSPs produced by acetylcholine.
- MAKE CONNECTIONS** Name one or more membrane activities that are common to fertilization and neurotransmitter release (see Figure 36.14).

For suggested answers, see Appendix A.

# 37 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 37.1

#### Neuron structure and organization reflect function in information transfer (pp. 752–753)

- Most neurons have branched **dendrites** that receive signals from other neurons and an **axon** that transmits signals to other cells at **synapses**. Neurons rely on **glia** for functions that include nourishment, insulation, and regulation.

- A **central nervous system (CNS)** and a **peripheral nervous system (PNS)** process information in three stages: sensory input, integration, and motor output to effector cells.

? How would severing an axon affect the flow of information in a neuron?

### CONCEPT 37.2

#### Ion pumps and ion channels establish the resting potential of a neuron (pp. 754–756)

- Ionic gradients generate a voltage difference, or **membrane potential**, across the plasma membrane of cells. The concentration of  $\text{Na}^+$  is higher outside than inside; the reverse is true for  $\text{K}^+$ . In resting neurons, the plasma membrane has many open potassium channels but few open sodium channels. Diffusion of ions, principally  $\text{K}^+$ , through channels generates a **resting potential**, with the inside more negative than the outside.

? Suppose you placed an isolated neuron in a solution similar to extracellular fluid and later transferred the neuron to a solution lacking any sodium ions. What change would you expect in the resting potential?

### CONCEPT 37.3

#### Action potentials are the signals conducted by axons (pp. 756–761)

- Neurons have gated ion channels that open or close in response to stimuli, leading to changes in the membrane potential. An increase in the magnitude of the membrane potential is a **hyperpolarization**; a decrease is a **depolarization**. Changes in membrane potential that vary continuously with the strength of a stimulus are known as **graded potentials**.
- An **action potential** is a brief, all-or-none depolarization of a neuron's plasma membrane. When a graded depolarization brings the membrane potential to **threshold**, many **voltage-gated ion channels** open, triggering an inflow of  $\text{Na}^+$  that

rapidly brings the membrane potential to a positive value. A negative membrane potential is restored by the inactivation of sodium channels and by the opening of many voltage-gated potassium channels, which increases  $\text{K}^+$  outflow. A **refractory period** follows, corresponding to the interval when the sodium channels remain inactivated.

- A nerve impulse travels from the axon hillock to the synaptic terminals by propagating a series of action potentials along the axon. The speed of conduction increases with the diameter of the axon and, in many vertebrate axons, with **myelination**. Action potentials in myelinated axons jump between the **nodes of Ranvier**, a process called **saltatory conduction**.

? In what ways do both positive and negative feedback contribute to the shape of an action potential?

### CONCEPT 37.4

#### Neurons communicate with other cells at synapses (pp. 761–765)

- In an electrical **synapse**, electrical current flows directly from one cell to another. In a chemical synapse, depolarization causes synaptic vesicles to fuse with the terminal membrane and release **neurotransmitter** into the synaptic cleft.
- At many synapses, the neurotransmitter binds to **ligand-gated ion channels** in the postsynaptic membrane, producing an **excitatory or inhibitory postsynaptic potential (EPSP or IPSP)**. The neurotransmitter then diffuses out of the cleft, is taken up by surrounding cells, or is degraded by enzymes. **Temporal** and **spatial summation** at the axon hillock determines whether a neuron generates an action potential.
- Different receptors for the same neurotransmitter produce different effects. Some neurotransmitter receptors activate signal transduction pathways, which can produce long-lasting changes in postsynaptic cells. Major neurotransmitters include **acetylcholine**; the amino acids **GABA**, **glutamate**, and glycine; **biogenic amines**; **neuropeptides**; and gases such as NO.

? Why are many drugs that are used to treat nervous system diseases or to affect brain function targeted to specific receptors rather than particular neurotransmitters?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- What happens when a resting neuron's membrane depolarizes?
  - There is a net diffusion of  $\text{Na}^+$  out of the cell.
  - The equilibrium potential for  $\text{K}^+$  ( $E_K$ ) becomes more positive.
  - The neuron's membrane voltage becomes more positive.
  - The neuron is less likely to generate an action potential.
  - The cell's inside is more negative than the outside.
- A common feature of action potentials is that they
  - cause the membrane to hyperpolarize and then depolarize.
  - can undergo temporal and spatial summation.
  - are triggered by a depolarization that reaches threshold.
  - move at the same speed along all axons.
  - require the diffusion of  $\text{Na}^+$  and  $\text{K}^+$  through ligand-gated channels to propagate.
- Where are neurotransmitter receptors located?
  - the nuclear membrane
  - the nodes of Ranvier
  - the postsynaptic membrane
  - synaptic vesicle membranes
  - the myelin sheath

### Level 2: Application/Analysis

- Why are action potentials usually conducted in one direction?
  - The nodes of Ranvier conduct potentials in one direction.
  - The brief refractory period prevents reopening of voltage-gated  $\text{Na}^+$  channels.
  - The axon hillock has a higher membrane potential than the terminals of the axon.
  - Ions can flow along the axon in only one direction.
  - Voltage-gated channels for both  $\text{Na}^+$  and  $\text{K}^+$  open in only one direction.
- Which of the following is a *direct* result of depolarizing the pre-synaptic membrane of an axon terminal?
  - Voltage-gated calcium channels in the membrane open.
  - Synaptic vesicles fuse with the membrane.
  - The postsynaptic cell produces an action potential.
  - Ligand-gated channels open, allowing neurotransmitters to enter the synaptic cleft.
  - An EPSP or IPSP is generated in the postsynaptic cell.
- Suppose a particular neurotransmitter causes an IPSP in postsynaptic cell X and an EPSP in postsynaptic cell Y. A likely explanation is that
  - the threshold value in the postsynaptic membrane is different for cell X and cell Y.
  - cell Y forms chemical synapses, whereas cell X forms electrical synapses.
  - the axon of cell X is myelinated, but that of cell Y is not.
  - only cell Y produces an enzyme that terminates the activity of the neurotransmitter.
  - cells X and Y express different receptor molecules for this particular neurotransmitter.

### Level 3: Synthesis/Evaluation

- WHAT IF?** Ouabain, a plant substance used in some cultures to poison hunting arrows, disables the sodium-potassium pump. What change in the resting potential would you expect to see if you treated a neuron with ouabain? Explain.
- WHAT IF?** If a drug mimicked the activity of GABA in the CNS, what general effect on behavior might you expect? Explain.
- DRAW IT** Suppose a researcher inserts a pair of electrodes at two different positions along the middle of an axon dissected out of a squid. By applying a depolarizing stimulus, the researcher brings the plasma membrane at both positions to threshold. Using the drawing below as a model, create one or more drawings that illustrate where each action potential would terminate.

### 10. SCIENTIFIC INQUIRY

From what you know about action potentials and synapses, propose two or three hypotheses for how various anesthetics might block pain.

### 11. FOCUS ON EVOLUTION

An action potential is an all-or-none event. This on/off signaling is an evolutionary adaptation of animals that must sense and act in a complex environment. It is possible to imagine a nervous system in which the action potentials are graded, with the amplitude depending on the size of the stimulus. What evolutionary advantage might on/off signaling have over a graded (continuously variable) kind of signaling?

### 12. FOCUS ON ORGANIZATION

In a short essay (100–150 words), describe how the structure and electrical properties of vertebrate neurons reflect similarities and differences with other animal cells.

For selected answers, see Appendix A.

# Nervous and Sensory Systems

▼ **Figure 38.1** Of what use is a star-shaped nose?

## KEY CONCEPTS

- 38.1** Nervous systems consist of circuits of neurons and supporting cells
- 38.2** The vertebrate brain is regionally specialized
- 38.3** The cerebral cortex controls voluntary movement and cognitive functions
- 38.4** Sensory receptors transduce stimulus energy and transmit signals to the central nervous system
- 38.5** The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles
- 38.6** The diverse visual receptors of animals depend on light-absorbing pigments

## OVERVIEW

### Sense and Sensibility

**T**unneling beneath the wetlands of eastern North America, the star-nosed mole (*Condylura cristata*) lives in almost total darkness. Virtually blind, the mole is nonetheless a remarkably quick predator, capable of detecting and eating its prey in as little as 120 milliseconds (msec). Central to the mole's hunting prowess are 11 pairs of appendages that protrude from its nose, forming a prominent star (**Figure 38.1**). Although they look a bit like fingers, these appendages are not used in grasping. Nor are they used to detect odors. Instead, they are specialized for detecting physical contact. Just below their surface lie 25,000 touch-sensitive receptors, more than are found in your whole hand. Over 100,000 neurons relay tactile information from these receptors to the mole's brain.

Gathering, processing, and organizing information are essential functions of all nervous systems. In this chapter, we'll begin by examining the basic organization of nervous systems. Next, we'll consider specialization in regions of the vertebrate brain and how brain activity makes information storage and organization possible. Finally, we'll investigate the sensory processes that convey information about an animal's external and internal environments to its brain.

## CONCEPT

### 38.1

### Nervous systems consist of circuits of neurons and supporting cells

The ability to sense and react originated billions of years ago in prokaryotes, enhancing survival and reproductive success in changing environments. Later in evolution, modified forms of these recognition and response processes provided a basis for communication between cells in an animal body. By the time of the Cambrian explosion more than 500 million years ago (see Concept 27.2), specialized systems of neurons had appeared that enabled animals to sense their surroundings and respond rapidly.

Hydras, jellies, and other cnidarians are the simplest animals with nervous systems. In most cnidarians, interconnected nerve cells form a diffuse **nerve net**

▲ **Figure 38.2 Nervous system organization.** (a) A hydra's nervous system contains individual neurons (purple) organized in a diffuse nerve net. (b–d) More complicated nervous systems have groups of neurons (blue) organized into nerves and often ganglia and a brain.

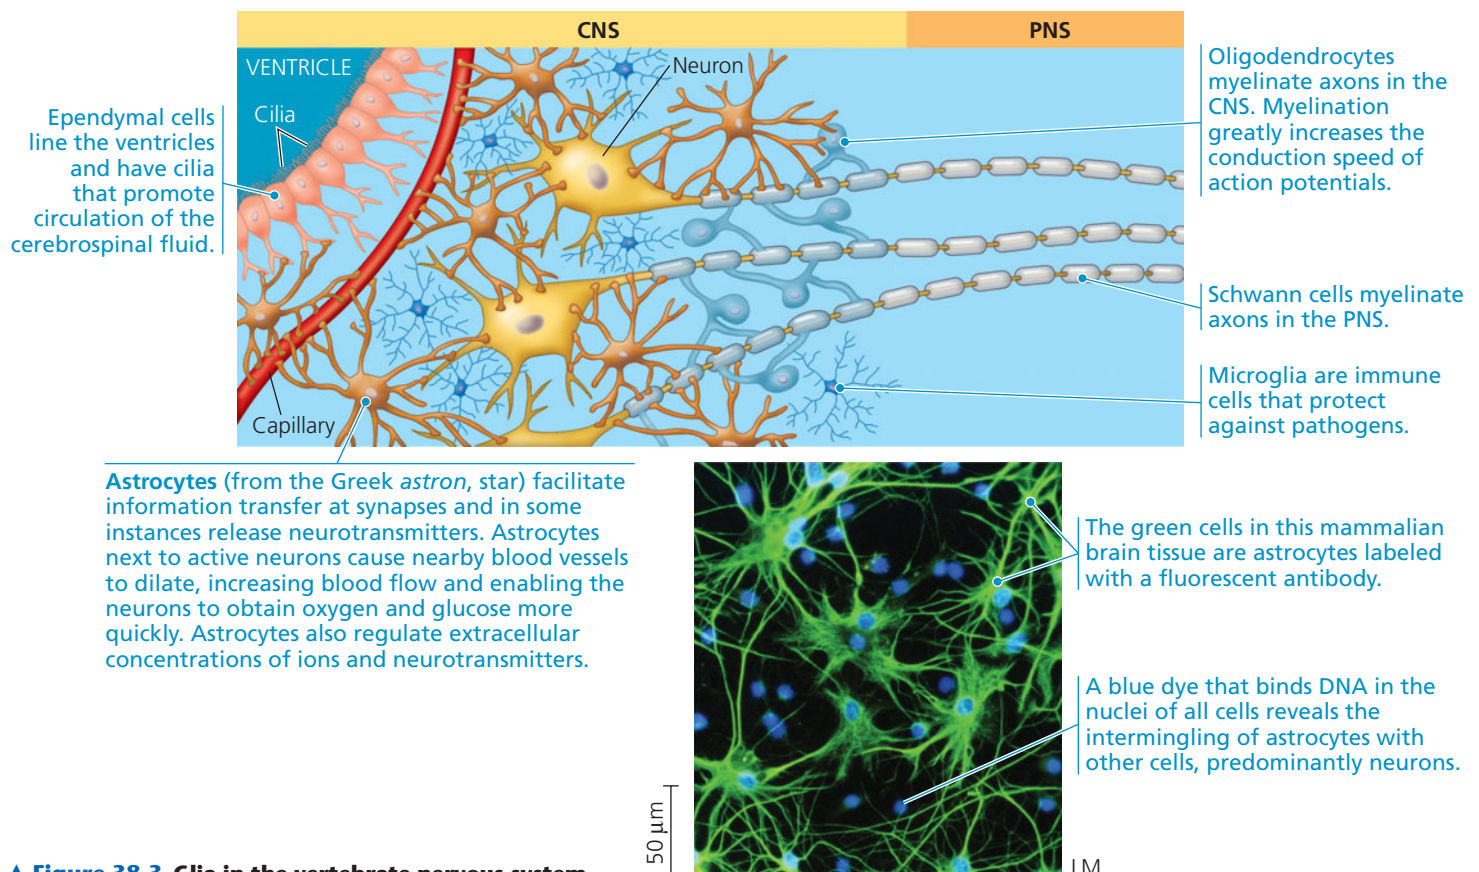

(Figure 38.2a), which controls the contraction and expansion of the gastrovascular cavity. In more complex animals, the axons of multiple nerve cells are often bundled together, forming **nerves**. These fibrous structures channel and organize information flow along specific routes through the nervous system.

Animals that have elongated, bilaterally symmetric bodies have even more specialized nervous systems. The organization of neurons in such animals reflects *cephalization*, an evolutionary trend toward a clustering of sensory neurons and interneurons at the anterior (front) end of the body. These anterior neurons communicate with cells elsewhere in the body, including neurons located in one or more nerve cords extending toward the posterior (rear) end. In nonsegmented worms, such as the planarian shown in Figure 38.2b, a small brain and longitudinal nerve cords constitute the simplest clearly defined **central nervous system (CNS)**. More complex invertebrates, such as arthropods (Figure 38.2c), have more complicated brains and ventral nerve cords that contain *ganglia*, segmentally arranged clusters of neurons.

In vertebrates (Figure 38.2d), the brain and spinal cord form the CNS; nerves and ganglia form the **peripheral nervous system (PNS)**.

## Glia

Throughout the vertebrate brain and spinal cord, glia nourish, support, and regulate the functioning of neurons. Figure 38.3 illustrates the major types of glia in an adult vertebrate.

▲ **Figure 38.3 Glia in the vertebrate nervous system.**

The essential functions of glia include their role in the development of the nervous system. In embryos, cells called *radial glia* form tracks along which newly formed neurons migrate from the neural tube, the structure that gives rise to the CNS. Later, star-shaped glia called **astrocytes** induce cells that line the capillaries in the CNS to form tight junctions (see Figure 4.27). The result is the *blood-brain barrier*, a separation between the extracellular environment of the CNS and the circulatory system that restricts the movement of most substances from the blood to the brain.

Glial cells not only support neurons, but also can contribute to the formation of new neurons. It was long thought that adult brains do not create new neurons; however, in 1998 researchers discovered that the adult human brain contains neural stem cells, which divide indefinitely and can give rise to new neurons. More recently, studies with mice have shown that the neural stem cells are astrocytes and that the new neurons they produce play an essential role in learning and memory.

## Organization of the Vertebrate Nervous System

In vertebrates, the spinal cord runs lengthwise inside the vertebral column, known as the spine (Figure 38.4). The spinal

▲ **Figure 38.4 The vertebrate nervous system.** The central nervous system consists of the brain and spinal cord (yellow). Left-right pairs of cranial nerves, spinal nerves, and ganglia make up most of the peripheral nervous system (dark gold).

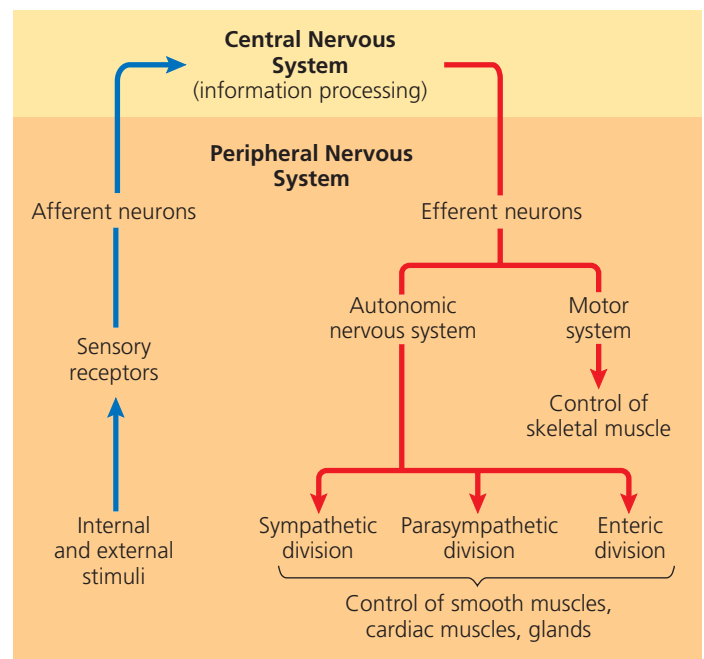

cord conveys information to and from the brain and generates basic patterns of locomotion. It also acts independently of the brain as part of the simple nerve circuits that produce certain **reflexes**, the body's automatic responses to particular stimuli. For example, the spinal cord controls the reflex that jerks your hand away if you accidentally touch a hot pan.

Both the brain and the spinal cord contain gray and white matter. **Gray matter** consists mainly of neuron cell bodies and glia. **White matter** consists of bundled axons, whose myelin sheaths are responsible for the light color of this portion of the CNS. In the spinal cord, white matter makes up the outer layer, where it links the CNS to sensory and motor neurons of the PNS. In the brain, white matter is predominantly located in the interior, where signaling between neurons functions in learning, feeling emotions, processing sensory information, and generating commands.

The CNS also contains fluid-filled spaces, called *ventricles* in the brain and the *central canal* in the spinal cord. The fluid inside, called *cerebrospinal fluid*, is formed in the brain by filtering arterial blood. It circulates through the ventricles and central canal and then drains into the veins, supplying the CNS with nutrients and hormones and carrying away wastes.

## The Peripheral Nervous System

The PNS transmits information to and from the CNS and plays a large role in regulating both an animal's movement and its internal environment (Figure 38.5). Sensory information reaches the CNS along PNS neurons designated as *afferent* (from the Latin, meaning "to carry toward"). Following information processing within the CNS, instructions travel

▲ **Figure 38.5 Functional hierarchy of the vertebrate peripheral nervous system.**

to muscles, glands, and endocrine cells along PNS neurons designated as *effluent* (meaning “to carry away”). Most nerves contain both afferent and efferent neurons.

The PNS has two efferent components: the motor system and the autonomic nervous system (see Figure 38.5). The **motor system** consists of neurons that carry signals to skeletal muscles. Motor control can be voluntary, as when you raise your hand to ask a question, or involuntary, as in a reflex. In contrast, regulation of smooth and cardiac muscles by the **autonomic nervous system** is generally involuntary. The three divisions of the autonomic nervous system—enteric, sympathetic, and parasympathetic—together control the organs of the digestive, cardiovascular, excretory, and endocrine systems. For example, networks of neurons that form the **enteric division** of the autonomic nervous system are active in the digestive tract, pancreas, and gallbladder.

The sympathetic and parasympathetic divisions of the autonomic nervous system have largely antagonistic (opposite) functions in regulating organ function. Activation of the **sympathetic division** is responsible for the “fight-or-flight” response, a state of hyperarousal with which we and other animals respond to a threat. In mammals, the heart beats faster, digestion slows or stops, and the adrenal medulla secretes more epinephrine (adrenaline). Activation of the **parasympathetic division** generally causes opposite responses that promote calming and a return to self-maintenance functions (“rest and digest”).

As we have seen, each component of the PNS has functions specific to particular locations in the body. We therefore describe the PNS as having regional specialization, a property also apparent in the brain, our next topic.

CONCEPT CHECK 38.1

- 1. Which division of the autonomic nervous system would likely be activated if a student learned that an exam she had forgotten about would start in 5 minutes? Explain.
- 2. **WHAT IF?** Suppose a person had an accident that severed a small nerve required to move some of the fingers of the right hand. Would you also expect an effect on sensation from those fingers?

For suggested answers, see Appendix A.

CONCEPT 38.2

The vertebrate brain is regionally specialized

We turn now to the vertebrate brain, a structure that in humans contains 100 billion neurons. How are so many cells organized into circuits and networks that can perform highly sophisticated information processing, storage, and retrieval? To study this question, let’s begin with **Figure 38.6**, on the next two pages, which explores the overall architecture of the brain. Use this figure to trace how brain structures arise during embryonic development;

as a reference for their size, shape, and location in the adult brain; and as an introduction to their best-understood functions.

In examining brain organization and function, we’ll first consider activity cycles and the physiological basis of emotions.

Arousal and Sleep

If you’ve ever drifted off to sleep while listening to a lecture (or reading a textbook), you know that your attentiveness and mental alertness can change rapidly. Such transitions are regulated by the brainstem and cerebrum, which control arousal and sleep. Arousal is a state of awareness of the external world. Sleep is a state in which external stimuli are received but not consciously perceived.

Contrary to appearances, sleep is an active state, at least for the brain. By placing electrodes at multiple sites on the scalp, researchers can record patterns of electrical activity—brain waves—in an electroencephalogram (EEG). These recordings reveal that brain wave frequencies change as the brain progresses through distinct stages of sleep.

Arousal and sleep are controlled in part by clusters of neurons in the midbrain and pons. These neurons control the timing of sleep periods characterized by rapid eye movements (REM) and by vivid dreams. Sleep is also regulated by the biological clock, discussed later, and by regions of the forebrain that regulate sleep intensity and duration.

Some animals have evolutionary adaptations that allow for substantial activity during sleep. Bottlenose dolphins, for example, swim while sleeping, rising to the surface to breathe air on a regular basis. How do they manage this feat? As in other mammals, the forebrain of dolphins is divided into two halves, the right and left hemispheres. Noting that dolphins sleep with one eye open and one closed, researchers hypothesized that only one side of the dolphin brain is asleep at a time. EEG recordings from each hemisphere of sleeping dolphins support this hypothesis (**Figure 38.7**).

Key

-  Low-frequency waves characteristic of sleep
-  High-frequency waves characteristic of wakefulness

**▲ Figure 38.7 Dolphins can be asleep and awake at the same time.** EEG recordings were made separately for the two sides of a dolphin’s brain. At each time point, low-frequency activity was recorded in one hemisphere while higher-frequency activity typical of being awake was recorded in the other hemisphere.

The brain is the most complex organ in the human body. Surrounded by the thick bones of the skull, the brain is divided into a set of distinctive structures, some of which are visible in the magnetic resonance image (MRI) shown at right of an adult's head. The diagram below traces the development of these structures in the embryo. Their major functions are explained on the facing page.

## Human Brain Development

As a human embryo develops, the neural tube forms three anterior bulges—the **forebrain**, **midbrain**, and **hindbrain**—that together produce the adult brain. The midbrain and portions of the hindbrain give rise to the **brainstem**, a stalk that joins with the spinal cord at the base of the brain. The rest of the hindbrain gives rise to the **cerebellum**, which lies behind the brainstem. The third anterior bulge, the forebrain, develops into the diencephalon, including the neuroendocrine tissues of the brain, and the telencephalon, which becomes the **cerebrum**. Rapid, expansive growth of the telencephalon during the second and third months causes the outer portion, or cortex, of the cerebrum to extend over and around much of the rest of the brain.

## The Cerebrum

The cerebrum controls skeletal muscle contraction and is the center for learning, emotion, memory, and perception. It is divided into right and left **cerebral hemispheres**. The **cerebral cortex** is vital for perception, voluntary movement, and learning.

Like the rest of the cerebrum, the cerebral cortex

is divided into right and left sides. The left side receives information from, and controls the movement of, the right side

of the body, and vice versa. A thick band of axons known as the **corpus callosum** enables the right and left cerebral cortices to communicate. Deep within the white matter, clusters of neurons called *basal nuclei* serve as centers for planning and learning movement sequences. Damage to these sites during fetal development can result in cerebral palsy, a disorder resulting from a disruption in the transmission of motor commands to the muscles.

Adult brain viewed from the rear

## The Cerebellum

The cerebellum coordinates movement and balance and helps in learning and remembering motor skills. The cerebellum receives sensory information about the positions of the joints and the

lengths of the muscles, as well as input from the auditory (hearing) and visual systems. It also monitors motor commands issued by the cerebrum. The cerebellum

integrates this information as it carries out coordination and error checking during motor and perceptual functions. Hand-eye coordination is an example of cerebellar control; if the cerebellum is damaged, the eyes can follow a moving object, but they will not stop at the same place as the object. Hand movement toward the object will also be erratic.

## The Diencephalon

The diencephalon gives rise to the thalamus, hypothalamus, and epithalamus. The **thalamus** is the main input center for sensory information going to the cerebrum. Incoming information from all the senses is sorted in the thalamus and sent to the appropriate cerebral centers for further processing. The thalamus is formed by two masses, each roughly the size and shape of a walnut.

A much smaller structure, the **hypothalamus**, constitutes a control center that includes the body's thermostat as well as the central biological clock. Through its regulation of the pituitary gland, the hypothalamus regulates hunger and thirst, plays a role in sexual and mating behaviors, and initiates the fight-or-flight response.

The hypothalamus is also the source of posterior pituitary hormones and of releasing hormones that act on the anterior pituitary. The *epithalamus* includes the pineal gland, the source of melatonin. It also contains one of several clusters of capillaries that generate cerebrospinal fluid from blood.

## The Brainstem

The brainstem consists of the midbrain, the **pons**, and the **medulla oblongata** (commonly called the *medulla*). The midbrain receives and integrates several types of sensory information, which it then sends on to specific regions of the forebrain. All sensory axons involved in hearing either terminate

in the midbrain or pass through it on their way to the cerebrum. In addition, the midbrain coordinates visual reflexes, such as the peripheral vision reflex: The head turns toward

an object approaching from the side without the brain having formed an image of the object.

A major function of the pons and medulla is to transfer information between the PNS and the midbrain and forebrain.

The pons and medulla also help coordinate large-scale body movements,

such as running and climbing. Most axons that carry instructions about these movements cross from one side of the CNS to the other in the medulla. As a result, the right side of the brain controls much of the movement of the left side of the body, and vice versa. An additional function of the medulla is the control of several automatic, homeostatic functions, including breathing, heart and blood vessel activity, swallowing, vomiting, and digestion. The pons also participates in some of these activities; for example, it regulates the breathing centers in the medulla.

## Biological Clock Regulation

Cycles of sleep and wakefulness are an example of a circadian rhythm, a daily cycle of biological activity. Such cycles, which occur in organisms ranging from bacteria to humans, rely on a **biological clock**, a molecular mechanism that directs periodic gene expression and cellular activity. Although biological clocks are typically synchronized to the cycles of light and dark in the environment, they can maintain a roughly 24-hour cycle even in the absence of environmental cues. For example, humans studied in a constant environment exhibit a sleep/wake cycle of 24.2 hours, with very little variation among individuals.

What normally links an animal's biological clock to environmental cycles of light and dark? In mammals, circadian rhythms are coordinated by a group of neurons in the hypothalamus called the **suprachiasmatic nucleus (SCN)**. (Certain clusters of neurons in the CNS are referred to as “nuclei.”) In response to sensory information from the eyes, the SCN acts as a pacemaker, synchronizing the biological clock in cells throughout the body to the natural cycles of day length. In the **Scientific Skills Exercise**, you can interpret data from an experiment and propose additional experiments to test the role of the SCN in hamster circadian rhythms.

### Scientific Skills Exercise

#### *Designing an Experiment Using Genetic Mutants*

**Does the SCN Control the Circadian Rhythm in Hamsters?** By surgically removing the SCN from laboratory mammals, scientists demonstrated that the SCN is required for circadian rhythms. But these studies did not reveal whether circadian rhythms originate in the SCN. To answer this question, researchers performed an SCN transplant experiment on wild-type and mutant hamsters (*Mesocricetus auratus*). Whereas for wild-type hamsters the period between cyclic peaks in activity is 24 hours in the absence of external cues, hamsters homozygous for the  $\tau$  (tau) mutation have a period lasting only about 20 hours. In this exercise, you will evaluate the design of this experiment and propose additional experiments to gain further insight.

**How the Experiment Was Done** The researchers surgically removed the SCN from wild-type and  $\tau$  hamsters. Several weeks later, each of these hamsters received a transplant of an SCN from a hamster of the opposite genotype. The researchers then measured the period length for the transplant recipients.

**Data from the Experiment** In 80% of the hamsters in which the SCN had been removed, transplanting an SCN from another hamster restored rhythmic activity. For hamsters in which an SCN transplant restored a circadian rhythm, the net effect of the two procedures (SCN removal and replacement) on the circadian cycle is graphed below. Each red line represents the change in the measured period for an individual hamster.

© 1990 AAAS

#### Interpret the Data

1. In a controlled experiment, researchers manipulate one variable at a time. What was the experimental variable in this study? Why did the researchers use more than one hamster for each procedure? What traits of the individual hamsters would likely have been controlled among the treatment groups?
2. For the wild-type hamsters that received  $\tau$  SCN transplants, what would have been an appropriate control?
3. What general trends does the graph reveal about the period of the circadian rhythm in transplant recipients? Do the trends differ for the wild-type and  $\tau$  recipients? Based on these data, what can you conclude about the role of the SCN in determining the period length?
4. In 20% of the hamsters, there was no restoration of rhythmic activity following the SCN transplant. What are some possible reasons for this finding? Do you think you can be confident of your conclusion about the role of the SCN based on data from 80% of the hamsters? Explain.
5. Suppose that researchers identified a mutant hamster that lacked rhythmic activity; that is, its circadian cycle had no regular pattern. Propose SCN transplant experiments using such a mutant along with (a) wild-type and (b)  $\tau$  hamsters. Predict the results of those experiments in light of your conclusion in question 3.

**Data from** M. R. Ralph et al., Transplanted suprachiasmatic nucleus determines circadian period, *Science* 247:975–978 (1990).

**MB** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

▲ **Figure 38.8** The limbic system.

## Emotions

Whereas a single structure in the brain controls the biological clock, generating and experiencing emotions depend on many brain structures, including the amygdala, hippocampus, and parts of the thalamus. As shown in **Figure 38.8**, these structures border the brainstem in mammals and are therefore termed the *limbic system* (from the Latin *limbus*, border).

Generating and experiencing emotion often require interactions between different regions of the brain. For example, laughing and crying both involve the limbic system interacting with sensory areas of the forebrain. Similarly, structures in the forebrain attach emotional “feelings” to survival-related functions controlled by the brainstem, including aggression, feeding, and sexuality.

Emotional experiences are sometimes stored as memories that can be recalled by similar circumstances. For example, a situation that causes you to remember a frightening event can trigger a faster heart rate, sweating, and mental state of fear, even if there is currently nothing scary or threatening in your surroundings. The brain structure that is most important for this emotional memory is the amygdala.

## The Brain’s Reward System and Drug Addiction

Emotions are strongly influenced by a neural circuit in the brain called the reward system. The reward system provides motivation for activities that enhance survival and reproduction, such as eating in response to hunger, drinking when thirsty, and engaging in sexual activity when aroused. Inputs to the reward system are received by neurons in a region near the base of the brain called the *ventral tegmental area (VTA)*. When activated, these neurons release dopamine from their synaptic terminals in specific regions of the cerebrum.

The brain’s reward system is dramatically affected by drug addiction, a disorder characterized by compulsive consumption of a drug and loss of control in limiting intake. Addictive drugs, which range from sedatives to stimulants and include

▲ **Figure 38.9** Effects of addictive drugs on the reward system of the mammalian brain. Addictive drugs alter the transmission of signals in the pathway formed by neurons of the ventral tegmental area (VTA).

**MAKE CONNECTIONS** Review depolarization in Concept 37.3. What effect would you expect if you depolarized the neurons in the VTA? Explain.

alcohol, cocaine, nicotine, and heroin, enhance the activity of the dopamine pathway (**Figure 38.9**). As addiction develops, there are also long-lasting changes in the reward circuitry. The result is a craving for the drug independent of any pleasure associated with consuming it.

Laboratory animals have proved especially useful in teaching us how the brain’s reward system works and how particular drugs affect its function. Rats, for example, will provide themselves with cocaine, heroin, or amphetamine when given a dispensing system linked to a lever in their cage. Furthermore, they exhibit addictive behavior in such circumstances, continuing to self-administer the drug rather than seek food, even to the point of starvation.

## Functional Imaging of the Brain

Functional imaging methods are transforming our understanding of normal and diseased brains. The first widely used technique was positron-emission tomography (PET), in which an injection of radioactive glucose enables a display of metabolic activity. Today, many studies rely on functional magnetic resonance imaging (fMRI). In fMRI, a subject lies with his or her head in

the center of a large, doughnut-shaped magnet. Brain activity in a region is detected by changes in the local oxygen concentration. By scanning the brain while the subject performs a task, such as forming a mental image of a person's face, researchers can correlate particular tasks with activity in specific brain areas.

In one experiment using fMRI, researchers mapped brain activity while subjects listened to music that they described as happy or sad (**Figure 38.10**). Listening to happy music led to increased activity in the nucleus accumbens, a brain structure important for the perception of pleasure (in fact, the nucleus accumbens is one of the targets of the reward system). In contrast, subjects who heard sad music had increased activity in the amygdala, the focus for emotional memory.

The range of fMRI applications includes monitoring recovery from stroke, mapping abnormalities in migraine

▲ **Figure 38.10 Functional brain imaging in the working brain.** Functional magnetic resonance imaging (fMRI) was used to reveal brain activity associated with happy or sad music.

**WHAT IF?** In the experiment that produced the images shown above, some regions of the brain were active under all conditions. What function might such regions carry out?

headaches, and increasing the effectiveness of brain surgery. This technique has even been used to explore sex-based differences in the CNS, demonstrating, for instance, that cerebral blood flow is higher on average in women than in men.

#### CONCEPT CHECK 38.2

1. When you wave your right hand, what part of your brain initiates the action?
2. People who are inebriated have difficulty touching their nose with their eyes closed. Based on this observation, name one of the brain regions impaired by alcohol.
3. **WHAT IF?** Suppose you examine two groups of individuals with CNS damage. In one group, the damage has resulted in a coma (a prolonged state of unconsciousness). In the other group, it has caused total paralysis (a loss of skeletal muscle function throughout the body). Relative to the position of the midbrain and pons, where is the likely site of damage in each group? Explain.

For suggested answers, see Appendix A.

## CONCEPT 38.3

### The cerebral cortex controls voluntary movement and cognitive functions

We turn now to the cerebrum, the part of the brain essential for language, cognition, memory, consciousness, and awareness of our surroundings. For the most part, cognitive functions reside in the cerebral cortex, the outer layer of the cerebrum. Within the cortex, sensory areas receive and process sensory information, association areas integrate the information, and motor areas transmit instructions to other parts of the body. In discussing the cortex, neurobiologists often

use four regions, or *lobes*, as physical landmarks. As shown in **Figure 38.11**, each side of the cortex has a frontal, temporal, occipital, and parietal lobe (each is named for a nearby bone of the skull).

#### Language and Speech

The mapping of cognitive functions within the cortex began in the 1800s when physicians studied the effects of damage to particular regions of the cortex by injuries, strokes, or tumors. The French physician Pierre Broca conducted postmortem (after

◀ **Figure 38.11 The human cerebral cortex.** Each side of the cerebral cortex is divided into four lobes, and each lobe has specialized functions, some of which are listed here. Some areas on the left side of the brain (shown here) have different functions from those on the right side (not shown).

▲ **Figure 38.12 Mapping language areas in the cerebral cortex.** These PET images show regions with different activity levels in one person's brain during four activities related to speech. Hearing words activates Wernicke's area, speaking words activates Broca's area, seeing words activates the visual cortex, and generating words (without reading them) activates parts of the frontal lobe.

death) examinations of patients who had been able to understand language but unable to speak. He discovered that many had defects in a small region of the left frontal lobe, now known as *Broca's area*. The German physician Karl Wernicke found that damage to a posterior portion of the left temporal lobe, now called *Wernicke's area*, abolished the ability to comprehend speech but not the ability to speak. More recently, PET studies have revealed activity in Broca's area during speech generation and Wernicke's area when speech is heard (**Figure 38.12**).

## Lateralization of Cortical Function

Both Broca's area and Wernicke's area reside in the left cortical hemisphere, reflecting a greater role with regard to language for the left side of the cerebrum than for the right side. The left hemisphere is also more adept at math and logical operations. In contrast, the right hemisphere appears to be dominant in the recognition of faces and patterns, spatial relations, and nonverbal thinking. The establishment of these differences in hemisphere function is called **lateralization**.

The two cortical hemispheres normally exchange information through the fibers of the corpus callosum (see Figure 38.6). Severing this connection (a treatment of last resort for the most extreme forms of epilepsy, a seizure disorder) results in a "split-brain" effect. In such patients, the two hemispheres function independently. The patients cannot read even a familiar word that appears in their left field of vision: The sensory information that travels from the left field of vision to the right hemisphere cannot reach the language centers in the left hemisphere.

## Information Processing

As we will discuss later in this chapter, some sensory input to the cerebral cortex comes from groups of receptors clustered in dedicated sensory organs, such as the eyes and nose. Other

sensory input originates in individual receptors in the hands, scalp, and elsewhere in the body. These somatic sensory, or *somatosensory*, receptors (from the Greek *soma*, body) provide information about touch, pain, pressure, temperature, and the position of muscles and limbs.

Most sensory information coming into the cortex is directed via the thalamus to primary sensory areas within the brain lobes. Information received at the primary sensory areas is passed along to nearby association areas, which process particular features in the sensory input. In the occipital lobe, for instance, some groups of neurons in the primary visual area are specifically sensitive to rays of light oriented in a particular direction. Once processed, sensory information passes to the prefrontal cortex, which helps plan actions. The cerebral cortex may then generate motor commands that cause particular behaviors, such as waving a hand.

## Frontal Lobe Function

In 1848, a horrific accident pointed to the role of the prefrontal cortex in temperament and decision making. Phineas Gage was the foreman of a railroad construction crew when an explosion drove an iron rod through his head. The rod, which was more than 3 cm in diameter at one end, entered his skull just below his left eye and exited through the top of his head, damaging large portions of his frontal lobe. Gage recovered, but his personality changed dramatically. He became emotionally detached, impatient, and erratic in his behavior.

Support for the hypothesis that Gage's brain injury and his personality change inform us about frontal lobe function comes from the fact that some frontal lobe tumors cause similar symptoms. Intellect and memory seem intact, but decision making is flawed and emotional responses are diminished. In the 20th century, the same problems resulted from frontal lobotomy, a surgical procedure that severs the connection between the prefrontal cortex and the limbic system. Together, these observations provide evidence that the frontal lobes have a substantial influence on what are called "executive functions."

Once a common treatment for severe behavioral disorders, frontal lobotomy is no longer in use. Instead, behavioral disorders are typically treated with medications.

## Evolution of Cognition in Vertebrates

**EVOLUTION** In nearly all vertebrates, the brain has the same number of divisions. Given this uniform overall structure, what changed during evolution that provided certain species with a capacity for advanced *cognition*, the perception and reasoning that constitute knowledge? One hypothesis is that higher order

reasoning required evolution of a highly convoluted cerebral cortex, such as is found in humans, other primates, and cetaceans (whales, dolphins, and porpoises). Indeed, in humans, the cerebral cortex accounts for about 80% of total brain mass.

Birds, on the other hand, lack a convoluted cerebral cortex and were long thought to have much lower intellectual capacity than primates and cetaceans. Experiments in recent years, however, have refuted this idea. Western scrub jays (*Aphelocoma californica*) can remember the relative period of time that has passed after they have stored and hid specific food items. Furthermore, African gray parrots (*Psittacus erithacus*) understand numerical and abstract concepts, such as “same,” “different,” and “none.”

The anatomical basis for sophisticated information processing in birds appears to be a nuclear (clustered) organization of neurons within the *pallium*, the top or outer portion of the brain (**Figure 38.13**). This arrangement is different from that seen in the human cerebral cortex, where six parallel layers of neurons are arranged tangential to the brain surface. Thus, evolution has resulted in two different types of outer brain organization in vertebrates, each of which supports complex and flexible brain function.

How did the bird pallium and human cerebral cortex arise during evolution? The current consensus is that the common ancestor of birds and mammals had a pallium in which neurons were organized into nuclei, as is still found in birds. Early in mammalian evolution, this nuclear organization was

transformed into a layered one. However, connectivity was maintained such that, for example, the thalamus relays sensory input relating to sights, sounds, and touch to the pallium in birds and the cerebral cortex in mammals.

Sophisticated information processing depends not only on the overall organization of a brain but also on small-scale changes that enable learning and encode memory. We’ll turn to these changes in the context of humans in the next section.

## Neural Plasticity

Although the overall organization of the CNS is established during embryonic development, the connections between neurons are subject to modification. This capacity for the nervous system to be remodeled, especially in response to its own activity, is called **neural plasticity**.

Much of the reshaping of the nervous system occurs at synapses. When the activity of a synapse coincides with that of other synapses, changes may occur that reinforce that synaptic connection. Conversely, when the activity of a synapse fails to correlate in this way with that of other synapses, the synaptic connection sometimes becomes weaker. In this way, synapses belonging to circuits that link information in useful ways are maintained, whereas those that convey bits of information lacking any context may be lost.

**Figure 38.14a** illustrates how activity-dependent events can result in either the addition or loss of a synapse. If you think of signals in the nervous system as traffic on a highway, such changes are comparable to adding or removing an entrance ramp. The net effect is to increase signaling between particular pairs of neurons and decrease signaling between other pairs. As shown in **Figure 38.14b**, changes can also strengthen or weaken signaling at a synapse. In our traffic analogy, this would be equivalent to widening or narrowing an entrance ramp.

Research indicates that *autism*, a developmental disorder that first appears early in childhood, involves a disruption of activity-dependent remodeling at synapses. Children with autism display impaired communication and social interaction, as well as stereotyped and repetitive behaviors.

## Memory and Learning

Neural plasticity is essential to the formation of memories. We are constantly checking what is happening against what just happened. We hold information for a time in **short-term memory** and then release it if it becomes irrelevant. If we wish to retain knowledge of a name, phone number, or other fact, the mechanisms of **long-term memory** are activated. If we later need to recall the name or number, we fetch it from long-term memory and return it to short-term memory.

Both short-term and long-term memory involve the storage of information in the cerebral cortex. In short-term memory, this information is accessed via temporary links formed in the hippocampus. When information is transferred to long-term memory, the links in the hippocampus are replaced by connections within

**▲ Figure 38.13 Comparison of regions for higher cognition in avian and human brains.** Although structurally different, the pallium of a songbird brain (top cross section) and the cerebral cortex of the human brain (bottom cross section) play similar roles in higher cognitive activities and make many similar connections with other brain structures.

## CONCEPT 38.4

### Sensory receptors transduce stimulus energy and transmit signals to the central nervous system

Much brain activity begins with sensory input. A stimulus is detected by a sensory receptor, and the resulting change in membrane potential in turn alters the transmission of action potentials to the CNS. When this information is decoded within the CNS, a sensation results. In this section, we'll examine these steps in more detail.

#### Sensory Reception and Transduction

A sensory pathway begins with **sensory reception**, the detection of a stimulus by sensory cells. Some sensory cells are themselves specialized neurons, whereas others are non-neuronal cells that regulate neurons (**Figure 38.15**). Some exist singly; others are collected in sensory organs, such as an eye.

The term **sensory receptor** is used to describe a sensory cell or organ, as well as the subcellular structure that detects stimuli. Many sensory receptors detect stimuli from outside the body, such as heat or chemicals, but there are also receptors for stimuli from within the body, such as blood pressure. Activating a sensory receptor does not necessarily require a large amount of stimulus energy. Most light receptors, for example, can detect a single quantum (photon) of light.

▼ **Figure 38.15** Neuronal and non-neuronal sensory receptors.

#### (a) Receptor is afferent neuron.

#### (b) Receptor regulates afferent neuron.

(a) Connections between neurons are strengthened or weakened in response to activity. High-level activity at the synapse of the postsynaptic neuron with presynaptic neuron N<sub>1</sub> leads to recruitment of additional axon terminals from that neuron. Lack of activity at the synapse with presynaptic neuron N<sub>2</sub> leads to loss of functional connections with that neuron.

(b) If two synapses on the same postsynaptic cell are often active at the same time, the strength of the postsynaptic response may increase at both synapses.

▲ **Figure 38.14 Neural plasticity.** Synaptic connections can change over time, depending on the activity level at the synapse.

the cerebral cortex itself. Some of this memory consolidation is thought to occur during sleep. Furthermore, the reactivation of the hippocampus that is required for memory consolidation likely forms the basis for at least some of our dreams.

What evolutionary advantage might be offered by organizing short-term and long-term memories differently? One hypothesis is that the delay in forming connections in the cerebral cortex allows long-term memories to be integrated gradually into the existing store of knowledge and experience, providing a basis for more meaningful associations. Consistent with this hypothesis, the transfer of information from short-term to long-term memory is enhanced by the association of new data with data previously learned and stored in long-term memory. For example, it's easier to learn a new card game if you already have "card sense" from playing other card games.

#### CONCEPT CHECK 38.3

1. Outline two mechanisms by which information flow between two neurons in adults can increase.
2. How do the functions of Broca's area and Wernicke's area each relate to the activity of the surrounding cortex?
3. **WHAT IF?** If a woman with a severed corpus callosum viewed a photograph of a familiar face, first in her left field of vision and then in her right field, why would she find it difficult to put a name to the face?

For suggested answers, see Appendix A.

Although animals use a range of sensory receptors to detect widely varying stimuli, the effect in all cases is to open or close ion channels. Thus, for example, ion channels either open or close when a substance outside the cell binds to a chemical receptor in the plasma membrane. The resulting flow of ions across the membrane changes the membrane potential.

The conversion of a stimulus to a change in the membrane potential of a sensory receptor is called **sensory transduction**, and the change in membrane potential is called a **receptor potential**. Receptor potentials are graded; their magnitude varies with the strength of the stimulus.

## Transmission

Sensory information is transmitted as nerve impulses, or action potentials. For many sensory receptors, transducing stimulus energy into a receptor potential initiates action potentials that travel to the CNS.

Neurons that act directly as sensory receptors produce action potentials and have an axon that extends into the CNS (see Figure 38.15). Non-neuronal sensory receptor cells form chemical synapses with sensory (afferent) neurons and typically respond to stimuli by increasing the rate at which the afferent neurons produce action potentials. (One exception is in the vertebrate visual system, discussed in Concept 38.6.)

The size of a receptor potential increases with stimulus intensity. If the receptor is a sensory neuron, a larger receptor potential results in more frequent action potentials (**Figure 38.16**). If the receptor is not a sensory neuron, a larger receptor potential usually causes more neurotransmitter to be released.

Many sensory neurons spontaneously generate action potentials at a low rate. In these neurons, a stimulus does not switch production of action potentials on or off, but it does change *how often* an action potential is produced. In this manner, such neurons convey information about changes in stimulus intensity.

## Perception

When action potentials reach the brain via sensory neurons, circuits of neurons process this input, generating the brain's **perception** of the stimuli. Perceptions—such as colors,

smells, and sounds—are constructions formed in the brain and do not exist outside it. So, if a tree falls and no animal is present to hear it, is there a sound? The falling tree certainly produces pressure waves in the air, but there is no sound unless an animal senses the waves and its brain perceives them.

An action potential triggered by light striking the eye has the same properties as an action potential triggered by air vibrating in the ear. How, then, do we distinguish sights, sounds, and other stimuli? The answer lies in the connections that link sensory receptors to the brain. Action potentials from sensory receptors travel along neurons that are dedicated to a particular stimulus; these dedicated neurons form synapses with particular neurons in the brain or spinal cord. As a result, the brain distinguishes stimuli such as sight or sound solely by the path along which the action potentials have arrived.

## Amplification and Adaptation

The transduction of stimuli by sensory receptors may be modified by amplification and adaptation. **Amplification** is the strengthening of a sensory signal during transduction. The effect can be considerable: For example, an action potential conducted from the eye to the human brain has about 100,000 times as much energy as the few photons of light that triggered it.

Amplification that occurs in sensory receptor cells often requires signal transduction pathways involving second messengers. Because these pathways include enzyme-catalyzed reactions, they amplify signal strength through the formation of many product molecules by a single enzyme molecule. Amplification may also take place in accessory structures of a complex sense organ, as when the pressure associated with sound waves is enhanced by a factor of more than 20 before reaching receptors in the innermost part of the ear.

Upon continued stimulation, many receptors undergo a decrease in responsiveness termed **sensory adaptation** (not to be confused with the evolutionary term *adaptation*). Without sensory adaptation, you would be constantly aware of feeling every beat of your heart and every bit of clothing on your body. Adaptation also enables you to see, hear, and smell changes in the environment that vary widely in stimulus intensity.

## Types of Sensory Receptors

We commonly classify sensory receptors based on the kind of stimuli they transduce: mechanoreceptors, electromagnetic receptors, thermoreceptors, pain receptors, and chemoreceptors.

### Mechanoreceptors

**Mechanoreceptors** respond to forms of mechanical energy such as pressure, touch, stretch, motion, and sound. Mechanoreceptors typically consist of ion channels that are linked to structures that extend outside the cell, such as “hairs” (cilia), as well as internal cell structures, such as the cytoskeleton. Bending or stretching of the external structure generates tension that alters the permeability of the ion channels. This change in

▲ **Figure 38.16** Coding of stimulus intensity by a single sensory receptor.

ion permeability alters the membrane potential, resulting in a depolarization or hyperpolarization.

Some animals use mechanoreceptors to literally get a feel for their environment. For example, cats as well as many rodents have sensitive mechanoreceptors at the base of their whiskers. Because deflection of different whiskers triggers action potentials that reach different cells in the brain, an animal's whiskers provide detailed information about nearby objects.

### Electromagnetic Receptors

**Electromagnetic receptors** detect various forms of electromagnetic energy, such as light, electricity, and magnetism. For example, snakes have very sensitive receptors that detect the infrared radiation emitted by warm prey (**Figure 38.17a**). Similarly, the platypus has electroreceptors on its bill that are thought to detect the electric field generated by the muscles of crustaceans and other prey. In a few cases, the animal detecting the stimulus is also its source: Some fishes generate electric currents and then use electroreceptors to locate prey that disturb those currents.

Many animals appear to use Earth's magnetic field lines to orient themselves as they migrate (**Figure 38.17b**), and the iron-containing mineral magnetite may be responsible for this ability. Magnetite is found in many vertebrates (including salmon, pigeons, sea turtles, and humans), bees, and some molluscs.

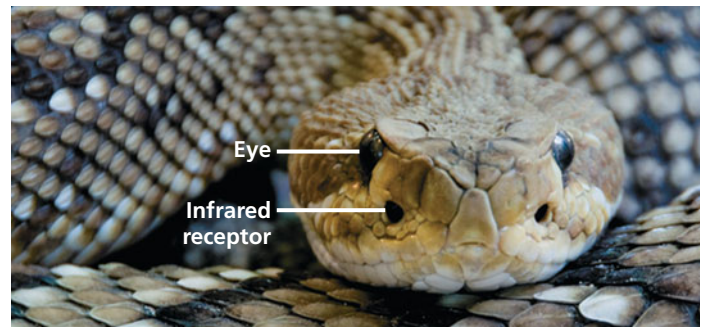

### Thermoreceptors

**Thermoreceptors** detect heat and cold. In humans, thermoreceptors located in the skin and in the anterior hypothalamus send information to the body's thermostat in the posterior hypothalamus. Our understanding of thermoreception has increased recently, thanks to scientists with an appreciation for fiery foods. It turns out that exposing sensory neurons to capsaicin—the molecule that makes jalapeno peppers taste “hot”—triggers calcium ion influx. When scientists identified the receptor protein that binds capsaicin, they made a fascinating discovery: The receptor opens a calcium channel in response not only to capsaicin, but also to high temperatures (42°C or higher). In essence, spicy foods taste “hot” because they activate the same receptors as hot soup and coffee. Similarly, the receptor for temperatures below 28°C is activated by menthol, a plant product that we perceive to have a “cool” flavor.

### Pain Receptors

Extreme pressure or temperature, as well as certain chemicals, can damage animal tissues. To detect stimuli that reflect such noxious (or harmful) conditions, animals rely on **nociceptors** (from the Latin *nocere*, to hurt), also called **pain receptors**. By triggering defensive reactions, such as withdrawal from danger, the perception of pain serves an important function.

In humans, certain naked dendrites act as nociceptors by detecting noxious thermal, mechanical, or chemical stimuli. The capsaicin receptor is thus a nociceptor as well as a thermoreceptor. Although nociceptor density is highest in skin, some pain receptors are associated with other organs.

(a) This rattlesnake and other pit vipers have a pair of infrared receptors, one anterior to and just below each eye. These organs are sensitive enough to detect the infrared radiation emitted by a warm mouse a meter away. The snake moves its head from side to side until the radiation is detected equally by the two receptors, indicating that the mouse is straight ahead.

(b) Some migrating animals, such as these beluga whales, apparently sense Earth's magnetic field and use the information, along with other cues, for orientation.

▲ **Figure 38.17 Specialized electromagnetic receptors.**

Chemicals produced in an animal's body sometimes enhance the perception of pain. For example, damaged tissues produce prostaglandins, which act as local regulators of inflammation. Prostaglandins worsen pain by increasing nociceptor sensitivity to noxious stimuli; aspirin and ibuprofen reduce pain by inhibiting the synthesis of prostaglandins.

### Chemoreceptors

**Chemoreceptors** can be general, transmitting information about total solute concentration—or specific, responding to individual kinds of molecules. Osmoreceptors in the mammalian brain, for example, detect changes in the solute concentration of the blood and stimulate thirst when osmolarity increases. Most animals also have receptors for specific molecules, including glucose, oxygen, carbon dioxide, and amino acids.

The perceptions of **olfaction** (smell) and **gustation** (taste) both depend on chemoreceptors. In the case of terrestrial animals, smell is the detection of **odorants** that are carried through the air, and taste is the detection of chemicals called **tastants** that are present in a solution. The insect repellent DEET (*N,N*-diethyl-meta-toluamide) works by blocking the chemoreceptor in mosquitoes that detects an odorant produced by humans. Humans can distinguish thousands of different odors, each caused by a structurally distinct odorant. This level of sensory discrimination requires many different odorant receptors. In 2004, Richard Axel and Linda Buck shared a

## CONCEPT 38.5

### The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles

Hearing and the perception of body equilibrium, or balance, are related in most animals. For both senses, mechanoreceptor cells produce receptor potentials when settling particles or moving fluid causes deflection of cell-surface structures.

### Sensing of Gravity and Sound in Invertebrates

To sense gravity and maintain equilibrium, most invertebrates rely on mechanoreceptors located in organs called **statocysts** (Figure 38.19). In a typical statocyst, ciliated receptor cells line a chamber that contains one or more *statoliths*, which are grains of sand or other dense granules. When statoliths settle, they stimulate mechanoreceptors at the low point in the chamber. In experiments in which statoliths were replaced with metal shavings, researchers “tricked” crayfish into swimming upside down by using magnets to pull the shavings to the upper end of the statocysts located at the base of their antennae.

Many (perhaps most) insects have body hairs that vibrate in response to sound waves. Hairs of different stiffnesses and lengths vibrate at different frequencies. Many insects also detect sound by means of vibration-sensitive organs, which consist in some species of a tympanic membrane (eardrum) stretched over an internal air chamber. For cockroaches, these organs can provide enough warning for the insect to avoid being crushed by a descending human foot.

### Hearing and Equilibrium in Mammals

In mammals, as in most other terrestrial vertebrates, the sensory organs for hearing and equilibrium are closely associated. Figure 38.20 explores the structure and function of these organs in the human ear.

#### ► Figure 38.19 The statocyst of an invertebrate.

The settling of granules called statoliths to the low point in the chamber bends cilia on receptor cells in that location, providing the brain with information about the orientation of the body with respect to gravity.

(b) Taste buds in all regions of the tongue contain sensory receptor cells specific for each of the five taste types.

© 2010 Pearson Education, Inc.

#### ▲ Figure 38.18 Human taste receptors.

Nobel Prize for their discovery of a family of more than 1,000 odorant receptor genes—about 3% of all human genes.

With regard to tastants, humans (and other mammals) recognize just five types: sweet, sour, salty, bitter, and umami. Umami (Japanese for “delicious”) is elicited by the amino acid glutamate. Often used as a flavor enhancer, monosodium glutamate (MSG) occurs naturally in foods such as meat and aged cheese, imparting a quality described as savory.

For decades, many researchers assumed that a taste cell could have more than one type of receptor. However, recent experiments have shown that a taste cell in fact has a single receptor type, programming the cell to detect only one of the five tastes (Figure 38.18). Taste receptor cells are organized into **taste buds**, most of which are found in projections called papillae. In contrast to the common misconception, any region of the tongue with taste buds can detect any of the five types of taste.

#### CONCEPT CHECK 38.4

1. Which one of the five categories of sensory receptors is primarily dedicated to external stimuli?
2. Why can eating “hot” peppers cause a person to sweat?
3. **WHAT IF?** If you stimulated a sensory neuron of an animal electrically, how would the animal perceive that stimulation?

For suggested answers, see Appendix A.

## 1 Overview of Ear Structure

The **outer ear** consists of the external pinna and the auditory canal, which collect sound waves and channel them to the **tympanic membrane** (eardrum), which separates the outer ear from the middle ear. In the **middle ear**, three small bones—the malleus (hammer), incus (anvil), and stapes (stirrup)—transmit vibrations to the **oval window**, which is a membrane beneath the stapes. The middle ear also opens into the **Eustachian tube**, which connects to the pharynx and equalizes pressure between the middle ear and the atmosphere. The **inner ear** consists of fluid-filled chambers, including the **semicircular canals**, which function in equilibrium, and the coiled **cochlea** (from the Latin meaning “snail”), a bony chamber that is involved in hearing.

## 2 The Cochlea

The cochlea has two large canals—an upper vestibular canal and a lower tympanic canal—separated by a smaller cochlear duct. Both canals are filled with fluid.

## 4 Hair Cell

Projecting from each hair cell is a bundle of rod-shaped “hairs,” each containing a core of actin filaments. Vibration of the basilar membrane in response to sound raises and lowers the hair cells, bending the hairs against the surrounding fluid and the tectorial membrane. When the hairs within the bundle are displaced, mechanoreceptors are activated, changing the membrane potential of the hair cell.

## 3 The Organ of Corti

The floor of the cochlear duct, the basilar membrane, bears the **organ of Corti**, which contains the mechanoreceptors of the ear, hair cells with hairs projecting into the cochlear duct. Many of the hairs are attached to the tectorial membrane, which hangs over the organ of Corti like an awning. Sound waves make the basilar membrane vibrate, which results in bending of the hairs and depolarization of the hair cells.

## Hearing

Vibrating objects, such as a plucked guitar string or the vocal cords of a classmate, create pressure waves in the surrounding air. In hearing, the ear transduces this mechanical stimulus (pressure waves) into nerve impulses that the brain perceives as sound. To hear music, speech, or other sounds in our environment, we rely on **hair cells**, sensory receptors with hair-like projections on the cell surface that detect motion. Before the vibration waves reach the hair cells, however, they are amplified and transformed by several accessory structures.

The first steps in hearing involve structures in the ear that convert the vibrations of moving air to pressure waves in fluid. Upon reaching the outer ear, moving air causes the tympanic membrane to vibrate. The three bones of the middle ear transmit the vibrations to the oval window, a membrane on the cochlea's surface. When one of those bones, the stapes, vibrates against the oval window, it creates pressure waves in the fluid (called perilymph) inside the cochlea.

Upon entering the vestibular canal, the pressure waves push down on the cochlear duct and basilar membrane. In response, the basilar membrane and attached hair cells vibrate up and down. The hairs projecting from the moving hair cells are deflected by the fixed tectorial membrane, which lies above (see Figure 38.20). With each vibration, the hairs bend first in one direction and then the other, causing ion channels in the hair cells to open or close (Figure 38.21). The result is a change in auditory nerve sensations that the brain interprets as sound.

Once pressure waves travel through the vestibular canal, they pass around the apex (tip) of the cochlea and dissipate as they strike the **round window**. This damping of sound waves

resets the apparatus for the next round of vibrations that arrives.

The ear conveys information about two important sound variables: volume and pitch. *Volume* (loudness) is determined by the amplitude, or height, of the sound wave. A large-amplitude wave causes more vigorous vibration of the basilar membrane, greater bending of the hairs on hair cells, and more action potentials in the sensory neurons. *Pitch* is a function of a sound wave's frequency, the number of vibrations per unit time. High-frequency waves produce high-pitched sounds, whereas low-frequency waves produce low-pitched sounds.

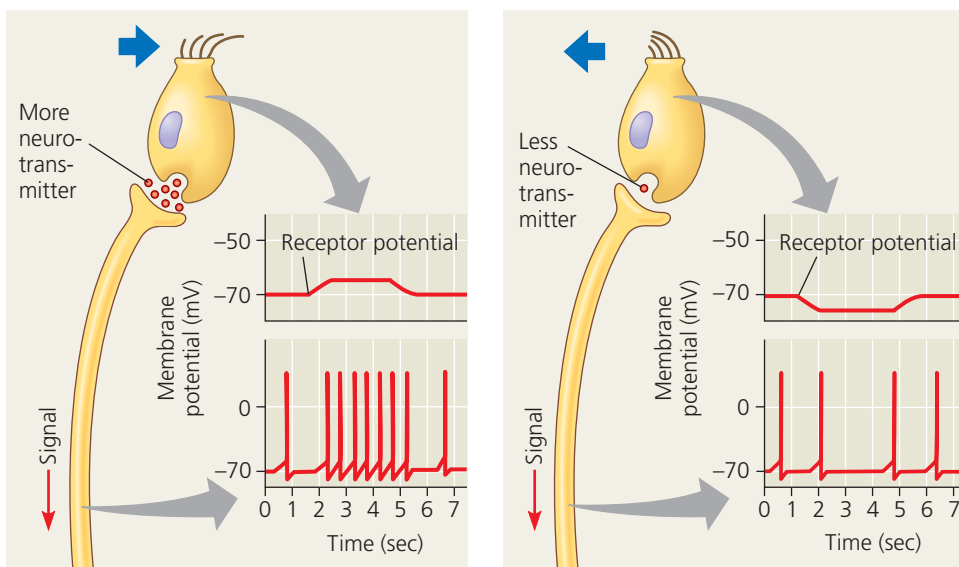

The cochlea can distinguish pitch because the basilar membrane is not uniform along its length: It is relatively narrow and stiff at the base of the cochlea near the oval window and wider and more flexible at the apex. Each region of the basilar membrane is tuned to a particular vibration frequency. Signals triggered by sounds are relayed to specific parts of the cerebral cortex according to the region of the basilar membrane in which the signals originated. Consequently, when a particular site in our cortex is stimulated, we perceive sound of a particular pitch.

## Equilibrium

Several organs in the inner ear of humans and most other mammals detect body movement, position, and balance. Situated in a vestibule behind the oval window, the chambers called the **utricle** and **saccul**e allow us to perceive position with respect to gravity or linear movement (Figure 38.22). Each chamber contains hair cells that project into a gelatinous material. Embedded in this gel are small calcium carbonate particles called otoliths ("ear stones"). When you tilt your head,

the otoliths press on the hairs protruding into the gel. The hair cell receptors transform this deflection into a change in the output of sensory neurons, signaling the brain that your head is at an angle. The otoliths are also responsible for your ability to perceive acceleration, as, for example, when a stationary car in which you are sitting pulls forward.

Three fluid-filled semicircular canals connected to the utricle detect turning of the head and other angular acceleration. Because the three canals are arranged in the three spatial planes, they detect angular motion of the head in any direction. If you spin in place, the fluid in each canal eventually comes to equilibrium and remains in that state until you stop. At that point, the moving fluid encounters a stationary cupula (see Figure 38.22), triggering the false sensation of angular motion that we call dizziness.

(a) Bending of hairs in one direction

(b) Bending of hairs in other direction

▲ **Figure 38.21 Sensory reception by hair cells.** Bending of a hair cell bundle in one direction depolarizes the hair cell. This increases neurotransmitter release, resulting in more frequent action potentials in the sensory neuron. Bending in the other direction has the opposite effect.

© 2001 Pearson Education, Inc.

### CONCEPT CHECK 38.5

1. How are otoliths adaptive for burrowing mammals, such as the star-nosed mole?
2. **WHAT IF?** Suppose a series of pressure waves in your cochlea caused a vibration of the basilar membrane that moved gradually from the apex toward the base. How would your brain interpret this stimulus?
3. **WHAT IF?** If the stapes became fused to the other middle ear bones or to the oval window, how would this condition affect hearing? Explain.

For suggested answers, see Appendix A.

### Light-Detecting Organs

Most invertebrates have some kind of light-detecting organ. One of the simplest is that of planarians (**Figure 38.23**). A pair of ocelli (singular, *ocellus*), which are sometimes called eyespots, are located in the head region. Photoreceptors in each ocellus receive light only through an opening where there are no pigmented cells. By comparing the rates of action potentials coming from the two ocelli, the planarian is able to move away from a light source until it reaches a shaded location, where a rock or other object is likely to hide it from predators.

## CONCEPT 38.6

### The diverse visual receptors of animals depend on light-absorbing pigments

The ability to detect light has a central role in the interaction of nearly all animals with their environment. Although the organs used for vision vary considerably among animals, the underlying mechanism for capturing light is the same, suggesting a common evolutionary origin.

### Evolution of Visual Perception

**EVOLUTION** Light detectors in animals range from simple clusters of cells that detect only the direction and intensity of light to complex organs that form images. These diverse light detectors all contain **photoreceptors**, cells that contain light-absorbing pigment molecules. Furthermore, the genes that specify where and when photoreceptors arise during embryonic development are shared among flatworms, annelids, arthropods, and vertebrates. It is thus very probable that the genetic underpinnings of all photoreceptors were already present in the earliest bilaterian animals.

**▲ Figure 38.23 Ocelli and orientation behavior of a planarian.**

## Compound Eyes

Insects and crustaceans have compound eyes, as do some polychaete worms. A **compound eye** consists of anywhere from a few to up to several thousand light detectors called **ommatidia** (the “facets” of the eye), each with its own light-focusing lens (**Figure 38.24**). Each ommatidium detects light from a small portion of the visual field (the area seen when the eyes point forward). A compound eye is very effective at detecting movement, an important adaptation for flying insects and small animals constantly threatened with predation.

## Single-Lens Eyes

Among invertebrates, **single-lens eyes** are found in some jellies and polychaete worms, as well as in spiders and many

► **Figure 38.24**

**Compound eyes.** The faceted eyes on the head of a fly form a repeating pattern visible in this photomicrograph.

molluscs. A single-lens eye works somewhat like a camera. The eye of an octopus or squid, for example, has a small opening, the **pupil**, through which light enters. Like a camera's adjustable aperture, the **iris** expands or contracts, changing the diameter of the pupil to let in more light or less light. Behind

▼ **Figure 38.25** Exploring the Structure of the Human Eye

© 2010 Pearson Education, Inc.

## 1 Overview of Eye Structure

Starting from the outside, the human eye is surrounded by the conjunctiva, a mucous membrane (not shown); the sclera, a connective tissue; and the choroid, a thin, pigmented layer. At the front, the sclera forms the transparent *cornea* and the choroid forms the colored *iris*. By changing size, the iris regulates the amount of light entering the pupil, the hole in the center of the iris. Just inside the choroid, the neurons and photoreceptors of the **retina** form the innermost layer of the eyeball. The optic nerve exits the eye at the optic disk.

The **lens**, a transparent disk of protein, divides the eye into two cavities. In front of the lens lies the *aqueous humor*, a clear watery substance. Blockage of ducts that drain this fluid can produce glaucoma, a condition in which increased pressure in the eye damages the optic nerve, causing vision loss. Behind the lens lies the jellylike *vitreous humor* (illustrated here in the lower portion of the eyeball).

## 2 The Retina

Light (coming from left in the above view) strikes the retina, passing through largely transparent layers of neurons before reaching the rods and cones, two types of photoreceptors that differ in shape and in function. The neurons of the retina then relay visual information captured by the photoreceptors to the optic nerve and brain along the pathways shown with red arrows. Each *bipolar cell* receives information from several rods or cones, and each *ganglion cell* gathers input from several bipolar cells. *Horizontal* and *amacrine cells* integrate information across the retina.

One region of the retina, the optic disk, lacks photoreceptors. As a result, this region forms a “blind spot” where light is not detected.

the pupil, a single lens focuses light on a layer of photoreceptors. Similar to a camera's focusing action, muscles in an invertebrate's single-lens eye move the lens forward or backward, focusing on objects at different distances.

The eyes of all vertebrates have a single lens. In fishes, focusing is as in invertebrates, with the lens moving forward or backward. In other species, including mammals, focusing is achieved by changing the shape of the lens.

## The Vertebrate Visual System

The human eye will serve as our model of vision in vertebrates. As described in **Figure 38.25**, vision begins when photons of light enter the eye and strike the rods and cones. Remember, however, that it is actually the brain that "sees." Thus, to

understand vision, we must examine how the capture of light by rods and cones changes the production of action potentials and then follow these signals to the visual centers of the brain, where images are perceived.

### Sensory Transduction in the Eye

The transduction of visual information to the nervous system begins with the capture of light by the molecule retinal. Retinal can exist as two alternative isomers, forms with the same types and number of atoms but with a different arrangement of chemical bonds. Looking at Figure 38.25, you can see that the *cis* isomer of retinal has a bent shape while the *trans* isomer is straight. When light strikes the eye, the energy of each photon is captured by converting *cis*-retinal to *trans*-retinal.

© 2010 Pearson Education, Inc.

© 2010 Pearson Education, Inc.

## 3 Photoreceptor Cells

Humans have two main types of photoreceptor cells: rods and cones. Within the outer segment of a rod or cone is a stack of membranous disks in which *visual pigments* are embedded. **Rods** are more sensitive to light but do not distinguish colors; they enable us to see at night, but only in black and white. **Cones** provide color vision, but, being less sensitive, contribute very little to night vision. There are three types of cones. Each has a different sensitivity across the visible spectrum, providing an optimal response to red, green, or blue light.

In the colorized SEM shown above, cones (green), rods (light tan), and adjacent neurons (purple) are visible. The pigmented epithelium, which was removed in this preparation, would be to the right.

## 4 Visual Pigments

Vertebrate visual pigments consist of a light-absorbing molecule called **retinal** (a derivative of vitamin A) bound to a membrane protein called an **opsin**. Seven  $\alpha$  helices of each opsin molecule span the disk membrane. The visual pigment of rods, shown here, is called **rhodopsin**.

Retinal exists as two isomers. Absorption of light shifts one bond in retinal from a *cis* to a *trans* arrangement, converting the molecule from an angled shape to a straight shape. This change in configuration destabilizes and activates the opsin protein to which retinal is bound.

Once retinal captures light, sensory transduction continues as a cascade of events, outlined in **Figure 38.26**. The formation of *trans*-retinal activates rhodopsin, which activates a G protein, which in turn activates an enzyme called phosphodiesterase. The substrate for this enzyme is cyclic GMP, which in the dark binds to sodium ion ( $\text{Na}^+$ ) channels and keeps them open. When phosphodiesterase hydrolyses cyclic GMP,  $\text{Na}^+$  channels close, and the cell becomes hyperpolarized.

The signal transduction pathway in photoreceptor cells normally shuts off as enzymes convert retinal back to the *cis* form, returning rhodopsin to its inactive state. In very bright light, however, rhodopsin remains active, and the response in the rods becomes saturated. If the amount of light entering the eyes decreases abruptly, the rods do not regain full responsiveness for several minutes. This is why you are temporarily blinded if you pass quickly from the bright sunshine into a movie theater or other dark environment. (Because light activation changes the color of rhodopsin from purple to yellow, rods in which the light response is saturated are often described as “bleached.”)

### Processing of Visual Information in the Retina

The processing of visual information begins in the retina itself, where both rods and cones form synapses with bipolar cells (see Figure 38.25). In the dark, rods and cones are depolarized and continually release the neurotransmitter glutamate

at these synapses. Some bipolar cells depolarize in response to glutamate, whereas others hyperpolarize. When light strikes the rods and cones, they hyperpolarize, shutting off their release of glutamate. In response, the bipolar cells that are depolarized by glutamate hyperpolarize, and those that are hyperpolarized by glutamate depolarize.

Signals from rods and cones can follow several different pathways in the retina. Some information passes directly from photoreceptors to bipolar cells to ganglion cells. In other cases, horizontal cells carry signals from one rod or cone to other photoreceptors and to several bipolar cells. Amacrine cells also contribute to signal processing, distributing information from one bipolar cell to several ganglion cells.

A single ganglion cell receives information from an array of rods and cones, each of which responds to light coming from a particular location. Together, the rods and cones that feed information to one ganglion cell define a *receptive field*—the part of the visual field to which the ganglion cell can respond. The fewer rods or cones that supply a single ganglion cell, the smaller the receptive field is. A smaller receptive field typically results in a sharper image because the information about where light has struck the retina is more precise.

### Processing of Visual Information in the Brain

Axons of ganglion cells form the optic nerves that transmit sensations from the eyes to the brain (see Figure 38.25). The two optic nerves meet at the *optic chiasm* near the center of

**▲ Figure 38.26 Production of the receptor potential in a rod cell.** In rods (and cones), the receptor potential triggered by light is a hyperpolarization, not a depolarization.

**?** Which steps in the cascade of events shown here provide an opportunity for amplification, the strengthening of the sensory signal?

the base of the cerebral cortex. Axons in the optic nerves are routed at the optic chiasm such that sensations from the left visual field of both eyes are transmitted to the right side of the brain, and sensations from the right visual field are transmitted to the left side of the brain. (Note that each visual field, whether right or left, involves input from both eyes.)

Researchers estimate that at least 30% of the cerebral cortex, comprising hundreds of millions of neurons in perhaps dozens of integrating centers, takes part in formulating what we actually “see.” Determining how these centers integrate such components of our vision as color, motion, depth, shape, and detail is the focus of much exciting research.

### Color Vision

Among vertebrates, most fishes, amphibians, and reptiles, including birds, have very good color vision. Humans and other primates also see color well, but are among the minority of mammals with this ability. Many mammals are nocturnal, and having a high proportion of rods in the retina is an adaptation that gives these animals keen night vision. Cats, for instance, are usually most active at night; they have limited color vision and probably see a pastel world during the day.

In humans, the perception of color is based on three types of cones, each with a different visual pigment—red, green, or blue. The three visual pigments, called *photopsins*, are formed from the binding of retinal to three distinct opsin proteins. Slight differences in the opsin proteins cause each photopsin to absorb light optimally at a different wavelength.

Abnormal color vision typically results from mutations in the genes for one or more photopsin proteins. Because the human genes for the red and green pigments are located on the X chromosome, a mutation in one copy of either gene can disrupt color vision in males. For this reason, color blindness is more common in males than in females (5–8% of males, fewer than 1% of females) and nearly always affects

perception of red or green. (The human gene for the blue pigment is on chromosome 7.)

### The Visual Field

The brain not only processes visual information but also controls what information is captured. One important type of control is focusing, which, as noted earlier, in humans occurs by changing the shape of the lens. When you focus your eyes on a close object, your lenses become almost spherical. When you view a distant object, your lenses are flattened.

Although our peripheral vision allows us to see objects over a nearly 180° range, the distribution of photoreceptors across the eye limits both what we see and how well we see it. Overall, the human retina contains about 125 million rods and about 6 million cones. At the **fovea**, the center of the visual field, there are no rods but a very high density of cones—about 150,000 cones per square millimeter. The ratio of rods to cones increases with distance from the fovea, with the peripheral regions having only rods. In daylight, you achieve your sharpest vision by looking directly at an object, such that light shines on the tightly packed cones in your fovea. At night, looking directly at a dimly lit object is ineffective, since the rods—the more sensitive light receptors—are found outside the fovea. For this reason, you see a dim star best by focusing on a point just to one side of it.

#### CONCEPT CHECK 38.6

1. Contrast the light-detecting organs of planarians and flies. How is each organ adaptive for the lifestyle of the animal?
2. **WHAT IF?** The human brain receives more action potentials when our eyes are exposed to light even though our photoreceptors release more neurotransmitter in the dark. Propose an explanation.
3. **MAKE CONNECTIONS** Compare the function of retinal in the eye with that of the pigment chlorophyll in a plant photosystem (see Concept 8.2).

For suggested answers, see Appendix A.

## 38 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 38.1

**Nervous systems consist of circuits of neurons and supporting cells (pp. 768–771)**

- Nervous systems range in complexity from simple **nerve nets** to highly centralized nervous systems. In vertebrates, the **central nervous system (CNS)**, consisting of the brain and the spinal cord, integrates information, while the **nerves** of the **peripheral nervous system (PNS)** transmit sensory and motor signals between the CNS and the rest of the body. The simplest circuits in the vertebrate nervous system control **reflex** responses, in which

sensory input is linked to motor output without involvement of the brain. Vertebrate neurons are supported by **glia**, which nourish, support, and regulate neuron function.

- Afferent neurons carry sensory signals to the CNS. Efferent neurons function in either the **motor system**, which carries signals to skeletal muscles, or the **autonomic nervous system**, which regulates smooth and cardiac muscles. The **sympathetic division** and **parasympathetic division** of the autonomic nervous system have antagonistic effects on a diverse set of target organs, while the **enteric division** controls the activity of many digestive organs.

**?** In what ways do different types of *glia* support the growth and survival of neurons?

## CONCEPT 38.2

### The vertebrate brain is regionally specialized (pp. 771–776)

- The cerebrum has two hemispheres, each of which consists of cortical **gray matter** overlying **white matter** and basal nuclei. The basal nuclei are important in planning and learning movements. The **pons** and **medulla oblongata** are relay stations for information traveling between the PNS and the cerebrum. The pons, together with the **brainstem** and parts of the forebrain, also regulate sleep and arousal. The **cerebellum** helps coordinate motor, perceptual, and cognitive functions. The **thalamus** is the main center through which sensory information passes to the **cerebrum**. The **hypothalamus** regulates homeostasis and basic survival behaviors. Within the hypothalamus, the **suprachiasmatic nucleus (SCN)** acts as the pacemaker for circadian rhythms. The **amygdala** plays a key role in recognizing and recalling a number of emotions.

? What roles do the midbrain, cerebellum, thalamus, and cerebrum play in vision and responses to visual input?

## CONCEPT 38.3

### The cerebral cortex controls voluntary movement and cognitive functions (pp. 776–779)

- Each side of the **cerebral cortex** has four lobes that contain primary sensory areas and association areas. Specific types of sensory input enter the primary sensory areas. Association areas integrate information from different sensory areas. Broca's area and Wernicke's area are essential for generating and understanding language. In birds, a brain region called the pallium contains clustered nuclei that carry out functions similar to those performed by the cerebral cortex of mammals.
- Reshaping of the nervous system can involve the loss or addition of synapses or the strengthening or weakening of signaling at synapses. This capacity for remodeling is termed **neural plasticity**. **Short-term memory** relies on temporary links in the hippocampus. In **long-term memory**, these temporary links are replaced by connections within the cerebral cortex.

? After an accident, a patient has trouble with language and has paralysis on one side of the body. Which side would you expect to be paralyzed? Why?

## CONCEPT 38.4

### Sensory receptors transduce stimulus energy and transmit signals to the central nervous system (pp. 779–782)

- The detection of a stimulus precedes **sensory transduction**, the change in the membrane potential of a **sensory receptor** in response to a stimulus. The resulting **receptor potential** controls transmission of action potentials to the CNS, where sensory information is integrated to generate a **perception**. The frequency of action potentials in an axon and the number of axons activated determine stimulus strength. The identity of the axon carrying the signal encodes the nature or quality of the stimulus.
- Mechanoreceptors** respond to stimuli such as pressure, touch, stretch, motion, and sound. **Electromagnetic receptors** detect different forms of electromagnetic radiation. **Thermoreceptors** signal surface and core temperatures of the body. Pain is detected by a group of **nociceptors** that respond to excess heat, pressure, or specific classes of chemicals. **Chemoreceptors** detect either total solute concentration or specific molecules, as in smell (**olfaction**) and taste (**gustation**). In humans, sensory cells have receptors for more than 1,000 **odorants** and five taste perceptions.

? To simplify sensory receptor classification, why might it make sense to eliminate nociceptors as a distinct class?

## CONCEPT 38.5

### The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles (pp. 782–785)

- Most invertebrates sense their orientation with respect to gravity by means of **statocysts**. Specialized **hair cells** form the basis for hearing and balance in mammals. In mammals, the **tympanic membrane** (eardrum) transmits sound waves to bones of the middle ear, which transmit the waves through the **oval window** to the fluid in the coiled **cochlea** of the inner ear. Pressure waves in the fluid vibrate the basilar membrane, depolarizing hair cells and triggering action potentials that travel via the auditory nerve to the brain. Receptors in the inner ear function in balance and equilibrium.

? When a person hears music, how are volume and pitch encoded in signals sent to the brain?

## CONCEPT 38.6

### The diverse visual receptors of animals depend on light-absorbing pigments (pp. 785–789)

- Invertebrates have varied light detectors, including simple light-sensitive eyespots, image-forming **compound eyes**, and **single-lens eyes**. In the vertebrate eye, a single **lens** is used to focus light on **photoreceptors** in the **retina**. Both **rods** and **cones** contain a pigment, **retinal**, bonded to a protein (**opsin**). Absorption of light by retinal triggers a signal transduction pathway that hyperpolarizes the photoreceptors, causing them to release less neurotransmitter. Synapses transmit information from photoreceptors to cells that integrate information and convey it to the brain along axons that form the optic nerve.

? How does the processing of visual information sent to the vertebrate brain differ from that of hearing or olfaction?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. Patients with damage to Wernicke's area have difficulty
  - a. coordinating limb movement.
  - b. generating speech.
  - c. recognizing faces.
  - d. understanding language.
  - e. experiencing emotion.
2. The cerebral cortex does *not* play a major role in
  - a. short-term memory.
  - b. long-term memory.
  - c. circadian rhythm.
  - d. foot-tapping rhythm.
  - e. breath holding.
3. The middle ear converts
  - a. air pressure waves to fluid pressure waves.
  - b. fluid pressure waves to air pressure waves.
  - c. air pressure waves to nerve impulses.
  - d. fluid pressure waves to nerve impulses.
  - e. pressure waves to hair cell movements.
4. If the following events are arranged in the order in which they occur for an animal hiding in response to seeing a predator, which is the fourth event in the series?
  - a. signaling by an afferent PNS neuron
  - b. signaling by an efferent PNS neuron
  - c. information processing in the CNS
  - d. activation of a sensory receptor
  - e. activation of a motor system

### Level 2: Application/Analysis

5. Injury to just the hypothalamus would most likely disrupt
  - a. short-term memory.
  - b. coordination during locomotion.
  - c. executive functions, such as decision making.
  - d. sorting of sensory information.
  - e. regulation of body temperature.
6. Which sensory distinction is *not* encoded by a difference in which axon transfers the information to the brain?
  - a. white and red
  - b. red and green
  - c. loud and faint
  - d. salty and sweet
  - e. spicy and cool

### Level 3: Synthesis/Evaluation

7. Although some sharks close their eyes just before they bite, their bites are on target. Researchers have noted that sharks often misdirect their bites at metal objects and that they can find batteries buried under sand. This evidence suggests that sharks keep track of their prey during the split second before they bite in the same way that
  - a. a rattlesnake finds a mouse in its burrow.
  - b. an insect avoids being stepped on.
  - c. a star-nosed mole locates its prey in tunnels.
  - d. a platypus locates its prey in a muddy river.
  - e. a flatworm avoids light places.
8. **SCIENTIFIC INQUIRY**  
Consider an individual who had been fluent in American Sign Language before suffering an injury to his left cerebral hemisphere. After the injury, he could still understand signs but could not readily generate signs that represented his thoughts. Propose two hypotheses that could explain this finding. How might you distinguish between them?
9. **FOCUS ON EVOLUTION**  
Scientists often use measures of “higher-order thinking” to assess intelligence in other animals. For example, birds are judged to have sophisticated thought processes because they can use tools and make use of abstract concepts. What problems do you see in defining intelligence in these ways?
10. **FOCUS ON ORGANIZATION**  
In a short essay (100–150 words), describe at least three ways in which the structure of the lens of the human eye is well adapted to its function in vision.

For selected answers, see Appendix A.

## OVERVIEW

### The How and Why of Animal Activity

Unlike most animals, male fiddler crabs (genus *Uca*) are highly asymmetric. One claw grows to giant proportions, half the mass of the crab's entire body (**Figure 39.1**). The name *fiddler* comes from the crab's behavior as it feeds on algae from the mudflats where it lives: The smaller front claw moves to and from the mouth in front of the enlarged claw. At times, however, the male waves his large claw in the air. What triggers this behavior? What purpose does it serve?

▼ **Figure 39.1** What prompts a fiddler crab to wave its giant claw?

Claw-waving behavior by a male fiddler crab has two functions. Waving the claw, which can be used as a weapon, helps the crab *repel* other males wandering too close to his burrow. Vigorous claw waving also helps him *attract* females who wander through the crab colony in search of a mate. After the male fiddler crab lures a female to his burrow, he seals her in with mud or sand in preparation for mating.

Animal behaviors, whether solitary or social, fixed or variable, are based on physiological systems and processes. An individual **behavior** is an action carried out by muscles under control of the nervous system. Examples include an animal using its throat muscles to produce a song, releasing a scent to mark its territory, or simply waving a claw. Behavior is an essential part of acquiring nutrients and finding a partner for sexual reproduction. Behavior also contributes to homeostasis, as when honeybees huddle to conserve heat. In short, all of physiology contributes to behavior, and behavior influences all of physiology.

Many behaviors, especially those involved in recognition and communication, rely on specialized body structures or form. For instance, the enormous claw of a male fiddler crab enables recognition by rival males and by potential mates. Similarly, having eyes on stalks high above his head enables the male crab to identify other crabs from far away. As these examples illustrate, the process of natural selection that shapes behaviors also influences the evolution of animal anatomy.

In this chapter, we'll begin by considering the structure and function of muscles and skeletons, as well as mechanisms of animal movement. These topics will lead us naturally to the questions of how behavior is controlled, how it develops during an animal's life, and how it is influenced by genes and the environment. Finally, we'll investigate the ways in which behavior evolves over many generations. Moving our study from an animal's inner workings to its interactions with the outside world will set the stage for exploring ecology (the focus of Unit Seven).

## CONCEPT 39.1

### The physical interaction of protein filaments is required for muscle function

The touch-guided foraging of a star-nosed mole, the upside-down swimming of a crayfish with manipulated statocysts, and the light-avoiding maneuvers of planarians are examples of specific behaviors triggered by sensory inputs to the nervous system (see Chapter 38). Underlying these diverse behaviors are common fundamental mechanisms—feeding, swimming, and crawling all require muscle activity in response to nervous system input.

Muscle cell contraction relies on the interaction between protein structures called thin and thick filaments. The major component of **thin filaments** is the globular protein actin. In thin filaments, two strands of polymerized actin are coiled around one another; similar actin structures called microfilaments function in cell motility (see Concept 4.6). **Thick filaments** are staggered arrays of myosin molecules. Muscle contraction is the product of filament movement powered by chemical energy; muscle relaxation is a passive process. To understand how filaments contribute to muscle contraction, we'll begin with the skeletal muscle of vertebrates.

#### Vertebrate Skeletal Muscle

Vertebrate **skeletal muscle**, which moves individual bones and the whole body, is made up of a hierarchy of smaller and smaller units (**Figure 39.2**). Most skeletal muscles consist of a bundle of long fibers running parallel to the length of the muscle. Each fiber is a single cell that contains multiple nuclei, reflecting its formation by the fusion of many embryonic cells. Inside the fiber lies a longitudinal bundle of **myofibrils**, which contain the thin and thick filaments.

The myofibrils in muscle fibers are made up of repeating sections called **sarcomeres**, which are the basic contractile units of skeletal muscle. The borders of the sarcomeres line up in adjacent myofibrils, forming a pattern of light and dark bands (striations) visible with a light microscope. Therefore,

© 1998 Pearson Education, Inc.

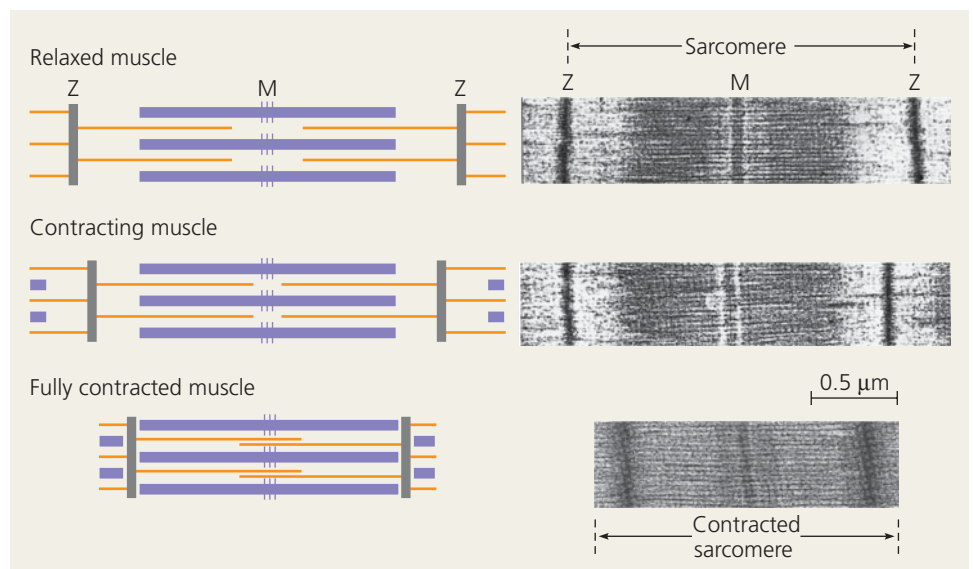

▲ **Figure 39.2** The structure of skeletal muscle.

skeletal muscle is also sometimes called *striated muscle*. As shown in Figure 39.2, thin filaments attach at the ends of the sarcomeres (Z lines), while thick filaments are anchored in the middle (M line). In a muscle fiber at rest, thick and thin filaments partially overlap. Near the edge of the sarcomere there are only thin filaments, whereas the zone in the center contains only thick filaments. This arrangement is the key to how the sarcomere, and hence the whole muscle, contracts.

## The Sliding-Filament Mechanism of Muscle Contraction

A contracting muscle shortens, but the filaments that bring about contraction stay the same length. To explain this apparent paradox, we'll focus first on a single sarcomere. As shown in **Figure 39.3**, the filaments slide past each other, much like the segments of a telescoping support pole. According to the widely accepted **sliding-filament model**, the thin and thick filaments interact and actually ratchet past each other, powered by myosin molecules.

**Figure 39.4** illustrates the cycles of change in the myosin molecule that form the basis for the longitudinal sliding of the thick and thin filaments.

**▲ Figure 39.3 The sliding-filament model of muscle contraction.** The drawings on the left show that the lengths of the thick (myosin) filaments (purple) and thin (actin) filaments (orange) remain the same as a muscle fiber contracts.

**▲ Figure 39.4 Myosin-actin interactions underlying muscle fiber contraction.**

**?** When ATP binds, what prevents the filaments from sliding back into their original positions?

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Muscle Contraction.

Each myosin molecule has a long “tail” and a globular “head.” The tail adheres to the tails of other myosin molecules, binding together the thick filament. The head, which extends to the side, can bind ATP. Hydrolysis of this ATP converts myosin to a high-energy form that binds to actin, forming a cross-bridge. The myosin head then returns to its low-energy form as it pulls the thin filament toward the center of the sarcomere. When a new molecule of ATP binds to the head, the cross-bridge is broken.

Muscle contraction requires repeated cycles of binding and release. In each cycle, the myosin head freed from a cross-bridge cleaves the newly bound ATP and binds to actin farther along the thin filament. A thick filament contains approximately 350 myosin heads, each of which forms and re-forms about five cross-bridges per second, driving the thick and thin filaments past each other.

A typical muscle fiber at rest contains only enough ATP for a few contractions. To power repetitive contractions, the muscle cell relies on two other storage compounds: creatine phosphate and glycogen. Transferring a phosphate group from creatine phosphate to ADP in an enzyme-catalyzed reaction synthesizes additional ATP. In this way, the resting supply of creatine phosphate can sustain contractions for about 15 seconds. ATP stores are also replenished when glycogen is broken down to glucose, which can be used to generate ATP by either aerobic respiration or glycolysis (see Chapter 7). Using a typical muscle fiber’s glycogen store, glycolysis can support about 1 minute of sustained contraction, whereas aerobic respiration can power contractions for nearly an hour.

### The Role of Calcium and Regulatory Proteins

Calcium ions ( $\text{Ca}^{2+}$ ) and proteins bound to actin play crucial roles in muscle contraction and relaxation. **Tropomyosin**, a regulatory protein, and the **troponin complex**, a set of additional regulatory proteins, are bound to the actin strands of thin filaments. In a muscle fiber at rest, tropomyosin covers the myosin-binding sites along the thin filament, preventing actin and myosin from interacting (**Figure 39.5a**). When  $\text{Ca}^{2+}$  accumulates in the cytosol, it binds to the troponin complex, causing tropomyosin bound along the actin strands to shift position and expose the myosin-binding sites on the thin filament (**Figure 39.5b**). Thus, when the  $\text{Ca}^{2+}$  concentration rises in the cytosol, the thin and thick filaments slide past each other, and the muscle fiber contracts. When the  $\text{Ca}^{2+}$  concentration falls, the binding sites are covered, and contraction stops.

Motor neurons cause muscle contraction by triggering the release of  $\text{Ca}^{2+}$  into the cytosol of muscle cells with which they form synapses. This regulation of  $\text{Ca}^{2+}$  concentration is a multistep process involving a network of membranes and compartments within the muscle cell. As you read the following description, refer to the overview and diagram in **Figure 39.6**.

When an action potential arrives at the synaptic terminal of a motor neuron, it causes the neurotransmitter acetylcholine

▲ **Figure 39.5 The role of regulatory proteins and calcium in muscle fiber contraction.** Each thin filament consists of two strands of actin, tropomyosin, and the troponin complex.

to be released. Binding of acetylcholine to receptors on the muscle fiber leads to a depolarization, triggering an action potential. Within the muscle fiber, the action potential spreads deep into the interior, following infoldings of the plasma membrane called **transverse (T) tubules**. These make close contact with the **sarcoplasmic reticulum (SR)**, a specialized endoplasmic reticulum. As the action potential spreads along the T tubules, it triggers changes in the SR, opening  $\text{Ca}^{2+}$  channels. Calcium ions stored in the interior of the SR flow through open channels into the cytosol and bind to the troponin complex, initiating muscle fiber contraction.

When motor neuron input stops, the filaments slide back to their starting position. Relaxation begins as transport proteins in the SR pump  $\text{Ca}^{2+}$  in from the cytosol. When the  $\text{Ca}^{2+}$  concentration in the cytosol drops to a low level, the regulatory proteins bound to the thin filament shift back to their starting position, once again blocking the myosin-binding sites. At the same time, the  $\text{Ca}^{2+}$  pumped from the cytosol accumulates in the SR, providing the stores needed to respond to the next action potential.

There are several human diseases that cause paralysis by interfering with motor neurons’ ability to excite skeletal muscle fibers. In amyotrophic lateral sclerosis (ALS; also known as Lou Gehrig’s disease), motor neurons in the spinal cord and brainstem degenerate, and muscle fibers atrophy. ALS is progressive and usually fatal within five years after symptoms appear. In myasthenia gravis, an autoimmune disease, a person produces antibodies to the acetylcholine receptors of skeletal muscle. As the immune system attacks these receptors, transmission between motor neurons and

The electrical, chemical, and molecular events regulating skeletal muscle contraction are shown in a cutaway view of a muscle cell and in the enlarged diagram below. Action potentials (red arrows) triggered by the motor neuron sweep across the muscle fiber and into it along the transverse (T) tubules, initiating the movements of calcium (green dots) that regulate muscle activity.

© 1998 Pearson Education, Inc.

muscle fibers declines. Myasthenia gravis can generally be controlled with drugs that inhibit acetylcholinesterase or suppress the immune system.

### Nervous Control of Muscle Tension

Whereas an individual skeletal muscle fiber's contraction is a brief all-or-none twitch, contraction of a whole muscle, such as the biceps in your upper arm, is graded—you can voluntarily alter the extent and strength of its contraction. There are two basic mechanisms by which the nervous system produces graded contractions of whole muscles: (1) by varying the number of muscle fibers that contract and (2) by varying the rate at which muscle fibers are stimulated. Let's consider each mechanism in turn.

In vertebrates, each motor neuron may synapse with many muscle fibers, although each fiber is controlled by only one motor neuron. A **motor unit** consists of a single motor neuron and all the muscle fibers it controls (**Figure 39.7**). When a motor neuron produces an action potential, all the muscle fibers in its motor unit contract as a group. The strength of the resulting contraction depends on how many muscle fibers the motor neuron controls. In the whole muscle, there may be hundreds of motor units.

▲ **Figure 39.7 Motor units in a vertebrate skeletal muscle.** Each muscle fiber (cell) forms synapses with only one motor neuron, but each motor neuron typically synapses with many muscle fibers. A motor neuron and all the muscle fibers it controls constitute a motor unit.

▲ **Figure 39.8 Summation of twitches.** This graph illustrates how the number of action potentials in a short period of time influences the tension developed in a muscle fiber.

? How could the nervous system cause a skeletal muscle to produce the most forceful contraction it is capable of?

The force (tension) developed by a muscle progressively increases as more and more of the motor neurons controlling the muscle are activated, a process called *recruitment* of motor neurons. Depending on the number of motor neurons your brain recruits and the size of their motor units, you can lift a fork or something much heavier, like your biology textbook. Some muscles, especially those that hold up the body and maintain posture, are almost always partially contracted. In such muscles, the nervous system may alternate which motor units are activated, reducing the length of time any one set of fibers is contracted.

The nervous system regulates muscle contraction not only by controlling which motor units are activated, but also by varying the rate of muscle fiber stimulation. A single action potential produces a twitch lasting about 100 msec or less. If a second action potential arrives before the muscle fiber has completely relaxed, the two twitches add together, resulting in greater tension (**Figure 39.8**). Further summation occurs as the rate of stimulation increases. When the rate is so high that the muscle fiber cannot relax at all between stimuli, the twitches fuse into one smooth, sustained contraction called **tetanus**. (Although this smooth, sustained contraction is part of normal muscle function, tetanus is also the name of a disease of uncontrolled muscle contraction caused by a bacterial toxin.)

### Types of Skeletal Muscle Fibers

Our discussion to this point has focused on the general properties of vertebrate skeletal muscles. There are, however, several distinct types of skeletal muscle fibers, each of which is adapted to a particular set of functions. Scientists typically classify these varied fiber types both by the source of ATP used to power their activity and by the speed of their contraction (**Table 39.1**).

**Table 39.1** Types of Skeletal Muscle Fibers

	Slow Oxidative	Fast Oxidative	Fast Glycolytic
Contraction speed	Slow	Fast	Fast
Major ATP source	Aerobic respiration	Aerobic respiration	Glycolysis
Rate of fatigue	Slow	Intermediate	Fast
Mitochondria	Many	Many	Few
Myoglobin content	High (red muscle)	High (red muscle)	Low (white muscle)

**Oxidative and Glycolytic Fibers** Fibers that rely mostly on aerobic respiration are called oxidative fibers. Such fibers are specialized in ways that enable them to make use of a steady energy supply: They have many mitochondria, a rich blood supply, and a large amount of an oxygen-storing protein called **myoglobin**. A brownish red pigment, myoglobin binds oxygen more tightly than does hemoglobin, enabling oxidative fibers to extract oxygen from the blood efficiently. In contrast, glycolytic fibers have a larger diameter and less myoglobin. Also, glycolytic fibers use glycolysis as their primary source of ATP and fatigue more readily than oxidative fibers. These different fiber types are readily apparent in the muscle of poultry and fish: The dark meat is made up of oxidative fibers rich in myoglobin, and the light meat is composed of glycolytic fibers.

**Fast-Twitch and Slow-Twitch Fibers** Muscle fibers vary in the speed with which they contract: **Fast-twitch fibers** develop tension two to three times faster than **slow-twitch fibers**. Fast fibers enable brief, rapid, powerful contractions. Slow fibers, often found in muscles that maintain posture, can sustain long contractions. A slow fiber has less sarcoplasmic reticulum and pumps  $\text{Ca}^{2+}$  more slowly than a fast fiber. Because  $\text{Ca}^{2+}$  remains in the cytosol longer, a muscle twitch in a slow fiber lasts about five times as long as one in a fast fiber.

The difference in contraction speed between slow-twitch and fast-twitch fibers mainly reflects the rate at which their myosin heads hydrolyze ATP. However, there isn't a one-to-one relationship between contraction speed and ATP source. Whereas all slow-twitch fibers are oxidative, fast-twitch fibers can be either glycolytic or oxidative (see Table 39.1).

Most human skeletal muscles contain both fast- and slow-twitch fibers, although the muscles of the eye and hand are exclusively fast-twitch. In a muscle that has a mixture of fast and slow fibers, the relative proportions of each are genetically determined. However, if such a muscle is used repeatedly for activities requiring high endurance, some fast glycolytic fibers can develop into fast oxidative fibers. Because fast oxidative fibers fatigue more slowly than fast glycolytic fibers, the result will be a muscle that is more resistant to fatigue.

▲ **Figure 39.9 Specialization of skeletal muscle.** The male toadfish (*Opsanus tau*) uses superfast muscles surrounding its swim bladder to produce its mating call.

The skeletal muscles of some vertebrates twitch at rates far faster than any human muscle. For example, superfast muscles produce a dove's coo and a rattlesnake's rattle. The fastest such muscles, however, surround the gas-filled swim bladder of the male toadfish (**Figure 39.9**). In producing its characteristic "boat whistle" mating call, the toadfish can contract and relax these muscles more than 200 times per second.

## Other Types of Muscle

Although all muscles share the same fundamental mechanism of contraction—actin and myosin filaments sliding past each other—animals have more than one type of muscle. Vertebrates, for example, have cardiac muscle and smooth muscle in addition to skeletal muscle.

Vertebrate **cardiac muscle** is found in only one part of the body: the heart. Like skeletal muscle, cardiac muscle is striated. Whereas skeletal muscle fibers do not produce action potentials unless stimulated by a motor neuron, cardiac muscle cells have ion channels in their plasma membrane that cause rhythmic depolarizations, triggering action potentials without input from the nervous system. Action potentials of cardiac muscle cells last up to 20 times longer than those of skeletal muscle fibers.

Plasma membranes of adjacent cardiac muscle cells interlock at specialized regions called **intercalated disks**, where gap junctions provide direct electrical coupling between the cells (see Figure 4.27). Thus, the action potential generated by specialized cells in one part of the heart spreads to all other cardiac muscle cells, causing the whole heart to contract. A long refractory period prevents summation and tetanus.

**Smooth muscle** in vertebrates is found mainly in the walls of hollow organs, such as blood vessels and organs of the digestive tract. Smooth muscle cells lack striations because their filaments are not regularly arrayed. Instead, the thick

filaments are scattered throughout the cytoplasm, and the thin filaments are attached to structures called dense bodies, some of which are tethered to the plasma membrane. Some smooth muscle cells contract only when stimulated by neurons of the autonomic nervous system. Others are electrically coupled to one another and can generate action potentials without input from neurons. Smooth muscles contract and relax more slowly than striated muscles.

Although  $\text{Ca}^{2+}$  regulates smooth muscle contraction, the mechanism for regulation is different from that in skeletal and cardiac muscle. Smooth muscle cells have no troponin complex or T tubules, and their sarcoplasmic reticulum is not well developed. During an action potential,  $\text{Ca}^{2+}$  enters the cytosol mainly through the plasma membrane. Calcium ions cause contraction by binding to the protein calmodulin, which activates an enzyme that phosphorylates the myosin head, enabling cross-bridge activity.

Invertebrates have muscle cells similar to vertebrate skeletal and smooth muscle cells, and arthropod skeletal muscles are nearly identical to those of vertebrates. However, because the flight muscles of insects are capable of independent, rhythmic contraction, the wings of some insects can actually beat faster than action potentials can arrive from the central nervous system. Another interesting evolutionary adaptation has been discovered in the muscles that hold a clam's shell closed. The thick filaments in these muscles contain a protein called paramyosin that enables the muscles to remain contracted for as long as a month with only a low rate of energy consumption.

### CONCEPT CHECK 39.1

1. Contrast the role of  $\text{Ca}^{2+}$  in the contraction of a skeletal muscle fiber and a smooth muscle cell.
2. **WHAT IF?** Why are the muscles of an animal that has recently died likely to be stiff?
3. **MAKE CONNECTIONS** How does the activity of tropomyosin and troponin in muscle contraction compare with the activity of a competitive inhibitor in enzyme action? (See Figure 6.17.)

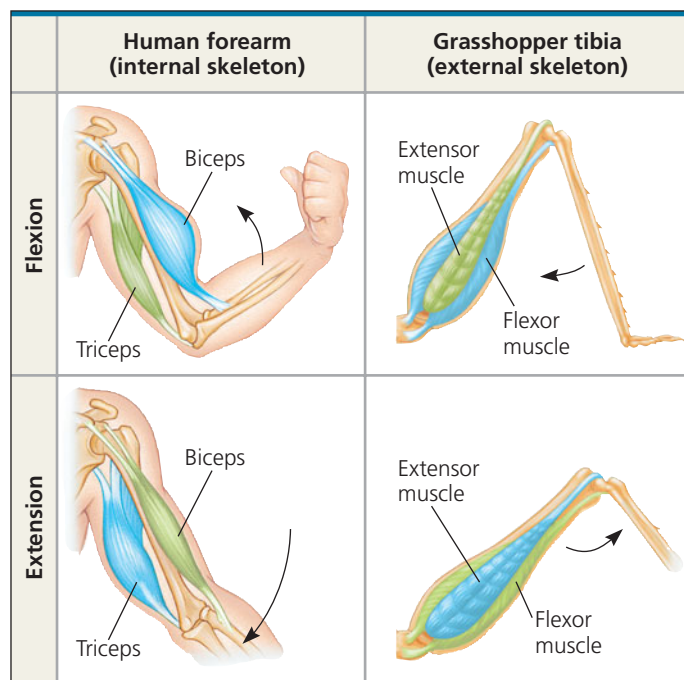

For suggested answers, see Appendix A.

## CONCEPT 39.2

### Skeletal systems transform muscle contraction into locomotion

Converting muscle contraction to movement requires a skeleton—a rigid structure to which muscles can attach. An animal changes its shape or location by contracting muscles that connect two parts of its skeleton.

Because muscles exert force only during contraction, moving a body part back and forth typically requires two muscles attached to the same section of the skeleton. We can see such an arrangement of muscles in the upper portion of a human arm or grasshopper leg (**Figure 39.10**). Although we call such

**▲ Figure 39.10 The interaction of muscles and skeletons in movement.** Back-and-forth movement of a body part is generally accomplished by antagonistic muscles. This arrangement works with either an internal skeleton, as in mammals, or an external skeleton, as in insects.

muscles an antagonistic pair, their function is actually cooperative, coordinated by the nervous system. For example, when you extend your arm, motor neurons trigger your triceps muscle to contract while the absence of neuronal input allows your biceps to relax.

Vital for movement, the skeletons of animals also function in support and protection. Most land animals would collapse if they had no skeleton to support their mass. Even an aquatic animal would be formless without a framework to maintain its shape. In many animals, a hard skeleton also protects soft tissues. For example, the vertebrate skull protects the brain, and the ribs of terrestrial vertebrates form a cage around the heart, lungs, and other internal organs.

### Types of Skeletal Systems

Although we tend to think of skeletons only as interconnected sets of bones, skeletons come in many different forms. Hardened support structures can be external (as in exoskeletons), internal (as in endoskeletons), or even absent (as in fluid-based, or hydrostatic, skeletons).

#### Hydrostatic Skeletons

A **hydrostatic skeleton** consists of fluid held under pressure in a closed body compartment. This is the main type of skeleton in most cnidarians, flatworms, nematodes (roundworms), and annelids (segmented worms). These animals control their form and movement by using muscles to change the shape

of fluid-filled compartments. For example, a hydra (a cnidarian) elongates its body by closing its mouth and constricting its central gastrovascular cavity. Because water cannot be compressed very much, decreasing the diameter of the cavity forces the cavity to become longer.

Worms use hydrostatic skeletons in diverse ways to move through their environment. In planarians and other flatworms, muscles in the body wall exert localized forces against the interstitial fluid. In nematodes, longitudinal muscles contracting around the fluid-filled body cavity move the animal forward by wavelike motions called undulations. In earthworms and many other annelids, circular and longitudinal muscles act together to change the shape of individual fluid-filled segments, which are divided by septa. These shape changes bring about **peristalsis**, a movement produced by rhythmic waves of muscle contractions passing from front to back (**Figure 39.11**).

▲ **Figure 39.11 Crawling by peristalsis.** Contraction of the longitudinal muscles thickens and shortens the earthworm; contraction of the circular muscles constricts and elongates it.

Hydrostatic skeletons are well suited for life in aquatic environments. On land, they provide support for crawling and burrowing and may cushion internal organs. However, a hydrostatic skeleton cannot support walking or running, in which an animal's body is held off the ground.

## Exoskeletons

The clamshell you find on a beach once served as an **exoskeleton**, a hard encasement deposited on an animal's surface. The shells of clams and most other molluscs are made of calcium carbonate secreted by the mantle, a sheetlike extension of the body wall. Clams and other bivalves close their hinged shell using muscles attached to the inside of this exoskeleton. As the animal grows, it enlarges its shell by adding to the outer edge.

Insects and other arthropods have a jointed **cuticle**, a coat secreted by the epidermis. About 30–50% of the cuticle consists of **chitin**, a polysaccharide similar to cellulose. Fibrils of chitin are embedded in a protein matrix, forming a composite material that is strong and flexible. Except in body parts that must be flexible, such as leg joints, the cuticle may be hardened by cross-linking the matrix proteins. Muscles attach to knobs and plates of the cuticle that extend into the interior of the body. With each growth spurt, an arthropod must shed its exoskeleton (molt) and produce a larger one.

## Endoskeletons

Animals ranging from sponges to mammals have a hardened internal skeleton, or **endoskeleton**, buried within their soft tissues. In sponges, the endoskeleton often consists of hard needlelike structures of inorganic material (see Figure 27.3). Echinoderms' bodies are reinforced by ossicles, hard plates composed of magnesium carbonate and calcium carbonate crystals. While the ossicles of sea urchins are tightly bound, those of sea stars are more loosely linked, allowing a sea star to change the shape of its arms.

Chordates have an endoskeleton consisting of cartilage, bone, or some combination of these materials. The human skeleton is built from more than 200 bones (**Figure 39.12**). Some are fused together; others are connected at joints by ligaments that allow freedom of movement in a manner determined by the joint architecture (**Figure 39.13**).

## Size and Scale of Skeletons

An exoskeleton needs to cover and protect an animal's body, but what determines how thick an endoskeleton must be? Consider a mouse. Its weight is proportional to its volume, a *cubic* measurement (roughly height times width times length). However, the strength of a bone, such as that in the mouse's leg, is proportional to cross-sectional area (and thus the *square* of the radius). We can predict that if we scaled up a mouse to the size of an elephant, the legs of the giant mouse would be too thin to support its weight. Indeed, large animals do have very different body proportions from those of small animals.

▲ **Figure 39.12** Bones and joints of the human skeleton.

Based on physical principles, we might also predict that the size of an animal's leg bones should be directly proportional to the strain imposed by its body weight. However, it turns out that body posture—the position of the legs relative to the main body—is more important than leg size, at least in mammals and birds. Muscles and tendons (connective tissue that joins muscle to bone) hold the legs of large mammals relatively straight and positioned under the body and actually bear most of the load.

## Types of Locomotion

For most animals, activities such as obtaining food, avoiding danger, and finding a mate involve **locomotion**—active travel from place to place. To move, an animal must expend energy

▼ **Figure 39.13** Types of joints.

### Ball-and-socket joint

Ball-and-socket joints are found where the humerus contacts the shoulder girdle and where the femur contacts the pelvic girdle. These joints enable the arms and legs to rotate and move in several planes.

### Hinge joint

Hinge joints, such as between the humerus and the head of the ulna, restrict movement to a single plane.

### Pivot joint

Pivot joints enable rotating the forearm at the elbow and turning the head from side to side.

to overcome two forces: friction and gravity. As you will see next, the amount of energy required to oppose friction or gravity is often reduced by an animal body plan adapted for movement in a particular environment.

## Flying

Active flight (in contrast to gliding downward from a tree) has evolved in only a few animal groups: insects, reptiles (including birds), and, among the mammals, bats. One group of flying reptiles, the pterosaurs, died out millions of years ago, leaving birds and bats as the only flying vertebrates.

Gravity poses a major problem for a flying animal because its wings must develop enough lift to overcome gravity's downward force. The key to flight is wing shape. All wings are airfoils—structures whose shape alters air currents in a way that helps animals or airplanes stay aloft. As for the body to which the wings attach, a sleek, fusiform (torpedo-like) shape helps reduce drag.

Flying animals are relatively light, with body masses ranging from less than a gram for some insects to about 20 kg for the largest flying birds. Many flying animals have structural adaptations that contribute to low body mass. Birds, for example, have no urinary bladder or teeth and have relatively large bones with air-filled regions that help lessen the bird's mass.

### Locomotion on Land

On land, an animal must be able to support itself and move against gravity, but air poses relatively little resistance, at least at moderate speeds. When an animal walks, runs, or hops, its leg muscles expend energy both to propel it and to keep it from falling down. With each step, the leg muscles must overcome inertia by accelerating a leg from a standing start. Thus, on land, powerful muscles and strong skeletal support are more important than a streamlined shape.

Diverse adaptations for traveling on land have evolved in various vertebrates. For example, kangaroos have large, powerful muscles in their hind legs, suitable for hopping (**Figure 39.14**). As a kangaroo lands after each leap, tendons in its hind legs momentarily store energy. The farther the animal hops, the more energy its tendons store. Like the energy in a compressed spring, the energy stored in the tendons is available for the next jump, reducing the total amount of energy the animal must expend to travel. Human legs also retain some energy during walking or

▲ **Figure 39.14 Energy-efficient locomotion on land.** Members of the kangaroo family travel from place to place mainly by leaping on their large hind legs. Kinetic energy momentarily stored in tendons after each leap provides a boost for the next leap. In fact, a large kangaroo hopping at 30 km/hr uses no more energy per minute than it does at 6 km/hr. The large tail helps balance the kangaroo when it leaps as well as when it sits.

running, although a considerably smaller share than the legs of a kangaroo.

Balance is another prerequisite for walking, running, or hopping. A kangaroo's large tail helps balance its body during leaps and forms a stable tripod with its hind legs when it moves slowly. Similarly, a cat, dog, or horse keeps three feet on the ground when walking. Bipedal animals, such as humans and birds, keep part of at least one foot on the ground when walking. At running speeds, momentum more than foot contact keeps the body upright, enabling all the feet to be off the ground briefly.

Crawling poses a very different situation. Because much of its body is in contact with the ground, a crawling animal must exert considerable effort to overcome friction. You have read how earthworms crawl by peristalsis. Many snakes crawl by undulating their entire body from side to side. Assisted by large, movable scales on its underside, a snake's body pushes against the ground, propelling the animal forward. In contrast, boa constrictors and pythons creep straight forward, driven by muscles that lift belly scales off the ground, tilt the scales forward, and then push them backward against the ground.

### Swimming

Because most animals are reasonably buoyant in water, overcoming gravity is less of a problem for swimming than for movement on land or through the air. However, water is a much denser and more viscous medium than air, and thus drag (friction) is a major problem for aquatic animals. A fusiform (torpedo-like) shape is a common adaptation of fast swimmers, such as tuna.

Although most animal phyla include species that swim, swimming occurs in diverse ways. For instance, many insects and four-legged vertebrates use their legs as oars to push against the water. Squids, scallops, and some cnidarians are jet-propelled, taking in water and squirting it out in bursts. Sharks and bony fishes swim by moving their body and tail from side to side, while whales and dolphins move by undulating their body and tail up and down.

All these forms of locomotion place different energetic demands on animals. In the **Scientific Skills Exercise**, you can interpret a graph that compares the relative energy costs of flying, running, and swimming.

#### CONCEPT CHECK 39.2

1. In what way are septa an important feature of the earthworm skeleton?
2. Contrast swimming and flying in terms of the main problems they pose and the adaptations that allow animals to overcome those problems.
3. **WHAT IF?** When using your arms to lower yourself into a chair, you bend your arms without using your biceps. Explain how this is possible. (*Hint:* Think about gravity as an antagonistic force.)

For suggested answers, see Appendix A.

## Interpreting a Graph with Log Scales

**What Are the Energy Costs of Locomotion?** In the 1960s, animal physiologist Knut Schmidt-Nielsen, at Duke University, wondered whether general principles govern the energy costs of different forms of locomotion among diverse animal species. To answer this question, he drew on his own experiments as well as those of other researchers. In this exercise, you will analyze the combined results of these studies and evaluate the rationale for plotting the experimental data on a graph with logarithmic scales.

**How the Experiments Were Done** Researchers measured the rate of oxygen consumption or carbon dioxide production in animals that ran on treadmills, flew in wind tunnels, or swam in water flumes. From these measurements, Schmidt-Nielsen calculated the amount of energy each animal used to transport a given amount of body mass over a given distance (in calories per kilogram per meter).

**Data from the Experiments** Schmidt-Nielsen plotted the cost of running, flying, and swimming versus body mass on a single graph with logarithmic (log) scales for the axes. He then drew a best-fit straight line through the data points for each form of locomotion. (On the graph below, only the best-fit lines are shown.)

### Interpret the Data

- The body masses of the animals used in these experiments ranged from about 0.001 g to 1,000,000 g, and their rates of energy use ranged from about 0.1 cal/kg·m to 100 cal/kg·m. If you were to plot these data on a graph with linear instead of log scales for the axes, how would you draw the axes so that all of the data would be visible? What is the advantage of using log scales for plotting data with a wide range of values? (For additional information about graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
- Based on the graph, how much greater is the energy cost of flying for an animal that weighs 10<sup>-3</sup> g than for an animal that weighs 1 g? For any given form of locomotion, which travels more efficiently, a larger animal or a smaller animal?
- The slopes of the flying and swimming lines are very similar. Based on your answer to question 2, if the energy cost of a 2-g swimming animal is 1.2 cal/kg·m, what is the estimated energy cost of a 2-kg swimming animal?
- Considering animals with a body mass of about 100 g, rank the three forms of locomotion from highest energy cost to lowest energy cost. Were these the results you expected, based on your own experience? What could explain the energy cost of running compared with that of flying or swimming?
- Schmidt-Nielsen calculated the swimming cost for a mallard duck and found that it was nearly 20 times as high as the swimming cost for a salmon of the same body mass. What could explain the greater swimming efficiency of salmon?

**Data from** K. Schmidt-Nielsen, Locomotion: Energy cost of swimming, flying, and running, *Science* 177:222–228 (1972).

A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

## CONCEPT 39.3

### Discrete sensory inputs can stimulate both simple and complex behaviors

So far we have been discussing the mechanics of animal behaviors—how the animal body produces the movements that make up a particular behavior. In the rest of the chapter, we'll take a broader look at the function of animal behaviors as well as their evolution.

What approach do biologists use to determine how behaviors arise and what functions they serve? The Dutch scientist Niko Tinbergen, a pioneer in the study of animal behavior, suggested that understanding any behavior requires answering four questions, which can be summarized as follows:

- What stimulus elicits the behavior, and what physiological mechanisms mediate the response?

- How does the animal's experience during growth and development influence the response?
- How does the behavior aid survival and reproduction?
- What is the behavior's evolutionary history?

Tinbergen's first two questions ask about *proximate causation*: “how” a behavior occurs or is modified. The last two questions ask about *ultimate causation*: “why” a behavior occurs in the context of natural selection.

The idea of ultimate causation is central to **behavioral ecology**, the study of the ecological and evolutionary basis for animal behavior. As we explore this vibrant area of modern biological research, we'll also review studies on proximate causation by Tinbergen and two other early researchers—Karl von Frisch and Konrad Lorenz—that earned the three scientists a Nobel Prize in 1973.

In addressing Tinbergen's first question, the nature of the stimuli that trigger behavior, we'll begin with behavioral responses to well-defined stimuli, starting with an example from Tinbergen's own experiments.

## Fixed Action Patterns

As part of his research, Tinbergen kept fish tanks containing three-spined sticklebacks (*Gasterosteus aculeatus*). Male sticklebacks, which have red bellies, attack other males that invade their nesting territories. Tinbergen noticed that his male sticklebacks also behaved aggressively when a red truck passed within view of their tank. Inspired by this chance observation, he carried out experiments showing that the red color of an intruder's underside is what provokes the attack behavior. A male stickleback will not attack a fish lacking red coloration (note that female sticklebacks never have red bellies), but will attack even unrealistic models if they contain areas of red color (**Figure 39.15**).

The territorial response of male sticklebacks is an example of a **fixed action pattern**, a sequence of unlearned acts directly linked to a simple stimulus. Fixed action patterns are essentially unchangeable and, once initiated, usually carried to completion. The trigger for the behavior is an external cue called a **sign stimulus**, such as a red object prompting the male stickleback's aggressive behavior.

(a) A male stickleback fish attacks other male sticklebacks that invade its nesting territory. The red belly of the intruding male (left) acts as the sign stimulus that releases the aggressive behavior.

(b) The realistic model at the top, without a red underside, produces no aggressive response in a male three-spined stickleback. The other models, with red undersides, produce strong responses.

▲ **Figure 39.15 Sign stimuli in a classic fixed action pattern.**

? Suggest an explanation for why this behavior evolved (its ultimate causation).

## Migration

Environmental stimuli not only trigger behaviors but also provide cues that animals use to carry out those behaviors. For example, a wide variety of birds, fishes, and other animals use environmental cues to guide **migration**—a regular, long-distance change in location. In the course of migration, many animals pass through environments they have not previously encountered. How, then, do they find their way in these foreign settings?

Some migrating animals track their position relative to the sun, even though the sun's position relative to Earth changes throughout the day. Animals can adjust for these changes by means of a *circadian clock*, an internal mechanism that maintains a 24-hour activity rhythm or cycle. For example, experiments have shown that migrating birds orient differently relative to the sun at distinct times of the day.

Although the sun as well as stars can provide clues for navigation, these landmarks can be obscured by clouds. How do migrating animals overcome this problem? A simple experiment with homing pigeons provides one answer. On an overcast day, placing a small magnet on the head of a homing pigeon prevents it from returning efficiently to its roost. Researchers concluded that pigeons sense their position relative to Earth's magnetic field and can thereby navigate without solar or celestial cues.

## Behavioral Rhythms

Although the circadian clock plays a small but significant role in navigation by some migrating species, it has a major role in the daily activity of all animals. The clock is responsible for a circadian rhythm, a daily cycle of rest and activity (see Concept 38.2). The clock is normally synchronized with the light and dark cycles of the environment but can maintain rhythmic activity even under constant environmental conditions, such as during hibernation.

Some behaviors, such as migration and reproduction, reflect biological rhythms with a longer cycle, or period, than the circadian rhythm. Behavioral rhythms linked to the yearly cycle of seasons are called *circannual rhythms*. Although migration and reproduction typically correlate with food availability, these behaviors are not a direct response to changes in food intake. Instead, circannual rhythms, like circadian rhythms, are influenced by the periods of daylight and darkness in the environment. For example, studies with several bird species have shown that an artificial environment with extended daylight can induce out-of-season migratory behavior.

Not all biological rhythms are linked to the light and dark cycles in the environment. Consider, for instance, the fiddler crab shown in Figure 39.1. The male's claw-waving courtship behavior is linked not to day length but to the timing of the new and full moon. Why? Fiddler crabs begin their lives as plankton, settling in the mudflats after several larval stages. By courting at the time of the new or full moon, crabs link their

reproduction to the times of greatest tidal movement. The tides disperse larvae to deeper waters, where they complete early development in relative safety.

## Animal Signals and Communication

Claw waving by fiddler crabs during courtship is an example of one animal (the male crab) generating the stimulus that guides the behavior of another animal (the female crab). A stimulus transmitted from one animal to another is called a **signal**. Signal transmission and reception constitute animal **communication**, an essential element of interactions between individuals.

### Forms of Animal Communication

Let's consider the courtship behavior of the fruit fly, *Drosophila melanogaster*, as an introduction to the four common modes of animal communication: visual, chemical, tactile, and auditory.

Fruit fly courtship constitutes an example of a *stimulus-response chain*, in which the response to each stimulus is itself the stimulus for the next behavior. In the first step, a male sees a female of the same species and orients his body toward hers. He also uses his olfactory system to detect chemicals released into the air by the female. The male then approaches and touches the female with a foreleg. This touching, or tactile communication, alerts the female to the male's presence. In the third stage of courtship, the male extends and vibrates his wing, producing a specific courtship song. This auditory communication informs the female whether the male is of the same species. Only if all of these forms of communication are successful will the female allow the male to attempt copulation.

The information content of animal communication varies considerably. One of the most remarkable examples is the symbolic language of the European honeybee (*Apis mellifera*), discovered in the early 1900s by Austrian researcher Karl von Frisch. Using glass-walled observation hives, he and his students spent several decades observing honeybees. Methodical recordings of bee movements enabled von Frisch to decipher a "dance language" that returning foragers use to inform other bees about the distance and direction of travel to food sources (**Figure 39.16**). When the other bees then exit the hive, they fly almost directly to the area indicated by the returning foragers.

(a) Worker bees cluster around a bee that recently returned from a foraging trip.

(b) The round dance indicates that food is near.

(c) The waggle dance, performed when food is distant, resembles a figure eight (below). Distance is indicated by the number of abdominal waggles performed in the straight-run part of the dance. Direction is indicated by the angle (in relation to the vertical surface of the hive) of the straight run.

Location **A**: Food source is in same direction as sun.

Location **B**: Food source is in direction opposite sun.

Location **C**: Food source is 30° to right of sun.

**▲ Figure 39.16 Honeybee dance language.** Honeybees returning to the hive communicate the location of food sources through the symbolic language of a dance.

### Pheromones

Animals that communicate through odors or tastes emit chemical substances called **pheromones**. Pheromones are especially common among mammals and insects and often relate to reproductive behavior. For example, pheromones are the basis for the chemical communication in fruit fly courtship. Pheromones are not limited to short-distance signaling, however. Male silk-worm moths have receptors that can detect the pheromone from a female moth from several kilometers away.

In a honeybee colony, pheromones produced by the queen and her daughters, the workers, maintain the hive's complex social order. One pheromone (once called the queen

substance) has a particularly wide range of effects. It attracts workers to the queen, inhibits development of ovaries in workers, and attracts males (drones) to the queen during her mating flights out of the hive.

Pheromones can also serve as alarm signals. For example, when a minnow is injured, a substance released from the fish's skin disperses in the water, causing nearby minnows to become more vigilant and seek safety near the lake bottom.

As we have seen, the forms of animal communication used to convey information are quite diverse. In general, the form of communication that evolves is closely related to an animal's lifestyle and environment. For example, most terrestrial mammals are nocturnal, which makes visual displays relatively ineffective. Instead, these species use olfactory and auditory signals, which work as well in the dark as in the light. In contrast, most birds are diurnal (active mainly in daytime) and communicate primarily by visual and auditory signals. Humans are also diurnal and, like birds, use primarily visual and auditory communication. We can thus appreciate the songs and bright colors used by birds to communicate but miss many chemical cues on which other mammals base their behavior.

So far in this chapter, we have explored the types of stimuli that elicit behaviors—the first part of Tinbergen's first question. The second part of that question—the physiological mechanisms that mediate responses—involve the nervous, muscular, and skeletal systems: Stimuli activate sensory receptors, triggering signals that are processed in the central nervous system and result in motor outputs that constitute behavior. Thus, we are ready to focus on Tinbergen's second question—how experience influences behavior.

CONCEPT CHECK 39.3

- 1. If an egg rolls out of the nest, a mother graylag goose will retrieve it by nudging it with her beak and head. If researchers remove the egg or substitute a ball during this process, the goose continues to bob her beak and head while she moves back to the nest. Explain how and why this behavior occurs.
- 2. **MAKE CONNECTIONS** How is the lunar-linked rhythm of fiddler crab courtship similar in mechanism and function to the seasonal timing of plant flowering? (See Concept 31.2.)

For suggested answers, see Appendix A.

CONCEPT 39.4

Learning establishes specific links between experience and behavior

For some behaviors—such as a fixed action pattern, a courtship stimulus-response chain, and pheromone signaling—nearly all individuals in a population behave the same. Behavior that is developmentally fixed in this way is known as **innate behavior**. Other behaviors, however, vary with experience and thus differ between individuals.

Experience and Behavior

Tinbergen's second question asks how an animal's experiences during growth and development influence the response to stimuli. One informative approach to this question is a **cross-fostering study**, in which the young of one species are placed in the care of adults from another species. The extent to which the offspring's behavior changes in such a situation provides a measure of how the social and physical environment influences behavior.

Certain mouse species have behaviors well suited for cross-fostering studies. For example, male California mice (*Peromyscus californicus*) are highly aggressive toward other mice and provide extensive parental care. In contrast, male white-footed mice (*Peromyscus leucopus*) are less aggressive and engage in little parental care. When the pups of each species were placed in the nests of the other species, the cross-fostering altered some behaviors of both species (**Table 39.2**). For instance, male California mice raised by white-footed mice were less aggressive toward intruders. Thus, experience during development can strongly influence aggressive behavior in these rodents.

One of the most important findings of the cross-fostering experiments with mice was that the influence of experience on behavior can be passed on to progeny: When the cross-fostered California mice became parents, they spent less time retrieving offspring who wandered off than did California mice raised by their own species. Thus, experience during development can modify physiology in a way that alters parental behavior, extending the influence of environment to a subsequent generation.

The influence of genetics and environment on human behavior can be explored by a **twin study**, in which researchers compare the behavior of identical twins raised apart with the behavior of those raised in the same household. Twin studies have been instrumental in studying human behavioral disorders, including schizophrenia, anxiety disorders, and alcoholism.

Learning

One powerful way that an animal's environment can influence its behavior is through **learning**, the modification of behavior based on specific experiences. The capacity for learning

Table 39.2 Influence of Cross-Fostering on Male Mice*			
Species	Aggression Toward an Intruder	Aggression in Neutral Situation	Paternal Behavior
California mice fostered by white-footed mice	Reduced	No difference	Reduced
White-footed mice fostered by California mice	No difference	Increased	No difference

\*Comparisons are with mice raised by parents of their own species.

depends on nervous system organization established during development following instructions encoded in the genome. Learning itself involves the formation of memories by specific changes in neuronal connectivity (see Concept 38.3). Therefore, the essential challenge for research into learning is not to decide between nature (genes) and nurture (environment), but rather to explore the contributions of *both* nature and nurture in shaping learning and, more generally, behavior.

### Imprinting

For some offspring, recognizing and being recognized by a parent is essential for survival. In the young, this learning often takes the form of **imprinting**, the establishment of a long-lasting behavioral response to a particular individual. Imprinting can take place only during a specific time in development, called the **sensitive period**. Among gulls, for instance, the sensitive period for a parent to bond with its young lasts one to two days. During the sensitive period, the young imprint on their parent and learn basic behaviors, while the parent learns to recognize its offspring. If bonding does not occur, the parent will not care for the offspring, leading to the death of the offspring and a decrease in the reproductive success of the parent.

How do the young know on whom—or what—to imprint? Experiments with many species of waterfowl indicate that young birds have no innate recognition of “mother.” Rather, they identify with the first object they encounter that has certain key characteristics. In the 1930s, the Austrian researcher Konrad Lorenz showed that the principal *imprinting stimulus* in greylag geese (*Anser anser*) is a nearby object that is moving away from the young. When incubator-hatched goslings spent their first few hours with Lorenz rather than with a goose, they imprinted on him and steadfastly followed him from then on (**Figure 39.17a**). Furthermore, they showed no recognition of their biological mother.

Imprinting has become an important component of efforts to save endangered species, such as the whooping crane (*Grus americana*). Scientists tried raising whooping cranes in captivity by using sandhill cranes (*Grus canadensis*) as foster parents. However, because the whooping cranes imprinted on their foster parents, none formed a *pair-bond* (strong attachment) with a whooping crane mate. To avoid such problems, captive breeding programs now isolate young cranes, exposing them to the sights and sounds of members of their own species.

Scientists have made further use of imprinting to teach cranes born in captivity to migrate along safe routes. Young whooping cranes are imprinted on humans in “crane suits” and then are allowed to follow these “parents” as they fly ultralight aircraft along selected migration routes (**Figure 39.17b**). Importantly, these cranes still pair-bond with other whooping cranes, indicating that the crane costumes have the features required to direct “normal” imprinting.

(a) These young greylag geese imprinted on ethologist Konrad Lorenz.

(b) A pilot wearing a crane suit and flying an ultralight plane acts as a surrogate parent to direct the migration of whooping cranes.

▲ **Figure 39.17 Imprinting.** Imprinting can be altered to (a) investigate animal behavior or (b) direct animal behavior.

? Suppose the geese following Lorenz were bred to each other. How might their imprinting on Lorenz affect their offspring? Explain.

### Spatial Learning and Cognitive Maps

Every natural environment has spatial variation, as in locations of nest sites, hazards, food, and prospective mates. Therefore, an organism’s fitness may be enhanced by the capacity for **spatial learning**, the establishment of a memory that reflects the environment’s spatial structure.

The idea of spatial learning intrigued Tinbergen while he was a graduate student in the Netherlands. At that time, he was studying the female digger wasp (*Philanthus triangulum*), which nests in small burrows dug into sand dunes. When a wasp leaves her nest to go hunting, she hides the entrance to the burrow from potential intruders by covering it with sand. When she returns, however, she flies directly to her hidden nest, despite the presence of hundreds of other burrows in the area. How does she accomplish this feat? Tinbergen hypothesized that a wasp locates her nest by learning its position relative to visible landmarks. To test his hypothesis, he carried out an experiment in the wasps' natural habitat (**Figure 39.18**). By manipulating objects around nest entrances, he demonstrated that digger wasps engage in spatial learning.

In some animals, spatial learning involves the formation of a **cognitive map**, a representation in the nervous system of the spatial relationships between objects in an animal's surroundings. One striking example is found in the Clark's nutcracker (*Nucifraga columbiana*), a relative of ravens, crows, and jays. In the fall, nutcrackers hide pine seeds for retrieval during the winter. By experimentally varying the distance between landmarks in the birds' environment, researchers discovered that birds used the halfway point between landmarks, rather than a fixed distance, to find their hidden food stores.

### Associative Learning

Learning often involves making associations between experiences. Consider, for example, a blue jay (*Cyanocitta cristata*) that ingests a brightly colored monarch butterfly (*Danaus plexippus*). Substances that the monarch accumulates from milkweed plants cause the blue jay to vomit almost immediately (**Figure 39.19**). Following such experiences, blue jays avoid attacking monarchs and similar-looking butterflies. The ability to associate one environmental feature (such as a color) with another (such as a foul taste) is called **associative learning**.

Studies reveal that animals can learn to link many pairs of features of their environment, but not all. For example, pigeons can learn to associate danger with a sound but not with a color. However, they can learn to associate a color with food. What does this mean? The development and organization of the pigeon's nervous system apparently restrict the associations that can be formed. Moreover, such restrictions are not limited to birds. Rats, for example, can learn to avoid illness-inducing foods on the basis of smells, but not on the basis of sights or sounds.

If we consider how behavior evolves, the fact that some animals can't learn to make particular associations appears logical. The associations an animal can readily form typically reflect relationships likely to occur in nature. Conversely, associations that can't be formed are those unlikely to be of selective advantage in a native environment. In the case of a rat's diet in the wild, for example, a harmful food is far more likely to have a certain odor than to be associated with a particular sound.

### ▼ Figure 39.18 Inquiry

#### Does a digger wasp use landmarks to find her nest?

**Experiment** A female digger wasp covers the entrance to her underground nest while foraging long distances for food, but she can return later to the exact location and uncover her hidden nest. Niko Tinbergen hypothesized that the female, before flying off, learns visual landmarks that mark her nest location. To test this hypothesis, he first marked one nest with a ring of pinecones while the wasp was in the nest. After leaving the nest to forage, the wasp returned to the nest successfully.

Two days later, after the wasp had again left, Tinbergen shifted the ring of pinecones away from the nest. Then he waited to observe the wasp's behavior.

**Results** When the wasp returned, she flew to the center of the pinecone circle instead of to the nearby nest. Repeating the experiment with many wasps, Tinbergen obtained the same results.

© 1998 Pearson Education, Inc.

**Conclusion** The experiment supported the hypothesis that digger wasps use visual landmarks to keep track of their nests.

**Source** N. Tinbergen, *The Study of Instinct*, Clarendon Press, Oxford (1951).

**WHAT IF?** Suppose the digger wasp had returned to her original nest site, despite the pinecones having been moved. What alternative hypotheses might you propose regarding how the wasp finds her nest and why the pinecones didn't misdirect the wasp?

### Cognition and Problem Solving

The most complex forms of learning involve **cognition**—the process of knowing that involves awareness, reasoning, recollection, and judgment. Many animals, including insects, appear to exhibit cognition in controlled laboratory studies. For

## CONCEPT 39.5

### Selection for individual survival and reproductive success can explain most behaviors

We turn now to Tinbergen's third question—how behavior enhances survival and reproduction in a population. We'll begin by examining an activity essential for success in both endeavors: gathering food. Food-obtaining behavior, or **foraging**, includes not only eating but also any activities an animal uses to search for, recognize, and capture food items.

#### Evolution of Foraging Behavior

**EVOLUTION** The fruit fly allows us to examine one way foraging behavior might have evolved. Variation in a gene called *forager* (*for*) dictates how far *Drosophila* larvae travel when foraging. On average, larvae carrying the *for<sup>R</sup>* ("Rover") allele travel nearly twice as far while foraging as larvae with the *for<sup>s</sup>* ("sitter") allele.

Both the *for<sup>R</sup>* and *for<sup>s</sup>* alleles are present in natural populations. What circumstances might favor one or the other allele? The answer became apparent in experiments that maintained flies at either low or high population densities for many generations. Larvae in populations kept at a low density foraged over shorter distances than those in populations kept at high density (**Figure 39.20**). Furthermore, the *for<sup>s</sup>* allele increased in frequency in the low-density populations, whereas the *for<sup>R</sup>* allele increased in frequency in the high-density group. These changes make sense. At a low population density, short-distance foraging yields sufficient food, while long-distance foraging would result in unnecessary energy expenditure. Under crowded conditions, long-distance foraging could

**▲ Figure 39.20 Evolution of foraging behavior by laboratory populations of *Drosophila melanogaster*.** After 74 generations of living at low population density, *D. melanogaster* larvae (populations R1–R3) followed foraging paths significantly shorter than those of *D. melanogaster* larvae that had lived at high density (populations K1–K3).

**▲ Figure 39.19 Associative learning.** Having eaten and vomited a monarch butterfly, a blue jay has probably learned to avoid this species.

example, an experiment using Y-shaped mazes demonstrated that honeybees can distinguish between "same" and "different."

The information-processing ability of a nervous system can also be revealed in **problem solving**, the cognitive activity of devising a method to proceed from one state to another in the face of obstacles. For example, if a chimpanzee is placed in a room with several boxes on the floor and a banana hung high out of reach, the chimp can assess the situation and stack the boxes, enabling it to reach the food. Such problem-solving behavior is highly developed in some mammals, especially primates and dolphins. Notable examples have also been observed in some bird species. In one study, ravens were confronted with food hanging from a branch by a string. After failing to grab the food in flight, one raven flew to the branch and alternately pulled up and stepped on the string until the food was within reach. A number of other ravens eventually arrived at similar solutions. Nevertheless, some ravens failed to solve the problem, indicating that problem-solving success in this species, as in others, varies with individual experience and abilities.

Many animals learn to solve problems by observing the behavior of other individuals. Young wild chimpanzees, for example, learn how to crack open oil palm nuts with two stones by copying experienced chimpanzees. This type of learning through observing others is called **social learning**. Social learning forms the roots of **culture**, which can be defined as a system of information transfer through social learning or teaching that influences the behavior of individuals in a population. Cultural transfer of information can alter behavioral phenotypes and thereby influence the fitness of individuals.

#### CONCEPT CHECK 39.4

1. How might associative learning explain why different species of stinging insects have similar colors?
2. **WHAT IF?** How might you position and manipulate objects in a lab to test whether an animal can use a cognitive map to remember the location of food?
3. **MAKE CONNECTIONS** How could a learned behavior contribute to speciation? (See Concept 22.1.)

For suggested answers, see Appendix A.

enable larvae to move beyond areas depleted of food. Thus, an interpretable evolutionary change in behavior occurred in the course of the experiment.

## Mating Behavior and Mate Choice

Just as foraging is crucial for individual survival, mating behavior and mate choice play a major role in determining reproductive success. These behaviors include seeking or attracting mates, choosing among potential mates, competing for mates, and caring for offspring.

### Mating Systems and Sexual Dimorphism

Although we tend to think of mating simply as the union of a male and a female, species vary greatly with regard to *mating systems*, the length and number of relationships between males and females. In some species, there are no strong pair-bonds. In others, mates form a relationship of some duration that is **monogamous** (one male mating with one female) or **polygamous** (an individual of one sex mating with several of the other). Polygamous relationships involve either *polygyny*, a single male and multiple females, or *polyandry*, a single female and multiple males.

The extent to which males and females differ in appearance, a characteristic known as *sexual dimorphism*, typically varies with the type of mating system (**Figure 39.21**). Among monogamous species, males and females often look very similar. In contrast, among polygamous species, the sex that attracts multiple mating partners is typically showier and larger than the opposite sex. We'll discuss the evolutionary basis of these differences shortly.

### Mating Systems and Parental Care

The needs of the young are an important factor constraining the evolution of mating systems. Most newly hatched birds, for instance, cannot care for themselves. Rather, they require a large, continuous food supply, a need that is difficult for a single parent to meet. In such cases, a male that stays with and helps a single mate may ultimately have more viable offspring than if it went off to seek additional mates. This may explain why many birds are monogamous. In contrast, for birds with young that can feed and care for themselves almost immediately after hatching, the males derive less benefit from staying with their partner. Males of these species, such as pheasants and quail, can maximize their reproductive success by seeking other mates, and polygyny is relatively common in such birds. In the case of mammals, the lactating female is often the only food source for the young; males usually play no role in raising the young. In mammalian species where males protect the females and young, such as lions, a male or small group of males typically cares for a harem of many females.

Another factor influencing mating behavior and parental care is *certainty of paternity*. Young born to or eggs laid by a female definitely contain that female's genes. However, even

(a) In monogamous species, such as these western gulls, males and females are difficult to distinguish using external characteristics only.

(b) Among polygynous species, such as elk, the male (right) is often highly ornamented.

(c) In polyandrous species, such as these red-necked phalaropes, females (right) are generally more ornamented than males.

▲ **Figure 39.21** Relationship between mating system and male and female forms.

▲ **Figure 39.22 Paternal care by a male jawfish.** The male jawfish, which lives in tropical marine environments, holds the eggs it has fertilized in its mouth, keeping them aerated and protecting them from egg predators until the young hatch.

within a normally monogamous relationship, a male other than the female's usual mate may have fathered that female's offspring.

The certainty of paternity is relatively low in most species with internal fertilization because the acts of mating and birth (or mating and egg laying) are separated over time. This could explain why exclusively male parental care is rare in bird and mammal species. However, the males of many species with internal fertilization engage in behaviors that appear to increase their certainty of paternity. These behaviors include guarding females, removing any sperm from the female reproductive tract before copulation, and introducing large quantities of sperm that displace the sperm of other males.

Certainty of paternity is high when egg laying and mating occur together, as in external fertilization. This may explain why parental care in aquatic invertebrates, fishes, and amphibians, when it occurs at all, is at least as likely to be by males as by females (**Figure 39.22**). Among fishes and amphibians, parental care occurs in less than 10% of species with internal fertilization but in more than half of species with external fertilization.

It is important to note that certainty of paternity does not mean that animals are aware of those factors when they behave a certain way. Parental behavior correlated with certainty of paternity exists because it has been reinforced over generations by natural selection. Nevertheless, the relationship between certainty of paternity and male parental care remains an area of active research.

### Sexual Selection and Mate Choice

Sexual dimorphism results from sexual selection, a form of natural selection in which differences in reproductive success among individuals are a consequence of differences in mating success (see Chapter 21). Sexual selection can take the form of *intersexual selection*, in which members of one sex choose

▲ **Figure 39.23 Male stalk-eyed flies.** Male eye span plays a role in mate selection by females and, as shown here, in ritualized contests between males. In such contests, two males face off, with the male whose eye span is smaller very often retreating without any combat taking place.

mates on the basis of characteristics of the other sex, such as courtship songs, or *intrasexual selection*, which involves competition between members of one sex for mates.

Mate preferences of females may play a central role in the evolution of male behavior and anatomy through intersexual selection. Consider, for example, the courtship behavior of stalk-eyed flies. The eyes of these insects are at the tips of stalks, which are longer in males than in females (**Figure 39.23**). During courtship, a male approaches the female headfirst. Researchers have shown that females are more likely to mate with males that have relatively long eyestalks. Why would females favor this seemingly arbitrary trait? Ornaments such as long eyestalks in these flies or bright coloration in birds correlate in general with health and vitality (see Concept 21.4). A female whose mate choice is a healthy male is likely to produce more offspring that survive to reproduce.

Our consideration of stalk-eyed flies illustrates how female choice can select for one best type of male. This insect also shows how male competition for mates can reinforce the tendency for reduced variation among males. The length of the eyestalks of the male flies in **Figure 39.23** is an important factor in conflict between males. This competition takes the form of an *agonistic behavior*, an often-ritualized contest that determines which competitor gains access to a resource, such as a mate.

### CONCEPT CHECK 39.5

1. Why does the mode of fertilization correlate with the presence or absence of male parental care?
2. **MAKE CONNECTIONS** Balancing selection can maintain variation at a locus (see Concept 21.4). Based on the foraging experiments described in this chapter, devise a simple hypothesis to explain the presence of both *for<sup>R</sup>* and *for<sup>S</sup>* alleles in natural fly populations.

For suggested answers, see Appendix A.

## Inclusive fitness can account for the evolution of behavior, including altruism

**EVOLUTION** We now come to the focus of Tinbergen’s fourth question—the evolutionary history of behaviors. First we’ll look at the genetic control of a behavior. Next, we’ll examine the genetic variation underlying the evolution of particular behaviors. Finally, we’ll see how expanding the definition of fitness beyond individual survival can help explain “selfless” behavior.

### Genetic Basis of Behavior

Although variation in multiple genes can bring about distinct behaviors, variation in a single locus is sometimes sufficient to bring about dramatic differences in behavior. One striking example is the behavior of two closely related species of voles, which are small, mouse-like rodents. Male meadow voles (*Microtus pennsylvanicus*) are solitary and do not form lasting relationships with mates. Following mating, they pay little attention to their pups. In contrast, male prairie voles (*Microtus ochrogaster*) form a pair-bond with a single female after they mate (**Figure 39.24**). Male prairie voles hover over their young pups, licking them and carrying them, while acting aggressively toward intruders.

The peptide neurotransmitter vasopressin is critical for the partnering and parental behavior of male voles. Released during mating, vasopressin binds to a specific receptor in the

central nervous system. When male prairie voles are given a drug that inhibits the brain receptor for vasopressin, they fail to form pair-bonds after mating.

The vasopressin receptor gene is highly expressed in the brains of prairie voles but not meadow voles. Testing the hypothesis that vasopressin receptor levels in the brain regulate postmating behavior, researchers inserted the vasopressin receptor gene from prairie voles into meadow voles. The male meadow voles carrying this gene not only developed brains with higher levels of the vasopressin receptor, but also showed many of the same mating behaviors as male prairie voles, such as pair-bonding. Thus, although many genes influence pair-bonding and parenting among voles, a change in vasopressin receptor levels is sufficient to alter the development of these behaviors.

### Genetic Variation and the Evolution of Behavior

Behavioral differences between closely related species, such as meadow and prairie voles, are common. Significant differences in behavior can also be found *within* a species. When behavioral variation between populations of a species corresponds to variation in environmental conditions, it may be evidence of past evolution.

#### Case Study: Variation in Prey Selection

An example of genetically based behavioral variation within a species involves prey selection by the western garter snake (*Thamnophis elegans*). The natural diet of this species differs widely across its range in California. Coastal populations feed predominantly on banana slugs (*Ariolimax californicus*) (**Figure 39.25**). Inland populations feed on frogs, leeches, and fish, but not banana slugs. In fact, banana slugs are rare or absent in the inland habitats.

► **Figure 39.24** A pair of prairie voles (*Microtus ochrogaster*) huddling. Male North American prairie voles associate closely with their mates, as shown here, and contribute substantially to the care of young.

▲ **Figure 39.25** Western garter snake from a coastal habitat eating a banana slug. Experiments indicate that the preference of these snakes for banana slugs may be influenced mainly by genetics rather than by environment.

When researchers offered banana slugs to snakes from each wild population, most coastal snakes readily ate them, whereas inland snakes tended to refuse. To what extent does genetic variation contribute to a fondness for banana slugs? To answer this question, researchers collected pregnant snakes from each wild population and housed them in separate cages in the laboratory. While still very young, the offspring were offered a small piece of banana slug on each of ten days. More than 60% of the young snakes from coastal mothers ate banana slugs on eight or more of the ten days. In contrast, fewer than 20% of the young snakes from inland mothers ate a piece of banana slug even once. Banana slugs thus appear to be a genetically acquired taste.

How did a genetically determined difference in feeding preference come to match the snakes' habitats so well? It turns out that the coastal and inland populations also vary with respect to their ability to recognize and respond to odor molecules produced by banana slugs. Researchers hypothesize that when inland snakes colonized coastal habitats more than 10,000 years ago, some of them could recognize banana slugs by scent. Because these snakes took advantage of this food source, they had higher fitness than snakes in the population that ignored the slugs. Over hundreds or thousands of generations, the capacity to recognize the slugs as prey increased in frequency in the coastal population. The marked variation in behavior observed today between the coastal and inland populations may be evidence of this past evolutionary change.

## Altruism

We typically assume that behaviors are selfish; that is, they benefit the individual at the expense of others, especially competitors. For example, superior foraging ability by one individual may leave less food for others. The problem comes, however, with "unselfish" behaviors. How can such behaviors arise through natural selection? To answer this question, let's look more closely at some examples of unselfish behavior and consider how they might arise.

In discussing selflessness, we will use the term **altruism** to describe a behavior that reduces an animal's individual fitness but increases the fitness of other individuals in the population. Consider, for example, the Belding's ground squirrel, which lives in the western United States and is vulnerable to predators such as coyotes and hawks. A squirrel that sees a predator approach often gives a high-pitched alarm call that alerts unaware individuals to retreat to their burrows. Note that for the squirrel that warns others, the conspicuous alarm behavior increases the risk of being killed because it brings attention to the caller's location.

Altruism is also observed in naked mole rats (*Heterocephalus glaber*), highly social rodents that live underground in southern and northeastern Africa. The naked mole rat, which is almost hairless and nearly blind, lives in colonies of 75 or more individuals (**Figure 39.26**). Each colony has only one reproducing female, the queen, who mates with one to three males, called kings. The rest of the colony consists of

▲ **Figure 39.26** Naked mole rats, a species of colonial mammal that exhibits altruistic behavior. Pictured here is a queen nursing offspring while surrounded by other members of the colony.

nonreproductive females and males who at times sacrifice themselves to protect the queen or kings from snakes or other predators. How can such behavior be maintained by evolution if it does not enhance the survival and reproductive success of the self-sacrificing individuals?

## Inclusive Fitness

The selection for altruistic behavior is most readily apparent in the case of parents sacrificing for their offspring. When parents sacrifice their own well-being to produce and aid offspring, this actually increases the fitness of the parents because it maximizes their genetic representation in the population. However, individuals sometimes help others who are not their offspring.

Biologist William Hamilton proposed that an animal could increase its genetic representation in the next generation by helping close relatives other than its own offspring. Like parents and offspring, full siblings have half their genes in common. Therefore, selection might also favor helping siblings or helping one's parents produce more siblings. This idea led to Hamilton's idea of **inclusive fitness**, the total effect an individual has on proliferating its genes by producing its own offspring *and* by providing aid that enables other close relatives to produce offspring.

## Hamilton's Rule and Kin Selection

According to Hamilton, the three key variables in an act of altruism are the benefit to the recipient, the cost to the altruist, and the coefficient of relatedness. The benefit,  $B$ , is the average number of *extra* offspring that the recipient of an altruistic act produces. The cost,  $C$ , is how many *fewer* offspring the altruist produces. The **coefficient of relatedness**,  $r$ , equals the fraction of genes that, on average, are shared. Natural selection favors altruism when the benefit to the recipient multiplied by the coefficient of relatedness exceeds the cost to the altruist—in other words, when  $rB > C$ . This statement is called **Hamilton's rule**.

To better understand Hamilton's rule, let's apply it to a human population in which the average individual has two children. We'll imagine that a young man is close to drowning in

heavy surf, and his sister risks her life to swim out and pull her sibling to safety. If the young man had drowned, his reproductive output would have been zero; but now, if we use the average, he can father two children. The benefit to the man is thus two offspring ( $B = 2$ ). What cost is incurred by his sister? Let's say that she has a 25% chance of drowning in attempting the rescue. The cost of the altruistic act to the sister is then 0.25 times

2, the number of offspring she would be expected to have if she had stayed on shore ( $C = 0.25 \times 2 = 0.5$ ). Finally, we note that a brother and sister share half their genes on average ( $r = 0.5$ ). One way to see this is in terms of the segregation of homologous chromosomes that occurs during meiosis of gametes (**Figure 39.27**). Plugging in the values, we find that  $rB = 0.5 \times 2 = 1$ , whereas  $C = 0.5$ . Because  $rB$  is greater than  $C$ , Hamilton's rule is satisfied; thus, natural selection would favor this altruistic act.

Averaging over many individuals and generations, any particular gene in a sister faced with the situation described will be passed on to more offspring if she risks the rescue than if she does not. Among the genes propagated in this way may be some that contribute to altruistic behavior. Natural selection that thus favors altruism by enhancing the reproductive success of relatives is called **kin selection**.

Kin selection weakens with hereditary distance. Consequently, natural selection would not favor rescuing a cousin unless the surf were less treacherous. Along these lines, the geneticist J. B. S. Haldane joked that he would not lay down his life for one brother, but would do so for two brothers or eight cousins.

**▲ Figure 39.27 The coefficient of relatedness between siblings.** The red band indicates a particular allele (version of a gene) present on one chromosome, but not its homolog, in parent A. Sibling 1 has inherited the allele from parent A. There is a probability of  $\frac{1}{2}$  that sibling 2 will also inherit this allele from parent A. Any allele present on one chromosome of either parent will behave similarly. The coefficient of relatedness between the two siblings is thus  $\frac{1}{2}$ , or 0.5.

#### CONCEPT CHECK 39.6

1. Explain why geographic variation in garter snake prey choice might indicate that the behavior evolved by natural selection.
2. **WHAT IF?** The coefficient of relatedness of an individual to a full (nontwin) sibling or to either parent is the same: 0.5. Is this also true in the cases of polyandry and polygyny?
3. **WHAT IF?** Suppose you applied Hamilton's logic to a situation in which one individual is past reproductive age. Could there still be a selection for an altruistic act? Explain.

For suggested answers, see Appendix A.

## 39 Chapter Review

### SUMMARY OF KEY CONCEPTS

#### CONCEPT 39.1

**The physical interaction of protein filaments is required for muscle function (pp. 793–799)**

- The muscle cells (fibers) of vertebrate **skeletal muscle** contain **myofibrils** composed of **thin filaments** of (mostly) actin and **thick filaments** of myosin. These filaments are organized into repeating units called **sarcomeres**. Myosin heads, energized by the hydrolysis of ATP, bind to the thin filaments, forming cross-bridges, and then release upon binding ATP anew. As this cycle repeats, the thick and thin filaments slide past each other, contracting the muscle fiber.

- Motor neurons release acetylcholine, triggering action potentials in muscle fibers that stimulate  $\text{Ca}^{2+}$  release from the **sarcoplasmic reticulum**. When the  $\text{Ca}^{2+}$  binds the **troponin complex**, **tropomyosin** moves, exposing the myosin-binding sites on actin and thus initiating cross-bridge formation. A **motor unit** consists of a motor neuron and the muscle fibers it controls. A twitch results from a single action potential. Skeletal muscle fibers can be **slow-** or **fast-twitch** and oxidative or glycolytic.
- **Cardiac muscle**, found in the heart, consists of striated cells that are electrically connected by **intercalated disks** and that can generate action potentials without input from neurons. In **smooth muscles**, contractions may be initiated by the muscles themselves or by stimulation from neurons in the autonomic nervous system.

? Describe the differences between oxidative and glycolytic muscle fibers.

## CONCEPT 39.2

### Skeletal systems transform muscle contraction into locomotion (pp. 799–803)

- Skeletal muscles, often in antagonistic pairs, contract and pull against the skeleton. Skeletons may be **hydrostatic** and maintained by fluid pressure, as in worms; hardened into **exoskeletons**, as in insects; or internal **endoskeletons**, as in vertebrates.
- Each form of **locomotion**—swimming, movement on land, or flying—presents a particular challenge. For example, swimmers need to overcome friction but face less of a challenge from gravity than do animals that move on land or fly.

? Explain how microscopic and macroscopic anchoring of muscle filaments enables you to bend your elbow.

## CONCEPT 39.3

### Discrete sensory inputs can stimulate both simple and complex behaviors (pp. 803–806)

- **Behavior** is the sum of responses to external and internal stimuli. In behavioral studies, proximate, or “how,” questions focus on the stimuli that trigger a behavior and on genetic, physiological, and anatomical mechanisms underlying a behavioral act. Ultimate, or “why,” questions address evolutionary significance.
- A **fixed action pattern** is a largely invariant behavior triggered by a simple cue known as a **sign stimulus**. Migratory movements involve navigation, which can be based on orientation relative to the sun, the stars, or Earth’s magnetic field. Animal behavior is often synchronized to the circadian cycle of light and dark in the environment or to cues that cycle over the seasons.
- The transmission and reception of **signals** constitute animal **communication**. Animals use visual, auditory, chemical, and tactile signals. Chemical substances called **pheromones** transmit information between members of a species in behaviors ranging from foraging to courtship.

? How is migration based on circannual rhythms poorly suited for adaptation to global climate change?

## CONCEPT 39.4

### Learning establishes specific links between experience and behavior (pp. 806–809)

- **Cross-fostering studies** can be used to measure the influence of social environment and experience on behavior.

- **Learning**, the modification of behavior based on experience, can take many forms:

? Pigeons can learn to associate color with a food but not with danger. How might this observation be explained in terms of the selective forces acting during evolution?

## CONCEPT 39.5

### Selection for individual survival and reproductive success can explain most behaviors (pp. 809–811)

- Controlled experiments in the laboratory can give rise to interpretable evolutionary changes in behavior.
- Sexual dimorphism correlates with the type of mating relationship between males and females. These include **monogamous** and **polygamous** mating systems. Variations in mating system and mode of fertilization affect certainty of paternity, which has a significant influence on mating behavior and parental care.

? In some spider species, the female eats the male immediately after copulation. How might you explain this behavior from an evolutionary perspective?

## CONCEPT 39.6

### Inclusive fitness can account for the evolution of behavior, including altruism (pp. 812–814)

- Research on voles has revealed that variation in a single gene can determine differences in complex behaviors involved in both mating and parenting.
- When behavioral variation within a species corresponds to variation in environmental conditions, it may be evidence of past evolution.
- **Altruism** can be explained by the concept of **inclusive fitness**, the total effect an individual has on proliferating its genes by producing its own offspring *and* by providing aid that enables close

relatives to produce offspring. **Kin selection** favors altruistic behavior by enhancing the reproductive success of relatives.

**?** *If an animal were unable to distinguish close from distant relatives, would the concept of inclusive fitness still be applicable? Explain.*

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- During the contraction of a vertebrate skeletal muscle fiber, calcium ions
  - break cross-bridges by acting as a cofactor in the hydrolysis of ATP.
  - bind with troponin, changing its shape so that the myosin-binding sites on actin are exposed.
  - transmit action potentials from the motor neuron to the muscle fiber.
  - spread action potentials through the T tubules.
  - re-establish the polarization of the plasma membrane following an action potential.
- Which of the following is true of innate behaviors?
  - Their expression is only weakly influenced by genes.
  - They occur with or without environmental stimuli.
  - They are limited to invertebrate animals.
  - They are expressed in most individuals in a population.
  - They occur in invertebrates and some vertebrates but not mammals.
- According to Hamilton's rule,
  - natural selection does not favor altruistic behavior that causes the death of the altruist.
  - natural selection favors altruistic acts when the resulting benefit to the recipient, corrected for relatedness, exceeds the cost to the altruist.
  - natural selection is more likely to favor altruistic behavior that benefits an offspring than altruistic behavior that benefits a sibling.
  - the effects of kin selection are larger than the effects of direct natural selection on individuals.
  - altruism is always reciprocal.
- The binding of calcium to the troponin complex
  - activates myosin kinase, causing phosphorylation of myosin heads.
  - disrupts cross-bridges, allowing filaments to slide past each other.
  - allows tropomyosin to bind actin.
  - opens ion channels, allowing sodium to rush into the muscle cells.
  - causes tropomyosin to shift position, exposing myosin binding sites on actin.

### Level 2: Application/Analysis

- Curare, a substance that blocks the acetylcholine receptors on skeletal muscle, will cause
  - rapid muscle twitches.
  - sustained muscle contraction (tetanus).
  - muscle relaxation.
  - specific disruption of blood pressure and digestive functions.
  - no effect in the absence of acetylcholinesterase.

- Although many chimpanzees live in environments containing oil palm nuts, members of only a few populations use stones to crack open the nuts. The likely explanation is that
  - the behavioral difference is caused by genetic differences between populations.
  - members of different populations have different nutritional requirements.
  - the cultural tradition of using stones to crack nuts has arisen in only some populations.
  - members of different populations differ in learning ability.
  - members of different populations differ in manual dexterity.
- Which of the following is *not* required for a behavioral trait to evolve by natural selection?
  - In each individual, the form of the behavior is determined entirely by genes.
  - The behavior varies among individuals.
  - An individual's reproductive success depends in part on how the behavior is performed.
  - Some component of the behavior is genetically inherited.
  - An individual's genotype influences its behavioral phenotype.

### Level 3: Synthesis/Evaluation

#### 8. SCIENTIFIC INQUIRY

From your knowledge of the cellular mechanism of muscle contraction, propose a hypothesis to explain how paramyosin enables clamshell muscles to remain contracted for long periods. How would you test your hypothesis experimentally?

#### 9. SCIENTIFIC INQUIRY

Scientists studying scrub jays found that "helpers" often assist mated pairs of birds in raising their young. The helpers lack territories and mates of their own. Instead, they help the territory owners gather food for their offspring. Propose a hypothesis to explain what advantage there might be for the helpers to engage in this behavior instead of seeking their own territories and mates. How would you test your hypothesis? If it is correct, what results would you expect your tests to yield?

#### 10. FOCUS ON EVOLUTION

We often explain our behavior in terms of subjective feelings, motives, or reasons, but evolutionary explanations are based on reproductive fitness. What is the relationship between the two kinds of explanation? For instance, is a human explanation for behavior, such as "falling in love," incompatible with an evolutionary explanation?

#### 11. FOCUS ON INFORMATION

Learning is defined as a change in behavior based on experience. In a short essay (100–150 words), describe the role of heritable information in the acquisition of learning, using some examples from imprinting and associative learning.

*For selected answers, see Appendix A.*

# Unit 7 Ecology

## 40 Population Ecology and the Distribution of Organisms

Ecologists study the interactions of organisms and the environment to understand the **distribution of species**. **Populations** of a species may be relatively stable in size or fluctuate greatly, driven by ecological and evolutionary factors.

## 41 Species Interactions

Populations of different species interact in ecological **communities** through processes such as competition, predation, and symbiosis.

## 42 Ecosystems and Energy

Energy flow and chemical cycling occur in an **ecosystem**, the community of organisms living in an area and the physical factors with which they interact. Within an ecosystem, organisms transfer **energy** through trophic levels and are characterized by their main source of nutrition and energy.

## 43 Global Ecology and Conservation Biology

Throughout the biosphere, human activities are altering trophic structures, energy flow, and natural disturbance—ecosystem processes on which all species depend. Efforts to sustain ecosystem processes and to preserve biodiversity from habitat loss and other threats comprise the fields of **global ecology** and **conservation biology**.

# Population Ecology and the Distribution of Organisms

▼ **Figure 40.1** What threatens this amphibian's survival?

## KEY CONCEPTS

- 40.1** Earth's climate influences the structure and distribution of terrestrial biomes
- 40.2** Aquatic biomes are diverse and dynamic systems that cover most of Earth
- 40.3** Interactions between organisms and the environment limit the distribution of species
- 40.4** Dynamic biological processes influence population density, dispersion, and demographics
- 40.5** The exponential and logistic models describe the growth of populations
- 40.6** Population dynamics are influenced strongly by life history traits and population density

## OVERVIEW

### Discovering Ecology

When University of Delaware undergraduate Justin Yeager spent his summer abroad in Costa Rica, all he wanted was to see the tropical rain forest and to practice his Spanish. Instead, he discovered a population of the variable harlequin toad (*Atelopus varius*), a species thought to be extinct in the mountain slopes of Costa Rica and Panama, where it once lived (**Figure 40.1**). During the 1980s and 1990s, roughly two-thirds of the 82 known species of harlequin toads vanished. Scientists think that a disease-causing chy-

trid fungus, *Batrachochytrium dendrobatidis*, contributed to many of these extinctions. Why was the fungus suddenly thriving in the rain forest? Cloudier days and warmer nights associated with global warming appear to have created an environment ideal for its success. As of early 2012, the toad species that Yeager found was surviving as a single known population of fewer than 100 individuals.

What environmental factors limit the geographic distribution of harlequin toads? How do variations in their food supply or interactions with other species, such as pathogens, affect the size of their population? Questions like these are the subject of **ecology** (from the Greek *oikos*, home, and *logos*, study), the scientific study of the interactions between organisms and the environment. As shown in **Figure 40.2**, ecological interactions occur at a hierarchy of scales from single organisms to the globe.

Ecology is a rigorous experimental science that requires a breadth of biological knowledge. Ecologists observe nature, generate hypotheses, manipulate environmental variables, and observe outcomes. Figure 40.2 provides a conceptual framework for the field of ecology as well as an organizational framework for this unit. In this chapter, we'll first consider how Earth's climate and other factors determine the location of major life zones on land and in the oceans. We'll then examine how ecologists investigate what controls the distribution of species and the density and size of populations. The next three chapters focus on community, ecosystem, and global ecology, as we explore how ecologists apply biological knowledge to predict the global consequences of human activities and to conserve Earth's biodiversity.

Ecologists work at different levels of the biological hierarchy, from individual organisms to the planet. Here we present a sample research question for each level of the hierarchy.

### Global Ecology

The **biosphere** is the global ecosystem—the sum of all the planet's ecosystems and landscapes. **Global ecology** examines how the regional exchange of energy and materials influences the functioning and distribution of organisms across the biosphere.

- ◀ How does ocean circulation affect the global distribution of crustaceans?

### Landscape Ecology

A **landscape** (or seascape) is a mosaic of connected ecosystems. Research in **landscape ecology** focuses on the factors controlling exchanges of energy, materials, and organisms across multiple ecosystems.

- ◀ To what extent do the trees lining a river serve as corridors of dispersal for animals?

### Ecosystem Ecology

An **ecosystem** is the community of organisms in an area and the physical factors with which those organisms interact. **Ecosystem ecology** emphasizes energy flow and chemical cycling between organisms and the environment.

- ◀ What factors control photosynthetic productivity in a temperate grassland ecosystem?

### Community Ecology

A **community** is a group of populations of different species in an area. **Community ecology** examines how interactions between species, such as predation and competition, affect community structure and organization.

- ◀ What factors influence the diversity of species that make up a forest?

### Population Ecology

A **population** is a group of individuals of the same species living in an area. **Population ecology** analyzes factors that affect population size and how and why it changes through time.

- ◀ What environmental factors affect the reproductive rate of flamingos?

### Organismal Ecology

**Organismal ecology**, which includes the subdisciplines of physiological, evolutionary, and behavioral ecology, is concerned with how an organism's structure, physiology, and behavior meet the challenges posed by its environment.

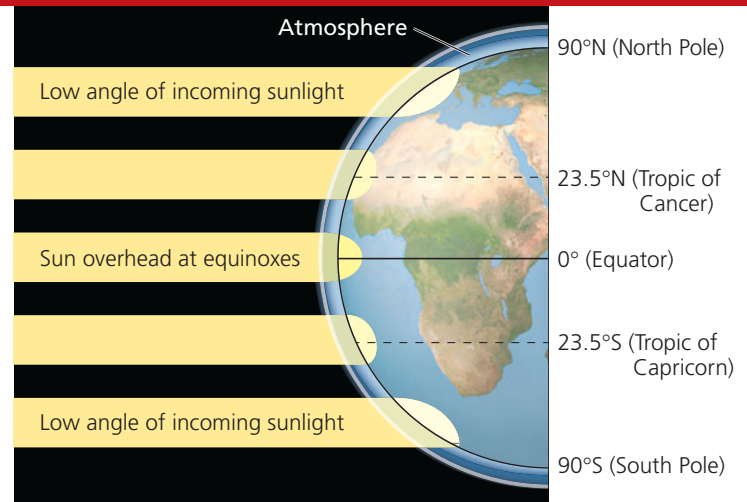

- ◀ How do hammerhead sharks select a mate?

## Latitudinal Variation in Sunlight Intensity

Earth's curved shape causes latitudinal variation in the intensity of sunlight. Because sunlight strikes the **tropics** (those regions that lie between 23.5° north latitude and 23.5° south latitude) most directly, more heat and light per unit of surface area are delivered there. At higher latitudes, sunlight strikes Earth at an oblique angle, and thus the light energy is more diffuse on Earth's surface.

## Global Air Circulation and Precipitation Patterns

Intense solar radiation near the equator initiates a global pattern of air circulation and precipitation. High temperatures in the tropics evaporate water from Earth's surface and cause warm, wet air masses to rise (blue arrows) and flow toward the poles. As the rising air masses cool, they release much of their water content, creating abundant precipitation in tropical regions. The high-altitude air masses, now dry, descend (tan arrows) toward Earth around 30° north and south, absorbing moisture from the land and creating an arid climate conducive to the development of the deserts that are common at those latitudes. Some of the descending air then flows toward the poles. At latitudes around 60° north and south, the air masses again rise and release abundant precipitation (though less than in the tropics). Some of the cold, dry rising air then flows to the poles, where it descends and flows back toward the equator, absorbing moisture and creating the comparatively rainless and bitterly cold climates of the polar regions.

Air flowing close to Earth's surface creates predictable global wind patterns. As Earth rotates on its axis, land near the equator moves faster than that at the poles, deflecting the winds from the vertical paths shown above and creating the more easterly and westerly flows shown at left. Cooling trade winds blow from east to west in the tropics; prevailing westerlies blow from west to east in the temperate zones, defined as the regions between the Tropic of Cancer and the Arctic Circle and between the Tropic of Capricorn and the Antarctic Circle.

## CONCEPT 40.1

### Earth's climate influences the structure and distribution of terrestrial biomes

The most significant influence on the distribution of organisms on land and in the oceans is **climate**, the long-term, prevailing weather conditions in a given area. Four physical factors—temperature, precipitation, sunlight, and wind—are particularly important components of climate. Such **abiotic**, or nonliving, factors are the chemical and physical attributes of the environment that influence the distribution and abundance of organisms. **Biotic**, or living, factors—the other organisms that are part of an individual's environment—similarly influence the distribution and abundance of life.

We begin by describing patterns in **macroclimate**, which is climate at the global, regional, and landscape levels.

#### Global Climate Patterns

Global climate patterns are determined largely by the input of solar energy and Earth's movement in space. The sun warms the atmosphere, land, and water. This warming establishes the temperature variations, cycles of air and water movement, and evaporation of water that cause dramatic latitudinal variations in climate. **Figure 40.3** summarizes Earth's climate patterns and how they are formed.

#### Regional Effects on Climate

Climate patterns include seasonal variation and can be modified by other factors, such as large bodies of water and mountain ranges.

##### Seasonality

As described in **Figure 40.4**, Earth's tilted axis of rotation and its annual passage around the sun cause strong seasonal cycles in middle to high latitudes. In addition to global changes in day length, solar radiation, and temperature, the changing angle of the sun over the course of the year affects local environments. For example, the belts of wet and dry air on either side of the equator move slightly northward and southward with the changing angle of the sun, producing marked wet and dry seasons around 20° north and 20° south latitude, where many tropical deciduous forests grow. In addition, seasonal changes in wind patterns alter ocean currents, sometimes causing the upwelling of cold water from deep ocean layers. This nutrient-rich water stimulates the growth of surface-dwelling phytoplankton and the organisms that feed on them.

##### Bodies of Water

Ocean currents influence climate along the coasts of continents by heating or cooling overlying air masses that pass across the land. Coastal regions are also generally wetter than inland areas at the same latitude. The cool, misty climate produced by the cold California Current that flows southward along western North America supports a coniferous rain forest

▲ **Figure 40.4 Seasonal variation in sunlight intensity.** Because Earth is tilted on its axis relative to its plane of orbit around the sun, the intensity of solar radiation varies seasonally. This variation is smallest in the tropics and increases toward the poles.

▲ **Figure 40.5** Circulation of surface water in the oceans around North America. The California Current carries cold water southward along the western coast of North America. Along the eastern coast, the warm water of the Gulf Stream flows northward to northern Europe.

ecosystem along much of the continent's Pacific coast and large redwood groves farther south (Figure 40.5). Conversely, the west coast of northern Europe has a mild climate because the Gulf Stream carries warm water from the equator to the North Atlantic. As a result, northwestern Europe is warmer during winter than southeastern Canada, which is farther south but is cooled by the Labrador Current flowing south from the coast of Greenland.

Because of the high specific heat of water (see Chapter 2), oceans and large lakes tend to moderate the climate of nearby land. During a hot day, when land is warmer than the water, air over the land heats up and rises, drawing a cool breeze from the water across the land (Figure 40.6). In contrast, because temperatures drop more quickly over land than over water at night, air over the now warmer water rises, drawing cooler air from the land back out over the water and replacing it with warmer air from offshore.

► **Figure 40.6** How large bodies of water and mountains affect climate. This figure illustrates what can happen on a hot summer day.

## Mountains

Like large bodies of water, mountains influence air flow over land. When warm, moist air approaches a mountain, the air rises and cools, releasing moisture on the windward side of the peak (see Figure 40.6). On the leeward side, cooler, dry air descends, absorbing moisture and producing a “rain shadow” that determines where many deserts are found, including the Mojave Desert of western North America and the Gobi Desert of Asia.

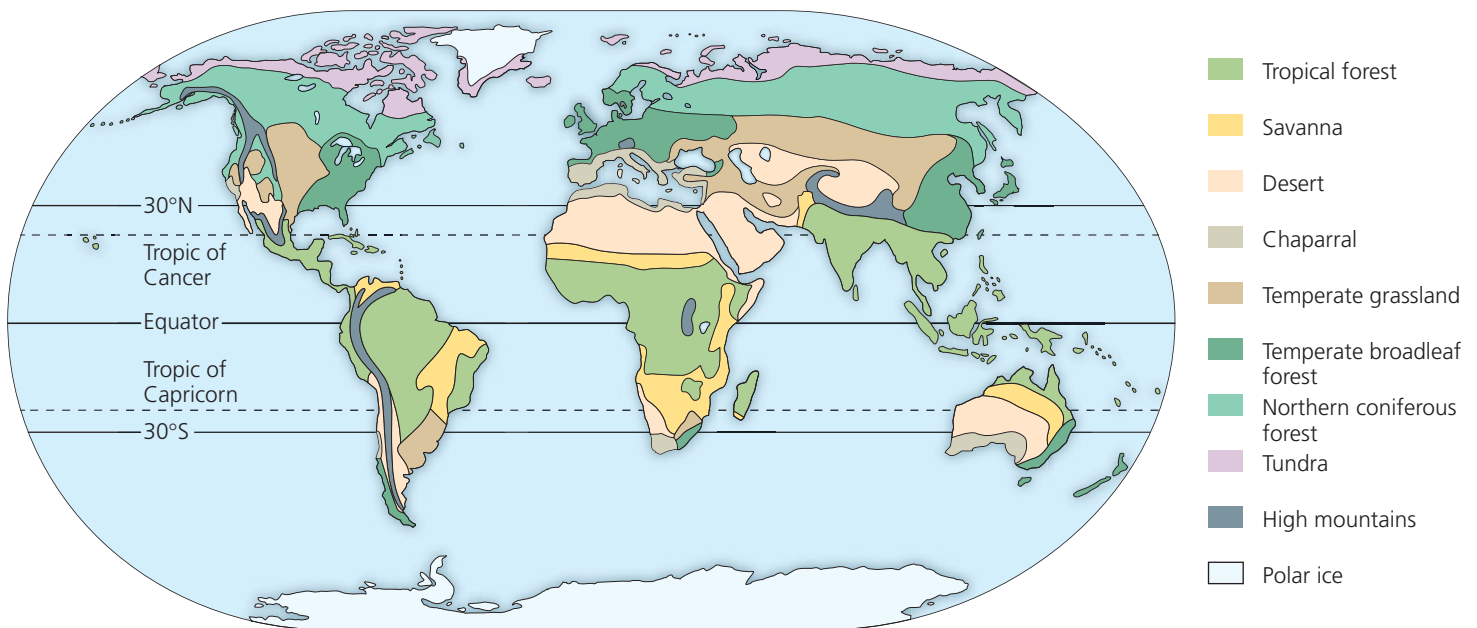

Mountains also affect the amount of sunlight reaching an area and the local temperature. South-facing slopes in the Northern Hemisphere receive more sunlight than north-facing slopes and are therefore warmer and drier. In many

mountains of western North America, spruce and other conifers grow on the cooler north-facing slopes, but shrubby, drought-resistant plants inhabit the south-facing slopes. In addition, every 1,000-m increase in elevation produces an average temperature drop of approximately 6°C, equivalent to that produced by an 880-km increase in latitude. This is one reason that high-elevation communities at a given latitude can be similar to communities at lower elevations much farther from the equator.

## Climate and Terrestrial Biomes

Throughout this book, you have seen examples of how climate influences where individual species are found (see Figure 8.18, for instance). We turn now to the role of climate in determining the nature and location of Earth's **biomes**, major life zones characterized by vegetation type (in terrestrial biomes) or by the physical environment (in aquatic biomes, which we will survey in Concept 40.2).

▲ **Figure 40.7 The distribution of major terrestrial biomes.** Although biomes are mapped here with sharp boundaries, biomes actually grade into one another, sometimes over large areas.

Because of the latitudinal patterns of climate described in Figure 40.3, the locations of terrestrial biomes also show strong latitudinal patterns (Figure 40.7). One way to highlight the importance of climate on the distribution of biomes is to construct a **climograph**, a plot of the annual mean temperature and precipitation in a particular region (Figure 40.8). Notice, for instance, that grasslands in North America are typically drier than forests and that deserts are drier still.

Factors other than mean temperature and precipitation also play a role in determining where biomes exist. For example, some areas in North America with a particular combination of temperature and precipitation support a temperate broadleaf forest, but other areas with similar values for these variables support a coniferous forest (see the overlap in Figure 40.8). One reason for this variation is that climographs are based on annual *averages*, but the *pattern* of climatic variation is often as important as the average climate. Some areas may receive regular precipitation throughout the year, whereas other areas may have distinct wet and dry seasons.

Natural and human-caused disturbances also alter the distribution of biomes. A **disturbance** is an event such as a storm, fire, or human activity that changes a community, removing organisms from it and altering resource availability. For instance, frequent fires can kill woody plants and keep a savanna from becoming the woodland that climate alone would support. Hurricanes and other storms create openings for new species in many tropical and temperate forests. Human-caused disturbances have altered much of Earth's surface, replacing natural communities with urban and agricultural ones.

▲ **Figure 40.8 A climograph for some major types of biomes in North America.** The areas plotted here encompass the ranges of annual mean temperature and precipitation in the biomes.

## General Features of Terrestrial Biomes

Most terrestrial biomes are named for major physical or climatic features and for their predominant vegetation. Temperate grasslands, for instance, are generally found in middle latitudes, where the climate is more moderate than in the tropics or polar regions, and are dominated by various grass species (see Figure 40.7). Each biome is also characterized by microorganisms, fungi, and animals adapted to that

particular environment. Temperate grasslands are usually more likely than temperate forests to be populated by large grazing mammals and to have arbuscular mycorrhizal fungi (see Figure 29.13).

Although Figure 40.7 shows distinct boundaries between the biomes, terrestrial biomes usually grade into each other without sharp boundaries. The area of intergradation, called an **ecotone**, may be wide or narrow.

Vertical layering in the shapes and sizes of plants is an important feature of terrestrial biomes. In many forests, the layers from top to bottom consist of the upper **canopy**, the low-tree layer, the shrub understory, the ground layer of herbaceous plants, the forest floor (litter layer), and the root layer. Layering of vegetation provides different habitats for animals, which sometimes exist in well-defined feeding groups, from the insectivorous birds and bats that feed above canopies to the

small mammals, worms, and arthropods that search for food in the litter and root layers below.

**Figure 40.9** summarizes the major features of terrestrial biomes.

#### CONCEPT CHECK 40.1

1. Explain how the sun's unequal heating of Earth's surface leads to the development of deserts around 30° north and south of the equator.
2. Identify the natural biome in which you live, and summarize its abiotic and biotic characteristics. Do these reflect your actual surroundings? Explain.
3. **WHAT IF?** If global warming increases average temperatures on Earth by 4°C in this century, predict which biome is most likely to replace tundra in some locations as a result (see Figures 40.7 and 40.8). Explain your answer.

For suggested answers, see Appendix A.

### ▼ Figure 40.9 Exploring Terrestrial Biomes

#### Tropical Forest

**Distribution** Equatorial and sub-equatorial regions

**Climate** Temperature is usually high, averaging 25–29°C with little seasonal variation. In **tropical rain forests**, rainfall is relatively constant, about 200–400 cm annually. In **tropical dry forests**, precipitation averages about 150–200 cm annually, with a six- to seven-month dry season.

**Organisms** Tropical forests are vertically layered, and plants compete strongly for light. Broadleaf evergreen trees are dominant in rain forests, whereas many dry forest trees drop their leaves during the

dry season. Tropical forests are home to millions of animal species, including an estimated 5–30 million still undescribed species of insects, spiders, and other arthropods. Animal diversity is higher than in any other terrestrial biome. The animals are adapted to the vertically layered environment and are often inconspicuous.

**Human Impact** Humans long ago established thriving communities in tropical forests. Rapid population growth leading to agriculture and development is now destroying many tropical forests.

A tropical rain forest in Costa Rica

#### Savanna

**Distribution** Equatorial and sub-equatorial regions

**Climate** Rainfall averages 30–50 cm per year in **savannas** and is seasonal, with a dry season that can last up to nine months. Temperature averages 24–29°C but varies seasonally more than in tropical forests.

**Organisms** Scattered trees often are thorny and have small leaves, an apparent adaptation to the relatively dry conditions. Fires are common in the dry season, and the dominant plant species are fire-adapted and tolerant of seasonal drought. Grasses

and small nonwoody plants called forbs make up most of the ground cover. Large plant-eating mammals, such as wildebeests and zebras, and predators, including lions and hyenas, are common inhabitants. However, the dominant herbivores are insects, especially termites.

**Human Impact** The earliest humans likely lived in savannas. Overly frequent fires set by humans reduce tree regeneration by killing the seedlings and saplings. Cattle ranching and overhunting have led to declines in large-mammal populations.

A savanna in Kenya

Organ Pipe Cactus National Monument, Arizona

## Desert

**Distribution** Deserts occur in bands near 30° north and south latitude or at other latitudes in the interior of continents (for instance, the Gobi Desert of north-central Asia).

**Climate** Precipitation is low and highly variable, generally less than 30 cm per year. Temperature varies seasonally and daily. It may exceed 50°C in hot deserts and fall below –30°C in cold deserts.

**Organisms** Desert landscapes are dominated by low, widely scattered vegetation. Common plants include succulents such as cacti or euphorbs, deeply rooted shrubs, and herbs that grow during the infrequent moist periods. Desert plant adaptations include tolerance to heat and desiccation, water storage, reduced leaf surface area,

and physical defenses such as spines and toxins in leaves. Many desert plants carry out  $C_4$  or CAM photosynthesis. Common desert animals include scorpions, ants, beetles, snakes, lizards, migratory and resident birds, and seed-eating rodents. Many species in hot deserts are active at night, when the air is cooler. Water conservation is a common adaptation, and some animals can obtain all their water by breaking down carbohydrates in seeds.

**Human Impact** Long-distance transport of water and deep groundwater wells have allowed humans to maintain substantial populations in deserts. Urbanization and conversion to irrigated agriculture have reduced the natural biodiversity of some deserts.

## Chaparral

**Distribution** Midlatitude coastal regions on several continents

**Climate** Annual precipitation is typically 30–50 cm and is highly seasonal, with rainy winters and dry summers. Fall, winter, and spring are cool, with average temperatures of 10–12°C. Average summer temperature can reach 30°C.

**Organisms** Chaparral is dominated by shrubs and small trees adapted to frequent fires. Some fire-adapted shrubs produce seeds that will germinate only after a hot fire; food reserves stored in their roots

enable them to resprout quickly and use nutrients released by the fire. Adaptations to drought include tough, evergreen leaves, which reduce water loss. Animals include browsers, such as deer and goats, that feed on twigs and buds of woody vegetation; there are also many species of insects, amphibians, small mammals, and birds.

**Human Impact** Chaparral areas have been heavily settled and reduced through conversion to agriculture and urbanization. Humans contribute to the fires that sweep across the chaparral.

An area of chaparral in California

A grassland in Mongolia

## Temperate Grassland

**Distribution** Typically at midlatitudes, often in the interior of continents

**Climate** Annual precipitation in **temperate grasslands** generally averages 30 to 100 cm and can be highly seasonal, with relatively dry winters and wet summers. Average temperatures frequently are below –10°C in winter and reach 30°C in summer.

**Organisms** Dominant plants are grasses and forbs, which vary in height from a few centimeters to 2 m in tallgrass prairie. Many grassland plants have adaptations that help them survive periodic,

protracted droughts and fire. Grazing by large mammals such as bison and wild horses helps prevent establishment of woody shrubs and trees. Burrowing mammals, such as prairie dogs in North America, are also common.

**Human Impact** Because of their deep, fertile soils, temperate grasslands in North America and Eurasia have frequently been converted to farmland. In some drier grasslands, cattle and other grazers have turned parts of the biome into desert.

## Northern Coniferous Forest

**Distribution** In a broad band across northern North America and Eurasia to the edge of the arctic tundra, the **northern coniferous forest**, or *taiga*, is the largest terrestrial biome.

**Climate** Annual precipitation generally ranges from 30 to 70 cm. Winters are cold. Some areas of coniferous forest in Siberia typically range in temperature from  $-50^{\circ}\text{C}$  in winter to over  $20^{\circ}\text{C}$  in summer.

**Organisms** Cone-bearing trees (conifers), such as pine, spruce, fir, and hemlock, are common, and some species depend on fire to regenerate. The conical shape of many conifers prevents

snow from accumulating and breaking their branches, and their needle-like or scalelike leaves reduce water loss. Plant diversity in the shrub and herb layers is lower than in temperate broadleaf forests. Many migratory birds nest in northern coniferous forests. Mammals include moose, brown bears, and Siberian tigers. Periodic outbreaks of insects can kill vast tracts of trees.

**Human Impact** Although they have not been heavily settled by human populations, northern coniferous forests are being logged at a fast rate, and old-growth stands may soon disappear.

A coniferous forest in Norway

A temperate broadleaf forest in New Jersey

## Temperate Broadleaf Forest

**Distribution** Midlatitudes in the Northern Hemisphere, with smaller areas in Chile, South Africa, Australia, and New Zealand

**Climate** Precipitation averages about 70 to 200 cm annually. Significant amounts fall during all seasons, with winter snow in some forests. Winter temperatures average around  $0^{\circ}\text{C}$ . Summers are humid, with maximum temperatures near  $35^{\circ}\text{C}$ .

**Organisms** The dominant plants of **temperate broadleaf forests** in the Northern Hemisphere are deciduous trees, which drop their leaves before

winter, when low temperatures would reduce photosynthesis. In Australia, evergreen eucalyptus trees are common. In the Northern Hemisphere, many mammals hibernate in winter, while many bird species migrate to areas with warmer climates.

**Human Impact** Temperate broadleaf forests have been heavily settled globally. Logging and land clearing for agriculture and urban development have destroyed virtually all the original deciduous forests in North America, but these forests are returning over much of their former range.

## Tundra

**Distribution** **Tundra** covers expansive areas of the Arctic, amounting to 20% of Earth's land surface. High winds and low temperatures produce alpine tundra on very high mountaintops at all latitudes, including the tropics.

**Climate** Precipitation averages 20 to 60 cm annually in arctic tundra but may exceed 100 cm in alpine tundra. Winters are cold, with average temperatures in some areas below  $-30^{\circ}\text{C}$ . Summer temperatures generally average less than  $10^{\circ}\text{C}$ .

**Organisms** The vegetation of tundra is mostly herbaceous, typically a mixture

of mosses, grasses, and forbs, with some dwarf shrubs, trees, and lichens. A permanently frozen soil layer called permafrost restricts the growth of plant roots. Large grazing musk oxen are resident, while caribou and reindeer are migratory. Predators include bears, wolves, foxes, and snowy owls. Many bird species migrate to the tundra for summer nesting.

**Human Impact** Tundra is sparsely settled but has become the focus of significant mineral and oil extraction in recent years.

Dovrefjell National Park, Norway

## CONCEPT 40.2

# Aquatic biomes are diverse and dynamic systems that cover most of Earth

All types of aquatic biomes are found across the globe and show far less latitudinal variation than terrestrial biomes (**Figure 40.10**). Ecologists distinguish between freshwater and marine biomes on the basis of physical and chemical differences. Salt concentrations generally average 3% in marine biomes but are less than 0.1% in freshwater biomes.

The oceans make up the largest marine biome, covering about 75% of Earth's surface. Water evaporated from the oceans provides most of the planet's rainfall, and ocean temperatures have a major effect on global climate and wind patterns (see Figure 40.3). Marine algae and photosynthetic bacteria also supply a substantial portion of the world's oxygen and consume large amounts of atmospheric carbon dioxide.

Freshwater biomes are closely linked to the soils and biotic components of the surrounding terrestrial biome. Freshwater biomes are also influenced by the patterns and speed of water flow and the climate to which the biome is exposed.

## Zonation in Aquatic Biomes

Many aquatic biomes are divided into vertical and horizontal zones, as illustrated for a lake in **Figure 40.11**. Light is

▲ **Figure 40.11 Zonation in a lake.** A lake environment is generally classified on the basis of three physical criteria: light penetration (photic and aphotic zones), distance from shore and water depth (littoral and limnetic zones), and whether the environment is open water (pelagic zone) or bottom (benthic zone).

absorbed by water and by photosynthetic organisms, so its intensity decreases rapidly with depth. The upper **photic zone** is where there is sufficient light for photosynthesis, and the lower **aphotic zone** is where little light penetrates. These two zones together make up the **pelagic zone**. At the bottom of these zones, deep or shallow, is the **benthic zone**, which consists of organic and inorganic sediments and is occupied by communities of organisms called the **benthos**.

Thermal energy from sunlight warms surface waters, but the deeper waters remain cold. In the ocean and in most

## ▼ Figure 40.10 Exploring Aquatic Biomes

### Wetlands and Estuaries

#### Physical and Chemical Environment

**Wetlands** are inundated by water at least sometimes and support plants adapted to water-saturated soil. In an **estuary**, the transition zone between a river and the sea, seawater flows up and down the estuary channel during the changing tides. Nutrients from upstream make wetlands and estuaries among the most productive habitats on Earth. Because of high organic production by plants and decomposition by microorganisms, the water and soils are often low in dissolved oxygen. Both habitats filter dissolved nutrients and chemical pollutants.

**Geologic Features** Wetlands develop in diverse habitats, including shallow basins, the flooded banks of rivers and streams, and lake coasts. Along seacoasts, sediments

from rivers and tidal waters create channels, islands, and mudflats in estuaries.

**Organisms** Water-saturated soils favor the growth of plants, such as cattails and sedges in wetlands and saltmarsh grasses in estuaries, that can grow in water or in soil that is anaerobic at times. In freshwater wetlands, herbivores may include crustaceans, aquatic insect larvae, and muskrats, and carnivores may include dragonflies, frogs, alligators, and herons. Estuaries support an abundance of oysters, crabs, and fish species that humans eat. Many marine invertebrates and fishes use estuaries as breeding grounds.

A basin wetland in the United Kingdom

**Human Impact** Draining and filling have destroyed up to 90% of wetlands. Filling, dredging, and upstream pollution have disrupted estuaries worldwide.

An oligotrophic lake in Alberta, Canada

### Physical and Chemical Environment

Standing bodies of water range from ponds a few square meters in area to lakes covering

## Streams and Rivers

### Physical and Chemical Environment

Headwater streams are generally cold, clear, turbulent, and swift. Downstream in larger rivers, the water is generally warmer and more turbid because of suspended sediment. The salt and nutrient content of streams and rivers increases from the headwaters to the mouth, but oxygen content typically decreases.

**Geologic Features** Headwater stream channels are often narrow, have a rocky bottom, and alternate between shallow sections and deeper pools. Rivers are generally wide and meandering. River

## Lakes

thousands of square kilometers. Light decreases with depth, creating photic and aphotic zones. Temperate lakes may have a seasonal thermocline; tropical lowland lakes have a thermocline year-round.

**Oligotrophic lakes** are nutrient-poor and generally oxygen-rich; **eutrophic lakes** are nutrient-rich and often depleted of oxygen in the deepest zone in summer and if covered with ice in winter. High rates of decomposition in deeper layers of eutrophic lakes cause periodic oxygen depletion.

**Geologic Features** Oligotrophic lakes may become more eutrophic over time as runoff adds sediments and nutrients. They tend to have less surface area relative to their depth than eutrophic lakes.

**Organisms** Rooted and floating aquatic plants live in the **littoral zone**, the shallow, well-lit waters close to shore. The **limnetic zone**, where water is too deep to support rooted aquatic plants, is inhabited by a variety of phytoplankton, including cyanobacteria, and small drifting heterotrophs, or zooplankton, that graze on the phytoplankton. The benthic zone is inhabited by assorted invertebrates whose species composition depends partly on oxygen levels. Fishes live in all zones with sufficient oxygen.

**Human Impact** Runoff from fertilized land and dumping of wastes lead to nutrient enrichment, which can produce algal blooms, oxygen depletion, and fish kills.

bottoms are often silty from sediments deposited through time.

**Organisms** Headwater streams that flow through grasslands or deserts may be rich in phytoplankton or rooted aquatic plants. Diverse fishes and invertebrates inhabit unpolluted rivers and streams. In streams flowing through forests, organic matter from terrestrial vegetation is the primary source of food for aquatic consumers.

**Human Impact** Municipal, agricultural, and industrial pollution degrade water quality and can kill aquatic organisms. Dams impair the natural flow of streams

A headwater stream in Washington

and rivers and threaten migratory species such as salmon.

A rocky intertidal zone on the Oregon coast

**Physical and Chemical Environment** An **intertidal zone** is periodically submerged and exposed by the tides, twice daily on

## Intertidal Zones

most marine shores. Upper strata experience longer exposures to air and greater variations in temperature and salinity, conditions that limit the distributions of many organisms to particular strata. Oxygen and nutrient levels are generally high and are renewed with each turn of the tides.

**Geologic Features** The rocky or sandy substrates of intertidal zones select for particular behavior and anatomy among intertidal organisms. The configuration of bays or coastlines influences the magnitude of tides and the exposure of intertidal zones to waves.

**Organisms** Diverse and plentiful marine algae grow on rocks in intertidal zones. Sandy intertidal zones exposed to waves

generally lack attached plants or algae, while those in protected bays or lagoons often support rich beds of seagrass and algae. Some animals have structural adaptations that enable them to attach to rocks. Many animals in sandy or muddy intertidal zones, such as worms, clams, and predatory crustaceans, bury themselves and feed as the tides bring food. Other common animals are sponges, sea anemones, and small fishes.

**Human Impact** Oil pollution has disrupted many intertidal areas. Rock walls and barriers built to reduce erosion from waves and storm surges disrupt some areas.

A coral reef in the Red Sea

### Physical and Chemical Environment

**Coral reefs** are formed largely from the calcium carbonate skeletons of corals. Shallow reef-building corals live in the

## Coral Reefs

clear photic zone of tropical oceans, primarily near islands and along the edge of some continents. They are sensitive to temperatures below about 18–20°C and above 30°C. Deep-sea coral reefs are found at a depth of 200–1,500 m. Corals require high oxygen levels and are excluded by high inputs of fresh water and nutrients.

**Geologic Features** Corals require a solid substrate for attachment. A typical coral reef begins as a fringing reef on a young, high island, forms an offshore barrier reef later, and becomes a coral atoll as the older island submerges.

**Organisms** Unicellular algae live within the tissues of the corals in a mutualism that

provides the corals with organic molecules. Diverse multicellular red and green algae also contribute substantial amounts of photosynthesis. Corals are the predominant animals on coral reefs, but fish and invertebrate diversity is also exceptionally high. Animal diversity on coral reefs rivals that of tropical forests.

**Human Impact** Collecting of coral skeletons and overfishing have reduced populations of corals and reef fishes. Global warming and pollution may be contributing to large-scale coral death. Development of coastal mangroves for aquaculture has also reduced spawning grounds for many species of reef fishes.

## Oceanic Pelagic Zone

**Physical and Chemical Environment** The **oceanic pelagic zone** is a vast realm of open blue water, whose surface is constantly mixed by wind-driven currents. Because of higher water clarity, the photic zone extends to greater depths than in coastal marine waters. Oxygen content is generally high. Nutrient levels are generally lower than in coastal waters. Mixing of surface and deeper waters in fall and spring renews nutrients in the photic zones of temperate and high-latitude ocean areas.

**Geologic Features** This biome covers approximately 70% of Earth's surface. It has

an average depth of nearly 4,000 m and a maximum depth of more than 10,000 m.

**Organisms** The dominant photosynthetic organisms are bacteria and other phytoplankton, which drift with the currents and account for half of global productivity. Zooplankton, including protists, worms, krill, jellies, and small larvae of invertebrates and fishes, eat the phytoplankton. Free-swimming animals include large squids, fishes, sea turtles, and marine mammals.

**Human Impact** Overfishing has depleted fish stocks in all oceans, which have also been polluted by waste dumping.

Open ocean near Iceland

A deep-sea hydrothermal vent community

### Physical and Chemical Environment

The **marine benthic zone** consists of the seafloor. Except for shallow, near-coastal areas, the marine benthic zone is dark. Water temperature declines with depth, while pressure increases. Organisms in the very

## Marine Benthic Zone

deep benthic, or abyssal, zone are adapted to continuous cold (about 3°C) and high water pressure. Oxygen concentrations are generally sufficient to support diverse animal life.

**Geologic Features** Soft sediments cover most of the benthic zone, but there are areas of rocky substrate on reefs, submarine mountains, and new oceanic crust.

**Organisms** Photosynthetic organisms, mainly seaweeds and filamentous algae, live in shallow benthic areas with sufficient light. In the dark, hot environments near **deep-sea hydrothermal vents**, the food producers are chemoautotrophic prokaryotes. Coastal benthic communities include numerous invertebrates and fishes. Below the

photic zone, most consumers depend entirely on organic matter raining down from above. Among the animals of the deep-sea hydrothermal vent communities are giant tube worms (pictured at left), some more than 1 m long. They are nourished by chemoautotrophic prokaryotes that live as symbionts within their bodies. Many other invertebrates, including arthropods and echinoderms, are also abundant around the hydrothermal vents.

**Human Impact** Overfishing has decimated important benthic fish populations, such as the cod of the Grand Banks off Newfoundland. Dumping of organic wastes has created oxygen-deprived benthic areas.

lakes, a narrow layer of abrupt temperature change called a **thermocline** separates the more uniformly warm upper layer from more uniformly cold deeper waters.

In both freshwater and marine environments, communities are distributed according to water depth, degree of light penetration, distance from shore, and whether they are found in open water or near the bottom. Plankton and many fish species live in the relatively shallow photic zone (see Figure 40.11). Most of the deep ocean is virtually devoid of light (the aphotic zone) and harbors relatively little life.

#### CONCEPT CHECK 40.2

The first two questions refer to Figure 40.10.

1. Why are phytoplankton, and not benthic algae or rooted aquatic plants, the dominant photosynthetic organisms of the oceanic pelagic zone?
2. **MAKE CONNECTIONS** Many organisms living in estuaries experience both freshwater and saltwater conditions each day with the rising and falling of tides. Explain how these changing conditions challenge the survival of these organisms (see Concept 32.3).
3. **WHAT IF?** Water leaving a reservoir behind a dam is often taken from deep layers of the reservoir. Would you expect fish found in a river below a dam in summer to be species that prefer colder or warmer water than fish found in an undammed river? Explain.

For suggested answers, see Appendix A.

## CONCEPT 40.3

### Interactions between organisms and the environment limit the distribution of species

So far in this chapter, we've examined Earth's climate and the characteristics of terrestrial and aquatic biomes. We've also introduced the range of biological levels at which ecologists work (see Figure 40.2). In this section, we'll examine how ecologists determine what factors control the distribution of species, such as the harlequin toad shown in Figure 40.1.

Species distributions are a consequence of both ecological and evolutionary interactions through time. The differential

survival and reproduction of individuals that lead to evolution occur in *ecological time*, the minute-to-minute time frame of interactions between organisms and the environment. Through natural selection, organisms adapt to their environment over the time frame of many generations, in *evolutionary time*. One example of how events in ecological time have led to evolution is the selection for beak depth in Galápagos finches (see Figures 21.1 and 21.2). On the island of Daphne Major, finches with larger, deeper beaks were better able to survive during a drought because they could eat the large, hard seeds that were available. Finches with shallower beaks, which required smaller, softer seeds that were in short supply, were less likely to survive and reproduce. Because beak depth is hereditary in this species, the generation of finches born after the drought had beaks that were deeper than those of previous generations.

Biologists have long recognized global and regional patterns in the distribution of organisms (see the discussion of biogeography in Chapter 19). Kangaroos, for instance, are found in Australia but nowhere else on Earth. Ecologists ask not only *where* species occur, but also *why* species occur where they do: What factors determine their distribution? Ecologists generally need to consider multiple factors and alternative hypotheses when attempting to explain the distribution of species. To see how ecologists might arrive at such an explanation, let's work our way through the series of questions in the flowchart in **Figure 40.12**.

### Dispersal and Distribution

One factor that contributes greatly to the global distribution of organisms is **dispersal**, the movement of individuals or gametes away from their area of origin or from centers of high population density. A biogeographer who studies the distributions of species in the context of evolutionary theory might consider dispersal in hypothesizing why there are no kangaroos in North America: A barrier may have kept them from reaching the continent. While land-bound kangaroos have not reached North America under their own power, other organisms that disperse more readily, such as some birds, have. The dispersal of organisms is critical to understanding the role of geographic isolation in evolution (see Chapter 22) as well as the broad patterns of species distribution that we see around the world today.

**▲ Figure 40.12 Flowchart of factors limiting geographic distribution.** As ecologists study the factors limiting a species' distribution, they often consider a series of questions like the ones shown here.

**?** How might the importance of various abiotic factors differ for aquatic and terrestrial ecosystems?

To determine if dispersal is a key factor limiting the distribution of a species, ecologists observe the results of intentional or accidental transplants of the species to areas where it was previously absent. For a transplant to be considered successful, some of the organisms must not only survive in the new area but also reproduce there sustainably. If a transplant is successful, then we can conclude that the *potential* range of the species is larger than its *actual* range; in other words, the species *could* live in certain areas where it currently does not.

Species introduced to new geographic locations often disrupt the communities and ecosystems to which they have been introduced and spread far beyond the area of introduction (see Chapter 43). Consequently, ecologists rarely move species to new geographic regions. Instead, they document the outcome when a species has been transplanted for other purposes, such as to introduce game animals or predators of pest species, or when a species has been accidentally transplanted.

## Biotic Factors

If dispersal does not limit the distribution of a species, our next question is whether biotic factors—other species—are responsible. Often, negative interactions with predators (organisms that kill their prey) or herbivores (organisms that eat plants or algae) restrict the ability of a species to survive and reproduce.

**Figure 40.13** describes a specific case of an herbivore, a sea urchin, limiting the distribution of a food species, a seaweed.

In addition to predation and herbivory, the presence or absence of pollinators, food resources, parasites, pathogens, or competing organisms can act as a biotic limitation on species distribution. Some of the most striking cases of limitation occur when humans accidentally or intentionally introduce exotic predators or pathogens into new areas and wipe out native species. You will encounter examples of these impacts in Chapter 43, where we discuss conservation biology.

## Abiotic Factors

The last question in the flowchart in Figure 40.12 considers whether abiotic factors, such as temperature, water, oxygen, salinity, sunlight, or soil, might be limiting a species'

### ▼ Figure 40.13 Inquiry

#### Does feeding by sea urchins limit seaweed distribution?

**Experiment** W. J. Fletcher, of the University of Sydney, Australia, reasoned that if sea urchins are a limiting biotic factor for seaweed growth in a particular ecosystem, then more seaweeds should invade an area from which sea urchins have been removed. To isolate the effect of sea urchins from that of a seaweed-eating mollusc, the limpet, he removed only urchins, only limpets, or both from study areas adjacent to a control site.

**Results** Fletcher observed a large difference in seaweed growth between areas with and without sea urchins.

**Conclusion** Removing both limpets and urchins resulted in the greatest increase in seaweed cover, indicating that both species have some influence on seaweed distribution. But since removing only urchins greatly increased seaweed growth while removing only limpets had little effect, Fletcher concluded that sea urchins have a much greater effect than limpets in limiting seaweed distribution.

**Source** W. J. Fletcher, Interactions among subtidal Australian sea urchins, gastropods, and algae: Effects of experimental removals, *Ecological Monographs* 57:89–109 (1987).

**WHAT IF?** If removing only limpets did not result in an increase in seaweed growth compared to the control, suggest a reason why removing both urchins and limpets resulted in greater seaweed growth than removing only urchins.

distribution. If the physical conditions at a site do not allow a species to survive and reproduce, then the species will not be found there.

- **Temperature** Environmental temperature is an important factor in the distribution of organisms because of its effect on biological processes. Cells may rupture if the water they contain freezes (at temperatures below 0°C), and the proteins of most organisms denature at temperatures above 45°C. Most organisms function best within a specific range of environmental temperature.
- **Water and Oxygen** Variation in water availability among habitats is another important factor in species distribution. Species living at the seashore or in tidal wetlands can dry out as the tide recedes, and terrestrial organisms face a nearly constant threat of drying. Many amphibians, such as

the harlequin toad in Figure 40.1, are particularly vulnerable to drying because they use their moist, delicate skin for gas exchange.

Water affects oxygen availability in aquatic environments and in flooded soils. Because oxygen diffuses slowly in water, its concentration can be low in certain aquatic systems and soils, limiting cellular respiration and other physiological processes. Oxygen concentrations can be particularly low in both deep ocean and deep lake waters and sediments where organic matter is abundant.

- **Salinity** The salt concentration of water in the environment affects the water balance of organisms through osmosis. Most aquatic organisms are restricted to either freshwater or saltwater habitats by their limited ability to osmoregulate (see Chapter 32). Although most terrestrial organisms can excrete excess salts from specialized glands or in feces or urine, salt flats and other high-salinity habitats typically have few species of plants or animals.
- **Sunlight** Sunlight absorbed by photosynthetic organisms provides the energy that drives most ecosystems, and too little sunlight can limit the distribution of photosynthetic species. In forests, shading by leaves in the treetops makes competition for light especially intense, particularly for seedlings growing on the forest floor. In aquatic environments, most photosynthesis occurs near the surface, where sunlight is more available.
- **Rocks and Soil** On land, the pH, mineral composition, and physical structure of rocks and soil limit the distribution of plants and therefore of the animals that feed on them. The pH of soil can limit the distribution of organisms directly, through extreme acidic or basic conditions, or indirectly, by affecting the solubility of nutrients and toxins.

In a river, the composition of the rocks and soil that make up the substrate (riverbed) can affect water chemistry, which in turn influences the resident organisms. In freshwater and marine environments, the structure of the substrate determines the organisms that can attach to it or burrow into it.

So far in this chapter, you have seen how the distributions of biomes and organisms depend on abiotic and biotic factors. In the rest of the chapter, we'll continue to work our way through the hierarchy outlined in Figure 40.2, focusing on how abiotic and biotic factors influence the ecology of populations.

#### CONCEPT CHECK 40.3

1. Give examples of human actions that could expand a species' distribution by changing (a) its dispersal or (b) its biotic interactions.
2. **WHAT IF?** You suspect that deer are restricting the distribution of a tree species by preferentially eating the seedlings of the tree. How might you test this hypothesis?

For suggested answers, see Appendix A.

## CONCEPT 40.4

### Dynamic biological processes influence population density, dispersion, and demographics

Population ecology explores how biotic and abiotic factors influence the density, distribution, and size of populations. A population is a group of individuals of a single species living in the same general area. Members of a population rely on the same resources, are influenced by similar environmental factors, and are likely to interact and breed with one another. Populations evolve as natural selection acts on heritable variations among individuals, changing the frequencies of alleles and traits over time. Evolution remains a central theme as we view populations in the context of ecology.

Populations are often described by their boundaries and size (number of individuals). Ecologists investigating a population define boundaries appropriate to the organism and to the questions being asked. A population's boundaries may be natural ones, as in the case of kangaroos in Australia, or they may be arbitrarily defined by an investigator—for example, a specific county in Minnesota for a study of oak trees.

#### Density and Dispersion

The **density** of a population is the number of individuals per unit area or volume: the number of oak trees per square kilometer in the Minnesota county or the number of bacteria per milliliter in a culture. **Dispersion** is the pattern of spacing among individuals within the boundaries of the population.

#### Density: A Dynamic Perspective

In rare cases, population size and density can be determined by counting all individuals within the boundaries of the population.

▲ **Figure 40.14** Population dynamics.

We could count all the sea stars in a tide pool, for instance. Large mammals that live in herds, such as elephants, can sometimes be counted accurately from airplanes. In most cases, however, it is impractical or impossible to count all individuals in a population. Instead, ecologists use a variety of sampling techniques to estimate densities and total population sizes. For example, they might count the number of oak trees in several randomly located  $100 \times 100$  m plots, calculate the average density in the plots, and then extend the estimate to the population size in the entire area. Such estimates are most accurate when there are many sample plots and when the habitat is fairly homogeneous. In other cases, instead of counting single organisms, population ecologists estimate density from an indicator of population size, such as the number of nests, burrows, tracks, or fecal droppings.

Density is not a static property but changes as individuals are added to or removed from a population (**Figure 40.14**). Additions occur through birth (which we define here to include all forms of reproduction) and **immigration**, the influx of new individuals from other areas. The factors that remove individuals from a population are death (mortality) and **emigration**, the movement of individuals out of a population and into other locations.

While birth and death rates influence the density of all populations, immigration and emigration also alter the density of many populations. Long-term studies of Belding's ground squirrels (*Spermophilus beldingi*) in the vicinity of Tioga Pass, in the Sierra Nevada of California, showed that some of the squirrels moved nearly 2 km from where they were born. This long-distance movement made them immigrants to other populations. In fact, immigrants made up 1–8% of the males and 0.7–6% of the females in the study population. Such immigration is a meaningful biological exchange between populations over time.

### Patterns of Dispersion

Within a population's geographic range, local densities may differ substantially, creating contrasting patterns of dispersion. Differences in local density are among the most important characteristics for a population ecologist to study, since they provide insight into the environmental associations and social interactions of individuals in the population.

The most common pattern of dispersion is *clumped*, in which individuals are aggregated in patches. Plants and fungi are often clumped where soil conditions and other environmental factors favor germination and growth. Insects and salamanders may be clumped under a rotting log because of the higher humidity there. Clumping of animals may also be associated with mating behavior. Sea stars group together in tide pools, where food is readily available and where they can breed successfully (**Figure 40.15a**). Forming groups may also increase the effectiveness of predation or defense; for example, a wolf pack is more likely than a single wolf to subdue a moose, and a flock of birds is more likely than a single bird to warn of a potential attack.

(a) **Clumped.** Sea stars group together where food is abundant.

(b) **Uniform.** Nesting king penguins exhibit uniform spacing, maintained by aggressive interactions between neighbors.

(c) **Random.** Dandelions grow from windblown seeds that land at random and later germinate.

▲ **Figure 40.15** Patterns of dispersion within a population's geographic range.

A *uniform*, or evenly spaced, pattern of dispersion may result from direct interactions between individuals in the population. Some plants secrete chemicals that inhibit the germination and growth of nearby individuals that could compete for resources. Animals often exhibit uniform dispersion as a result of antagonistic social interactions, such as **territoriality**—the defense of a bounded physical space against encroachment by other individuals (**Figure 40.15b**). Uniform patterns are rarer than clumped patterns.

In *random* dispersion (unpredictable spacing), the position of each individual in a population is independent of other individuals. This pattern occurs in the absence of strong attractions or repulsions among individuals or where key physical or chemical factors are relatively constant across the study area. Plants established by windblown seeds, such as dandelions, may be randomly distributed in a fairly uniform habitat (Figure 40.15c).

## Demographics

The factors that influence population density and dispersion patterns—ecological needs of a species, structure of the environment, and interactions among individuals within the population—also influence other characteristics of populations. **Demography** is the study of the vital statistics of populations and how they change over time. Of particular interest to demographers are birth rates and death rates. A useful way to summarize some of the vital statistics of a population is to make a life table.

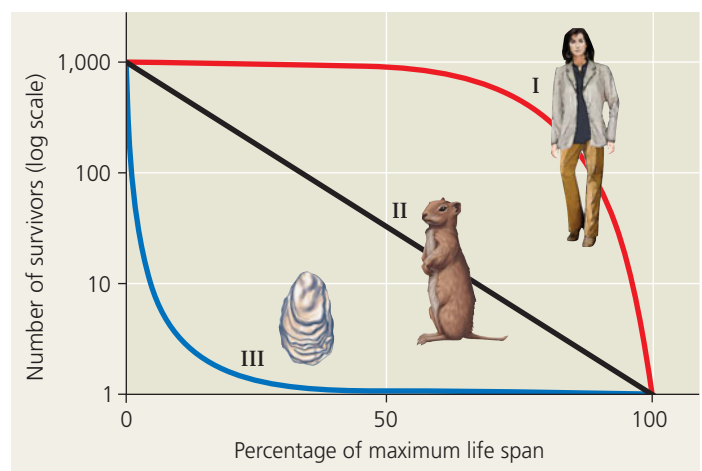

### Life Tables

About a century ago, when life insurance first became available, insurance companies began to estimate how long, on average, people of a given age could be expected to live. To do this, demographers developed **life tables**, age-specific summaries of the survival pattern of a population. Population ecologists adapted this approach to the study of populations in general.

The best way to construct a life table is to follow the fate of a **cohort**, a group of individuals of the same age, from birth until all of the individuals are dead. To build the life table, we need to determine the number of individuals that die in each age-group and to calculate the proportion of the cohort surviving from one age class to the next.

### Survivorship Curves

A graphic method of representing some of the data in a life table is a **survivorship curve**, a plot of the proportion or numbers in a cohort still alive at each age. Generally, a survivorship curve begins with a cohort of a convenient size—say, 1,000 individuals. Though diverse, survivorship curves can be classified into three general types (Figure 40.16). A Type I curve is flat at the start, reflecting low death rates during early and middle life, and then drops steeply as death rates increase among older age-groups. Many large mammals, including humans, that produce few offspring but provide them with good care exhibit this kind of curve. In contrast, a Type III curve drops sharply at the start, reflecting very high death rates for the young, but flattens out as death rates decline for those few individuals that survive the early period of die-off. This type of curve is usually associated with organisms that produce very large numbers of offspring but provide little or no care, such as long-lived plants, many fishes, and most marine invertebrates. An oyster, for example, may release millions of eggs, but most larvae hatched from fertilized

▲ **Figure 40.16 Idealized survivorship curves: Types I, II, and III.** The y-axis is logarithmic and the x-axis is on a relative scale so that species with widely varying life spans can be presented together on the same graph.

eggs die from predation or other causes. Those few offspring that survive long enough to attach to a suitable substrate and begin growing a hard shell tend to survive for a relatively long time. Type II curves are intermediate, with a constant death rate over the organism's life span. This kind of survivorship occurs in some rodents, invertebrates, lizards, and annual plants.

Many species fall somewhere between these basic types of survivorship or show more complex patterns. In birds, mortality is often high among the youngest individuals (as in a Type III curve) but fairly constant among adults (as in a Type II curve). Some invertebrates, such as crabs, may show a “stair-stepped” curve, with brief periods of increased mortality during molts, followed by periods of lower mortality when their protective exoskeleton is hard.

In populations not experiencing immigration or emigration, survivorship is one of the two key factors determining changes in population size. The other key factor determining population trends is reproductive rate.

### Reproductive Rates

Demographers who study sexually reproducing species generally ignore the males and concentrate on the females in a population because only females produce offspring. Therefore, demographers view populations in terms of females giving rise to new females. The simplest way to describe the reproductive pattern of a population is to ask how reproductive output varies with the ages of females.

A **reproductive table**, or fertility schedule, is an age-specific summary of the reproductive rates in a population. It is constructed by measuring the reproductive output of a cohort from birth until death. For a sexual species, the reproductive table tallies the number of female offspring produced by each age-group. **Table 40.1** illustrates a reproductive table for Belding's ground squirrels. Reproductive output for sexual organisms such as birds and mammals is the product of the

## The exponential and logistic models describe the growth of populations

Populations of all species have the potential to expand greatly when resources are abundant. To appreciate the potential for population increase, consider a bacterium that can reproduce by fission every 20 minutes under ideal laboratory conditions. There would be two bacteria after 20 minutes, four after 40 minutes, and eight after 60 minutes. If reproduction continued at this rate for a day and a half without mortality, there would be enough bacteria to form a layer 30 cm deep over the entire globe. Unlimited growth cannot occur for long in nature, however. As population density increases, each individual has access to fewer resources. Ecologists study population growth in idealized conditions and in the more realistic conditions where different factors limit growth. We'll examine both scenarios in this section.

### Per Capita Rate of Increase

Imagine a population consisting of a few individuals living in an ideal, unlimited environment. Under these conditions, there are no external limits on the abilities of individuals to harvest energy, grow, and reproduce. The population will increase in size with every birth and with the immigration of individuals from other populations, and it will decrease in size with every death and with the emigration of individuals out of the population. We can thus define a change in population size during a fixed time interval with the following verbal equation:

$$\begin{array}{ccccccc} \text{Change in} & & \text{Immigrants} & & \text{Emigrants} \\ \text{population} & = & \text{entering} & - & \text{Deaths} & - & \text{leaving} \\ \text{size} & & \text{population} & & & & \text{population} \end{array}$$

For now, we will simplify the equation by ignoring the effects of immigration and emigration.

We can use mathematical notation to express our simplified equation more concisely. If  $N$  represents population size and  $t$  represents time, then  $\Delta N$  is the change in population size and  $\Delta t$  is the time interval (appropriate to the life span or generation time of the species) over which we are evaluating population growth. (The Greek letter delta,  $\Delta$ , indicates change, such as change in time.) Using  $B$  for the number of births in the population during the time interval and  $D$  for the number of deaths, we can rewrite the verbal equation:

$$\frac{\Delta N}{\Delta t} = B - D$$

Next, we can convert this simple model to one in which births and deaths are expressed as the average number of births and deaths per individual (per capita) during the specified time interval. The *per capita birth rate* is the number of offspring produced per unit time by an average member of the population. If, for example, there are 34 births per year in a population of 1,000 individuals, the annual per capita birth rate

**Table 40.1** Reproductive Table for Belding's Ground Squirrels at Tioga Pass

Age (years)	Proportion of Females Weaning a Litter	Mean Size of Litters (Males + Females)	Mean Number of Females in a Litter	Average Number of Female Offspring*
0–1	0.00	0.00	0.00	0.00
1–2	0.65	3.30	1.65	1.07
2–3	0.92	4.05	2.03	1.87
3–4	0.90	4.90	2.45	2.21
4–5	0.95	5.45	2.73	2.59
5–6	1.00	4.15	2.08	2.08
6–7	1.00	3.40	1.70	1.70
7–8	1.00	3.85	1.93	1.93
8–9	1.00	3.85	1.93	1.93
9–10	1.00	3.15	1.58	1.58

**Source** P. W. Sherman and M. L. Morton, Demography of Belding's ground squirrel, *Ecology* 65:1617–1628 (1984).

\*The average number of female offspring is the proportion weaning a litter multiplied by the mean number of females in a litter.

proportion of females of a given age that are breeding and the number of female offspring of those breeding females. Multiplying these numbers gives the average number of female offspring for each female in a given age-group (the last column in Table 40.1). For Belding's ground squirrels, which begin to reproduce at age 1 year, reproductive output rises to a peak at 4 years of age and then falls off in older females.

Reproductive tables vary considerably by species. Squirrels, for example, have a litter of two to six young once a year for less than a decade, whereas oak trees may drop thousands of acorns a year for hundreds of years. Mussels and other invertebrates may release millions of eggs and sperm in a spawning cycle. However, a high reproductive rate will not lead to rapid population growth unless conditions are near ideal for the growth and survival of offspring, as you'll learn in the next section.

### CONCEPT CHECK 40.4

- DRAW IT** Each female of a particular fish species produces millions of eggs per year. Draw and label the most likely survivorship curve for this species, and explain your choice.
- Imagine that you are constructing a life table for a different population of Belding's ground squirrels than the one shown in Table 40.1. If the proportion of females aged 5–6 years weaning a litter is 0.74 and the mean number of females in a litter is 3.01, what is the average number of female offspring for this cohort in a year?
- MAKE CONNECTIONS** A male stickleback fish attacks other males that invade its nesting territory (see Figure 39.15a). Predict the likely pattern of dispersion for male sticklebacks, and explain your reasoning.

For suggested answers, see Appendix A.

is 34/1,000, or 0.034. If we know the annual per capita birth rate (symbolized by  $b$ ), we can use the formula  $B = bN$  to calculate the expected number of births per year in a population of any size. For example, if the annual per capita birth rate is 0.034 and the population size is 500,

$$B = bN = 0.034 \times 500 = 17 \text{ per year}$$

Similarly, the *per capita death rate* (symbolized by  $m$ , for mortality) allows us to calculate the expected number of deaths per unit time in a population, using the formula  $D = mN$ . If  $m = 0.016$  per year, we would expect 16 deaths per year in a population of 1,000 individuals. The per capita birth and death rates can be calculated from estimates of population size and data in life tables and reproductive tables (for example, Table 40.1).

Now we can revise the population growth equation again, using per capita birth and death rates rather than the numbers of births and deaths:

$$\frac{\Delta N}{\Delta t} = bN - mN$$

One final simplification is in order. Population ecologists are most interested in the *difference* between the per capita birth rate and the per capita death rate. This difference is the *per capita rate of increase*, or  $r$ :

$$r = b - m$$

The value of  $r$  indicates whether a given population is growing ( $r > 0$ ) or declining ( $r < 0$ ). **Zero population growth (ZPG)** occurs when the per capita birth and death rates are equal ( $r = 0$ ). Births and deaths still occur in such a population, of course, but they balance each other exactly.

Using the per capita rate of increase, we can now rewrite the equation for change in population size as

$$\frac{\Delta N}{\Delta t} = rN$$

Remember that this equation is for a specific time interval (often one year) and does not include immigration or emigration. Most ecologists prefer to use differential calculus to express population growth *instantaneously*:

$$\frac{dN}{dt} = r_{\text{inst}}N$$

Here,  $r_{\text{inst}}$  is the instantaneous per capita rate of increase.

## Exponential Growth

Earlier we described a population whose members all have access to abundant food and are free to reproduce at their physiological capacity. Population increase under these ideal conditions is called **exponential population growth**. Under these conditions, the per capita rate of increase may assume the maximum rate for the species, denoted as  $r_{\text{max}}$ . The equation for exponential population growth is

$$\frac{dN}{dt} = r_{\text{max}}N$$

**▲ Figure 40.17 Population growth predicted by the exponential model.** This graph compares growth in two populations with different values of  $r_{\text{max}}$ . Increasing the value of  $r_{\text{max}}$  from 0.5 to 1.0 increases the rate of rise in population size over time, as reflected by the relative slopes of the curves at any given population size.

The size of a population that is growing exponentially increases at a constant rate, resulting eventually in a J-shaped growth curve when population size is plotted over time (**Figure 40.17**). Although the maximum *rate* of increase is constant, the population grows more quickly when it is large than when it is small; thus, the curves in Figure 40.17 get progressively steeper over time. This occurs because population growth depends on  $N$  as well as  $r_{\text{max}}$ , and larger populations experience more births (and deaths) than small ones growing at the same per capita rate. It is also clear from Figure 40.17 that a population with a higher maximum rate of increase ( $dN/dt = 1.0N$ ) will grow faster than one with a lower rate of increase ( $dN/dt = 0.5N$ ).

The J-shaped curve of exponential growth is characteristic of some populations that are introduced into a new environment or whose numbers were drastically reduced and are rebounding. For example, the population of elephants in Kruger National Park, South Africa, grew exponentially for approximately 60 years after they were first protected from hunting (**Figure 40.18**). The increasing number of elephants eventually caused enough damage to vegetation in the park that a collapse in their food supply was likely. To protect other species and the ecosystem before that happened, park managers began limiting the elephant population by using birth control and exporting elephants to other countries.

## Carrying Capacity

The exponential growth model assumes that resources are unlimited, which is rarely the case in the real world. Ultimately, there is a limit to the number of individuals that can occupy a habitat. Ecologists define **carrying capacity**, symbolized by  $K$ ,

▲ **Figure 40.18** Exponential growth in the African elephant population of Kruger National Park, South Africa.

as the maximum population size that a particular environment can sustain. Carrying capacity varies over space and time with the abundance of limiting resources. Energy, shelter, refuge from predators, nutrient availability, water, and suitable nesting sites can all be limiting factors. For example, the carrying capacity for bats may be high in a habitat with abundant flying insects and roosting sites, but lower where there is abundant food but fewer suitable shelters.

Crowding and resource limitation can have a profound effect on population growth rate. If individuals cannot obtain sufficient resources to reproduce, the per capita birth rate ( $b$ ) will decline. If they cannot consume enough energy to maintain themselves or if disease increases with density, the per capita death rate ( $m$ ) may increase. A decrease in  $b$  or an increase in  $m$  lowers the per capita rate of increase ( $r$ ).

## The Logistic Growth Model

We can modify our mathematical model to include changes in growth rate as  $N$  increases. In the **logistic population growth** model, the per capita rate of increase approaches zero as the population size nears its carrying capacity.

To construct the logistic model, we start with the exponential population growth model and add an expression that reduces the per capita rate of increase as  $N$  increases. If the maximum sustainable population size (carrying capacity) is  $K$ , then  $K - N$  is the number of additional individuals the environment can support, and  $(K - N)/K$  is the fraction of  $K$  that is still available for population growth. By multiplying the exponential rate of increase  $r_{\max}N$  by  $(K - N)/K$ , we modify the change in population size as  $N$  increases:

$$\frac{dN}{dt} = r_{\max}N \frac{(K - N)}{K}$$

When  $N$  is small compared with  $K$ , the term  $(K - N)/K$  is close to 1, and the per capita rate of increase,  $r_{\max}(K - N)/K$ , approaches the maximum rate of increase. But when  $N$  is large and resources are limiting, then  $(K - N)/K$  is close to 0, and

**Table 40.2** Logistic Growth of a Hypothetical Population ( $K = 1,500$ )

Population Size ( $N$ )	Maximum Rate of Increase ( $r_{\max}$ )	$\frac{K - N}{K}$	Per Capita Rate of Increase $\frac{(K - N)}{K} r_{\max}$	Population Growth Rate* $r_{\max}N \frac{(K - N)}{K}$
25	1.0	0.98	0.98	+25
100	1.0	0.93	0.93	+93
250	1.0	0.83	0.83	+208
500	1.0	0.67	0.67	+333
750	1.0	0.50	0.50	+375
1,000	1.0	0.33	0.33	+333
1,500	1.0	0.00	0.00	0

\*Rounded to the nearest whole number.

the per capita rate of increase is small. When  $N$  equals  $K$ , the population stops growing. **Table 40.2** shows calculations of population growth rate for a hypothetical population growing according to the logistic model, with  $r_{\max} = 1.0$  per individual per year. Notice that the overall population growth rate is highest, +375 individuals per year, when the population size is 750, or half the carrying capacity. At a population size of 750, the per capita rate of increase remains relatively high (one-half the maximum rate), but there are more reproducing individuals ( $N$ ) in the population than at lower population sizes.

As shown in **Figure 40.19**, the logistic model of population growth produces a sigmoid (S-shaped) growth curve when  $N$

▲ **Figure 40.19** Population growth predicted by the logistic model. The rate of population growth decreases as population size ( $N$ ) approaches the carrying capacity ( $K$ ) of the environment. The red line shows logistic growth in a population where  $r_{\max} = 1.0$  and  $K = 1,500$  individuals. For comparison, the blue line illustrates a population continuing to grow exponentially with the same  $r_{\max}$ .

## Using the Logistic Equation to Model Population Growth

**What Happens to the Size of a Population When It Overshoots Its Carrying Capacity?** In the logistic population growth model, the per capita rate of population increase approaches zero as the population size ( $N$ ) approaches the carrying capacity ( $K$ ). Under some conditions, however, a population in the laboratory or the field can overshoot  $K$ , at least temporarily. For instance, if food becomes limiting to a population, there may be a delay before reproduction declines, and  $N$  may briefly exceed  $K$ . In this exercise, you will use the logistic equation to model the growth of the hypothetical population in Table 40.2 when  $N > K$ .

### Interpret the Data

1. Assuming that  $r_{\max} = 1.0$  and  $K = 1,500$ , calculate the population growth rate for four cases where population size ( $N$ ) is greater than carrying capacity ( $K$ ):  $N = 1,510$ ; 1,600; 1,750; and 2,000 individuals. To do this, first write the equation for population growth rate given in Table 40.2. Plug in the values for each of the four cases, starting with  $N = 1,510$ , and solve the equation for each one. Which population size has the highest growth rate?
2. If  $r_{\max}$  is doubled, predict how the population growth rates will change for the four population sizes given in question 1. Now calculate the population growth rate for the same four cases, this time assuming that  $r_{\max} = 2.0$  (and  $K$  still = 1,500).
3. Now let's see how the growth of a real-world population of *Daphnia* corresponds to this model. At what times in Figure 40.20b is the *Daphnia* population changing in ways that correspond to the values you calculated? Hypothesize why the population drops below the carrying capacity briefly late in the experiment.

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

is plotted over time (the red line). New individuals are added to the population most rapidly at intermediate population sizes, when there is not only a breeding population of substantial size, but also lots of available space and other resources in the environment. The population growth rate decreases dramatically as  $N$  approaches  $K$ .

Note that we haven't said anything yet about *why* the population growth rate decreases as  $N$  approaches  $K$ . For a population's growth rate to decrease, the birth rate  $b$  must decrease, the death rate  $m$  must increase, or both. Later in this chapter, we'll consider some of the factors affecting these rates, including the presence of disease, predation, and limited amounts of food and other resources. In the **Scientific Skills Exercise**, you can model what happens to a population if  $N$  becomes *greater* than  $K$ .

## The Logistic Model and Real Populations

The growth of laboratory populations of some small animals, such as beetles and crustaceans, and of some microorganisms, such as bacteria, *Paramecium*, and yeasts, fits an

► **Figure 40.20**  
**How well do these populations fit the logistic growth model?** In each graph, the black dots plot the measured growth of the population, and the red curve is the growth predicted by the logistic model.

**(a) A *Paramecium* population in the lab.** Growth in a small culture closely approximates logistic growth if the researcher maintains a constant environment.

**(b) A *Daphnia* (water flea) population in the lab.** Growth in a small culture does not correspond well to the logistic model. This population overshoots the carrying capacity of its artificial environment before reaching an approximately stable size.

S-shaped curve fairly well under conditions of limited resources (**Figure 40.20a**). These populations are grown in a constant environment lacking predators and competing species that may reduce growth of the populations, conditions that rarely occur in nature.

The assumptions built into the logistic model clearly do not apply to all populations. It assumes that populations adjust instantaneously to growth and approach carrying capacity smoothly. In reality, there is often a delay before the negative effects of an increasing population are realized. If food becomes limiting for a population, for instance, reproduction will decline eventually, but females may use their energy reserves to continue reproducing for a short time. This may cause the population to overshoot its carrying capacity temporarily, as shown for the water fleas in **Figure 40.20b**. Other populations fluctuate greatly, making it difficult even to define carrying capacity. We'll examine some possible reasons for such fluctuations later in this chapter.

The logistic model is a useful starting point for thinking about how populations grow and for constructing more complex models. The model is also important in conservation biology for predicting how rapidly a particular population might increase in numbers after it has been reduced to a small size and for estimating sustainable harvest rates for wildlife populations. Conservation biologists can use the model to estimate the critical size below which populations of certain organisms may become extinct.

#### CONCEPT CHECK 40.5

1. Why does a constant rate of increase ( $r_{\max}$ ) for a population produce a growth curve that is J-shaped?
2. Explain why a population that fits the logistic growth model increases more rapidly at intermediate size than at relatively small and large sizes.
3. **MAKE CONNECTIONS** Many viruses are pathogens of animals and plants (see Concept 17.3). How might the presence of pathogens alter the carrying capacity of a population? Explain.

For suggested answers, see Appendix A.

## CONCEPT 40.6

### Population dynamics are influenced strongly by life history traits and population density

**EVOLUTION** What environmental factors keep populations from growing indefinitely? Why are some populations fairly stable in size, while others are not? The answers to these questions depend in part on the traits of individuals, influenced through time by natural selection, and also on factors in the environment that vary with population density.

In every species, there are trade-offs between survival and reproductive traits such as frequency of reproduction, number of offspring (number of seeds produced by plants; litter or clutch size for animals), and investment in parental care. The traits that affect an organism's schedule of reproduction and survival make up its **life history**. A life history entails three main variables: when reproduction begins (the age at first reproduction or age at maturity), how often the organism reproduces, and how many offspring are produced per reproductive episode.

#### "Trade-offs" and Life Histories

No organism could produce unlimited numbers of offspring *and* provision them well. There is a trade-off between reproduction and survival. For instance, researchers in Scotland found that female red deer that reproduced in a given summer were more likely to die the next winter than were females that did not reproduce.

Selective pressures influence the trade-off between the number and size of offspring. Plants and animals whose young

are likely to die often produce many small offspring. Plants that colonize disturbed environments, for example, usually produce many small seeds, only a few of which may reach a suitable habitat. Small size may also increase the chance of seedling establishment by enabling the seeds to be carried longer distances to a broader range of habitats (**Figure 40.21a**). Animals that suffer high predation rates, such as quail, sardines, and mice, also tend to produce large numbers of offspring.

In other organisms, extra investment on the part of the parent greatly increases the offspring's chance of survival. Walnut and Brazil nut trees provision large seeds with nutrients that help the seedlings become established (**Figure 40.21b**). Primates generally bear only one or two offspring at a time; parental care and an extended period of learning in the first several years of life are very important to offspring fitness. Such provisioning and extra care can be especially important in habitats with high population densities.

Ecologists have attempted to connect differences in favored traits at different population densities with the logistic growth model discussed in Concept 40.5. Selection for traits that are sensitive to population density and are favored at high densities

(a) Dandelions grow quickly and release a large number of tiny fruits, each containing a single seed. Producing numerous seeds ensures that at least some will grow into plants that eventually produce seeds themselves.

(b) Some plants, such as the Brazil nut tree (right), produce a moderate number of large seeds in pods (above). Each seed's large endosperm provides nutrients for the embryo, an adaptation that helps a relatively large fraction of offspring survive.

▲ **Figure 40.21** Variation in the size of seed crops in plants.

is known as **K-selection**, or density-dependent selection. In contrast, selection for traits that maximize reproductive success in uncrowded environments (low densities) is called **r-selection**, or density-independent selection. These names follow from the variables of the logistic equation. *K*-selection is said to operate in populations living at a density near the limit imposed by their resources (the carrying capacity, *K*), where competition among individuals is stronger. Mature trees growing in an old-growth forest are an example of *K*-selected organisms. In contrast, *r*-selection is said to maximize *r*, the per capita rate of increase, and occurs in environments in which population densities are well below carrying capacity or individuals face little competition. Weeds growing in an abandoned agricultural field are an example of *r*-selected organisms.

## Population Change and Population Density

Similar to the case of *r-selection*, a birth rate or death rate that does *not* change with population density is said to be **density independent**. In a classic study of population regulation, Andrew Watkinson and John Harper, of the University of Wales, found that the mortality of dune fescue grass (*Vulpia fasciculata*) is mainly due to physical factors that kill similar proportions of a local population, regardless of its density. For example, drought stress that arises when the roots of the grass are uncovered by shifting sands is a density-independent factor. In contrast, and similar to *K-selection*, a death rate that rises as population density rises is said to be **density dependent**, as is a birth rate that falls with rising density. Watkinson and Harper found that reproduction by dune fescue declines as population density increases, in part because water or nutrients become more scarce. Thus, the key factors regulating birth rate in this population are density dependent, while death rate is largely regulated by density-independent factors. **Figure 40.22** shows how the combination of density-dependent reproduction and density-independent mortality can stop population growth, leading to an equilibrium population density in species such as dune fescue.

## Mechanisms of Density-Dependent Population Regulation

Without some type of negative feedback between population density and the rates of birth and death, a population would never stop growing. Density-dependent regulation provides that feedback, halting population growth through mechanisms that reduce birth rates or increase death rates. Several mechanisms of density-dependent population regulation are described in **Figure 40.23**.

These various examples of population regulation by negative feedback show how increased densities cause population growth rates to decline by affecting reproduction, growth, and survival. But while negative feedback helps explain why populations stop growing, it does not address why some populations fluctuate dramatically while others remain relatively stable. That is the topic we address next.

▲ **Figure 40.22 Determining equilibrium for population density.** This simple model considers only birth and death rates. (Immigration and emigration rates are assumed to be either zero or equal.) In this example, the birth rate changes with population density, while the death rate is constant. At the equilibrium density (*Q*), the birth and death rates are equal.

**DRAW IT** Redraw this figure for the case where the birth and death rates are both density dependent, as occurs for many species.

## Population Dynamics

All populations for which we have long-term data show some fluctuation in size. Such population fluctuations from year to year or place to place, called **population dynamics**, are influenced by many factors and in turn affect other species, including our own. For example, fluctuations in fish populations influence seasonal harvests of commercially important species. The study of population dynamics focuses on the complex interactions between biotic and abiotic factors that cause variation in population sizes.

## Stability and Fluctuation

Populations of large mammals were once thought to remain relatively stable over time, but long-term studies have challenged that idea. For instance, the moose population on Isle Royale in Lake Superior fluctuates substantially from year to year. What causes the size of this population to change so dramatically? Harsh weather, particularly cold winters, can weaken the moose and reduce food availability, decreasing the size of the population. When moose numbers are high, other factors, such as an increase in the density of ticks and other parasites, also cause the population to shrink.

Predation is an additional factor that regulates the population. Moose from the mainland colonized the island around 1900 by walking across the frozen lake. Wolves, which rely on moose for most of their food, followed around 1950. Because the lake has not frozen over in recent years, both populations have been isolated from immigration and emigration. Despite this isolation, the moose population experienced two major

As population density increases, many density-dependent mechanisms slow or stop population growth by decreasing birth rates or increasing death rates.

### Competition for Resources

Increasing population density intensifies competition for nutrients and other resources, reducing reproductive rates. Farmers minimize the effect of resource competition on the growth of grains such as wheat (*Triticum aestivum*) and other crops by applying fertilizers to reduce nutrient limitations on crop yield.

### Predation

Predation can be an important cause of density-dependent mortality if a predator captures more food as the population density of the prey increases. As a prey population builds up, predators may also feed preferentially on that species. Population increases in the collared lemming (*Dicrostonyx groenlandicus*) lead to density-dependent predation by several predators, including the snowy owl (*Bubo scandiacus*).

### Disease

If the transmission rate of a disease increases as a population becomes more crowded, then the disease's impact is density dependent. In humans, the respiratory diseases influenza (flu) and tuberculosis are spread through the air when an infected person sneezes or coughs. Both diseases strike a greater percentage of people in densely populated cities than in rural areas.

### Toxic Wastes

Yeasts, such as the brewer's yeast *Saccharomyces cerevisiae*, are used to convert carbohydrates to ethanol in winemaking. The ethanol that accumulates in the wine is toxic to yeasts and contributes to density-dependent regulation of yeast population size. The alcohol content of wine is usually less than 13% because that is the maximum concentration of ethanol that most wine-producing yeast cells can tolerate.

### Territoriality

Territoriality can limit population density when space becomes the resource for which individuals compete. Cheetahs (*Acinonyx jubatus*) use a chemical marker in urine to warn other cheetahs of their territorial boundaries. The presence of surplus, or nonbreeding, individuals is a good indication that territoriality is restricting population growth.

### Intrinsic Factors

Intrinsic physiological factors sometimes regulate population size. Reproductive rates of white-footed mice (*Peromyscus leucopus*) in a field enclosure can drop even when food and shelter are abundant. This drop in reproduction at high population density is associated with aggressive interactions and hormonal changes that delay sexual maturation and depress the immune system.

▲ **Figure 40.24** Fluctuations in moose and wolf populations on Isle Royale, 1959–2011.

**BioFlix** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on Population Ecology.

increases and collapses during the last 50 years (**Figure 40.24**). The first collapse coincided with a peak in the numbers of wolves from 1975 to 1980. The second collapse, around 1995, coincided with harsh winter weather, which increased the energy needs of the animals and made it harder for the moose to find food under the deep snow.

### Immigration, Emigration, and Metapopulations

So far, our discussion of population dynamics has focused mainly on the contributions of births and deaths. However, immigration and emigration also influence populations. When a population becomes crowded and resource competition increases (see **Figure 40.23**), emigration often increases.

Immigration and emigration are particularly important when a number of local populations are linked, forming a **metapopulation**. Local populations in a metapopulation can be thought of as occupying discrete patches of suitable habitat in a sea of otherwise unsuitable habitat. Such patches vary in size, quality, and isolation from other patches, factors that influence how many individuals move among the populations. If one population becomes extinct, the patch it occupied can be recolonized by immigrants from another population.

The Glanville fritillary (*Melitaea cinxia*) illustrates the movement of individuals between populations. This butterfly is found in about 500 meadows across the Åland Islands of Finland, but its potential habitat in the islands is much larger, approximately 4,000 suitable patches. New populations of the butterfly regularly appear and existing populations become extinct, constantly shifting the locations of the 500 colonized patches (**Figure 40.25**). The species persists in a balance of extinctions and recolonizations.

The metapopulation concept underscores the significance of immigration and emigration in the butterfly populations.

▲ **Figure 40.25** The Glanville fritillary: a metapopulation. On the Åland Islands, local populations of this butterfly (filled circles) are found in only a fraction of the suitable habitat patches (open circles) at any given time. Individuals can move between local populations and colonize unoccupied patches.

It also helps ecologists understand population dynamics and gene flow in patchy habitats, providing a framework for the conservation of species living in a network of habitat fragments and reserves. In fact, many aspects of population ecology that you have studied in this chapter have practical applications. Farmers may want to reduce the abundance of insect pests or stop the growth of an invasive weed that is spreading rapidly. Conservation ecologists need to know what environmental factors create favorable feeding or breeding habitats for endangered species, such as the white rhinoceros and the whooping crane. Management programs based on population-regulating factors have helped prevent the extinction of many endangered species.

### CONCEPT CHECK 40.6

1. In the fish called the peacock wrasse (*Symphodus tinca*), females disperse some of their eggs widely and lay other eggs in a nest. Only the latter receive parental care. Explain the trade-offs in reproduction that this behavior illustrates.
2. **WHAT IF?** Mice that experience stress such as a food shortage will sometimes abandon their young. Explain how this behavior might have evolved in the context of reproductive trade-offs and life history.
3. **MAKE CONNECTIONS** Negative feedback is a process that regulates biological systems (see Concept 32.1). Explain how the density-dependent birth rate of dune fescue grass exemplifies negative feedback.

For suggested answers, see Appendix A.

# 40 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 40.1

#### Earth's climate influences the structure and distribution of terrestrial biomes (pp. 820–826)

- Global **climate** patterns are largely determined by the input of solar energy and Earth's revolution around the sun.
- The changing angle of the sun over the year, bodies of water, and mountains exert seasonal, regional, and local effects on **macroclimate**.
- **Climographs** show that temperature and precipitation are correlated with **biomes**. Other factors also influence biome location.
- Terrestrial biomes are often named for major physical or climatic factors and for their predominant vegetation. Vertical layering is an important feature of terrestrial biomes.

? *Some arctic tundra ecosystems receive as little rainfall as deserts but have much more dense vegetation. Based on Figure 40.8, what climatic factor might explain this difference?*

### CONCEPT 40.2

#### Aquatic biomes are diverse and dynamic systems that cover most of Earth (pp. 827–830)

- Aquatic biomes are characterized primarily by their physical environment rather than by climate and are often layered with regard to light penetration, temperature, and community structure.
- In the ocean and in most lakes, an abrupt temperature change called a **thermocline** separates a more uniformly warm upper layer from more uniformly cold deeper waters.

? *In which aquatic biomes might you find an aphotic zone?*

### CONCEPT 40.3

#### Interactions between organisms and the environment limit the distribution of species (pp. 830–832)

- Ecologists want to know not only *where* species occur but also *why* those species occur where they do.
- The distribution of species may be limited by **dispersal**, **biotic** (living) factors, and **abiotic** (physical) factors, such as temperature extremes, salinity, and water availability.

? *If you were an ecologist studying the chemical and physical limits to the distributions of species, how might you rearrange the flowchart in Figure 40.12?*

### CONCEPT 40.4

#### Dynamic biological processes influence population density, dispersion, and demographics (pp. 832–835)

- Population **density**—the number of individuals per unit area or volume—reflects the interplay of births, deaths, immigration, and emigration. Environmental and social factors influence the **dispersion** of individuals.
- Populations increase from births and **immigration** and decrease from deaths and **emigration**. **Life tables**, **survivorship curves**, and **reproductive tables** summarize specific trends in **demography**.

? *Gray whales (*Eschrichtius robustus*) gather each winter near Baja California to give birth. How might such behavior make it easier for ecologists to estimate birth and death rates for the species?*

### CONCEPT 40.5

#### The exponential and logistic models describe the growth of populations (pp. 835–839)

- If immigration and emigration are ignored, a population's growth rate (the per capita rate of increase) equals its birth rate minus its death rate.
- The **exponential growth** equation  $dN/dt = r_{\max}N$  represents a population's potential growth in an unlimited environment, where  $r_{\max}$  is the maximum per capita rate of increase and  $N$  is the number of individuals in the population.

- Exponential growth cannot be sustained for long in any population. A more realistic population model limits growth by incorporating **carrying capacity** ( $K$ ), the maximum population size the environment can support. According to the **logistic growth** equation  $dN/dt = r_{\max}N(K - N)/K$ , growth levels off as population size approaches the carrying capacity.

- The logistic model fits few real populations perfectly, but it is useful for estimating possible growth.

? *As an ecologist who manages a wildlife preserve, you want to increase the preserve's carrying capacity for a particular endangered species. How might you go about accomplishing this?*

### CONCEPT 40.6

#### Population dynamics are influenced strongly by life history traits and population density (pp. 839–842)

- **Life history** traits are evolutionary outcomes reflected in the development, physiology, and behavior of organisms.
- **Density-dependent** changes in birth and death rates curb population increase through negative feedback. Density-dependent limiting factors include intraspecific competition for limited food or space, increased predation, disease, intrinsic physiological factors, and buildup of toxic substances.

- All populations exhibit some size fluctuations, and many undergo regular boom-and-bust cycles influenced by complex interactions between biotic and abiotic factors. A **metapopulation** is a group of populations linked by immigration and emigration.

**?** Name one biotic and one abiotic factor that contribute to yearly fluctuations in the size of the human population.

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

- Which of the following biomes is correctly paired with the description of its climate?
  - savanna—low temperature, precipitation uniform during the year
  - tundra—long summers, mild winters
  - temperate broadleaf forest—relatively short growing season, mild winters
  - temperate grasslands—relatively warm winters, most rainfall in summer
  - tropical forests—nearly constant day length and temperature
- A population's carrying capacity
  - may change as environmental conditions change.
  - can be accurately calculated using the logistic growth model.
  - generally remains constant over time.
  - increases as the per capita growth rate ( $r$ ) decreases.
  - can never be exceeded.

### Level 2: Application/Analysis

- When climbing a mountain, we can observe transitions in biological communities that are analogous to the changes
  - in biomes at different latitudes.
  - in different depths in the ocean.
  - in a community through different seasons.
  - in an ecosystem as it evolves over time.
  - across the United States from east to west.
- According to the logistic growth equation

$$\frac{dN}{dt} = r_{\max}N \frac{(K - N)}{K}$$

- the number of individuals added per unit time is greatest when  $N$  is close to zero.
- the per capita growth rate ( $r$ ) increases as  $N$  approaches  $K$ .
- population growth is zero when  $N$  equals  $K$ .
- the population grows exponentially when  $K$  is small.
- the birth rate ( $b$ ) approaches zero as  $N$  approaches  $K$ .

### Level 3: Synthesis/Evaluation

- DRAW IT** After examining Figure 40.13, you decide to study feeding relationships among sea otters, sea urchins, and kelp. You know that sea otters prey on sea urchins and that urchins eat kelp. At four coastal sites, you measure kelp abundance. Then you spend one day at each site and mark whether otters are present or absent every 5 minutes during the day. Make a graph that shows how otter density depends on kelp abundance, using the data below. Then formulate a hypothesis to explain the pattern you observed.

Site	Kelp Abundance (% cover)	Otter Density (# sightings per day)
1	75	98
2	15	18
3	60	85
4	25	36

- WHAT IF** If the direction of Earth's rotation reversed, the most predictable effect would be
  - no more night and day.
  - a big change in the length of the year.
  - winds blowing from west to east along the equator.
  - a loss of seasonal variation at high latitudes.
  - the elimination of ocean currents.

### 7. SCIENTIFIC INQUIRY

Jens Clausen and colleagues, at the Carnegie Institution of Washington, studied how the size of yarrow plants (*Achillea lanulosa*) growing on the slopes of the Sierra Nevada varied with elevation. They found that plants from low elevations were generally taller than plants from high elevations, as shown below:

**Source** J. Clausen et al., Experimental studies on the nature of species. III. Environmental responses of climatic races of *Achillea*, Carnegie Institution of Washington Publication No. 581 (1948).

Clausen and colleagues proposed two hypotheses to explain this variation within a species: (1) There are genetic differences between populations of plants found at different elevations. (2) The species has developmental flexibility and can assume tall or short growth forms, depending on local abiotic factors. If you had seeds from yarrow plants found at low and high elevations, what experiments would you perform to test these hypotheses?

### 8. FOCUS ON EVOLUTION

Discuss how the concept of time applies to ecological situations and evolutionary changes. Do ecological time and evolutionary time ever overlap? If so, what are some examples?

### 9. FOCUS ON INTERACTIONS

In a short essay (100–150 words), identify the factor or factors in Figure 40.23 that you think may ultimately be most important for density-dependent population regulation in humans, and explain your reasoning.

For selected answers, see Appendix A.

# 41 Species Interactions

## KEY CONCEPTS

- 41.1** Interactions within a community may help, harm, or have no effect on the species involved
- 41.2** Diversity and trophic structure characterize biological communities
- 41.3** Disturbance influences species diversity and composition
- 41.4** Biogeographic factors affect community diversity
- 41.5** Pathogens alter community structure locally and globally

## OVERVIEW

### Communities in Motion

**D**eep in the Lembeh Strait of Indonesia, a crab in the family Homolidae scuttles across the ocean floor holding a large sea urchin on its back (**Figure 41.1**). When a predatory fish arrives, the crab settles quickly into the sediments and puts its living shield to use. The fish darts in and tries to bite the crab. In response, the crab tilts the spiny sea urchin toward whichever side the fish attacks. The fish eventually gives up and swims away.

The “carrier crab” in Figure 41.1 clearly benefits from having the sea urchin on its back. But how does the sea urchin fare in this relationship? Its association with the crab might harm it, help it, or have no effect on its survival and reproduction. For example, the sea urchin may be harmed if the crab sets it

down in an unsuitable habitat or in a place where it is vulnerable to predators. On the other hand, the crab may also protect the sea urchin from predators while carrying it. Additional observations or experiments would be needed before ecologists could answer this question.

In Chapter 40, you learned how individuals within a population can affect other individuals of the same species. This chapter will examine ecological interactions between populations of different species. A group of populations of different species living close enough to interact is called a biological **community**. Ecologists define the boundaries of a particular community to fit their research questions: They might study the community of decomposers and other organisms living on a rotting log, the benthic community in Lake Superior, or the community of trees and shrubs in Great Smoky Mountains National Park in North Carolina and Tennessee.

We begin this chapter by exploring the kinds of interactions that occur between species in a community, such as the crab and sea urchin in Figure 41.1. We’ll then consider several factors that are most significant in structuring a community—in determining how many species there are, which

particular species are present, and the relative abundance of these species. Finally, we’ll apply some of the principles of community ecology to the study of human disease.

▼ **Figure 41.1** Which species benefits from this interaction?

## CONCEPT 41.1

### Interactions within a community may help, harm, or have no effect on the species involved

Some key relationships in the life of an organism are its interactions with individuals of other species in the community. These **interspecific interactions** include competition, predation, herbivory, symbiosis (including parasitism, mutualism, and commensalism), and facilitation. In this section, we will define and describe each of these interactions, recognizing that ecologists do not always agree on the precise boundaries of each type of interaction.

We will use the symbols + and – to indicate how each interspecific interaction affects the survival and reproduction of the two species engaged in the interaction. For example, predation is a +/– interaction, with a positive effect on the survival and reproduction of the predator population and a negative effect on that of the prey population. Mutualism is a ++ interaction because the survival and reproduction of both species are increased in the presence of the other. We use a 0 to indicate that a population is not affected by the interaction in any known way.

#### Competition

**Interspecific competition** is a –/– interaction that occurs when individuals of different species compete for a resource that limits their growth and survival. Weeds growing in a garden compete with garden plants for nutrients and water. Lynx and foxes in the northern forests of Alaska and Canada compete for prey such as snowshoe hares. In contrast, some resources, such as oxygen, are rarely in short supply, at least on land; most terrestrial species use this resource, but they do not usually compete for it.

#### Competitive Exclusion

What happens in a community when two species compete for limited resources? In 1934, Russian ecologist G. F. Gause studied this question using laboratory experiments with two species of ciliated protists, *Paramecium aurelia* and *Paramecium caudatum*. He cultured the species under stable conditions, adding a constant amount of food each day. When Gause grew the two species separately, each population grew rapidly and then leveled off at the apparent carrying capacity of the culture (see Figure 40.20a for an illustration of the logistic growth of *P. aurelia*). But when Gause grew the two species together, *P. caudatum* became extinct in the culture. Gause inferred that *P. aurelia* had a competitive edge in obtaining food. He concluded that two species competing for the same limiting resources cannot coexist permanently in the same place. In the absence of disturbance, one species will use the resources more efficiently and reproduce more rapidly than the other. Even a slight reproductive advantage will eventually lead to

local elimination of the inferior competitor, an outcome called **competitive exclusion**.

#### Ecological Niches and Natural Selection

**EVOLUTION** The influence of evolution is evident in the concept of the **ecological niche**, the specific set of biotic and abiotic resources that an organism uses in its environment. American ecologist Eugene Odum used the following analogy to explain the niche concept: If an organism's habitat is its “address,” the niche is the organism's “profession.” The niche of a tropical tree lizard, for instance, includes the temperature range it tolerates, the size of branches on which it perches, the time of day when it is active, and the sizes and kinds of insects it eats. Such factors define the lizard's niche, or ecological role—how it fits into an ecosystem.

We can use the niche concept to restate the principle of competitive exclusion: Two species cannot coexist permanently in a community if their niches are identical. However, ecologically similar species *can* coexist in a community if one or more significant differences in their niches arise through time. Evolution by natural selection can result in one of the species using a different set of resources or similar resources at different times of the day or year. The differentiation of niches that enables similar species to coexist in a community is called **resource partitioning** (Figure 41.2). You can think of resource partitioning in a community as “the

*A. distichus* perches on fence posts and other sunny surfaces.

*A. insolitus* usually perches on shady branches.

**▲ Figure 41.2 Resource partitioning among Dominican Republic lizards.** Seven species of *Anolis* lizards live in close proximity, and all feed on insects and other small arthropods. However, competition for food is reduced because each lizard species has a different preferred perch, thus occupying a distinct niche.

ghost of competition past”—the indirect evidence of earlier interspecific competition resolved by the evolution of niche differentiation.

As a result of competition, a species' *fundamental niche*, which is the niche potentially occupied by that species, is often different from its *realized niche*, the portion of its fundamental niche that it actually occupies in a particular environment. Ecologists can identify the fundamental niche of a species by testing the range of conditions in which it grows and reproduces in the absence of competitors. They can also test whether a potential competitor limits a species' realized niche

### ▼ Figure 41.3 Inquiry

#### Can a species' niche be influenced by interspecific competition?

**Experiment** Ecologist Joseph Connell studied two barnacle species—*Chthamalus stellatus* and *Balanus balanoides*—that have a stratified distribution on rocks along the coast of Scotland. *Chthamalus* is usually found higher on the rocks than *Balanus*. To determine whether the distribution of *Chthamalus* is the result of interspecific competition with *Balanus*, Connell removed *Balanus* from the rocks at several sites.

**Results** *Chthamalus* spread into the region formerly occupied by *Balanus*.

**Conclusion** Interspecific competition makes the realized niche of *Chthamalus* much smaller than its fundamental niche.

**Source** J. H. Connell, The influence of interspecific competition and other factors on the distribution of the barnacle *Chthamalus stellatus*, *Ecology* 42:710–723 (1961).

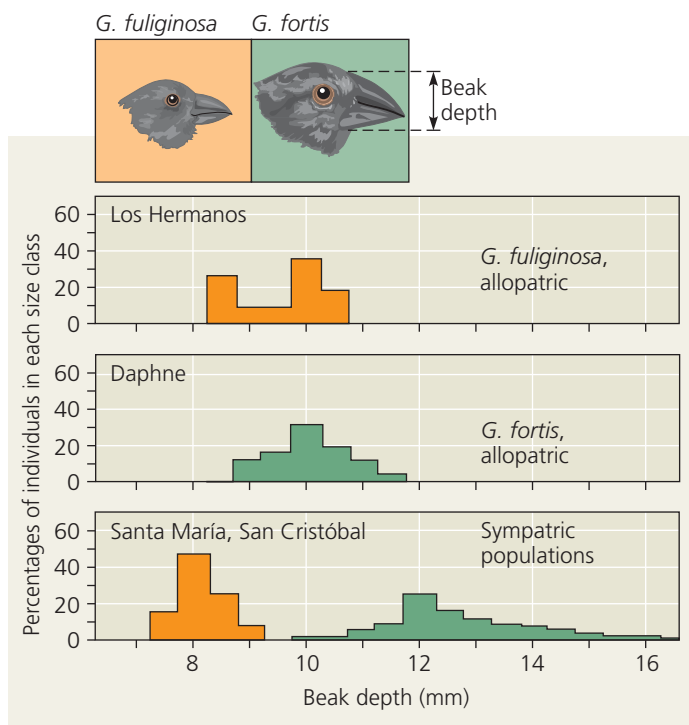

See the related Experimental Inquiry Tutorial in MasteringBiology.

**WHAT IF?** Other observations showed that *Balanus* cannot survive high on the rocks because it dries out during low tides. How would *Balanus*'s realized niche compare with its fundamental niche?

by removing the competitor and seeing if the first species expands into the newly available space. The classic experiment depicted in **Figure 41.3** clearly showed that competition between two barnacle species kept one species from occupying part of its fundamental niche.

### Character Displacement

Closely related species whose populations are sometimes allopatric (geographically separate; see Chapter 22) and sometimes sympatric (geographically overlapping) provide more evidence for the importance of competition in structuring communities. In some cases, the allopatric populations of such species are morphologically similar and use similar resources. By contrast, sympatric populations, which would potentially compete for resources, show differences in body structures and in the resources they use. This tendency for characteristics to diverge more in sympatric than in allopatric populations of two species is called **character displacement**. An example of character displacement in Galápagos finches is shown in **Figure 41.4**.

**▲ Figure 41.4 Character displacement: indirect evidence of past competition.** Allopatric populations of *Geospiza fuliginosa* and *Geospiza fortis* on Los Hermanos and Daphne Islands have similar beak morphologies (top two graphs) and presumably eat similarly sized seeds. However, where the two species are sympatric on Santa María and San Cristóbal, *G. fuliginosa* has a shallower, smaller beak and *G. fortis* a deeper, larger one (bottom graph), adaptations that favor eating different-sized seeds.

**?** If the beak length of *G. fortis* is typically 12% longer than the beak depth, what is the predicted beak length of *G. fortis* individuals with the smallest beak depths observed on Santa María and San Cristóbal Islands?

## Predation

**Predation** refers to a +/– interaction between species in which one species, the predator, kills and eats the other, the prey. Though the term *predation* generally elicits such images as a lion attacking and eating an antelope, it applies to a wide range of interactions. An animal that kills a plant by eating the plant's tissues can also be considered a predator. Because eating and avoiding being eaten are prerequisite to reproductive success, the adaptations of both predators and prey tend to be refined through natural selection (see Concept 27.5). In the **Scientific Skills Exercise**, you can interpret data from an experiment investigating a specific predator-prey interaction.

Many important feeding adaptations of predators are obvious and familiar. Most predators have acute senses that enable them to find and identify potential prey. Rattlesnakes and other pit vipers, for example, find their prey with a pair of

heat-sensing organs located between their eyes and nostrils (see Figure 38.17a). Many predators also have adaptations such as claws, teeth, stingers, or poison that help them catch and subdue their food. Predators that pursue their prey are generally fast and agile, whereas those that lie in ambush are often disguised in their environments.

Just as predators possess adaptations for capturing prey, potential prey animals have adaptations that help them avoid being eaten. Some common behavioral defenses are hiding, fleeing, and forming herds or schools. Active self-defense is less common, though some large grazing mammals vigorously defend their young from predators such as lions.

Animals also display a variety of morphological and physiological defensive adaptations. **Cryptic coloration**, or camouflage, makes prey difficult to see (**Figure 41.5a**). Mechanical or chemical defenses protect species such as porcupines and skunks. Some animals, including the European fire salamander, can synthesize toxins, whereas others accumulate toxins passively from the plants they eat. Animals with effective chemical defenses often exhibit bright **aposematic coloration**, or warning coloration, such as that of the poison dart frog (**Figure 41.5b**). Such coloration seems to be adaptive because predators often avoid brightly colored prey.

Some prey species are protected by their resemblance to other species. In **Batesian mimicry**, a palatable or harmless species mimics an unpalatable or harmful one. The larva of the hawkmoth *Hemeroplanes ornatus* puffs up its head and thorax when disturbed, looking like the head of a small venomous snake (**Figure 41.5c**). In this case, the mimicry even involves behavior; the larva weaves its head back and forth and hisses like a snake. In **Müllerian mimicry**, two or more unpalatable species, such as the cuckoo bee and yellow jacket, resemble each other (**Figure 41.5d**). In an example of convergent evolution, unpalatable animals in several different taxa have similar patterns of coloration: Black and yellow or red stripes characterize unpalatable animals as diverse as yellow jackets and coral snakes.

Many predators also use mimicry. The alligator snapping turtle has a tongue that resembles a wriggling worm, which is used to lure small fish. Any fish that tries to eat the “bait” is itself quickly consumed as the turtle's strong jaws snap closed.

## Herbivory

Ecologists use the term **herbivory** to refer to a +/– interaction in which an organism eats parts of a plant or alga. While large mammalian herbivores such as cattle, sheep, and water buffalo may be most familiar, most herbivores are actually invertebrates, such as grasshoppers, caterpillars, and beetles. In the ocean, herbivores include sea urchins, some tropical fishes, and certain mammals, including the manatee (**Figure 41.6**).

Like predators, herbivores have many specialized adaptations. Many herbivorous insects have chemical sensors on their feet that enable them to distinguish between toxic and nontoxic plants or between more nutritious and less nutritious plants. Some mammalian herbivores, such as goats, use their sense of smell to examine plants. They may also eat just a specific part of a plant, such as the flowers. Many herbivores also have specialized teeth or digestive systems adapted to processing vegetation (see Chapter 33).

Unlike prey animals, plants cannot run away to avoid being eaten. Instead, a plant's arsenal against herbivores may feature chemical toxins or structures such as spines and thorns. Among the plant compounds that serve as chemical weapons are the poison strychnine, produced by the tropical

▲ **Figure 41.6 A marine herbivore.** This West Indian manatee (*Trichechus manatus*) in Florida is grazing on *Hydrilla*, an introduced plant.

vine *Strychnos toxifera*, and nicotine, from the tobacco plant. Compounds that are not toxic to humans but may be distasteful to many herbivores are responsible for the familiar flavors of cinnamon, cloves, and peppermint.

## Symbiosis

When individuals of two or more species live in direct and intimate contact with one another, their relationship is called **symbiosis**. In this text, we define symbiosis to include all such

## Scientific Skills Exercise

### Using Bar Graphs and Scatter Plots to Present and Interpret Data

**Can a Native Predator Species Adapt Rapidly to an Introduced Prey Species?** Cane toads (*Bufo marinus*) were introduced to Australia in 1935 in a failed attempt to control an insect pest. Since then, the toads have spread throughout northeastern Australia, reaching a population of over 200 million today. Cane toads have glands that produce a toxin that is poisonous to snakes and other potential predators of the toads. In this exercise, you will graph and interpret data from a two-part experiment conducted to determine whether native Australian predators have developed resistance to the cane toad toxin.

**How the Experiment Was Done** In part 1, researchers collected 12 black snakes (*Pseudechis porphyriacus*) from areas where cane toads had existed for 40–60 years and another 12 from areas free of cane toads. They offered the snakes either a freshly killed native frog (*Limnodynastes peronii*, a species the snakes commonly eat) or a freshly killed cane toad from which the toxin gland had been removed (making the toad nonpoisonous). In part 2, researchers collected snakes from areas where cane toads had been present for 5–60 years. To assess how cane toad toxin affected these snakes, they injected small amounts of the toxin into the snakes' stomachs and measured the snakes' swimming speed in a small pool.

#### Data from the Experiment, Part 1

Type of Prey Offered	Percentage of Snakes That Ate Prey Offered in Each Area	
	Cane Toads Present in Area for 40–60 Years	No Cane Toads in Area
Native frog	100	100
Cane toad	0	50

© 2006 The Royal Society

#### Data from the Experiment, Part 2

Time Since First Exposure to Cane Toads (years)	5	10	10	20	50	60	60	60	60	60
Percentage Reduction in Swimming Speed	52	19	30	30	5	5	9	11	12	22

#### Interpret the Data

1. Make a bar graph of the data in part 1. (For additional information about graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
2. What do the data represented in the graph suggest about the effects of cane toads on the predatory behavior of black snakes in areas where the toads are and are not currently found?
3. Suppose an enzyme that deactivates the cane toad toxin evolves in black snakes living in areas with cane toads. If the researchers repeated part 1 of this study, predict how the results would change.
4. Identify the dependent and independent variables in part 2. Make a scatter plot of the data.
5. Based on the scatter plot, what conclusion would you draw about whether exposure to cane toads is having a selective effect on black snakes in this study? Explain.
6. Explain why a bar graph is an appropriate type of graph for presenting the data in part 1 and a scatter plot is an appropriate type for presenting the data in part 2.

**Data from** B. L. Phillips and R. Shine, An invasive species induces rapid adaptive change in a native predator: cane toads and black snakes in Australia, *Proceedings of the Royal Society B* 273:1545–1550 (2006).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

interactions, whether they are harmful, helpful, or neutral. Some biologists define symbiosis more narrowly as a synonym for mutualism, an interaction in which both species benefit.

### Parasitism

**Parasitism** is a  $+/-$  symbiotic interaction in which one organism, the **parasite**, derives its nourishment from another organism, its **host**, which is harmed in the process. Parasites that live within the body of their host, such as tapeworms, are called **endoparasites**; parasites that feed on the external surface of a host, such as ticks and lice, are called **ectoparasites**. In one particular type of parasitism, parasitoid insects—usually small wasps—lay eggs on or in living hosts. The larvae then feed on the body of the host, eventually killing it. Some ecologists have estimated that at least one-third of all species on Earth today are parasites.

Many parasites have complex life cycles involving multiple hosts. The blood fluke, which infects approximately 200 million people around the world, requires two hosts for its development: humans and freshwater snails. Some parasites change the behavior of their current host in ways that increase the likelihood that the parasite will reach its next host. For instance, crustaceans that are parasitized by acanthocephalan (spiny-headed) worms leave protective cover and move into the open, where they are more likely to be eaten by the birds that are the second host in the worm's life cycle.

Parasites can significantly affect the survival, reproduction, and density of their host population, either directly or indirectly. For example, ticks that live as ectoparasites on moose weaken their hosts by withdrawing blood and causing hair breakage and loss. In their weakened condition, the moose have a greater chance of dying from cold stress or predation by wolves (see Figure 40.24).

### Mutualism

Mutualistic symbiosis, or **mutualism**, is an interspecific interaction that benefits both species  $(+/+)$ . You have seen examples of mutualism in previous chapters: Examples of mutualism include nitrogen fixation by bacteria in the root nodules of legumes; cellulose digestion by microorganisms in the digestive systems of termites and ruminant mammals; and photosynthesis by unicellular algae in corals. In the acacia-ant example shown in **Figure 41.7**, both species can survive alone. In some other cases, though, such as termites and microorganisms, both species have lost the ability to survive on their own.

Mutualism typically involves the coevolution of related adaptations in both species, with changes in either species likely to affect the survival and reproduction of the other. For example, most flowering plants have adaptations such as nectar or fruit that attract animals that pollinate flowers or disperse seeds (see Chapter 30). In turn, many animals have adaptations that help them find and consume nectar.

(a) Certain species of acacia trees in Central and South America have hollow thorns that house stinging ants of the genus *Pseudomyrmex*. The ants feed on nectar produced by the tree and on protein-rich swellings along the bases of the leaves.

(b) The acacia benefits because the pugnacious ants, which attack anything that touches the tree, remove fungal spores, small herbivores, and debris. They also clip vegetation that grows close to the acacia.

▲ **Figure 41.7 Mutualism between acacia trees and ants.**

### Commensalism

An interaction between species that benefits one of the species but neither harms nor helps the other  $(+/0)$  is called **commensalism**. Commensal interactions are difficult to document in nature because any close association between species likely affects both species, even if only slightly. For instance, “hitchhiking” species, such as algae that live on the shells of aquatic turtles or barnacles that attach to whales, are sometimes considered commensal. The hitchhikers gain a place to grow while having seemingly little effect on their ride. However, they may reduce the hosts’ efficiency of movement in searching for food or escaping from predators. Conversely, the hitchhikers may help camouflage the hosts.

Some commensal associations involve one species obtaining food that is inadvertently exposed by another. Cattle egrets feed on insects flushed out of the grass by grazing bison, cattle,

▲ **Figure 41.8** A possible example of commensalism between cattle egrets and African buffalo.

and other herbivores (Figure 41.8). Because the birds typically find more prey when they follow herbivores, they clearly benefit from the association. Much of the time, the herbivores may be unaffected by the birds. However, they, too, may derive some benefit; the birds occasionally remove and eat ticks and other ectoparasites from the herbivores or may warn the herbivores of a predator's approach.

## Facilitation

Species can have positive effects (+/+ or 0/+) on the survival and reproduction of other species without necessarily living in the direct and intimate contact of a symbiosis. This type of interaction, called **facilitation**, is particularly common in plant ecology. For instance, the black rush *Juncus gerardii* makes the soil more hospitable for other plant species in some zones of New England salt marshes (Figure 41.9a). *Juncus* helps prevent salt buildup in the soil by shading the soil surface, which reduces evaporation. *Juncus* also prevents the salt marsh soils

(a) Salt marsh with *Juncus* (foreground)

▲ **Figure 41.9** Facilitation by black rush (*Juncus gerardii*) in New England salt marshes. Black rush increases the number of plant species that can live in the upper middle zone of the marsh.

from becoming oxygen depleted as it transports oxygen to its belowground tissues. In one study, when *Juncus* was removed from areas in the upper middle intertidal zone, those areas supported 50% fewer plant species (Figure 41.9b).

All five types of interactions discussed so far—competition, predation, herbivory, symbiosis, and facilitation—strongly influence the structure of communities. You'll see other examples of these interactions throughout this chapter.

### CONCEPT CHECK 41.1

1. Explain how interspecific competition, predation, and mutualism differ in their effects on the interacting populations of two species.
2. According to the principle of competitive exclusion, what outcome is expected when two species with identical niches compete for a resource? Why?
3. **MAKE CONNECTIONS** Figure 22.12 illustrates the formation of and possible outcomes for a hybrid zone over time. Imagine that two finch species colonize a new island and are capable of hybridizing (mating and producing viable offspring). The island contains two plant species, one with large seeds and one with small seeds, growing in isolated habitats. If the two finch species specialize in eating different plant species, would reproductive barriers be reinforced, weakened, or unchanged in this hybrid zone? Explain.

For suggested answers, see Appendix A.

## CONCEPT 41.2

### Diversity and trophic structure characterize biological communities

Along with the specific interactions described in the previous section, communities are also characterized by more general attributes, including how diverse they are and the feeding relationships of their species. In this section, you'll see why such ecological attributes are important. You'll also learn how a few species sometimes exert strong control on a community's structure, particularly on the composition, relative abundance, and diversity of its species.

## Species Diversity

The **species diversity** of a community—the variety of different kinds of organisms that make up the community—has two components. One is **species richness**, the number of different species in the community. The other is the **relative abundance** of the different species, the proportion each species represents of all individuals in the community.

Imagine two small forest communities, each with 100 individuals distributed among four tree species (A, B, C, and D) as follows:

Community 1: 25A, 25B, 25C, 25D

Community 2: 80A, 5B, 5C, 10D

The species richness is the same for both communities because they both contain four species of trees, but the relative abundance is very different (**Figure 41.10**). You would easily notice the four types of trees in community 1, but without looking carefully, you might see only the abundant species A in the second forest. Most observers would intuitively describe community 1 as the more diverse of the two communities.

Ecologists use many tools to compare the diversity of communities across time and space. They often calculate indexes of diversity based on species richness and relative abundance. One widely used index is the **Shannon diversity index** ( $H$ ):

$$H = -(p_A \ln p_A + p_B \ln p_B + p_C \ln p_C + \dots)$$

where A, B, C . . . are the species in the community,  $p$  is the relative abundance of each species, and  $\ln$  is the natural logarithm. A higher value of  $H$  indicates a more diverse community. Let's use this equation to calculate the Shannon diversity index of the two communities in Figure 41.10. For community 1,  $p = 0.25$  for each species, so

$$H = -4(0.25 \ln 0.25) = 1.39$$

For community 2,

$$H = -[0.8 \ln 0.8 + 2(0.05 \ln 0.05) + 0.1 \ln 0.1] = 0.71$$

▲ **Figure 41.10 Which forest is more diverse?** Ecologists would say that community 1 has greater species diversity, a measure that includes both species richness and relative abundance.

These calculations confirm that community 1 is more diverse.

Determining the number and relative abundance of species in a community can be challenging. Because most species in a community are relatively rare, it may be hard to obtain a sample size large enough to be representative. It is also difficult to census highly mobile or less visible organisms, such as insects and nocturnal species. The small size of microorganisms makes them particularly difficult to sample, so ecologists now use molecular tools to help determine microbial diversity (**Figure 41.11**).

### ▼ Figure 41.11 Research Method

#### Determining Microbial Diversity Using Molecular Tools

**Application** Ecologists are increasingly using molecular techniques, such as the analysis of restriction fragment length polymorphisms (RFLPs), to determine microbial diversity and richness in environmental samples. Noah Fierer and Rob Jackson, of Duke University, used RFLP analysis to compare the diversity of soil bacteria in 98 habitats across North and South America to help identify environmental variables associated with high bacterial diversity.

**Technique** Researchers first extract and purify DNA from the microbial community in each sample. They use the polymerase chain reaction (see Chapter 13) to amplify specific DNA (such as that encoding small ribosomal subunit RNA) and label the DNA with a fluorescent dye. Restriction enzymes then cut the amplified, labeled DNA into fragments of different lengths, which are separated by gel electrophoresis. The number and abundance of these fragments characterize the DNA profile of the sample. Based on their RFLP analysis, Fierer and Jackson calculated the Shannon diversity index ( $H$ ) of each sample. They then looked for a correlation between  $H$  and several environmental variables.

**Results** The diversity of the sampled bacteria was related almost exclusively to soil pH, with the Shannon diversity index being highest in neutral soils and lowest in acidic soils.

**Source** N. Fierer and R. B. Jackson, The diversity and biogeography of soil bacterial communities, *Proceedings of the National Academy of Sciences USA* 103:626–631 (2006).

▲ **Figure 41.12** Study plots at the Cedar Creek Natural History Area, site of long-term experiments in which researchers have manipulated plant diversity.

## Diversity and Community Stability

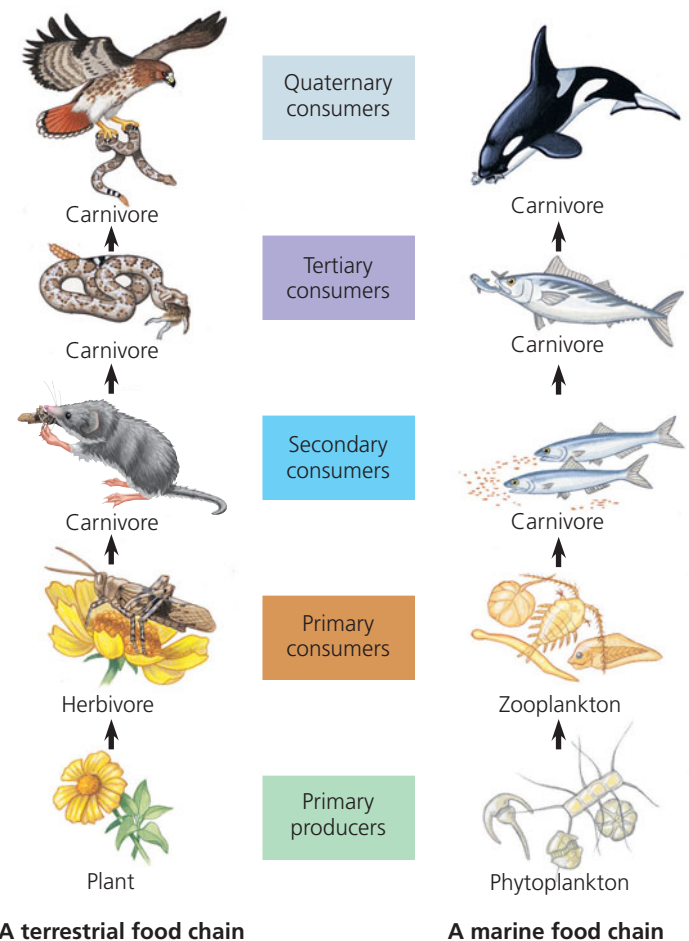

In addition to measuring species diversity, ecologists manipulate diversity in experimental communities in nature and in the laboratory. They do this to examine the potential benefits of diversity, including increased productivity and stability of biological communities.

Researchers at the Cedar Creek Natural History Area, in Minnesota, have been manipulating plant diversity in experimental communities for two decades (**Figure 41.12**). Higher-diversity communities generally are more productive and are better able to withstand and recover from environmental stresses, such as droughts. More diverse communities are also more stable year to year in their productivity. In one decade-long experiment, for instance, researchers at Cedar Creek created 168 plots, each containing 1, 2, 4, 8, or 16 perennial grassland species. The most diverse plots produced **biomass** (the total mass of all individuals in a population) much more consistently than the single-species plots each year.

Higher-diversity communities are often more resistant to **invasive species**, which are organisms that become established outside their native range. Scientists working in Long Island Sound, off the coast of Connecticut, created communities with different levels of diversity consisting of sessile marine invertebrates, including tunicates (see Concept 27.3). They then examined how vulnerable these experimental communities were to invasion by an exotic tunicate. They found that the exotic tunicate was four times more likely to survive in lower-diversity communities than in higher-diversity ones. The researchers concluded that relatively diverse communities captured more of the resources available in the system, leaving fewer resources for the invader and decreasing its survival.

## Trophic Structure

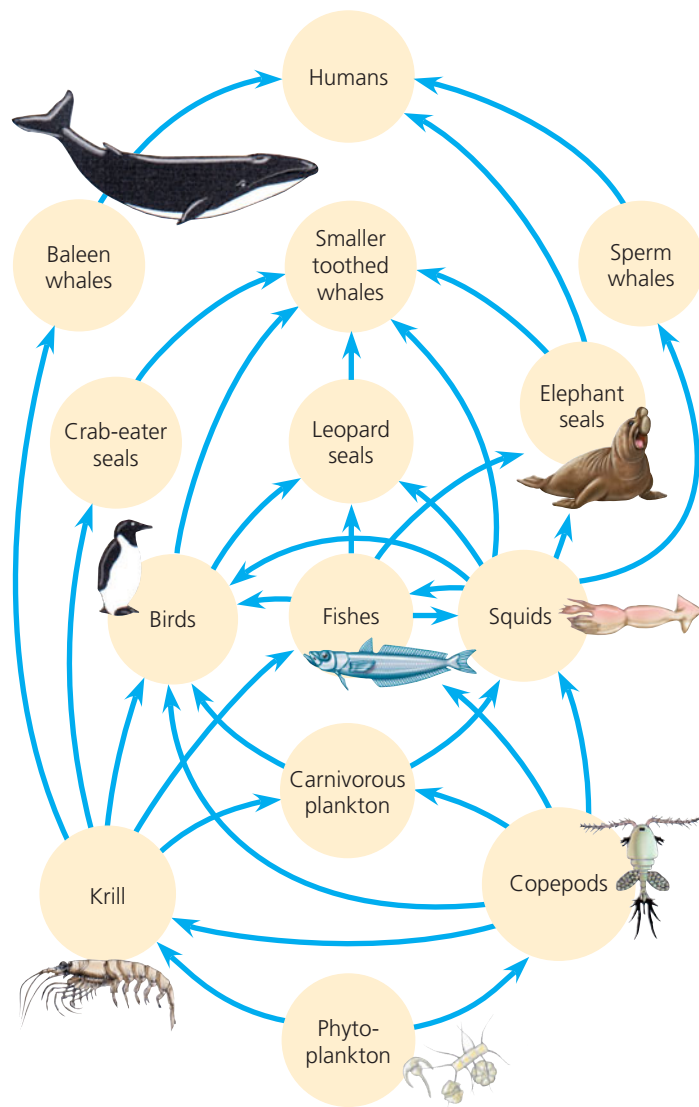

Experiments like the ones just described often examine the importance of diversity within one trophic level. The

▲ **Figure 41.13** Examples of terrestrial and marine food chains. The arrows trace energy and nutrients that pass through the trophic levels of a community when organisms feed on one another. Decomposers, which “feed” on organisms from all trophic levels, are not shown here.

structure and dynamics of a community also depend on the feeding relationships between organisms in different trophic levels. These relationships together make up the **trophic structure** of the community. The transfer of food energy up the trophic levels from its source in plants and other autotrophs (primary producers) through herbivores (primary consumers) to carnivores (secondary, tertiary, and quaternary consumers) and eventually to decomposers is referred to as a **food chain** (**Figure 41.13**).

In the 1920s, Oxford University biologist Charles Elton recognized that food chains are not isolated units but are linked together in **food webs**. Ecologists diagram the trophic relationships of a community using arrows linking species according to who eats whom. In an Antarctic pelagic community, for example, the primary producers are phytoplankton, which serve as food for the dominant grazing zooplankton, especially krill and copepods, both of which are crustaceans. These zooplankton species are in turn eaten by carnivores, including other plankton, penguins, seals, fishes, and baleen whales. Squids, which are carnivores that feed on fish and zooplankton, are another

▲ **Figure 41.14** An Antarctic marine food web. Arrows follow the transfer of food from the producers (phytoplankton) up through the trophic levels. For simplicity, this diagram omits decomposers.

important link in these food webs, as they are in turn eaten by seals and toothed whales (**Figure 41.14**).

Note that a given species may weave into the web at more than one trophic level. In the food web shown in Figure 41.14, krill feed on phytoplankton as well as on other grazing zooplankton, such as copepods.

## Species with a Large Impact

Certain species have an especially large impact on the structure of entire communities because they are highly abundant or play a pivotal role in community dynamics. The impact of these species occurs through trophic interactions and their influence on the physical environment.

**Dominant species** in a community are the species that are the most abundant or that collectively have the highest biomass. There is no single explanation for why a species

## ▼ Figure 41.15 Inquiry

### Is *Pisaster ochraceus* a keystone predator?

**Experiment** In rocky intertidal communities of western North America, the relatively uncommon sea star *Pisaster ochraceus* preys on mussels such as *Mytilus californianus*, a dominant species and strong competitor for space.

Robert Paine, of the University of Washington, removed *Pisaster* from an area in the intertidal zone and examined the effect on species richness.

**Results** In the absence of *Pisaster*, species richness declined as mussels monopolized the rock face and eliminated most other invertebrates and algae. In a control area where *Pisaster* was not removed, species richness changed very little.

**Conclusion** *Pisaster* acts as a keystone species, exerting an influence on the community that is not reflected in its abundance.

**Source** R. T. Paine, Food web complexity and species diversity, *American Naturalist* 100:65–75 (1966).

**WHAT IF?** Suppose that an invasive fungus killed most individuals of *Mytilus* at these sites. Predict how species richness would be affected if *Pisaster* were then removed.

becomes dominant in a community. One hypothesis suggests that dominant species are competitively superior in exploiting limited resources such as water or nutrients. Another hypothesis is that dominant species are most successful at avoiding predation or the impact of disease. This latter idea could explain the high biomass attained by some invasive species. Such species may not face the natural predators or parasites that would otherwise hold their populations in check.

In contrast to dominant species, **keystone species** are not usually abundant in a community. They exert strong control on community structure not by numerical might but by their pivotal ecological roles, or niches. **Figure 41.15** highlights the importance of a keystone species, a sea star, in maintaining the diversity of an intertidal community.

Other organisms exert their influence on a community not through trophic interactions but by changing their physical

**▲ Figure 41.16 Beavers as ecosystem engineers.** By felling trees, building dams, and creating ponds, beavers can transform large areas of forest into flooded wetlands.

environment. Species that dramatically alter their environment are called **ecosystem engineers** or, to avoid implying conscious intent, “foundation species.” A familiar ecosystem engineer is the beaver (Figure 41.16). The effects of ecosystem engineers on other species can be positive or negative, depending on the needs of the other species.

### Bottom-Up and Top-Down Controls

Simplified models based on relationships between adjacent trophic levels are useful for describing community organization. For example, consider the three possible relationships between plants ( $V$  for vegetation) and herbivores ( $H$ ):

$$V \rightarrow H \quad V \leftarrow H \quad V \leftrightarrow H$$

The arrows indicate that a change in the biomass of one trophic level causes a change in the other trophic level.  $V \rightarrow H$  means that an increase in vegetation will increase the numbers or biomass of herbivores, but not vice versa. In this situation, herbivores are limited by vegetation, but vegetation is not limited by herbivory. In contrast,  $V \leftarrow H$  means that an increase in herbivore biomass will decrease the abundance of vegetation, but not vice versa. A double-headed arrow indicates that each trophic level is sensitive to changes in the biomass of the other.

Two models of community organization are common: the bottom-up model and the top-down model. The  $V \rightarrow H$  linkage suggests a **bottom-up model**, which postulates a unidirectional influence from lower to higher trophic levels. In this case, the presence or absence of mineral nutrients ( $N$ ) controls plant ( $V$ ) numbers, which control herbivore ( $H$ ) numbers, which in turn control predator ( $P$ ) numbers. The simplified bottom-up model is thus  $N \rightarrow V \rightarrow H \rightarrow P$ . To change the community structure of a bottom-up community, you need to alter biomass at the lower trophic levels, allowing those changes to propagate up through the food web. If you add mineral nutrients to stimulate plant growth, then the higher trophic levels should also increase in biomass. If you change predator abundance, however, the effect should not extend down to the lower trophic levels.

In contrast, the **top-down model** postulates the opposite: Predation mainly controls community organization because predators limit herbivores, herbivores limit plants, and plants limit nutrient levels through nutrient uptake. The simplified top-down model,  $N \leftarrow V \leftarrow H \leftarrow P$ , is also called the *trophic cascade model*. In a lake community with four trophic levels, the model predicts that removing the top carnivores will increase the abundance of primary carnivores, in turn decreasing the number of herbivores, increasing phytoplankton abundance, and decreasing concentrations of mineral nutrients. The effects thus move down the trophic structure as alternating  $+/-$  effects.

Ecologists have applied the top-down model to improve water quality in polluted lakes. This approach, called **biomanipulation**, attempts to prevent algal blooms and eutrophication by altering the density of higher-level consumers instead of using chemical treatments. In lakes with three trophic levels, removing fish should improve water quality by increasing zooplankton density, thereby decreasing algal populations. In lakes with four trophic levels, adding top predators should have the same effect. We can summarize the scenario of three trophic levels with the following diagram:

Ecologists in Finland used biomanipulation to help purify Lake Vesijärvi, a large lake that was polluted with city sewage and industrial wastewater until 1976. After pollution controls reduced these inputs, the water quality of the lake began to improve. By 1986, however, massive blooms of cyanobacteria started to occur in the lake. These blooms coincided with an increase in the population of roach, a fish species that eats zooplankton, which otherwise keep the cyanobacteria and algae in check. To reverse these changes, ecologists removed nearly a million kilograms of fish between 1989 and 1993, reducing roach abundance by about 80%. At the same time, they added a fourth trophic level by stocking the lake with pike perch, a predatory fish that eats roach. The water became clear, and the last cyanobacterial bloom was in 1989. The lake remains clear even though roach removal ended in 1993.

As these examples show, communities vary in their degree of bottom-up and top-down control. To manage agricultural landscapes, parks, reservoirs, and fisheries, we need to understand each particular community’s dynamics.

## CONCEPT CHECK 41.2

1. What two components contribute to species diversity? Explain how two communities with the same number of species can differ in species diversity.
2. Based on the food web in Figure 41.14, identify all of the organisms that eat and are eaten by elephant seals.
3. **WHAT IF?** Consider a grassland with five trophic levels: grasses, mice, snakes, raccoons, and bobcats. If you released additional bobcats into the grassland, how would plant biomass change if the bottom-up model applied? If the top-down model applied? Explain.

For suggested answers, see Appendix A.

## CONCEPT 41.3

### Disturbance influences species diversity and composition

Decades ago, most ecologists favored the traditional view that biological communities are at equilibrium, a more or less stable balance, unless seriously disturbed by human activities. The “balance of nature” view focused on interspecific competition as a key factor determining community composition and maintaining stability in communities. *Stability* in this context refers to a community’s tendency to reach and maintain a relatively constant composition of species.

One of the earliest proponents of this view, F. E. Clements, of the Carnegie Institution of Washington, argued in the early 1900s that the community of plants at a site had only one stable equilibrium, a *climax community* controlled solely by climate. According to Clements, biotic interactions caused the species in this climax community to function as an integrated unit. His argument was based on the observation that certain species of plants are consistently found together, such as the oaks, maples, birches, and beeches in deciduous forests of the northeastern United States.

Other ecologists questioned whether most communities were at equilibrium or functioned as integrated units. A. G. Tansley, of Oxford University, challenged the concept of a climax community, arguing that differences in soils, topography, and other factors created many potential communities that were stable within a region. H. A. Gleason, of the University of Chicago, saw communities more as chance assemblages of species with similar abiotic requirements—for example, for temperature, rainfall, and soil type. Gleason and other ecologists also realized that disturbance keeps many communities from reaching a stable state in species diversity or composition. A **disturbance** is an event, such as a storm, fire, drought, or human activity, that changes a community by removing organisms from it or altering resource availability.

This recent emphasis on change has produced the **nonequilibrium model**, which describes most communities as constantly changing after disturbance. Even relatively stable

communities can be rapidly transformed into nonequilibrium communities. Let’s examine some of the ways disturbance influences community structure and composition.

### Characterizing Disturbance

The types of disturbances and their frequency and severity vary among communities. Storms disturb most communities, even many in the oceans through the action of waves. Fire is a significant disturbance; in fact, chaparral and some grassland biomes require regular burning to maintain their structure and species composition. Many streams and ponds are disturbed by spring flooding and seasonal drying. A high level of disturbance is generally the result of frequent *and* intense disturbance, while low disturbance levels can result from either a low frequency or low intensity of disturbance.

The **intermediate disturbance hypothesis** states that moderate levels of disturbance foster greater species diversity than do low or high levels of disturbance. High levels of disturbance reduce diversity by creating environmental stresses that exceed the tolerances of many species or by disturbing the community so often that slow-growing or slow-colonizing species are excluded. At the other extreme, low levels of disturbance can reduce species diversity by allowing competitively dominant species to exclude less competitive ones. Meanwhile, intermediate levels of disturbance can foster greater species diversity by opening up habitats for occupation by less competitive species. Such intermediate disturbance levels rarely create conditions so severe that they exceed the environmental tolerances or recovery rates of potential community members.

The intermediate disturbance hypothesis is supported by many terrestrial and aquatic studies. In one study, ecologists in New Zealand compared the richness of invertebrate taxa living in the beds of streams exposed to different frequencies and intensities of flooding (**Figure 41.17**). When floods occurred

▲ **Figure 41.17 Testing the intermediate disturbance hypothesis.** Researchers identified the taxa (species or genera) of invertebrates at two locations in each of 27 New Zealand streams. They assessed the intensity of flooding at each location using an index of streambed disturbance. The number of invertebrate taxa peaked where the intensity of flooding was at intermediate levels.

either very frequently or rarely, invertebrate richness was low. Frequent floods made it difficult for some species to become established in the streambed, while rare floods resulted in species being displaced by superior competitors. Invertebrate richness peaked in streams that had an intermediate frequency or intensity of flooding, as predicted by the hypothesis.

Although moderate levels of disturbance appear to maximize species diversity, small and large disturbances often have important effects on community structure. Small-scale disturbances can create patches of different habitats across a landscape, which help maintain diversity in a community. Large-scale disturbances are also a natural part of many communities. Much of Yellowstone National Park, for example, is dominated by lodgepole pine, a tree species that requires the rejuvenating influence of periodic fires. Lodgepole pinecones remain closed until exposed to intense heat. When a forest fire burns the trees, the cones open and the seeds are released. The new generation of lodgepole pines can then thrive on nutrients released from the burned trees and in the sunlight that is no longer blocked by taller trees.

In the summer of 1988, extensive areas of Yellowstone burned during a severe drought. By 1989, burned areas in the park were largely covered with new vegetation, suggesting that the species in this community are adapted to rapid recovery after fire (**Figure 41.18**). In fact, large-scale fires have periodically swept through the lodgepole pine forests of Yellowstone and other northern areas for thousands of years.

Studies of the Yellowstone forest community and many others indicate that they are nonequilibrium communities, changing continually because of natural disturbances and the internal processes of growth and reproduction. Mounting evidence suggests that nonequilibrium conditions are in fact the norm for most communities.

## Ecological Succession

Changes in the composition and structure of terrestrial communities are most apparent after some severe disturbance, such as a volcanic eruption or a glacier, strips away all the existing vegetation. The disturbed area may be colonized by a variety of species, which are gradually replaced by other species, which are in turn replaced by still other species—a process called **ecological succession**. When this process begins in a virtually lifeless area where soil has not yet formed, such as on a new volcanic island or on the rubble (moraine) left by a retreating glacier, it is called **primary succession**. In contrast, **secondary succession** occurs when an existing community has been cleared by some disturbance that leaves the soil intact, as in Yellowstone following the 1988 fires (see Figure 41.18).

During primary succession, the only life-forms initially present are often prokaryotes and protists. Lichens and mosses, which grow from windblown spores, are commonly the first macroscopic photosynthesizers to colonize such areas. Soil develops gradually as rocks weather and organic matter accumulates from the decomposed remains of the early colonizers. Once soil is present, the lichens and mosses are usually overgrown by grasses, shrubs, and trees that sprout from seeds blown in or carried in by animals. Eventually, an area is colonized by plants that become the community's dominant vegetation. Producing such a community through primary succession may take hundreds or thousands of years.

Early-arriving species and later-arriving ones are often linked by one of three processes. The early arrivals may *facilitate* the appearance of the later species by making the environment more favorable—for example, by increasing the fertility of the soil. Alternatively, the early species may *inhibit* establishment of the later species, so that successful colonization occurs in spite of, rather than because of, the activities of the early species.

(a) **Soon after fire.** The fire has left a patchy landscape. Note the unburned trees in the far distance.

(b) **One year after fire.** The community has begun to recover. Herbaceous plants, different from those in the former forest, cover the ground.

▲ **Figure 41.18 Recovery following a large-scale disturbance.** The 1988 Yellowstone National Park fires burned large areas of forests dominated by lodgepole pines.

Finally, the early species may be completely independent of the later species, which *tolerate* conditions created early in succession but are neither helped nor hindered by early species.

Ecologists have conducted some of the most extensive research on primary succession at Glacier Bay in southeastern Alaska, where glaciers have retreated more than 100 km since 1760 (**Figure 41.19**). By studying the communities on moraines at different distances from the mouth of the bay, ecologists can examine different stages in succession. **1** The exposed moraine is colonized first by pioneering species that include liverworts, mosses, fireweed, scattered *Dryas* (a mat-forming shrub), and willows. **2** After about three decades, *Dryas* dominates the plant community. **3** A few decades later, the area is invaded by alder, which forms dense thickets up to 9 m tall. **4** In the next two centuries, these alder stands are overgrown first by Sitka spruce and later by a combination of western hemlock and mountain hemlock. In areas of poor drainage, the forest floor of this spruce-hemlock forest is invaded by sphagnum moss, which holds water and acidifies the soil, eventually killing the trees. Thus, by about 300 years after glacial retreat, the vegetation consists of sphagnum bogs on the poorly drained flat areas and spruce-hemlock forest on the well-drained slopes.

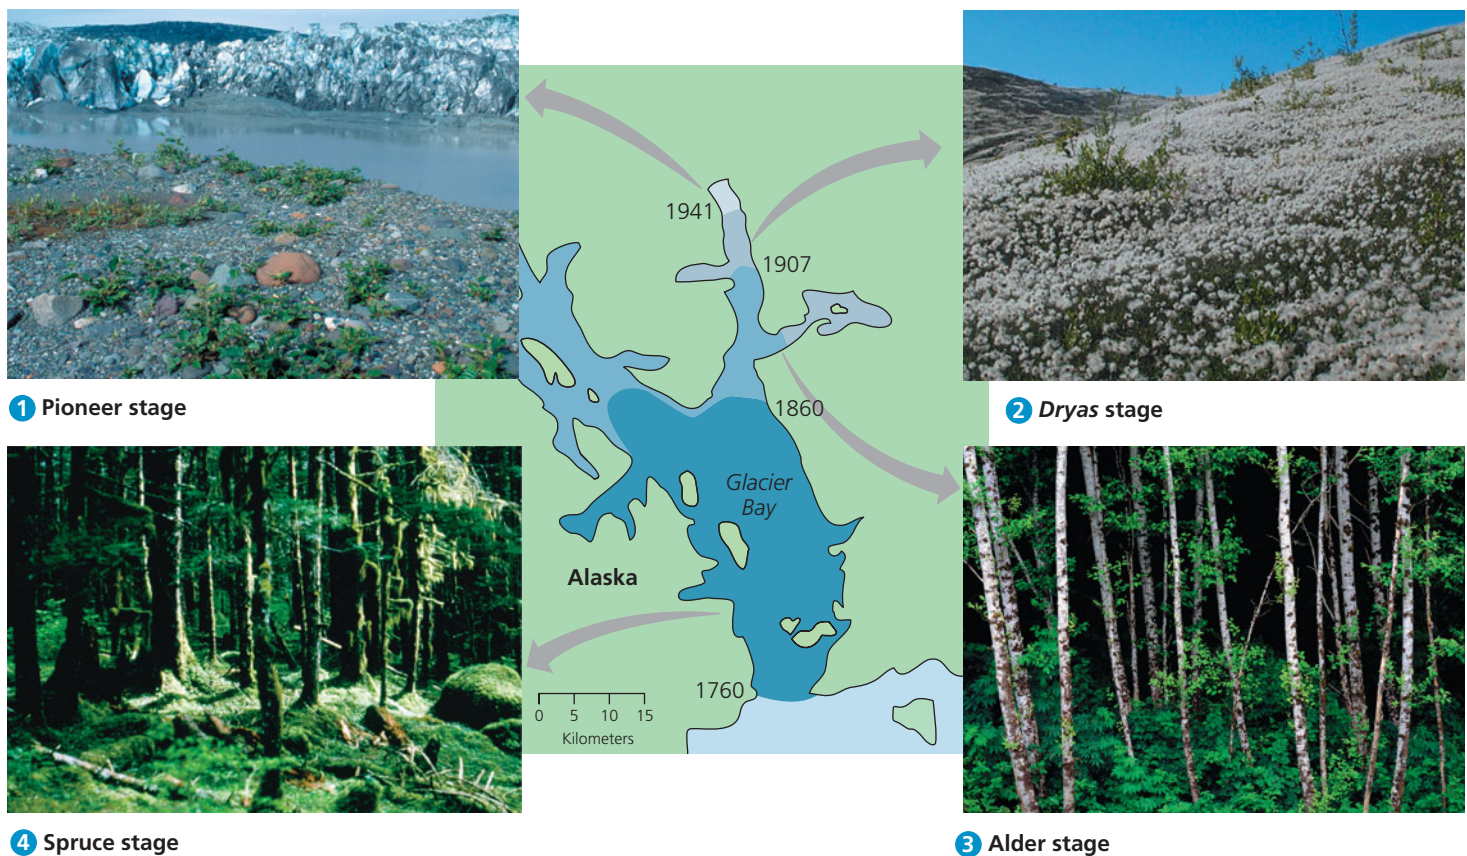

Succession on glacial moraines is related to environmental changes in soil nutrients and other environmental factors caused by transitions in the vegetation. Because the bare soil

after glacial retreat is low in nitrogen, almost all the pioneer plants begin succession with poor growth and yellow leaves due to nitrogen deficiency. The exceptions are *Dryas* and alder, which have symbiotic bacteria that fix atmospheric nitrogen (see Chapter 29). Soil nitrogen increases quickly during the alder stage of succession and keeps increasing during the spruce stage. By altering soil properties, pioneer plant species can facilitate colonization by new plant species during succession.

## Human Disturbance

Ecological succession is a response to disturbance of the environment, and the strongest agent of disturbance today is human activity. Agricultural development has disrupted what were once the vast grasslands of the North American prairie. Tropical rain forests are quickly disappearing as a result of clear-cutting for lumber, cattle grazing, and farmland. Centuries of overgrazing and agricultural disturbance have contributed to famine in parts of Africa by turning seasonal grasslands into vast barren areas.

Humans disturb marine ecosystems as well as terrestrial ones. The effects of ocean trawling, where boats drag weighted nets across the seafloor, are similar to those of clear-cutting a forest or plowing a field (**Figure 41.20**). The trawls scrape and scour corals and other life on the seafloor. In a typical year, ships trawl an area about the size of South America, 150 times larger than the area of forests that are clear-cut annually.

**▲ Figure 41.19 Glacial retreat and primary succession at Glacier Bay, Alaska.** The different shades of blue on the map show retreat of the glacier since 1760, based on historical descriptions.

▲ **Figure 41.20 Disturbance of the ocean floor by trawling.** These photos show the seafloor off northwestern Australia before (top) and after (bottom) deep-sea trawlers have passed.

Because disturbance by human activities is often severe, it reduces species diversity in many communities. In Chapter 43, we'll take a closer look at how human-caused disturbance is affecting the diversity of life.

#### CONCEPT CHECK 41.3

1. Why do high and low levels of disturbance usually reduce species diversity? Why does an intermediate level of disturbance promote species diversity?
2. During succession, how might the early species facilitate the arrival of other species?
3. **WHAT IF?** Most prairies experience regular fires, typically every few years. These disturbances tend to be relatively modest. How would the species diversity of a prairie likely be affected if no burning occurred for 100 years? Explain your answer.

For suggested answers, see Appendix A.

## CONCEPT 41.4

### Biogeographic factors affect community diversity

So far, we have examined relatively small-scale or local factors that influence the diversity of communities, including the effects of species interactions, dominant species, and many types of disturbances. Ecologists also recognize that large-scale biogeographic factors contribute to the range of diversity observed in communities. The contributions of two biogeographic factors in particular—the latitude of a community and the area it occupies—have been investigated for more than a century.

#### Latitudinal Gradients

In the 1850s, both Charles Darwin and Alfred Wallace pointed out that plant and animal life was generally more abundant and diverse in the tropics than in other parts of the globe. Since

that time, many researchers have confirmed this observation. One study found that a 6.6-hectare plot (1 ha = 10,000 m<sup>2</sup>) in tropical Malaysia contained 711 tree species, while a 2-ha plot of deciduous forest in Michigan typically contained just 10 to 15 tree species. Many groups of animals show similar latitudinal gradients.

The two key factors affecting latitudinal gradients of species richness are probably evolutionary history and climate. Over the course of evolutionary time, species richness may increase in a community as more speciation events occur (see Chapter 22). Tropical communities are generally older than temperate or polar communities, which have repeatedly “started over” after major disturbances from glaciations. Also, the growing season in tropical forests is about five times as long as in the tundra communities of high latitudes. In effect, biological time runs about five times as fast in the tropics as near the poles, so intervals between speciation events are shorter in the tropics.

Climate is a primary cause of the latitudinal gradient in richness and diversity. In terrestrial communities, the two main climatic factors correlated with diversity are sunlight and precipitation, both of which are relatively abundant in the tropics. These factors can be considered together by measuring a community's rate of **evapotranspiration**, the evaporation of water from soil and plants together. Evapotranspiration, a function of solar radiation, temperature, and water availability, is much higher in hot areas with abundant rainfall than in areas with low temperatures or low precipitation. *Potential evapotranspiration*, a measure of potential water loss that assumes that water is readily available, is determined by the amount of solar radiation and temperature and is highest in regions where both are plentiful. The species richness of animals as well as plants correlates well with both measures, as shown for vertebrates and potential evapotranspiration in **Figure 41.21**.

© 1991 University of Chicago Press

▲ **Figure 41.21 Energy, water, and species richness.** Vertebrate species richness in North America increases most predictably with potential evapotranspiration, expressed as rainfall equivalents (mm/yr).

## Area Effects

In 1807, naturalist and explorer Alexander von Humboldt described one of the first patterns of species richness to be recognized, the **species-area curve**: All other factors being equal, the larger the geographic area of a community, the more species it has, in part because larger areas offer a greater diversity of habitats and microhabitats. The basic concept of diversity increasing with increasing area applies in many situations, from surveys of ant diversity in New Guinea to studies of plant species richness on islands of different sizes.

Because of their isolation and limited size, islands provide excellent opportunities for studying the biogeographic factors that affect the species diversity of communities. By “islands,” we mean not only oceanic islands, but also habitat islands on land, such as lakes, mountain peaks, and habitat fragments—any patch surrounded by an environment not suitable for the “island” species. American ecologists Robert MacArthur and E. O. Wilson developed a general model of island biogeography, identifying the key determinants of species diversity on an island with a given set of physical characteristics.

Consider a newly formed oceanic island that receives colonizing species from a distant mainland. Two factors that determine the number of species on the island are the rate at which new species immigrate to the island and the rate at which species become extinct on the island. At any given time, an island’s immigration and extinction rates are affected by the number of species already present. As the number of species on the island increases, the immigration rate of new species decreases, because any individual reaching the island is less likely to represent a species that is not already present. At the same time, as more species inhabit an island, extinction rates on the island increase because of the greater likelihood of competitive exclusion.

Two physical features of the island further affect immigration and extinction rates: its size and its distance from the mainland. Small islands generally have lower immigration rates because potential colonizers are less likely to reach a small island than a large one. Small islands also have higher extinction rates because they generally contain fewer resources, have less diverse habitats, and have smaller populations. Distance from the mainland is also important; a closer island generally has a higher immigration rate and lower extinction rate than one farther away. Arriving colonists help sustain the presence of a species on a near island and prevent its extinction.

MacArthur and Wilson’s model is called the *island equilibrium model* because an equilibrium will eventually be reached where the rate of species immigration equals the rate of species extinction. The number of species at this equilibrium point is correlated with the island’s size and distance from the mainland. Like any ecological equilibrium, this species equilibrium is dynamic; immigration and extinction continue, and the exact species composition may change over time.

## ▼ Figure 41.22 Inquiry

### How does species richness relate to area?

**Field Study** Ecologists Robert MacArthur and E. O. Wilson studied the number of plant species on the Galápagos Islands in relation to the area of the different islands.

#### Results

**Conclusion** Plant species richness increases with island size, supporting the island equilibrium model.

**Source** R. H. MacArthur and E. O. Wilson, *The Theory of Island Biogeography*, Princeton University Press, Princeton, NJ (1967).

**WHAT IF?** Four islands in this study ranging in area from about 40 to 10,000 ha each contained about 50 plant species. What does such variation tell you about the simple assumptions of the island equilibrium model?

MacArthur and Wilson’s studies of the diversity of plants and animals on island chains support the prediction that species richness increases with island size, in keeping with the island equilibrium model (**Figure 41.22**). Species counts also fit the prediction that the number of species decreases with increasing remoteness of the island.

Over long periods, disturbances such as storms, adaptive evolutionary changes, and speciation generally alter the species composition and community structure on islands. Nonetheless, the island equilibrium model is widely applied in ecology. Conservation biologists in particular use it when designing habitat reserves or establishing a starting point for predicting the effects of habitat loss on species diversity.

#### CONCEPT CHECK 41.4

1. Describe two hypotheses that explain why species diversity is greater in tropical regions than in temperate and polar regions.
2. Describe how an island’s size and distance from the mainland affect the island’s species richness.
3. **WHAT IF?** Based on MacArthur and Wilson’s island equilibrium model, how would you expect the richness of birds on islands to compare with the richness of snakes and lizards?

For suggested answers, see Appendix A.

## Pathogens alter community structure locally and globally

Now that we have examined several important factors that structure biological communities, we will finish the chapter by examining community interactions involving **pathogens**—disease-causing organisms and viruses. Scientists have only recently come to appreciate how universal the effects of pathogens are in structuring ecological communities.

### Effects on Community Structure

Pathogens produce especially clear effects on community structure when they are introduced into new habitats. Coral reef communities, for example, are increasingly susceptible to the influence of newly discovered pathogens. White-band disease, caused by an unknown pathogen, has resulted in dramatic changes in the structure and composition of Caribbean reefs. The disease kills corals by causing their tissue to slough off in a band from the base to the tip of the branches. Because of the disease, staghorn coral (*Acropora cervicornis*) has virtually disappeared from the Caribbean since the 1980s. Populations of elkhorn coral (*Acropora palmata*) have also been decimated. Such corals provide key habitat for lobsters as well as snappers and other fish species. When the corals die, they are quickly overgrown by algae. Surgeonfish and other herbivores that feed on algae come to dominate the fish community. Eventually, the corals topple because of damage from storms and other disturbances. The complex, three-dimensional structure of the reef disappears, and diversity plummets.

Pathogens also influence community structure in terrestrial ecosystems. In the forests and savannas of California, trees of several species are dying from sudden oak death (SOD). This recently discovered disease is caused by the fungus-like protist *Phytophthora ramorum* (see Chapter 25). SOD was first described in California in 1995, when hikers noticed trees dying around San Francisco Bay. By 2011, it had spread more than 1,000 km. During that time, it killed more than a million oaks and other trees from the central California coast to southern Oregon. The loss of these oaks has led to the decreased abundance of at least five bird species, including the acorn woodpecker and the oak titmouse, that rely on the oaks for food and habitat. Although there is currently no cure for SOD, scientists recently sequenced the genome of *P. ramorum* in hopes of finding a way to fight the pathogen.

### Community Ecology and Zoonotic Diseases

Three-quarters of emerging human diseases and many of the most devastating diseases are caused by **zoonotic pathogens**—those that are transferred to humans from other animals, either through direct contact with an infected animal or by means of

an intermediate species, called a **vector**. The vectors that spread zoonotic diseases are often parasites, including ticks, lice, and mosquitoes.

Identifying the community of hosts and vectors for a pathogen can help prevent diseases such as Lyme disease, which is spread by ticks. For years, scientists thought that the primary host for the Lyme pathogen was the white-footed mouse because mice are heavily parasitized by young ticks (**Figure 41.23**). When researchers vaccinated mice against Lyme disease and released them into the wild, however, the number of infected ticks hardly changed. Further investigation in New York revealed that two inconspicuous shrew species were the hosts of more than half the ticks collected in the field. Identifying the dominant hosts for a pathogen provides information that may be used to control the hosts most responsible for spreading diseases.

Ecologists also use their knowledge of community interactions to track the spread of zoonotic diseases. For example, avian flu is caused by highly contagious viruses transmitted through the saliva and feces of birds (see Chapter 17). Most of these viruses affect wild birds mildly, but they often cause stronger symptoms in domesticated birds, the most common source of human infections. Since 2003, one particular viral strain, called H5N1, has killed hundreds of millions of poultry and more than 300 people. Millions more people are at risk of infection.

Control programs that quarantine domestic birds or monitor their transport may be ineffective if avian flu spreads naturally through the movements of wild birds. From 2003 to 2006, the H5N1 strain spread rapidly from southeast Asia into Europe and Africa, but by early 2012, it had not appeared in Australia or the Americas. The most likely place for infected wild birds to enter the Americas is Alaska, the entry point for ducks, geese, and shorebirds that migrate every year across the Bering Sea from Asia. Ecologists are studying the spread of the

▲ **Figure 41.23** Identifying Lyme disease host species. A student researcher collects ticks from a white-footed mouse. Genetic analysis of the ticks from a variety of hosts enabled scientists to identify the former hosts of other ticks collected in the field that were no longer attached to a host.

▲ **Figure 41.24 Tracking avian flu.** Graduate student Travis Booms, of Boise State University, bands a young gyrfalcon as part of a project to monitor the spread of the disease.

virus by trapping and testing migrating and resident birds in Alaska (**Figure 41.24**).

Human activities are transporting pathogens around the world at unprecedented rates. Genetic analyses suggest that *P. ramorum* likely came to North America from Europe in

nursery plants. Similarly, the pathogens that cause human diseases are spread by our global economy. H1N1, the virus that causes “swine flu” in humans, was first detected in Veracruz, Mexico, in early 2009. It quickly spread around the world when infected individuals flew on airplanes to other countries. By the time the outbreak ended in 2010, the first flu pandemic in 40 years had killed more than 17,000 people.

Community ecology provides the foundation for understanding the life cycles of pathogens and their interactions with hosts. Pathogen interactions are also greatly influenced by changes in the physical environment. To control pathogens and the diseases they cause, scientists need an ecosystem perspective—an intimate knowledge of how the pathogens interact with other species and with all aspects of their environment. Ecosystems are the subject of Chapter 42.

**CONCEPT CHECK 41.5**

1. What are pathogens?
2. **WHAT IF?** Rabies, a viral disease in mammals, is not currently found in the British Isles. If you were in charge of disease control there, what practical approaches might you employ to keep the rabies virus from reaching these islands?

For suggested answers, see Appendix A.

# 41 Chapter Review

## SUMMARY OF KEY CONCEPTS

**CONCEPT 41.1**

Interactions within a community may help, harm, or have no effect on the species involved (pp. 846–851)

Interaction	Description
Competition (–/–)	Two or more species compete for a resource that is in short supply.
Predation (+/–)	One species, the predator, kills and eats the other, the prey.
Herbivory (+/–)	An herbivore eats part of a plant or alga.
Symbiosis	Individuals of two or more species live in close contact with one another. Symbiosis includes:
Parasitism (+/–)	The <b>parasite</b> derives its nourishment from a second organism, its <b>host</b> , which is harmed.
Mutualism (+/+)	Both species benefit from the interaction.
Commensalism (+/0)	One species benefits from the interaction, while the other is unaffected by it.
Facilitation (+/+ or 0/+)	A species has positive effects on other species without intimate contact.

- **Competitive exclusion** states that two species competing for the same resources cannot coexist permanently in the same place. **Resource partitioning** is the differentiation of **ecological niches** that enables species to coexist in a community.

**?** Give an example of a pair of species that exhibit each interaction listed in the table above.

**CONCEPT 41.2**

Diversity and trophic structure characterize biological communities (pp. 851–856)

- **Species diversity** measures the number of species in a community—its **species richness**—and their **relative abundance**. A community with similar abundances of species is more diverse than one in which one or two species are abundant and the remainder are rare.
- **Trophic structure** is a key factor in community dynamics. **Food chains** link the trophic levels in a community. Branching food chains and complex trophic interactions form **food webs**.
- **Dominant species** are the most abundant species in a community and possess high competitive abilities. **Keystone species** are usually less abundant species that exert a disproportionate influence on community structure because of their ecological niche. **Ecosystem engineers** influence community structure through their effects on the physical environment.
- The **bottom-up model** proposes a unidirectional influence from lower to higher trophic levels. The **top-down model** proposes that control of each trophic level comes from the trophic level above.

**?** Based on indexes such as Shannon diversity, is a community of higher species richness always more diverse than a community of lower species richness? Explain.

**CONCEPT 41.3**

Disturbance influences species diversity and composition (pp. 856–859)

- Increasing evidence suggests that **disturbance** and lack of equilibrium, rather than stability and equilibrium, are the

norm for most communities. According to the **intermediate disturbance hypothesis**, moderate levels of disturbance can foster higher species diversity than can low or high levels of disturbance.

- **Ecological succession** is the sequence of community and ecosystem changes after a disturbance. **Primary succession** occurs where no soil exists when succession begins; **secondary succession** begins in an area where soil remains after a disturbance.
- Humans are the most widespread agents of disturbance, and their effects on communities often reduce species diversity.

**?** Is the disturbance pictured in Figure 41.20 more likely to initiate primary or secondary succession? Explain.

## CONCEPT 41.4

### Biogeographic factors affect community diversity (pp. 859–860)

- Species richness generally declines along a latitudinal gradient from the tropics to the poles. Climate influences the diversity gradient through energy (heat and light) and water.
- Species richness is directly related to a community's geographic size, a principle formalized in the **species-area curve**. The island equilibrium model maintains that species richness on an ecological island reaches an equilibrium where immigration is balanced by extinction.

**?** How have periods of glaciation influenced latitudinal patterns of diversity?

## CONCEPT 41.5

### Pathogens alter community structure locally and globally (pp. 861–862)

- Recent work has highlighted the role that **pathogens** play in structuring terrestrial and marine communities.
- **Zoonotic pathogens** are transferred from other animals to humans. Community ecology provides the framework for identifying key species interactions associated with such pathogens.

**?** In what way can a vector of a zoonotic pathogen differ from a host of the pathogen?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. The feeding relationships among the species in a community determine the community's
  - a. secondary succession.
  - b. ecological niche.
  - c. species richness.
  - d. species-area curve.
  - e. trophic structure.
2. Based on the intermediate disturbance hypothesis, a community's species diversity is increased by
  - a. frequent massive disturbance.
  - b. stable conditions with no disturbance.
  - c. moderate levels of disturbance.
  - d. human intervention to eliminate disturbance.
  - e. intensive disturbance by humans.

### Level 2: Application/Analysis

3. Which of the following could qualify as a top-down control on a grassland community?
  - a. limitation of plant biomass by rainfall amount
  - b. influence of temperature on competition among plants

- c. influence of soil nutrients on the abundance of grasses versus wildflowers
- d. effect of grazing intensity by bison on plant species diversity
- e. effect of humidity on plant growth rates

4. Community 1 contains 100 individuals distributed among four species (A, B, C, and D). Community 2 contains 100 individuals distributed among three species (A, B, and C).

Community 1: 5A, 5B, 85C, 5D

Community 2: 30A, 40B, 30C

Calculate the Shannon diversity index ( $H$ ) for each community. Which community is more diverse?

### Level 3: Synthesis/Evaluation

5. **DRAW IT** An important species in the Chesapeake Bay estuary is the blue crab (*Callinectes sapidus*). It is an omnivore, eating eelgrass and other primary producers as well as clams. It is also a cannibal. In turn, the crabs are eaten by humans and by the endangered Kemp's Ridley sea turtle. Based on this information, draw a food web that includes the blue crab. Assuming that the top-down model holds for this system, what would happen to the abundance of eelgrass if humans stopped eating blue crabs?

### 6. SCIENTIFIC INQUIRY

An ecologist studying plants in the desert performed the following experiment. She staked out two identical plots, each of which included a few sagebrush plants and numerous small annual wildflowers. She found the same five wildflower species in roughly equal numbers on both plots. She then enclosed one of the plots with a fence to keep out kangaroo rats, the most common grain-eaters of the area. After two years, four of the wildflower species were no longer present in the fenced plot, but one species had increased drastically. The control plot had not changed in species diversity. Using the principles of community ecology, propose a hypothesis to explain her results. What additional evidence would support your hypothesis?

### 7. FOCUS ON EVOLUTION

Explain why adaptations of particular organisms to interspecific competition may not necessarily represent instances of character displacement. What would a researcher have to demonstrate about two competing species to make a convincing case for character displacement?

### 8. FOCUS ON INFORMATION

In Batesian mimicry, a palatable species resembles an unpalatable one. Imagine that several individuals of a palatable, brightly colored fly species are carried by the wind to three remote islands. The first island has no predators of that species; the second has predators but no similarly colored, unpalatable species; and the third has both predators and a similarly colored, unpalatable species. In a short essay (100–150 words), predict what might happen to the coloration of the palatable species on each island over evolutionary time if coloration is a genetically controlled trait. Explain your predictions.

For selected answers, see Appendix A.

## MasteringBiology®

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# 42

## Ecosystems and Energy

### KEY CONCEPTS

- 42.1** Physical laws govern energy flow and chemical cycling in ecosystems
- 42.2** Energy and other limiting factors control primary production in ecosystems
- 42.3** Energy transfer between trophic levels is typically only 10% efficient
- 42.4** Biological and geochemical processes cycle nutrients and water in ecosystems
- 42.5** Restoration ecologists help return degraded ecosystems to a more natural state

### OVERVIEW

## Cool Ecosystem

**T**hree hundred meters below Taylor Glacier, in Antarctica, an unusual community of bacteria lives on sulfur- and iron-containing ions. These organisms thrive in harsh conditions, without light or oxygen and at a temperature of  $-10^{\circ}\text{C}$ , so low that the water would freeze if it weren't three times as salty as the ocean. How has this community survived, isolated from Earth's surface for at least 1.5 million years? The bacteria are chemoautotrophs, which obtain energy by oxidizing sulfur taken up from their sulfate-rich environment (see Chapter 24). They use iron as a final electron acceptor

in their reactions. When the water flows from the base of the glacier and comes into contact with air, the reduced iron in the water is oxidized and turns red before the water freezes. The distinctive color gives this area of the glacier its name—Blood Falls (**Figure 42.1**).

Together, the bacterial community and surrounding environment make up an **ecosystem**, the sum of all the organisms living in a given area and the abiotic factors with which they interact. An ecosystem can encompass a vast area, such as a lake or forest, or a microcosm, such as the space under a fallen log or a desert spring (**Figure 42.2**). As with populations and communities, the boundaries of ecosystems are not always discrete. Many ecologists view the entire biosphere as a global ecosystem, a composite of all of the local ecosystems on Earth.

Regardless of an ecosystem's size, two key ecosystem processes cannot be fully described by the population or community phenomena you have studied so far: energy flow and chemical cycling. Energy enters most ecosystems as sunlight. It is converted to chemical energy by autotrophs, passed to heterotrophs in the organic compounds of food, and dissipated as heat. Chemical elements, such as carbon and nitrogen, are cycled among abiotic and biotic components

of the ecosystem. Photosynthetic and chemosynthetic organisms take up these elements in inorganic form from the air, soil, and water and incorporate them into their biomass, some of which is consumed by animals. The elements are returned in inorganic form to the environment by the metabolism of plants and animals and by organisms such as bacteria and fungi that break down organic wastes and dead organisms.

▼ **Figure 42.1** Why is this Antarctic ice blood red?

▲ **Figure 42.2** A desert spring ecosystem.

Both energy and matter are transformed in ecosystems through photosynthesis and feeding relationships. But unlike matter, energy cannot be recycled. An ecosystem must be powered by a continuous influx of energy from an external source—in most cases, the sun. Energy flows through ecosystems, whereas matter cycles within and through them.

Resources critical to human survival and welfare, ranging from the food we eat to the oxygen we breathe, are products of ecosystem processes. In this chapter, we'll explore the dynamics of energy flow and chemical cycling, emphasizing the results of ecosystem experiments. One way to study ecosystem processes is to alter environmental factors, such as temperature or the abundance of nutrients, and measure how ecosystems respond. We'll also consider some of the impacts of human activities on energy flow and chemical cycling. Finally, we'll explore the growing science of restoration ecology, which focuses on returning degraded ecosystems to a more natural state.

## CONCEPT 42.1

### Physical laws govern energy flow and chemical cycling in ecosystems

Cells transform energy and matter, subject to the laws of thermodynamics (see Concept 6.1). Like cell biologists, ecosystem ecologists study how energy and matter are transformed within a system and measure the amounts of both that cross the system's boundaries. By grouping the species in a community into trophic levels based on feeding relationships (see Concept 41.2), we can follow the transformations of energy in an ecosystem and map the movements of chemical elements.

#### Conservation of Energy

Because ecosystem ecologists study the interactions of organisms with the physical environment, many ecosystem approaches are based on laws of physics and chemistry. The

first law of thermodynamics states that energy cannot be created or destroyed but only transferred or transformed. Plants and other photosynthetic organisms convert solar energy to chemical energy, but the total amount of energy does not change. The amount of energy stored in organic molecules must equal the total solar energy intercepted by the plant, minus the amounts reflected and dissipated as heat. Ecosystem ecologists often measure transfers within and across ecosystems, in part to understand how many organisms a habitat can support and how much food humans can harvest from a site.

One implication of the second law of thermodynamics, which states that every exchange of energy increases the entropy of the universe, is that energy conversions are inefficient. Some energy is always lost as heat. We can measure the efficiency of ecological energy conversions just as we measure the efficiency of light bulbs and car engines. Because the energy flowing through ecosystems is ultimately dissipated into space as heat, most ecosystems would vanish if the sun were not continuously providing energy to Earth.

#### Conservation of Mass

Matter, like energy, cannot be created or destroyed. This **law of conservation of mass** is as important for ecosystems as the laws of thermodynamics are. Because mass is conserved, we can determine how much of a chemical element cycles within an ecosystem or is gained or lost by that ecosystem over time.

Unlike energy, chemical elements are continually recycled within ecosystems. A carbon atom in  $\text{CO}_2$  can be released from the soil by a decomposer, taken up by grass through photosynthesis, consumed by a bison or other grazer, and returned to the soil in the bison's waste. The measurement and analysis of chemical cycling are important aspects of ecosystem ecology.

Although most elements are not gained or lost on a global scale, they can be gained by or lost from a particular ecosystem. In a forest, mineral nutrients—the essential elements that plants obtain from soil—typically enter as dust or as solutes dissolved in rainwater or leached from rocks in the ground. Nitrogen is also supplied through the biological process of nitrogen fixation (see Figure 29.11). In terms of losses, some elements return to the atmosphere as gases, and others are carried out of the ecosystem by moving water or by wind. Like organisms, ecosystems are open systems, absorbing energy and mass and releasing heat and waste products.

In nature, most gains and losses to ecosystems are small compared to the amounts recycled within them. Still, the balance between inputs and outputs determines whether an ecosystem is a source or a sink for a given element. If a mineral nutrient's outputs exceed its inputs, it will eventually limit production in that system. Human activities often change the balance of inputs and outputs considerably, as we'll see later in this chapter.

## Energy, Mass, and Trophic Levels

Ecologists group species into trophic levels based on their main source of nutrition and energy (see Concept 41.2). The trophic level that ultimately supports all others consists of autotrophs, also called the **primary producers** of the ecosystem. Most autotrophs are photosynthetic organisms that use light energy to synthesize sugars and other organic compounds, which they then use as fuel for cellular respiration and as building material for growth. Plants, algae, and photosynthetic prokaryotes are the most common autotrophs, although chemosynthetic prokaryotes are the primary producers in deep-sea hydrothermal vents (see Figure 40.10) and places deep underground or beneath ice (see Figure 42.1).

Organisms in trophic levels above the primary producers are heterotrophs, which depend directly or indirectly on the primary producers for their source of energy. Herbivores, which eat plants and other primary producers, are **primary consumers**. Carnivores that eat herbivores are **secondary consumers**, and carnivores that eat other carnivores are **tertiary consumers**.

Another group of heterotrophs is the **detritivores**, or **decomposers**, terms we use synonymously in this text to refer to consumers that get their energy from detritus. **Detritus** is nonliving organic material, such as the remains of dead organisms, feces, fallen leaves, and wood. Many detritivores are in turn eaten by secondary and tertiary consumers. Two important groups of detritivores are prokaryotes and fungi (**Figure 42.3**).

These organisms secrete enzymes that digest organic material; they then absorb the breakdown products, linking the consumers and primary producers in an ecosystem. In a forest, for instance, birds eat earthworms that have been feeding on leaf litter and its associated prokaryotes and fungi.

Detritivores also play a critical role in recycling chemical elements back to primary producers. Detritivores convert organic matter from all trophic levels to inorganic compounds usable by primary producers, closing the loop of an ecosystem's chemical cycling. Producers can then recycle these elements into organic compounds. If decomposition stopped, life would cease as detritus piled up and the supply of ingredients needed

▲ **Figure 42.3** Fungi decomposing a dead tree.

▲ **Figure 42.4** An overview of energy and nutrient dynamics in an ecosystem.

Energy enters, flows through, and exits an ecosystem, whereas chemical nutrients cycle primarily within it. In this generalized scheme, energy (dark orange arrows) enters from the sun as radiation, moves as chemical energy transfers through the food web, and exits as heat radiated into space. Most transfers of nutrients (blue arrows) through the trophic levels lead eventually to detritus; the nutrients then cycle back to the primary producers.

to synthesize new organic matter was exhausted. **Figure 42.4** summarizes the trophic relationships in an ecosystem.

### CONCEPT CHECK 42.1

1. Why is the transfer of energy in an ecosystem referred to as energy flow, not energy cycling?
2. **WHAT IF?** You are studying nitrogen cycling on the Serengeti Plain in Africa. During your experiment, a herd of migrating wildebeests grazes through your study plot. What would you need to know to measure their effect on nitrogen balance in the plot?
3. **MAKE CONNECTIONS** How does the second law of thermodynamics explain why an ecosystem's energy supply must be continually replenished? (See Concept 6.1 to review the laws of thermodynamics.)

For suggested answers, see Appendix A.

## CONCEPT 42.2

### Energy and other limiting factors control primary production in ecosystems

The theme of energy transfer underlies all biological interactions (see Chapter 1). In most ecosystems, the amount of light energy converted to chemical energy—in the form of organic compounds—by autotrophs during a given time period is the ecosystem's **primary production**. These photosynthetic products are the starting point for most studies of ecosystem

metabolism and energy flow. In ecosystems where the primary producers are chemoautotrophs, as described in the Overview, the initial energy input is chemical, and the initial products are the organic compounds synthesized by the microorganisms.

## Ecosystem Energy Budgets

Since most primary producers use light energy to synthesize energy-rich organic molecules, consumers acquire their organic fuels secondhand (or even third- or fourthhand) through food webs (see Figure 41.14). Therefore, the total amount of photosynthetic production sets the spending limit for the entire ecosystem's energy budget.

### The Global Energy Budget

Each day, Earth's atmosphere is bombarded by about  $10^{22}$  joules of solar radiation ( $1 \text{ J} = 0.239 \text{ cal}$ ). This is enough energy to supply the demands of the entire human population for approximately 20 years at 2010 energy consumption levels. The intensity of the solar energy striking Earth varies with latitude, with the tropics receiving the greatest input (see Figure 40.3). Most incoming solar radiation is absorbed, scattered, or reflected by clouds and dust in the atmosphere. The amount of solar radiation that ultimately reaches Earth's surface limits the possible photosynthetic output of ecosystems.

Only a small fraction of the sunlight that reaches Earth's surface is actually used in photosynthesis. Much of the radiation strikes materials that don't photosynthesize, such as ice and soil. Of the radiation that does reach photosynthetic organisms, only certain wavelengths are absorbed by photosynthetic pigments (see Figure 8.9); the rest is transmitted, reflected, or lost as heat. As a result, only about 1% of the visible light that strikes photosynthetic organisms is converted to chemical energy. Nevertheless, Earth's primary producers create about 150 billion metric tons ( $1.50 \times 10^{14} \text{ kg}$ ) of organic material each year.

### Gross and Net Production

Total primary production in an ecosystem is known as that ecosystem's **gross primary production (GPP)**—the amount of energy from light (or chemicals, in chemoautotrophic systems) converted to the chemical energy of organic molecules per unit time. Not all of this production is stored as organic material in the primary producers because they use some of the molecules as fuel in their own cellular respiration. **Net primary production (NPP)** is equal to gross primary production minus the energy used by the primary producers for their "autotrophic respiration" ( $R_a$ ):

$$\text{NPP} = \text{GPP} - R_a$$

On average, NPP is about one-half of GPP. To ecologists, NPP is the key measurement because it represents the storage of chemical energy that will be available to consumers in the ecosystem.

Net primary production can be expressed as energy per unit area per unit time ( $\text{J}/\text{m}^2 \cdot \text{yr}$ ) or as biomass (mass of vegetation) added per unit area per unit time ( $\text{g}/\text{m}^2 \cdot \text{yr}$ ). (Note that biomass is usually expressed in terms of the dry mass of organic material.) An ecosystem's NPP should not be confused with the total biomass of photosynthetic autotrophs present, a measure called the *standing crop*. Net primary production is the amount of *new* biomass added in a given period of time. Although a forest has a large standing crop, its NPP may actually be less than that of some grasslands; grasslands do not accumulate as much biomass as forests because animals consume the plants rapidly and because grasses and herbs decompose more quickly than trees do.

Satellites provide a powerful tool for studying global patterns of primary production (Figure 42.5). Images produced from satellite data show that different ecosystems vary considerably in their NPP. Tropical rain forests are among the most productive terrestrial ecosystems and contribute a large portion of the planet's NPP. Estuaries and coral reefs also have

#### ▼ Figure 42.5 Research Method

#### Determining Primary Production with Satellites

**Application** Because chlorophyll captures visible light (see Figure 8.9), photosynthetic organisms absorb more light at visible wavelengths (about 380–750 nm) than at near-infrared wavelengths (750–1,100 nm). Scientists use this difference in absorption to estimate the rate of photosynthesis in different regions of the globe using satellites.

**Technique** Most satellites determine what they "see" by comparing the ratios of wavelengths reflected back to them. Vegetation reflects much more near-infrared radiation than visible radiation, producing a reflectance pattern very different from that of snow, clouds, soil, and liquid water.

**Results** Scientists use the satellite data to help produce maps of primary production like the one in Figure 42.6.

► **Figure 42.6 Global net primary production.** This map is based on data collected by satellites, such as amount of sunlight absorbed by vegetation. Note that tropical land areas have the highest rates of production (yellow and red on the map).

**?** Does this global map accurately illustrate the importance of some highly productive habitats, such as wetlands, coral reefs, and coastal zones? Explain.

Net primary production  
(kg carbon/m<sup>2</sup>·yr)

very high NPP, but their contribution to the global total is small because these ecosystems cover only about one-tenth the area covered by tropical rain forests. In contrast, while the open oceans are relatively unproductive (**Figure 42.6**), their vast size means that together they contribute about as much global NPP as terrestrial systems do.

Whereas NPP can be stated as the amount of new biomass added in a given period of time, **net ecosystem production (NEP)** is a measure of the *total biomass accumulation* during that time. Net ecosystem production is defined as gross primary production minus the total respiration of all organisms in the system ( $R_T$ )—not just primary producers, as for the calculation of NPP, but decomposers and other heterotrophs as well:

$$\text{NEP} = \text{GPP} - R_T$$

NEP is useful to ecologists because its value determines whether an ecosystem is gaining or losing carbon over time. A forest may have a positive NPP but still lose carbon if heterotrophs release it as  $\text{CO}_2$  more quickly than primary producers incorporate it into organic compounds.

The most common way to estimate NEP is to measure the net flux (flow) of  $\text{CO}_2$  or  $\text{O}_2$  entering or leaving the ecosystem. If more  $\text{CO}_2$  enters than leaves, the system is storing carbon. Because  $\text{O}_2$  release is directly coupled to photosynthesis and respiration (see Figure 7.2), a system that is giving off  $\text{O}_2$  is also storing carbon. On land, ecologists typically measure only the net flux of  $\text{CO}_2$  from ecosystems because detecting small changes in  $\text{O}_2$  in a large atmospheric  $\text{O}_2$  pool is difficult. In the oceans, researchers use both approaches.

What limits production in ecosystems? To ask this question another way, what factors could we change to increase production for a given ecosystem? We'll address this question first for aquatic ecosystems.

## Primary Production in Aquatic Ecosystems

In aquatic (marine and freshwater) ecosystems, both light and nutrients are important in controlling primary production.

### Light Limitation

Because solar radiation drives photosynthesis, you would expect light to be a key variable in controlling primary production in oceans. Indeed, the depth of light penetration affects primary production throughout the photic zone of an ocean or lake (see Figure 40.11). About half of the solar radiation is absorbed in the first 15 m of water. Even in “clear” water, only 5–10% of the radiation may reach a depth of 75 m.

If light were the main variable limiting primary production in the ocean, we would expect production to increase along a gradient from the poles toward the equator, which receives the greatest intensity of light. However, you can see in Figure 42.6 that there is no such gradient. Another factor must strongly influence primary production in the ocean.

### Nutrient Limitation

More than light, nutrients limit primary production in most oceans and lakes. A **limiting nutrient** is the element that must be added for production to increase. The nutrient most often limiting marine production is either nitrogen or phosphorus. Concentrations of these nutrients are typically low in the photic zone because they are rapidly taken up by phytoplankton and because detritus tends to sink.

As detailed in **Figure 42.7**, nutrient enrichment experiments confirmed that nitrogen was limiting phytoplankton growth off the south shore of Long Island, New York. One practical application of this work is in preventing algal “blooms” caused by excess nitrogen runoff that fertilizes the phytoplankton. Prior to this research, phosphate contamination was thought to cause many such blooms in the ocean, but eliminating phosphates alone may not help unless nitrogen pollution is also controlled.

The macronutrients nitrogen and phosphorus are not the only nutrients that limit aquatic production. Several large areas of the ocean have low phytoplankton densities despite relatively high nitrogen concentrations. The Sargasso Sea,

## ▼ Figure 42.7 Inquiry

### Which nutrient limits phytoplankton production along the coast of Long Island?

**Experiment** Pollution from duck farms concentrated near Moriches Bay adds both nitrogen and phosphorus to the coastal water off Long Island, New York. To determine which nutrient limits phytoplankton growth in this area, John Ryther and William Dunstan, of the Woods Hole Oceanographic Institution, cultured the phytoplankton *Nannochloris atomus* with water collected from several sites, identified as A–G. They added either ammonium ( $\text{NH}_4^+$ ) or phosphate ( $\text{PO}_4^{3-}$ ) to some of the cultures.

**Results** The addition of ammonium caused heavy phytoplankton growth in the cultures, but the addition of phosphate did not.

© 1971 AAAS

**Conclusion** Since adding phosphorus, which was already in rich supply, did not increase *Nannochloris* growth, whereas adding nitrogen increased phytoplankton density dramatically, the researchers concluded that nitrogen is the nutrient that limits phytoplankton growth in this ecosystem.

**Source** J. H. Ryther and W. M. Dunstan, Nitrogen, phosphorus, and eutrophication in the coastal marine environment, *Science* 171:1008–1013 (1971).

**WHAT IF?** How would you expect the results of this experiment to change if new duck farms substantially increased the amount of pollution in the water? Explain your reasoning.

**Table 42.1** Nutrient Enrichment Experiment for Sargasso Sea Samples

Nutrients Added to Experimental Culture	Relative Uptake of $^{14}\text{C}$ by Cultures*
None (controls)	1.00
Nitrogen (N) + phosphorus (P) only	1.10
N + P + metals (excluding iron)	1.08
N + P + metals (including iron)	12.90
N + P + iron	12.00

\* $^{14}\text{C}$  uptake by cultures measures primary production.

upwelling stimulates growth of the phytoplankton that form the base of marine food webs, upwelling areas typically host highly productive, diverse ecosystems and are prime fishing locations. The largest areas of upwelling occur in the Southern Ocean (also called the Antarctic Ocean), along the equator, and in the coastal waters off Peru, California, and parts of western Africa.

In freshwater lakes, nutrient limitation is also common. During the 1970s, scientists showed that sewage and fertilizer runoff from farms and lawns adds large amounts of nutrients to lakes. Cyanobacteria and algae grow rapidly in response to these added nutrients. When the primary producers die, detritivores can reduce or even use up the available oxygen in the water through decomposition, also reducing the clarity of the water. The ecological impacts of this process, known as **eutrophication** (from the Greek *eutrophos*, well nourished), include the loss of many fish species from the lakes (see Figure 40.10).

Controlling eutrophication requires knowing which polluting nutrient is responsible. While nitrogen rarely limits primary production in lakes, a series of whole-lake experiments showed that phosphorus availability limits cyanobacterial growth. This and other ecological research led to the use of phosphate-free detergents and other important water quality reforms.

## Primary Production in Terrestrial Ecosystems

At regional and global scales, temperature and moisture are the main factors controlling primary production in terrestrial ecosystems. Tropical rain forests, with their warm, wet conditions that promote plant growth, are the most productive of all terrestrial ecosystems (see Figure 42.6). In contrast, low-productivity systems are generally hot and dry, like many deserts, or cold and dry, like arctic tundra. Between these extremes lie the temperate forest and grassland ecosystems, which have moderate climates and intermediate productivity.

The climate variables of moisture and temperature are very useful for predicting NPP in terrestrial ecosystems. Primary production is greater in wetter ecosystems, as shown for the

a subtropical region of the Atlantic Ocean, has some of the clearest water in the world because of its low phytoplankton density. Nutrient enrichment experiments have revealed that the availability of the micronutrient iron limits primary production there (**Table 42.1**). Windblown dust from land supplies most of the iron to the oceans but is relatively scarce in this and certain other regions compared to the oceans as a whole.

Areas of *upwelling*, where deep, nutrient-rich waters circulate to the ocean surface, have exceptionally high primary production. This fact supports the hypothesis that nutrient availability determines marine primary production. Because

▲ **Figure 42.8** A global relationship between net primary production and mean annual precipitation for terrestrial ecosystems.

plot of NPP and annual precipitation in **Figure 42.8**. Along with mean annual precipitation, a second useful predictor is *actual evapotranspiration*, the total amount of water transpired by plants and evaporated from a landscape. Evapotranspiration increases with the temperature and amount of solar energy available to drive evaporation and transpiration.

### Nutrient Limitations and Adaptations That Reduce Them

**EVOLUTION** Mineral nutrients in the soil also limit primary production in terrestrial ecosystems. As in aquatic systems, nitrogen and phosphorus are the nutrients that most commonly limit terrestrial production. Globally, nitrogen limits plant growth most. Phosphorus limitations are common in older soils where phosphate molecules have been leached away by water, such as in many tropical ecosystems. Phosphorus availability is also often low in the soils of deserts and other ecosystems with a basic pH, where some phosphorus precipitates and becomes unavailable to plants. Adding a nonlimiting nutrient, even one that is scarce, will not stimulate production. Conversely, adding more of the limiting nutrient will increase production until some other nutrient becomes limiting.

Various adaptations have evolved in plants that can increase their uptake of limiting nutrients. One important adaptation is the symbiosis between plant roots and nitrogen-fixing bacteria. Another is the mycorrhizal association between plant roots and fungi that supply phosphorus and other limiting elements to plants (see Concept 29.4). Plants also have root hairs and other anatomical features that increase their area of contact with the soil (see Chapter 28). Many plants release enzymes and other substances into the soil that increase the availability of limiting nutrients; such enzymes include phosphatases, which cleave a phosphate group from larger molecules and make it more soluble in the soil.

Studies relating nutrients to terrestrial primary production have practical applications in agriculture. Farmers maximize their crop yields by using fertilizers with the right balance of nutrients for the local soil and type of crop. This knowledge of limiting nutrients helps us feed billions of people today.

#### CONCEPT CHECK 42.2

1. Why is only a small portion of the solar energy that strikes Earth's atmosphere stored by primary producers?
2. How can ecologists experimentally determine the factor that limits primary production in an ecosystem?
3. **MAKE CONNECTIONS** Explain how nitrogen and phosphorus, the nutrients that most often limit primary production, are necessary for the Calvin cycle to function in photosynthesis (see Concept 8.3).

For suggested answers, see Appendix A.

## CONCEPT 42.3

### Energy transfer between trophic levels is typically only 10% efficient

The amount of chemical energy in consumers' food that is converted to new biomass during a given period is called the **secondary production** of the ecosystem. Consider the transfer of organic matter from primary producers to herbivores, the primary consumers. In most ecosystems, herbivores eat only a small fraction of plant material produced; globally, they consume only about one-sixth of total plant production. Moreover, they cannot digest all the plant material that they *do* eat, as anyone who has walked through a dairy farm will attest. Most of an ecosystem's production is eventually consumed by detritivores. Let's analyze the process of energy transfer and cycling more closely.

#### Production Efficiency

First we'll examine secondary production in one organism—a caterpillar. When a caterpillar feeds on a leaf, only about 33 J out of 200 J, or one-sixth of the potential energy in the leaf, is used for secondary production, or growth (**Figure 42.9**). The caterpillar stores some of the remaining energy in organic compounds that will be used for cellular respiration and passes the rest in its feces. Most of the energy in feces is eventually lost as heat after the feces are consumed by detritivores. The energy used for the caterpillar's respiration is also lost from the ecosystem as heat. This is why energy is said to flow through, not cycle within, ecosystems. Only the chemical energy stored by herbivores as biomass, through growth or the production of offspring, is available as food to secondary consumers.

We can measure the efficiency of animals as energy transformers using the following equation:

$$\text{Production efficiency} = \frac{\text{Net secondary production} \times 100\%}{\text{Assimilation of primary production}}$$

# Interpreting Quantitative Data in a Table

## How Efficient Is Energy Transfer in a Salt Marsh Ecosystem?

In a classic experiment, John Teal studied the flow of energy through the producers, consumers, and detritivores in a salt marsh. In this exercise, you will use the data from this study to calculate some measures of energy transfer between trophic levels in this ecosystem.

**How the Study Was Done** Teal measured the amount of solar radiation entering a salt marsh in Georgia over a year. He also measured the aboveground biomass of the dominant primary producers, which were grasses, as well as the biomass of the dominant consumers, including insects, spiders, and crabs, and of the detritus that flowed out of the marsh to the surrounding coastal waters. To determine the amount of energy in each unit of biomass, he dried the biomass, burned it in a calorimeter, and measured the amount of heat produced.

## Data from the Study

Form of Energy	kcal/m <sup>2</sup> · yr
Solar radiation	600,000
Gross grass production	34,580
Net grass production	6,585
Gross insect production	305
Net insect production	81
Detritus leaving marsh	3,671

## Interpret the Data

1. What proportion of the solar energy that reaches the marsh is incorporated into gross primary production? Into net primary production? (A proportion is the same as a percentage divided by 100. Both measures are useful for comparing relative efficiencies across different ecosystems.)
2. How much energy is lost by primary producers as respiration in this ecosystem? How much is lost as respiration by the insect population?
3. If all of the detritus leaving the marsh is plant material, what proportion of all net primary production leaves the marsh as detritus each year?

**Data from** J. M. Teal, Energy flow in the salt marsh ecosystem of Georgia, *Ecology* 43:614–624 (1962).

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

**▲ Figure 42.9 Energy partitioning within a link of the food chain.** Less than 17% of the caterpillar's food is actually used for secondary production (growth).

Net secondary production is the energy stored in biomass represented by growth and reproduction. Assimilation consists of the total energy taken in, not including losses in feces, used for growth, reproduction, and respiration. **Production efficiency**, therefore, is the percentage of energy stored in assimilated food that is *not* used for respiration. For the caterpillar in Figure 42.9, production efficiency is 33%; 67 J of the 100 J of assimilated energy is used for respiration. (The 100 J of energy lost as undigested material in feces does not count toward assimilation.) Birds and mammals typically have low production efficiencies, in the range of 1–3%, because they use so much energy in maintaining a constant, high body temperature. Insects and microorganisms are much more efficient, with production efficiencies averaging 40% or more.

## Trophic Efficiency and Ecological Pyramids

Let's scale up now from the production efficiencies of individual consumers to the flow of energy through trophic levels.

**Trophic efficiency** is the percentage of production transferred from one trophic level to the next. Trophic efficiencies must always be less than production efficiencies because they take into account not only the energy lost through respiration and contained in feces, but also the energy in organic material in a lower trophic level that is not consumed by the next trophic level. Trophic efficiencies are generally only about 10%. In other words, 90% of the energy available at one trophic level typically is *not* transferred to the next. This loss is multiplied over the length of a food chain. For example, if 10% of available energy is transferred from primary producers to primary consumers, such as caterpillars, and 10% of that energy is transferred to secondary consumers, called carnivores, then only 1% of net primary production is available to secondary consumers (10% of 10%). In the **Scientific Skills Exercise**, you

can calculate trophic efficiency and other measures of energy flow in a salt marsh ecosystem.

The progressive loss of energy along a food chain severely limits the abundance of top-level carnivores that an ecosystem can support. Only about 0.1% of the chemical energy fixed by photosynthesis can flow all the way through a food web to a tertiary consumer, such as a snake or a shark. This explains why most food webs include only about four or five trophic levels (see Chapter 41).

The loss of energy with each transfer in a food chain can be represented by a *pyramid of net production*, in which the

▲ **Figure 42.10 An idealized pyramid of net production.** This example assumes a trophic efficiency of 10% for each link in the food chain. Notice that primary producers convert only about 1% of the energy available to them to net primary production.

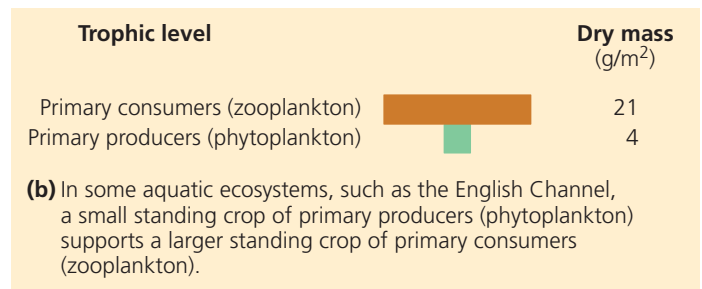

trophic levels are arranged in tiers (**Figure 42.10**). The width of each tier is proportional to the net production, expressed in joules, of each trophic level. The highest level, which represents top-level predators, contains relatively few individuals. The small population size typical of top predator species is one reason they tend to be vulnerable to extinction (as well as to the evolutionary consequences of small population size, discussed in Concept 21.3).

One important ecological consequence of low trophic efficiencies is represented in a *biomass pyramid*, in which each tier represents the standing crop (the total dry mass of all organisms) in one trophic level. Most biomass pyramids narrow sharply from primary producers at the base to top-level carnivores at the apex because energy transfers between trophic levels are so inefficient (**Figure 42.11a**). Certain aquatic ecosystems, however, have inverted biomass pyramids: Primary consumers outweigh the producers (**Figure 42.11b**). Such inverted biomass pyramids occur because the producers—phytoplankton—grow, reproduce, and are consumed so quickly by the zooplankton that they never develop a large population size, or standing crop. In other words, the phytoplankton have a short **turnover time**, which means they have a small standing crop compared to their production:

$$\text{Turnover time} = \frac{\text{Standing crop (g/m}^2\text{)}}{\text{Production (g/m}^2 \cdot \text{day)}}$$

Because the phytoplankton continually replace their biomass at such a rapid rate, they can support a biomass of zooplankton bigger than their own biomass. Nevertheless, because phytoplankton have much higher production than zooplankton, the pyramid of *production* for this ecosystem is still bottom-heavy, like the one in Figure 42.10.

The dynamics of energy flow through ecosystems have important implications for human consumers. Eating meat is a relatively inefficient way of tapping photosynthetic production. The same pound of soybeans that a person could eat for

▲ **Figure 42.11 Pyramids of biomass (standing crop).** Numbers denote the dry mass of all organisms at each trophic level.

protein produces only a fifth of a pound of beef or less when fed to a cow. Worldwide agriculture could, in fact, feed many more people and require less land if we all fed more efficiently—as primary consumers, eating plant material.

In the next section, we'll look at how the transfer of nutrients and energy through food webs is part of a larger picture of chemical cycling in ecosystems.

### CONCEPT CHECK 42.3

1. If an insect that eats plant seeds containing 100 J of energy uses 30 J of that energy for respiration and excretes 50 J in its feces, what is the insect's net secondary production? What is its production efficiency?
2. Tobacco leaves contain nicotine, a poisonous compound that is energetically expensive for the plant to make. What advantage might the plant gain by using some of its resources to produce nicotine?
3. **WHAT IF?** Detritivores are consumers that obtain their energy from detritus. How many joules of energy are potentially available to detritivores in the ecosystem represented in Figure 42.10?

For suggested answers, see Appendix A.

## CONCEPT 42.4 Biological and geochemical processes cycle nutrients and water in ecosystems

Although most ecosystems receive abundant solar energy, chemical elements are available only in limited amounts. Life therefore depends on the recycling of essential chemical

elements. Much of an organism's chemical stock is replaced continuously as nutrients are assimilated and waste products are released. When the organism dies, the atoms in its body are returned to the atmosphere, water, or soil by decomposers. Decomposition replenishes the pools of inorganic nutrients that plants and other autotrophs use to build new organic matter.

## Decomposition and Nutrient Cycling Rates

Decomposition is controlled by the same factors that limit primary production in aquatic and terrestrial ecosystems (see Concept 42.2). These factors include temperature, moisture, and nutrient availability. Decomposers usually grow faster and decompose material more quickly in warmer ecosystems (**Figure 42.12**). In tropical rain forests, most organic material decomposes in a few months to a few years, while in temperate forests, decomposition takes four to six years, on average. The difference is largely the result of the higher temperatures and more abundant precipitation in tropical rain forests.

Because decomposition in a tropical rain forest is rapid, relatively little organic material accumulates as leaf litter on the forest floor; about 75% of the nutrients in the ecosystem is present in the woody trunks of trees, and only about 10% is contained in the soil. Thus, the relatively low concentrations of some nutrients in the soil of tropical rain forests result from a short cycling time, not from a lack of these elements in the ecosystem. In temperate forests, where decomposition is much slower, the soil may contain as much as 50% of all the organic material in the ecosystem. The nutrients that are present in temperate forest detritus and soil may remain there for long periods before plants assimilate them.

Decomposition on land is also slower when conditions are either too dry for decomposers to thrive or too wet to supply them with enough oxygen. Ecosystems that are both cold and wet, such as peatlands, store large amounts of organic matter. Decomposers grow poorly there, and net primary production greatly exceeds decomposition.

In aquatic ecosystems, decomposition in anaerobic muds can take 50 years or longer. Bottom sediments are comparable to the detritus layer in terrestrial ecosystems; however, algae and aquatic plants usually assimilate nutrients directly from the water. Thus, the sediments often constitute a nutrient sink, and aquatic ecosystems are very productive only when there is exchange between the bottom layers of water and the water at the surface.

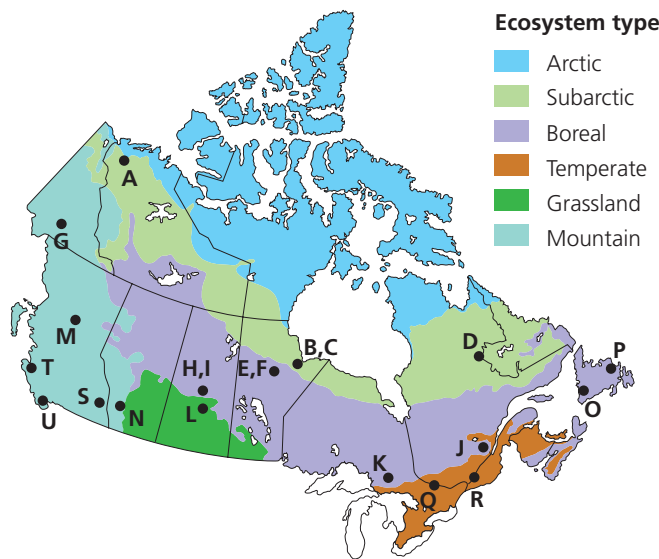

## Biogeochemical Cycles

Because nutrient cycles involve both biotic and abiotic components, they are called **biogeochemical cycles**. For convenience, we can recognize two general categories of biogeochemical cycles: global and local. Gaseous forms of carbon, oxygen, sulfur, and nitrogen occur in the atmosphere, and

### ▼ Figure 42.12 Inquiry

#### How does temperature affect litter decomposition in an ecosystem?

**Experiment** Researchers with the Canadian Forest Service placed identical samples of organic material—litter—on the ground in 21 sites across Canada (marked by letters on the map below). Three years later, they returned to see how much of each sample had decomposed.

**Results** The mass of litter decreased four times faster in the warmest ecosystem than in the coldest ecosystem.

**Conclusion** Decomposition rate increases with temperature across much of Canada.

**Source** T. R. Moore et al., Litter decomposition rates in Canadian forests, *Global Change Biology* 5:75–82 (1999).

**WHAT IF?** What factors other than temperature might also have varied across these 21 sites? How might this variation have affected the interpretation of the results?

cycles of these elements are essentially global. Other elements, including phosphorus, potassium, and calcium, are too heavy to occur as gases at Earth's surface. They cycle locally in terrestrial ecosystems and more broadly in aquatic ecosystems.

**Figure 42.13** provides a detailed look at the cycling of water, carbon, nitrogen, and phosphorus. When you study each

## ▼ Figure 42.13 Exploring Water and Nutrient Cycling

Examine each cycle closely, considering the major reservoirs of water, carbon, nitrogen, and phosphorus and the processes that drive each cycle. The widths of the arrows in the diagrams approximately reflect the relative contribution of each process to the movement of water or a nutrient in the biosphere.

### The Water Cycle

**Biological importance** Water is essential to all organisms, and its availability influences the rates of ecosystem processes, particularly primary production and decomposition in terrestrial ecosystems.

**Forms available to life** All organisms are capable of exchanging water directly with their environment. Liquid water is the primary physical phase in which water is used, though some organisms can harvest water vapor. Freezing of soil water can limit water availability to terrestrial plants.

**Reservoirs** The oceans contain 97% of the water in the biosphere. Approximately 2% is bound in glaciers and polar ice caps, and the remaining 1% is in lakes, rivers, and groundwater, with a negligible amount in the atmosphere.

**Key processes** The main processes driving the water cycle are evaporation of liquid water by solar energy, condensation of water vapor into clouds, and precipitation. Transpiration by terrestrial plants also moves large volumes of water into the atmosphere. Surface and groundwater flow can return water to the oceans, completing the water cycle.

### The Carbon Cycle

**Biological importance** Carbon forms the framework of the organic molecules essential to all organisms.

**Forms available to life** Photosynthetic organisms utilize CO<sub>2</sub> during photosynthesis and convert the carbon to organic forms that are used by consumers, including animals, fungi, and heterotrophic protists and prokaryotes.

**Reservoirs** The major reservoirs of carbon include fossil fuels, soils, the sediments of aquatic ecosystems, the oceans (dissolved carbon compounds), plant and animal biomass, and the atmosphere (CO<sub>2</sub>). The largest reservoir is sedimentary rocks such as limestone; however, this pool turns over very slowly. All organisms are capable of returning carbon directly to their environment in its original form (CO<sub>2</sub>) through respiration.

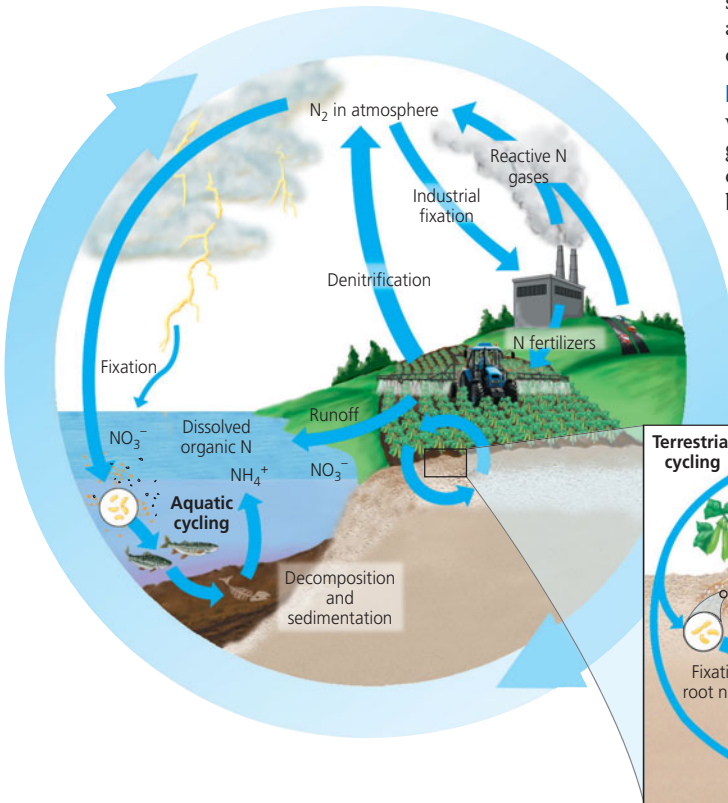

**Key processes** Photosynthesis by plants and phytoplankton removes substantial amounts of atmospheric CO<sub>2</sub> each year. This quantity is approximately equaled by CO<sub>2</sub> added to the atmosphere through cellular respiration by producers and consumers. The burning of fossil fuels and wood is adding significant amounts of additional CO<sub>2</sub> to the atmosphere. Over geologic time, volcanoes are also a substantial source of CO<sub>2</sub>.

**ANIMATION** Visit the Study Area in **MasteringBiology** for the BioFlix® 3-D Animation on The Carbon Cycle.

## The Nitrogen Cycle

**Biological importance** Nitrogen is part of amino acids, proteins, and nucleic acids and is often a limiting plant nutrient.

**Forms available to life** Plants can assimilate (use) two inorganic forms of nitrogen—ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ )—and some organic forms, such as amino acids. Various bacteria can use all of these forms as well as nitrite ( $\text{NO}_2^-$ ). Animals can use only organic forms of nitrogen.

**Reservoirs** The main reservoir of nitrogen is the atmosphere, which is 78% free nitrogen gas ( $\text{N}_2$ ). The other reservoirs of inorganic and organic nitrogen compounds are soils and the sediments of lakes, rivers, and oceans; surface water and groundwater; and the biomass of living organisms.

**Key processes** The major pathway for nitrogen to enter an ecosystem is via *nitrogen fixation*, the conversion of  $\text{N}_2$  to forms that can be used to synthesize organic nitrogen compounds. Certain bacteria, as well as lightning and volcanic activity, fix nitrogen naturally. Nitrogen inputs from human activities now outpace natural inputs on land. Two major contributors are industrially

produced fertilizers and legume crops that fix nitrogen via bacteria in their root nodules. Other bacteria in soil convert nitrogen to different forms. Some bacteria carry out denitrification, the reduction of nitrate to nitrogen gases. Human activities also release large quantities of reactive nitrogen gases, such as nitrogen oxides, to the atmosphere.

## The Phosphorus Cycle

**Biological importance** Organisms require phosphorus as a major constituent of nucleic acids, phospholipids, and ATP and other energy-storing molecules and as a mineral constituent of bones and teeth.

**Forms available to life** The most biologically important inorganic form of phosphorus is phosphate ( $\text{PO}_4^{3-}$ ), which plants absorb and use in the synthesis of organic compounds.

**Reservoirs** The largest accumulations of phosphorus are in sedimentary rocks of marine origin. There are also large quantities of phosphorus in soil, in the oceans (in dissolved form), and in organisms. Because soil particles bind  $\text{PO}_4^{3-}$ , the recycling of phosphorus tends to be quite localized in ecosystems.

**Key processes** Weathering of rocks gradually adds  $\text{PO}_4^{3-}$  to soil; some leaches into groundwater and surface water and may eventually reach the sea. Phosphate taken up by producers and incorporated into biological molecules may be eaten by consumers. Phosphate is returned to soil or water by either decomposition of biomass or excretion by consumers. Because there are no significant phosphorus-containing gases, only relatively small amounts of phosphorus move through the atmosphere, usually in the forms of dust and sea spray.

cycle, consider which steps are driven primarily by biological processes. For the carbon cycle, for instance, plants, animals, and other organisms control most of the key steps, including photosynthesis and decomposition. For the water cycle, however, purely physical processes control many key steps, such as evaporation from the oceans.

How have ecologists worked out the details of chemical cycling in various ecosystems? One common method is to follow the movement of naturally occurring, nonradioactive isotopes through the biotic and abiotic components of an ecosystem. Another method involves adding tiny amounts of radioactive isotopes of specific elements and tracing their progress. Scientists have also been able to make use of the radioactive carbon ( $^{14}\text{C}$ ) released into the atmosphere during atom bomb testing in the 1950s and early 1960s. Scientists use this “spike” of  $^{14}\text{C}$  to trace where and how quickly carbon flows into ecosystem components, including plants, soils, and ocean water.

### Case Study: Nutrient Cycling in the Hubbard Brook Experimental Forest

Since 1963, ecologists Herbert Bormann, Gene Likens, and their colleagues have been studying nutrient cycling at the Hubbard Brook Experimental Forest in the White Mountains of New Hampshire. Their research site is a deciduous forest that grows in six small valleys, each drained by a single creek. Impenetrable bedrock underlies the soil of the forest.

The research team first determined the mineral budget for each of six valleys by measuring the input and outflow of several key nutrients. They collected rainfall at several sites to measure the amount of water and dissolved minerals added to the ecosystem. To monitor the loss of water and minerals, they constructed a small concrete dam with a V-shaped spillway across the creek at the bottom of each valley (**Figure 42.14a**). They found that about 60% of the water added to the ecosystem as rainfall and snow exits through the stream, and the remaining 40% is lost by evapotranspiration.

Preliminary studies confirmed that internal cycling conserved most of the mineral nutrients in the system. For example, only about 0.3% more calcium ( $\text{Ca}^{2+}$ ) leaves a valley via its creek than is

added by rainwater, and this small net loss is probably replaced by chemical decomposition of the bedrock. During most years, the forest even registers small net gains of a few mineral nutrients, including nitrogen.

Experimental deforestation of a watershed dramatically increased the flow of water and minerals leaving the watershed (**Figure 42.14b**). Over three years, water runoff from the newly deforested watershed was 30–40% greater than in a control watershed, apparently because there were no plants to absorb and transpire water from the soil. Most remarkable was the loss of nitrate, whose concentration in the creek increased 60-fold, reaching levels considered unsafe for drinking water (**Figure 42.14c**). The Hubbard Brook deforestation study showed that the amount of nutrients leaving an intact forest ecosystem is controlled mainly by the plants. Retaining

(a) Concrete dams and weirs built across streams at the bottom of watersheds enabled researchers to monitor the outflow of water and nutrients from the ecosystem.

(b) One watershed was clear-cut to study the effects of the loss of vegetation on drainage and nutrient cycling. All of the original plant material was left in place to decompose.

(c) The concentration of nitrate in runoff from the deforested watershed was 60 times greater than in a control (unlogged) watershed.

▲ **Figure 42.14** Nutrient cycling in the Hubbard Brook Experimental Forest: an example of long-term ecological research.

A related Experimental Inquiry Tutorial can be assigned in MasteringBiology.

nutrients in ecosystems helps to maintain the productivity of the systems and, in some cases, to avoid problems caused by excess nutrient runoff (see Figure 42.7).

#### CONCEPT CHECK 42.4

1. **DRAW IT** For each of the four biogeochemical cycles detailed in Figure 42.12, draw a simple diagram that shows one possible path for an atom of that chemical from abiotic to biotic reservoirs and back.
2. Why does deforestation of a watershed increase the concentration of nitrates in streams draining the watershed?
3. **WHAT IF?** Why is nutrient availability in a tropical rain forest particularly vulnerable to logging?

For suggested answers, see Appendix A.

## CONCEPT 42.5

### Restoration ecologists help return degraded ecosystems to a more natural state

Ecosystems can recover naturally from most disturbances (including the experimental deforestation at Hubbard Brook) through the stages of ecological succession (see Concept 41.3). Sometimes that recovery takes centuries, though, particularly when human activities have degraded the environment. Tropical areas that are cleared for farming may quickly become unproductive because of nutrient losses. Mining activities may last for several decades, and the lands are often abandoned in a degraded state. Ecosystems can also be damaged by salts that build up in soils from irrigation and by toxic chemicals or oil spills. Biologists increasingly are called on to help restore and repair damaged ecosystems.

One of the basic assumptions of restoration ecology is that environmental damage is at least partly reversible. This

optimistic view must be balanced by a second assumption—that ecosystems are not infinitely resilient. Restoration ecologists therefore work to identify and manipulate the processes that most limit recovery of ecosystems from disturbances. Where disturbance is so severe that restoring all of a habitat is impractical, ecologists try to reclaim as much of a habitat or ecological process as possible, within the limits of the time and money available to them.

In extreme cases, the physical structure of an ecosystem may need to be restored before biological restoration can occur. If a stream was straightened to channel water quickly through a suburb, restoration ecologists may reconstruct a meandering channel to slow down the flow of water eroding the stream bank. To restore an open-pit mine, engineers may first grade the site with heavy equipment to reestablish a gentle slope, spreading topsoil when the slope is in place (**Figure 42.15**).

Once physical reconstruction of the ecosystem is complete—or when it is not needed—biological restoration is the next step. Two key strategies in biological restoration are bioremediation and biological augmentation.

#### Bioremediation

Using organisms—usually prokaryotes, fungi, or plants—to detoxify polluted ecosystems is known as **bioremediation**. Some plants and lichens adapted to soils containing heavy metals can accumulate high concentrations of toxic metals such as zinc, lead, and cadmium in their tissues. Restoration ecologists can introduce such species to sites polluted by mining and other human activities and then harvest these organisms to remove the metals from the ecosystem. For instance, researchers in the United Kingdom have discovered a lichen species that grows on soil polluted with uranium dust left over from mining. The lichen concentrates uranium in a dark pigment, making it useful as a biological monitor and potentially as a remediator.

(a) In 1991, before restoration

(b) In 2000, near the completion of restoration

▲ **Figure 42.15** A gravel and clay mine site in New Jersey before and after restoration.

Ecologists already use the abilities of many prokaryotes to carry out bioremediation of soils and water. Scientists have sequenced the genomes of at least ten prokaryotic species specifically for their bioremediation potential. One of the species, the bacterium *Shewanella oneidensis*, appears particularly promising. It can metabolize a dozen or more elements under aerobic and anaerobic conditions. In doing so, it converts soluble forms of uranium, chromium, and nitrogen to insoluble forms that are less likely to leach into streams or groundwater. Researchers at Oak Ridge National Laboratory, in Tennessee, stimulated the growth of *Shewanella* and other uranium-reducing bacteria by adding ethanol to groundwater contaminated with uranium; the bacteria can use ethanol as an energy source. In just five months, the concentration of soluble uranium in the ecosystem dropped by 80% (Figure 42.16).

(a) Wastes containing uranium were dumped in these four unlined pits for more than 30 years, contaminating soils and groundwater.

(b) After ethanol was added, microbial activity decreased the concentration of soluble uranium in groundwater near the pits.

▲ **Figure 42.16 Bioremediation of groundwater contaminated with uranium at Oak Ridge National Laboratory, Tennessee.**

## Biological Augmentation

In contrast to bioremediation, which is a strategy for removing harmful substances from an ecosystem, **biological augmentation** uses organisms to *add* essential materials to a degraded ecosystem. To augment ecosystem processes, restoration ecologists need to determine which factors, such as chemical nutrients, have been lost from a system and are limiting its recovery.

Encouraging the growth of plants that thrive in nutrient-poor soils often speeds up succession and ecosystem recovery. In alpine ecosystems of the western United States, nitrogen-fixing plants such as lupines are often planted to raise nitrogen concentrations in soils disturbed by mining and other activities. Once these nitrogen-fixing plants become established, other native species are better able to obtain enough soil nitrogen to survive. In other systems where the soil has been severely disturbed or where topsoil is missing entirely, plant roots may lack the mycorrhizal symbionts that help them meet their nutritional needs (see Chapter 26). Ecologists restoring a tallgrass prairie in Minnesota recognized this limitation and enhanced the recovery of native species by adding mycorrhizal symbionts to the soil they seeded.

Restoring the physical structure and plant community of an ecosystem does not necessarily ensure that animal species will recolonize a site and persist there. Because animals provide critical ecosystem services, including pollination and seed dispersal, restoration ecologists sometimes help wildlife reach and use restored ecosystems. They might release animals at a site or establish habitat corridors that connect a restored site to other places where the animals are found. They sometimes establish artificial perches for birds or dig burrows for other animals to use. Such efforts can improve the biodiversity of restored ecosystems and help the community persist.

## Restoration Projects Worldwide

Because restoration ecology is a relatively new discipline and because ecosystems are complex, many restoration ecologists advocate adaptive management: experimenting with several promising types of management to learn what works best.

The long-term objective of restoration is to return an ecosystem as much as possible to its predisturbance state. **Figure 42.17** explores four ambitious and successful restoration projects. The great number of such projects around the world and the dedication of the people engaged in them suggest that restoration ecology will continue to grow as a discipline for many years.

### CONCEPT CHECK 42.5

1. Identify the main goal of restoration ecology.
2. How do bioremediation and biological augmentation differ?
3. **WHAT IF?** In what way is the Kissimmee River project a more complete ecological restoration than the Maungatautari project (see Figure 42.17)?

For suggested answers, see Appendix A.

The examples highlighted on this page are just a few of the many restoration ecology projects taking place around the world.

### ► **Kissimmee River, Florida**

The Kissimmee River was converted from a meandering river to a 90-km canal, threatening many fish and wetland bird populations. Kissimmee River restoration has filled 12 km of drainage canal and reestablished 24 km of the original 167 km of natural river channel. Pictured here is a section of the

Kissimmee canal that has been plugged (wide, light strip on the right side of the photo), diverting flow into remnant river channels (center of the photo). The project will also restore natural flow patterns, which will foster self-sustaining populations of wetland birds and fishes.

### ◀ **Succulent Karoo, South Africa**

In this desert region of southern Africa, as in many arid regions, overgrazing by livestock has damaged vast areas. Private landowners and government agencies in South Africa are restoring large areas of this unique region,

revegetating the land and employing more sustainable resource management. The photo shows a small sample of the exceptional plant diversity of the Succulent Karoo; its 5,000 plant species include the highest diversity of succulent plants in the world.

### ► **Maungatautari, New Zealand**

Weasels, rats, pigs, and other introduced species pose a serious threat to New Zealand's native plants and animals, including kiwis, a group of flightless, ground-dwelling bird species. The goal of the Maungatautari restoration project is to exclude all exotic mammals from a 3,400-ha reserve located on a forested volcanic cone. A specialized fence

around the reserve eliminates the need to continue setting traps and using poisons that can harm native wildlife. In 2006, a pair of critically endangered takahe (a species of flightless rail) were released into the reserve in hopes of reestablishing a breeding population of this colorful bird on New Zealand's North Island.

### ◀ **Coastal Japan**

Seaweed and seagrass beds are important nursery grounds for a wide variety of fishes and shellfish. Once extensive but now reduced by development, these beds are being restored in the coastal

areas of Japan. Techniques include constructing suitable seafloor habitat, transplanting from natural beds using artificial substrates, and hand seeding (shown in this photograph).

# 42 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 42.1

#### Physical laws govern energy flow and chemical cycling in ecosystems (pp. 865–866)

- An **ecosystem** consists of all the organisms in a community and the abiotic factors with which they interact. The laws of physics and chemistry apply to ecosystems, particularly for the conservation of energy. Energy is conserved but degraded to heat during ecosystem processes.
- Based on the **law of conservation of mass**, ecologists study how much of a chemical element enters and leaves an ecosystem and cycles within it. Inputs and outputs are generally small compared to recycled amounts, but their balance determines whether the ecosystem gains or loses an element over time.

? Based on the second law of thermodynamics, would you expect the typical biomass of primary producers in an ecosystem to be greater than or less than the biomass of secondary producers in the same ecosystem? Explain your reasoning.

### CONCEPT 42.2

#### Energy and other limiting factors control primary production in ecosystems (pp. 866–870)

- **Primary production** sets the spending limit for the global energy budget. **Gross primary production** is the total energy assimilated by an ecosystem in a given period. **Net primary production**, the energy accumulated in autotroph biomass, equals gross primary production minus the energy used by the primary producers for respiration. **Net ecosystem production** is the total biomass accumulation of an ecosystem, defined as the difference between gross primary production and total ecosystem respiration.
- In aquatic ecosystems, light and nutrients limit primary production. In terrestrial ecosystems, climatic factors such as temperature and moisture affect primary production on a large geographic scale, but a soil nutrient is often the limiting factor in primary production locally.

? What additional variable do you need to know the value of in order to estimate NEP from NPP? Why might measuring this variable be difficult, for instance, in a sample of ocean water?

### CONCEPT 42.3

#### Energy transfer between trophic levels is typically only 10% efficient (pp. 870–872)

- The amount of energy available to each trophic level is determined by the net primary production and the **production efficiency**, the efficiency with which food energy is converted to biomass at each link in the food chain.
- The percentage of energy transferred from one trophic level to the next, called **trophic efficiency**, is typically 10%. Pyramids of net production and biomass reflect low trophic efficiency.

? Why would runners have a lower production efficiency when running a long-distance race than when they are sedentary?

### CONCEPT 42.4

#### Biological and geochemical processes cycle nutrients and water in ecosystems (pp. 872–877)

- Water moves in a global cycle driven by solar energy. The carbon cycle primarily reflects the reciprocal processes of photosynthesis and cellular respiration.
- The proportion of a nutrient in a particular form and its cycling in that form vary among ecosystems, largely because of differences in the rate of decomposition.
- Nutrient cycling is strongly regulated by vegetation. The Hubbard Brook case study showed that logging increases water runoff and can cause large losses of minerals.

? If decomposers usually grow faster and decompose material more quickly in warmer ecosystems, why is decomposition in hot deserts so slow?

### CONCEPT 42.5

#### Restoration ecologists help return degraded ecosystems to a more natural state (pp. 877–879)

- Restoration ecologists harness organisms to detoxify polluted ecosystems through the process of **bioremediation**.
- In **biological augmentation**, ecologists use organisms to add essential materials to ecosystems.

? In preparing a site for surface mining and later restoration, what would be the advantage of removing the shallow topsoil first and setting it aside separately from the deeper soil, rather than removing all soil at once and mixing it in a single pile?

## TEST YOUR UNDERSTANDING

### Level 1: Knowledge/Comprehension

1. Which of the following organisms is *incorrectly* paired with its trophic level?
  - a. cyanobacterium—primary producer
  - b. grasshopper—primary consumer
  - c. zooplankton—primary producer
  - d. eagle—tertiary consumer
  - e. fungus—detritivore
2. Which of these ecosystems has the *lowest* net primary production per square meter?
  - a. a salt marsh
  - b. an open ocean
  - c. a coral reef
  - d. a grassland
  - e. a tropical rain forest
3. The discipline that applies ecological principles to returning degraded ecosystems to a more natural state is known as
  - a. population viability analysis.
  - b. landscape ecology.
  - c. conservation ecology.
  - d. restoration ecology.
  - e. resource conservation.

### Level 2: Application/Analysis

4. Nitrifying bacteria participate in the nitrogen cycle mainly by
  - a. converting nitrogen gas to ammonia.
  - b. releasing ammonium from organic compounds, thus returning it to the soil.
  - c. converting ammonia to nitrogen gas, which returns to the atmosphere.
  - d. converting ammonium to nitrate, which plants absorb.
  - e. incorporating nitrogen into amino acids and organic compounds.
5. Which of the following has the greatest effect on the rate of chemical cycling in an ecosystem?
  - a. the ecosystem's rate of primary production
  - b. the production efficiency of the ecosystem's consumers
  - c. the rate of decomposition in the ecosystem
  - d. the trophic efficiency of the ecosystem
  - e. the location of the nutrient reservoirs in the ecosystem
6. The Hubbard Brook watershed deforestation experiment yielded all of the following results *except*:
  - a. Most minerals were recycled within a forest ecosystem.
  - b. The flow of minerals out of a natural watershed was offset by minerals flowing in.
  - c. Deforestation increased water runoff.
  - d. The nitrate concentration in waters draining the deforested area became dangerously high.
  - e. Calcium levels remained high in the soil of deforested areas.
7. Which of the following would be considered an example of bioremediation?
  - a. adding nitrogen-fixing microorganisms to a degraded ecosystem to increase nitrogen availability
  - b. using a bulldozer to regrade a strip mine
  - c. dredging a river bottom to remove contaminated sediments

- d. reconfiguring the channel of a river
  - e. adding seeds of a chromium-accumulating plant to soil contaminated by chromium
8. If you applied a fungicide to a cornfield, what would you expect to happen to the rate of decomposition and net ecosystem production (NEP)?
    - a. Both decomposition rate and NEP would decrease.
    - b. Both decomposition rate and NEP would increase.
    - c. Neither would change.
    - d. Decomposition rate would increase and NEP would decrease.
    - e. Decomposition rate would decrease and NEP would increase.

### Level 3: Synthesis/Evaluation

9. **DRAW IT** Draw a simplified global water cycle showing ocean, land, atmosphere, and runoff from the land to the ocean. Add these annual water fluxes to your drawing: ocean evaporation, 425 km<sup>3</sup>; ocean evaporation that returns to the ocean as precipitation, 385 km<sup>3</sup>; ocean evaporation that falls as precipitation on land, 40 km<sup>3</sup>; evapotranspiration from plants and soil that falls as precipitation on land, 70 km<sup>3</sup>; runoff to the oceans, 40 km<sup>3</sup>. Based on these global numbers, how much precipitation falls on land in a typical year?
10. **SCIENTIFIC INQUIRY**  
Using two neighboring ponds in a forest as your study site, design a controlled experiment to measure the effect of falling leaves on net primary production in a pond.
11. **FOCUS ON EVOLUTION**  
Some biologists have suggested that ecosystems are emergent, “living” systems capable of evolving. One manifestation of this idea is environmentalist James Lovelock’s Gaia hypothesis, which views Earth itself as a living, homeostatic entity—a kind of superorganism. If ecosystems are capable of evolving, would this be a form of Darwinian evolution? Why or why not?
12. **FOCUS ON ENERGY AND MATTER**  
As described in Concept 42.4, decomposition typically occurs quickly in moist tropical forests. However, waterlogging in the soil of some moist tropical forests results over time in a buildup of organic matter called “peat.” In a short essay (100–150 words), discuss the relationship of net primary production, net ecosystem production, and decomposition for such an ecosystem. Are NPP and NEP likely to be positive? What do you think would happen to NEP if a landowner drained the water from a tropical peatland, exposing the organic matter to air?

For selected answers, see Appendix A.

### MasteringBiology®

**Students** Go to **MasteringBiology** for assignments, the eText, and the Study Area with practice tests, animations, and activities.

**Instructors** Go to **MasteringBiology** for automatically graded tutorials and questions that you can assign to your students, plus Instructor Resources.

# Global Ecology and Conservation Biology

▼ **Figure 43.1** What will be the fate of this newly described lizard species?

## KEY CONCEPTS

- 43.1** Human activities threaten Earth's biodiversity
- 43.2** Population conservation focuses on population size, genetic diversity, and critical habitat
- 43.3** Landscape and regional conservation help sustain biodiversity
- 43.4** Earth is changing rapidly as a result of human actions
- 43.5** The human population is no longer growing exponentially but is still increasing rapidly
- 43.6** Sustainable development can improve human lives while conserving biodiversity

## OVERVIEW

### Psychedelic Treasure

Scurrying across a rocky outcrop, a lizard stops abruptly in a patch of sunlight. A conservation biologist senses the motion and turns to find a gecko splashed with rainbow colors, its bright orange legs and tail blending into a striking blue body, its head splotched with yellow and green. The psychedelic rock gecko (*Cnemaspis psychedelica*) was discovered in 2010 during an expedition to the Greater Mekong region of southeast Asia (**Figure 43.1**). Its known habitat is restricted to Hon Khoai, an island occupying just 8 km<sup>2</sup> (3 square miles) in southern Vietnam. Other new species found during the same series of expeditions include the Elvis monkey, which sports a hairdo like

that of a certain legendary musician. Between 2000 and 2010, biologists identified more than a thousand new species in the Greater Mekong region alone.

To date, scientists have described and named about 1.8 million species of organisms. Some biologists think that about 10 million more species currently exist; others estimate the number to be as high as 100 million. The greatest concentrations of species are found in the tropics. Unfortunately, tropical forests are being cleared at an alarming rate to support a burgeoning human population. In Vietnam, rates of deforestation are among the very highest in the world (**Figure 43.2**). What will become of the psychedelic rock gecko and other newly discovered species if such activities continue unchecked?

Throughout the biosphere, human activities are altering trophic structures, energy flow, chemical cycling, and natural disturbance—ecosystem processes on which we and all other species depend (see Chapter 42). We have physically altered nearly half of Earth's land surface, and we use over half of all accessible

surface fresh water. In the oceans, stocks of most major fisheries are shrinking because of overharvesting. By some estimates, we may be pushing more species toward extinction than the large asteroid that triggered the mass extinctions at the close of the Cretaceous period 65.5 million years ago (see Figure 23.10).

In this chapter, we apply a global perspective to the changes happening across Earth, focusing on a discipline that seeks to preserve life: **Conservation biology** integrates ecology, evolutionary biology, molecular biology, genetics,

▲ **Figure 43.2 Tropical deforestation in Vietnam.**

and physiology to conserve biological diversity at all levels. Efforts to sustain ecosystem processes and stem the loss of biodiversity also connect the life sciences with the social sciences, economics, and humanities.

We'll begin by taking a closer look at the biodiversity crisis and examining some of the conservation strategies being adopted to slow the rate of species loss. We'll also examine how human activities are altering the environment through climate change and other global processes, and we'll investigate the link between these alterations and the growing human population. Finally, we'll consider how decisions about long-term conservation priorities could affect life on Earth.

## CONCEPT 43.1

### Human activities threaten Earth's biodiversity

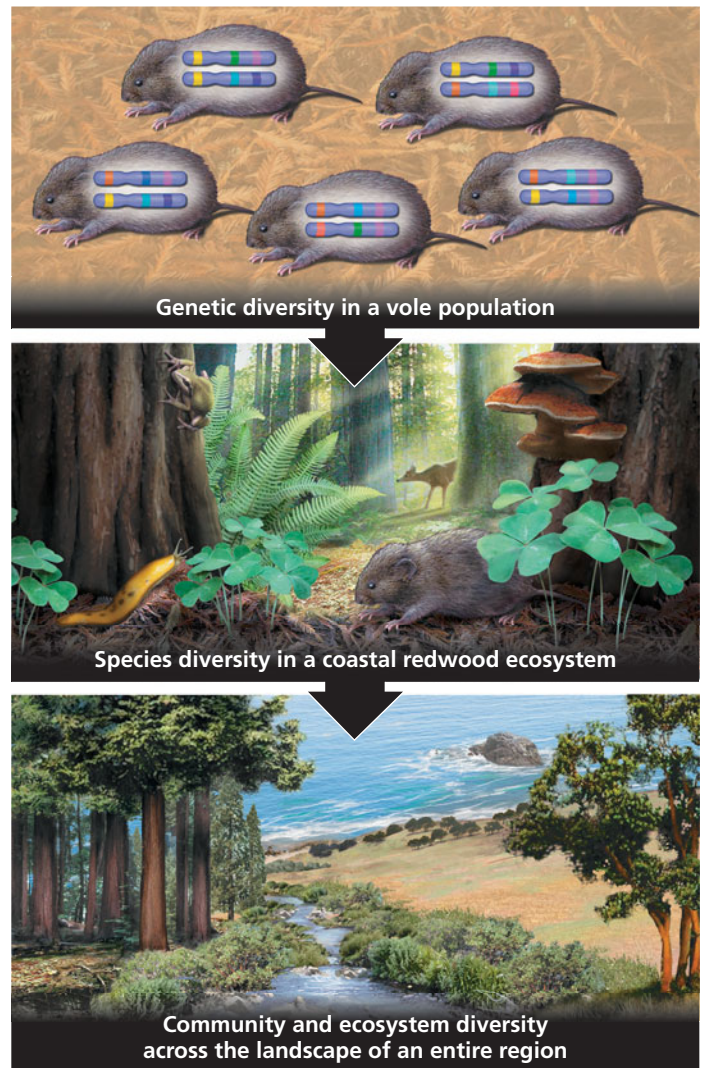

Extinction is a natural phenomenon that has been occurring since life first evolved; it is the high *rate* of extinction that is responsible for today's biodiversity crisis (see Chapter 23). Because we can only estimate the number of species currently existing, we cannot determine the exact rate of species loss. However, we do know that human activities threaten Earth's biodiversity at all levels.

#### Three Levels of Biodiversity

Biodiversity—short for biological diversity—can be considered at three main levels: genetic diversity, species diversity, and ecosystem diversity (**Figure 43.3**).

##### Genetic Diversity

Genetic diversity comprises not only the individual genetic variation *within* a population, but also the genetic variation *between* populations that is often associated with adaptations to local conditions (see Chapter 21). If one population becomes extinct, then a species may have lost some of the

▲ **Figure 43.3 Three levels of biodiversity.** The oversized chromosomes in the top diagram symbolize the genetic variation within the population.

genetic diversity that makes microevolution possible. This erosion of genetic diversity in turn reduces the adaptive potential of the species.

##### Species Diversity

Public awareness of the biodiversity crisis centers on species diversity—the variety of species in an ecosystem or across the biosphere (see Chapter 41). As more species are lost to extinction, species diversity decreases. The U.S. Endangered Species Act defines an **endangered species** as one that is “in danger of extinction throughout all or a significant portion of its range.”

**Threatened species** are those considered likely to become endangered in the near future. The following are just a few statistics that illustrate the problem of species loss:

- According to the International Union for Conservation of Nature and Natural Resources (IUCN), 12% of the 10,000 known species of birds and 21% of the 5,500 known species of mammals are threatened.

Philippine eagle

Yangtze River dolphin

▲ **Figure 43.4** A hundred heartbeats from extinction. These are two members of what E. O. Wilson calls the Hundred Heartbeat Club, species with fewer than 100 individuals remaining on Earth. The Yangtze River dolphin was even thought to be extinct, but a few individuals were reportedly sighted in 2007.

? To document that a species has actually become extinct, what factors would you need to consider?

- A survey by the Center for Plant Conservation showed that of the nearly 20,000 known plant species in the United States, 200 have become extinct since such records have been kept, and 730 are endangered or threatened.
- In North America, at least 123 freshwater animal species have become extinct since 1900, and hundreds more species are threatened. The extinction rate for North American freshwater fauna is about five times as high as that for terrestrial animals.

Extinction of species may also be local; for example, a species may be lost in one river system but survive in an adjacent one. Global extinction of a species means that it is lost from *all* the ecosystems in which it lived, leaving them permanently impoverished (**Figure 43.4**).

### Ecosystem Diversity

The variety of the biosphere's ecosystems is a third level of biological diversity. Because of the many interactions between populations of different species in an ecosystem, the local extinction of one species can have a negative impact on other species in the ecosystem (see Figure 41.15). For instance, bats called “flying foxes” are important pollinators and seed dispersers in the Pacific Islands, where they are increasingly hunted as a luxury food (**Figure 43.5**). Conservation biologists fear that the extinction of flying foxes would also harm the native plants of the Samoan Islands, where four-fifths of the tree species depend on flying foxes for pollination or seed dispersal.

▲ **Figure 43.5** The endangered Marianas “flying fox” bat (*Pteropus mariannus*), an important pollinator.

Some ecosystems have already been heavily affected by humans, and others are being altered at a rapid pace. Since European colonization, more than half of the wetlands in the contiguous United States have been drained and converted to agricultural and other uses. In California, Arizona, and New Mexico, roughly 90% of native riparian (streamside) communities have been affected by overgrazing, flood control, water diversions, lowering of water tables, and invasion by non-native plants.

### Biodiversity and Human Welfare

Why should we care about the loss of biodiversity? One reason is what Harvard biologist E. O. Wilson calls *biophilia*, our sense of connection to nature and all life. The belief that other species are entitled to life is a pervasive theme of many religions and the basis of a moral argument that we should protect biodiversity. There is also a concern for future human generations. Paraphrasing an old proverb, G. H. Brundtland, a former prime minister of Norway, said: “We must consider our planet to be on loan from our children, rather than being a gift from our ancestors.” In addition to such philosophical and moral justifications, species and genetic diversity bring us many practical benefits.

### Benefits of Species and Genetic Diversity

Many species that are threatened could potentially provide medicines, food, and fibers for human use, making biodiversity a crucial natural resource. Products from aspirin to antibiotics were originally derived from natural sources. In food production, if we lose wild populations of plants closely related to agricultural species, we lose genetic resources that could be used to improve crop qualities, such as disease resistance. For instance, plant breeders responded to devastating outbreaks of the grassy stunt virus in rice (*Oryza sativa*) by screening 7,000 populations of this species and its close relatives for

resistance to the virus. One population of a single relative, Indian rice (*Oryza nivara*), was found to be resistant to the virus, and scientists succeeded in breeding the resistance trait into commercial rice varieties. Today, the original disease-resistant population has apparently become extinct in the wild.

In the United States, about 25% of the prescriptions dispensed from pharmacies contain substances originally derived from plants. In the 1970s, researchers discovered that the rosy periwinkle (*Catharanthus roseus*), which grows on the island of Madagascar, off the coast of Africa, contains alkaloids that inhibit cancer cell growth. This discovery led to treatments for two deadly forms of cancer, Hodgkin's lymphoma and childhood leukemia, resulting in remission in most cases.

Rosy periwinkle

Each loss of a species means the loss of unique genes, some of which may code for enormously useful proteins. The enzyme Taq polymerase was first extracted from a bacterium, *Thermus aquaticus*, found in hot springs at Yellowstone National Park. This enzyme is essential for the polymerase chain reaction (PCR) because it is stable at the high temperatures required for automated PCR (see Figure 13.25). However, because millions of species may become extinct before we discover them, we stand to lose the valuable genetic potential held in their unique libraries of genes.

### Ecosystem Services

The benefits that individual species provide to humans are substantial, but saving individual species is only part of the reason for preserving ecosystems. We humans evolved in Earth's ecosystems, and we rely on these systems and their inhabitants for our survival. **Ecosystem services** encompass all the processes through which natural ecosystems help sustain human life. Ecosystems purify our air and water. They detoxify and decompose our wastes and reduce the impacts of extreme weather and flooding. The organisms in ecosystems pollinate our crops, control pests, and create and preserve our soils. Moreover, these diverse services are provided for free.

Perhaps because we don't attach a monetary value to the services of natural ecosystems, we generally undervalue them. In 1997, ecologist Robert Costanza and his colleagues estimated the value of Earth's ecosystem services at \$33 trillion per year, nearly twice the gross national product of all the countries on Earth at the time (\$18 trillion). It may be more realistic to do the accounting on a smaller scale. In 1996, New York City invested more than \$1 billion to buy land and restore habitat in the Catskill Mountains, the source of much of the city's fresh water. This investment was spurred by increasing pollution of the water by sewage, pesticides, and fertilizers. By harnessing

ecosystem services to purify its water naturally, the city saved \$8 billion it would have otherwise spent to build a new water treatment plant and \$300 million a year to run the plant.

There is growing evidence that the functioning of ecosystems, and hence their capacity to perform services, is linked to biodiversity. As human activities reduce biodiversity, we are reducing the capacity of the planet's ecosystems to perform processes critical to our own survival.

### Threats to Biodiversity

Many different human activities threaten biodiversity on local, regional, and global scales. The threats posed by these activities are of four major types: habitat loss, introduced species, overharvesting, and global change.

#### Habitat Loss

Human alteration of habitat is the single greatest threat to biodiversity throughout the biosphere. Habitat loss has been brought about by agriculture, urban development, forestry, mining, and pollution. As discussed later in this chapter, global climate change is already altering habitats today and will have an even larger effect later this century. When no alternative habitat is available or a species is unable to move, habitat loss may mean extinction. The IUCN implicates destruction of physical habitat for 73% of the species that have become extinct, endangered, vulnerable, or rare in the last few hundred years.

Habitat loss and fragmentation may occur over large regions. Approximately 98% of the tropical dry forests of Central America and Mexico have been cut down. The clearing of tropical rain forest in the state of Veracruz, Mexico, mostly for cattle ranching, has resulted in the loss of more than 90% of the original forest, leaving relatively small, isolated patches of forest. Other natural habitats have also been fragmented by human activities (Figure 43.6).

▲ **Figure 43.6** Habitat fragmentation in the foothills of Los Angeles. Development in the valleys may confine the organisms that inhabit the narrow strips of hillside.

In almost all cases, habitat fragmentation leads to species loss because the smaller populations in habitat fragments have a higher probability of local extinction. Prairie covered about 800,000 hectares (ha) of southern Wisconsin when Europeans first arrived in North America but occupies less than 800 ha today; most of the original prairie in this area is now used to grow crops. Plant diversity surveys of 54 Wisconsin prairie remnants conducted in 1948–1954 and repeated in 1987–1988 showed that the remnants lost between 8% and 60% of their plant species in the time between the two surveys.

Habitat loss is also a major threat to aquatic biodiversity. About 70% of coral reefs, among Earth's most species-rich aquatic communities, have been damaged by human activities. At the current rate of destruction, 40–50% of the reefs, home to one-third of marine fish species, could disappear in the next 30 to 40 years. Freshwater habitats are also being lost, often as a result of the dams, reservoirs, channel modification, and flow regulation now affecting most of the world's rivers. For example, the more than 30 dams and locks built along the Mobile River basin in the southeastern United States changed river depth and flow. While providing the benefits of hydroelectric power and increased ship traffic, these dams and locks also helped drive more than 40 species of mussels and snails to extinction.

### Introduced Species

**Introduced species**, also called exotic species, are those that humans move intentionally or accidentally from the species' native locations to new geographic regions. Human travel by ship and airplane has accelerated the transplant of species. Free from the predators, parasites, and pathogens that limit their populations in their native habitats, such transplanted species may spread rapidly through a new region.

Some introduced species disrupt their new community, often by preying on native organisms or outcompeting them for resources. The brown tree snake was accidentally introduced to the island of Guam from other parts of the South Pacific after World War II: It was a "stowaway" in military cargo. Since then, 12 species of birds and 6 species of lizards that the snakes ate have become extinct on Guam, which had no native snakes. The devastating zebra mussel, a filter-feeding mollusc, was introduced into the Great Lakes of North America in 1988, most likely in the ballast water of ships arriving from Europe. Zebra mussels form dense colonies and have disrupted freshwater ecosystems, threatening native aquatic species. They have also clogged water intake structures, causing billions of dollars in damage to domestic and industrial water supplies.

Humans have deliberately introduced many species with good intentions but disastrous effects. An Asian plant called kudzu, which the U.S. Department of Agriculture once introduced in the southern United States to help control erosion, has taken over large areas of the landscape there (**Figure 43.7**).

▲ **Figure 43.7** Kudzu, an introduced species, thriving in South Carolina.

Introduced species are a worldwide problem, contributing to approximately 40% of the extinctions recorded since 1750 and costing billions of dollars each year in damage and control efforts. There are more than 50,000 introduced species in the United States alone.

### Overharvesting

The term *overharvesting* refers generally to the harvesting of wild organisms at rates exceeding the ability of their populations to rebound. Species with restricted habitats, such as small islands, are particularly vulnerable to overharvesting. One such species was the great auk, a large, flightless seabird found on islands in the North Atlantic Ocean. By the 1840s, the great auk had been hunted to extinction to satisfy the human demand for its feathers, eggs, and meat.

Also susceptible to overharvesting are large organisms with low reproductive rates, such as elephants, whales, and rhinoceroses. The decline of Earth's largest terrestrial animals, the African elephants, is a classic example of the impact of overhunting. Largely because of the trade in ivory, elephant populations have been declining in most of Africa for the last 50 years. An international ban on the sale of new ivory resulted in increased poaching (illegal hunting), so the ban had little effect in much of central and eastern Africa. Only in South Africa, where once-decimated herds have been well protected for nearly a century, have elephant populations been stable or increasing (see Figure 40.18).

Conservation biologists increasingly use the tools of molecular genetics to track the origins of tissues harvested from endangered species. Researchers at the University of Washington have constructed a DNA reference map for the African elephant using DNA isolated from elephant dung. By comparing this reference map with DNA isolated from samples of ivory harvested either legally or by poachers, they can determine to within a few hundred kilometers where the elephants were killed (**Figure 43.8**). Such work in Zambia suggested that poaching rates were 30 times higher than previously estimated,

▲ **Figure 43.8 Ecological forensics and elephant poaching.**

These severed tusks were part of an illegal shipment of ivory intercepted on its way from Africa to Singapore in 2002. DNA-based evidence showed that the thousands of elephants killed for the tusks came from a relatively narrow east-west band centered in Zambia rather than from across Africa.

leading to improved antipoaching efforts by the Zambian government. Similarly, biologists using phylogenetic analyses of mitochondrial DNA (mtDNA) showed that some whale meat sold in Japanese fish markets came from illegally harvested endangered species (see Figure 20.6).

Many commercially important fish populations, once thought to be inexhaustible, have been decimated by overfishing. Demands for protein-rich food from an increasing human population, coupled with new harvesting technologies, such as long-line fishing and modern trawlers, have reduced these fish populations to levels that cannot sustain further exploitation. Until the past few decades, the North Atlantic bluefin tuna had little commercial value—just a few cents per pound for use in cat food. In the 1980s, however, wholesalers began airfreighting fresh, iced bluefin to Japan for sushi and sashimi. In that market, the fish now brings up to \$100 per pound (**Figure 43.9**). With increased harvesting spurred by such high prices, it took just ten years to reduce the western North Atlantic bluefin population to less than 20% of its 1980 size.

▲ **Figure 43.9 Overharvesting.** North Atlantic bluefin tuna are auctioned in a Japanese fish market.

## Global Change

The fourth threat to biodiversity, global change, alters the fabric of Earth's ecosystems at regional to global scales. Global change includes alterations in climate, atmospheric chemistry, and broad ecological systems that reduce the capacity of Earth to sustain life.

One of the first types of global change to cause concern was *acid precipitation*, which is rain, snow, sleet, or fog with a pH less than 5.2. The burning of wood and fossil fuels releases oxides of sulfur and nitrogen that react with water in air, forming sulfuric and nitric acids. The acids eventually fall to Earth's surface, harming some aquatic and terrestrial organisms.

In the 1960s, ecologists determined that lake-dwelling organisms in eastern Canada were dying because of air pollution from factories in the midwestern United States. Newly hatched lake trout, for instance, die when the pH drops below 5.4. Lakes and streams in southern Norway and Sweden were losing fish because of pollution generated in Great Britain and central Europe. By 1980, the pH of precipitation in large areas of North America and Europe averaged 4.0–4.5 and sometimes dropped as low as 3.0. (To review pH, see Concept 2.5.)

Environmental regulations and new technologies have enabled many countries to reduce sulfur dioxide emissions in recent decades. In the United States, sulfur dioxide emissions decreased more than 40% between 1993 and 2009, gradually reducing the acidity of precipitation (**Figure 43.10**). However, ecologists estimate that it will take decades for aquatic ecosystems to recover. Meanwhile, emissions of nitrogen oxides are increasing in the United States, and emissions of sulfur dioxide and acid precipitation continue to damage forests in Europe.

We will explore the importance of global change for Earth's biodiversity in more detail in Concept 43.4, where we examine such factors as climate change.

Although still acidic, the precipitation in this northeastern U.S. forest has been increasing in pH for more than three decades.

### CONCEPT CHECK 43.1

1. Explain why it is too narrow to define the biodiversity crisis as simply a loss of species.
2. Identify the four main threats to biodiversity and explain how each damages diversity.
3. **WHAT IF?** Imagine two populations of a fish species, one in the Mediterranean Sea and one in the Caribbean Sea. Now imagine two scenarios: (1) The populations breed separately, and (2) adults of both populations migrate yearly to the North Atlantic to interbreed. Which scenario would result in a greater loss of genetic diversity if the Mediterranean population were harvested to extinction? Explain your answer.

For suggested answers, see Appendix A.

▲ **Figure 43.11** Processes driving an extinction vortex.

variation. Since that time, however, the northern elephant seal populations have rebounded to about 150,000 individuals today, though their genetic variation remains relatively low. Thus, low genetic diversity does not always impede population growth.

### Case Study: The Greater Prairie Chicken and the Extinction Vortex

When Europeans arrived in North America, the greater prairie chicken (*Tympanuchus cupido*) was common from New England to Virginia and across the western prairies of the continent. Land cultivation for agriculture fragmented the populations of this species, and its abundance decreased rapidly (see Chapter 21). Illinois had millions of greater prairie chickens in the 19th century but fewer than 50 by 1993. Researchers found that the decline in the Illinois population was associated with a decrease in fertility. As a test of the extinction vortex hypothesis, scientists increased the genetic variation of the Illinois population by importing 271 birds from larger populations elsewhere (**Figure 43.12**). The Illinois population rebounded, confirming that it had been on its way to extinction until rescued by the transfusion of genetic variation.

### Minimum Viable Population Size

How small does a population have to be before it starts down an extinction vortex? The answer depends on the type of organism and other factors. Large predators that feed high on the food chain usually require extensive individual ranges, resulting in low population densities. Therefore, not all rare species concern conservation biologists. All populations, however, require some minimum size to remain viable.

The minimal population size at which a species is able to sustain its numbers is known as the **minimum viable population (MVP)**. MVP is usually estimated for a given species using computer models that integrate many factors. The calculation may include, for instance, an estimate of how many individuals in a small population are likely to be killed by a natural

## CONCEPT 43.2

### Population conservation focuses on population size, genetic diversity, and critical habitat

Biologists who work on conservation at the population and species levels use two main approaches. One approach focuses on populations that are small and hence often vulnerable. The other emphasizes populations that are declining rapidly, even if they are not yet small.

### Small-Population Approach

Small populations are particularly vulnerable to overharvesting, habitat loss, and the other threats to biodiversity that you read about in Concept 43.1. After such factors have reduced a population's size, the small size itself can push the population to extinction. Conservation biologists who adopt the small-population approach study the processes that cause extinctions once population sizes have been reduced.

### The Extinction Vortex: Evolutionary Implications of Small Population Size

**EVOLUTION** A small population is vulnerable to inbreeding and genetic drift, which draw the population down an **extinction vortex** toward smaller and smaller population size until no individuals survive (**Figure 43.11**). A key factor driving the extinction vortex is the loss of the genetic variation that enables evolutionary responses to environmental change, such as the appearance of new strains of pathogens. Both inbreeding and genetic drift can cause a loss of genetic variation (see Chapter 21), and their effects become more harmful as a population shrinks. Inbreeding often reduces fitness because offspring are more likely to be homozygous for harmful recessive traits.

Not all small populations are doomed by low genetic diversity, and low genetic variability does not automatically lead to permanently small populations. For instance, overhunting of northern elephant seals in the 1890s reduced the species to only 20 individuals—clearly a bottleneck with reduced genetic

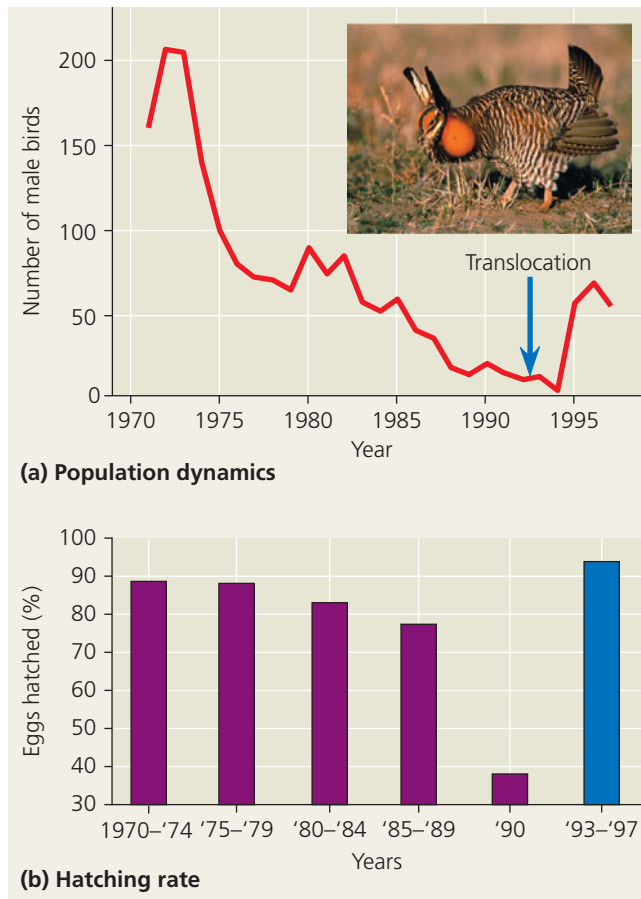

## ▼ Figure 43.12 Inquiry

### What caused the drastic decline of the Illinois greater prairie chicken population?

**Experiment** Researchers had observed that the population collapse of the greater prairie chicken was mirrored in a reduction in fertility, as measured by the hatching rate of eggs. Comparison of DNA samples from the Jasper County, Illinois, population with DNA from feathers in museum specimens showed that genetic variation had declined in the study population (see Figure 21.11). In 1992, Ronald Westemeier, Jeffrey Brawn, and colleagues began translocating prairie chickens from Minnesota, Kansas, and Nebraska in an attempt to increase genetic variation.

**Results** After translocation (blue arrow), the viability of eggs rapidly increased, and the population rebounded.

© 1998 AAAS

**Conclusion** Reduced genetic variation had started the Jasper County population of prairie chickens down the extinction vortex.

**Inquiry in Action** Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers*.

**WHAT IF?** Given the success of using transplanted birds as a tool for increasing the percentage of hatched eggs in Illinois, why wouldn't you transplant additional birds immediately to Illinois?

## Effective Population Size

Genetic variation is the key issue in the small-population approach. The *total* size of a population may be misleading because only certain members of the population breed successfully and pass their alleles on to offspring. Therefore, a meaningful estimate of MVP requires the researcher to determine the **effective population size**, which is based on the breeding potential of the population.

The following formula incorporates the sex ratio of breeding individuals into the estimate of effective population size, abbreviated  $N_e$ :

$$N_e = \frac{4N_fN_m}{N_f + N_m}$$

where  $N_f$  and  $N_m$  are, respectively, the number of females and the number of males that successfully breed. If we apply this formula to an idealized population whose total size is 1,000 individuals,  $N_e$  will also be 1,000 if every individual breeds and the sex ratio is 500 females to 500 males. In this case,  $N_e = (4 \times 500 \times 500) / (500 + 500) = 1,000$ . Any deviation from these conditions (not all individuals breed or there is not a 1:1 sex ratio) reduces  $N_e$ . For instance, if the total population size is 1,000 but only 400 females and 400 males breed, then  $N_e = (4 \times 400 \times 400) / (400 + 400) = 800$ , or 80% of the total population. Numerous life history traits can influence  $N_e$ , and alternative formulas for estimating  $N_e$  take into account factors such as family size, age at maturation, genetic relatedness among population members, the effects of gene flow between geographically separated populations, and population fluctuations.

In actual study populations,  $N_e$  is always some fraction of the total population. Thus, simply determining the total number of individuals in a small population does not provide a good measure of whether the population is large enough to avoid extinction. Whenever possible, conservation programs attempt to sustain total population sizes that include at least the minimum viable number of *reproductively active* individuals. The conservation goal of sustaining effective population size ( $N_e$ ) above MVP stems from the concern that populations retain enough genetic diversity to adapt as their environment changes.

## Case Study: Analysis of Grizzly Bear Populations

One of the first population viability analyses was conducted in 1978 by Mark Shaffer, of Duke University, as part of a long-term study of grizzly bears in Yellowstone National Park and its surrounding areas (**Figure 43.13**). A threatened species in the United States, the grizzly bear (*Ursus arctos horribilis*) is currently found in only 4 of the 48 contiguous states. Its populations in those states have been drastically reduced and fragmented. In 1800, an estimated 100,000 grizzlies ranged over about 500 million ha of habitat, while today only about 1,000 individuals in six relatively isolated populations range over less than 5 million ha.

catastrophe such as a storm. Once in the extinction vortex, two or three consecutive years of bad weather could finish off a population that is already below its MVP.

▲ **Figure 43.13 Long-term monitoring of a grizzly bear population.** The ecologist is fitting this tranquilized bear with a radio collar so that the bear's movements can be compared with those of other grizzlies in the Yellowstone National Park population.

Shaffer attempted to determine viable sizes for the Yellowstone grizzly population. Using life history data obtained for individual Yellowstone bears over a 12-year period, he simulated the effects of environmental factors on survival and reproduction. His models predicted that, given a suitable habitat, a Yellowstone grizzly bear population of 70–90 individuals would have about a 95% chance of surviving for 100 years. A slightly larger population of only 100 bears would have a 95% chance of surviving for twice as long, about 200 years.

How does the actual size of the Yellowstone grizzly population compare with Shaffer's predicted MVP? A current estimate puts the total grizzly bear population in the greater Yellowstone ecosystem at about 500 individuals. The relationship of this estimate to the effective population size,  $N_e$ , depends on several factors. Usually, only a few dominant males breed, and it may be difficult for them to locate females, since individuals inhabit such large areas. Moreover, females may reproduce only when there is abundant food. As a result,  $N_e$  is only about 25% of the total population size, or about 125 bears.

Because small populations tend to lose genetic variation over time, researchers have analyzed proteins, mtDNA, and short tandem repeats (see Chapter 18) to assess genetic variability in the Yellowstone grizzly bear population. All results to date indicate that the Yellowstone population has less genetic variability than other grizzly bear populations in North America.

How might conservation biologists increase the effective size and genetic variation of the Yellowstone grizzly bear population? Migration between isolated populations of grizzlies could increase both effective and total population sizes. Computer models predict that introducing only two unrelated bears each decade into a population of 100 individuals would reduce the loss of genetic variation by about half. For the grizzly bear, and probably for many other species with small populations, finding ways to promote dispersal among populations may be one of the most urgent conservation needs.

This case study and that of the greater prairie chicken bridge small-population models and practical applications in conservation. Next, we look at an alternative approach to understanding the biology of extinction.

## Declining-Population Approach

The declining-population approach focuses on threatened and endangered populations that show a downward trend, even if the population is far above its minimum viable population. The distinction between a declining population, which may not be small, and a small population, which may not be declining, is less important than the different priorities of the two approaches. The small-population approach emphasizes smallness itself as an ultimate cause of a population's extinction, especially through the loss of genetic diversity. In contrast, the declining-population approach emphasizes the environmental factors that caused a population decline in the first place. If, for instance, an area is deforested, then species that depend on trees will decline in abundance and become locally extinct, whether or not they retain genetic variation. The following case study is one example of how the declining-population approach has been applied to the conservation of an endangered species.

### Case Study: Decline of the Red-Cockaded Woodpecker

The red-cockaded woodpecker (*Picoides borealis*) is found only in the southeastern United States. It requires mature pine forests, preferably ones dominated by the longleaf pine, for its habitat. Most woodpeckers nest in dead trees, but the red-cockaded woodpecker drills its nest holes in mature, living pine trees. It also drills small holes around the entrance to its nest cavity, which causes resin from the tree to ooze down the trunk. The resin seems to repel predators, such as corn snakes, that eat bird eggs and nestlings.

Another critical habitat factor for the red-cockaded woodpecker is that the undergrowth of plants around the pine trunks must be low (**Figure 43.14a**). Breeding birds tend to abandon nests when vegetation among the pines is thick and higher than about 4.5 m (**Figure 43.14b**). Apparently, the birds need a clear flight path between their home trees and the neighboring feeding grounds. Periodic fires have historically swept through longleaf pine forests, keeping the undergrowth low.

One factor leading to the woodpecker's decline has been the destruction or fragmentation of suitable habitats by logging and agriculture. By recognizing key habitat factors, protecting some longleaf pine forests, and using controlled fires to reduce forest undergrowth, conservation managers have helped restore habitat that can support viable populations.

Sometimes conservation managers also help species colonize restored habitats. Because red-cockaded woodpeckers take months to excavate nesting cavities, researchers performed an experiment to see whether providing cavities for the birds would make them more likely to use a site. The

Red-cockaded woodpecker

(a) Forests that can sustain red-cockaded woodpeckers have low undergrowth.

(b) Forests that cannot sustain red-cockaded woodpeckers have high, dense undergrowth that interferes with the woodpeckers' access to feeding grounds.

**▲ Figure 43.14 A habitat requirement of the red-cockaded woodpecker.**

**?** *How is habitat disturbance necessary for the long-term survival of the woodpecker?*

researchers constructed cavities in pine trees at 20 restored sites and compared nesting rates there with rates in sites without constructed cavities. The results were dramatic. Cavities in 18 of the 20 sites with constructed cavities were colonized by red-cockaded woodpeckers, and new breeding groups formed only in those sites. Based on this experiment, conservationists initiated a habitat maintenance program that included controlled burning and excavation of new nesting cavities, enabling this endangered species to begin to recover.

## Weighing Conflicting Demands

Determining population numbers and habitat needs is only part of a strategy to save species. Scientists also need to weigh a species' needs against other conflicting demands.

Conservation biology often highlights the relationship between science, technology, and society. For example, an ongoing, sometimes bitter debate in the western United States pits habitat preservation for wolf, grizzly bear, and bull trout populations against job opportunities in the grazing and resource extraction industries. Programs that restocked wolves in Yellowstone National Park remain controversial for people concerned about human safety and for many ranchers concerned with potential loss of livestock outside the park.

Large, high-profile vertebrates are not always the focal point in such conflicts, but habitat use is almost always the issue. Should work proceed on a new highway bridge if it destroys the only remaining habitat of a species of freshwater mussel? If you owned a coffee plantation growing varieties that thrive in bright sunlight, would you be willing to change to shade-tolerant varieties that produce less coffee per hectare but can grow beneath trees that support large numbers of songbirds?

Another important consideration is the ecological role of a species. Because we cannot save every endangered species, we must determine which species are most important for conserving biodiversity as a whole. Identifying keystone species and finding ways to sustain their populations can be central to maintaining communities and ecosystems. In most situations, we must look beyond a species and consider the whole community and ecosystem as an important unit of biodiversity.

### CONCEPT CHECK 43.2

1. How does the reduced genetic diversity of small populations make them more vulnerable to extinction?
2. If there was a total of 50 individuals in the two Illinois populations of greater prairie chickens in 1993, what was the effective population size if 15 females and 5 males bred?
3. **WHAT IF?** In 2011, at least ten grizzly bears in the greater Yellowstone ecosystem were killed through contact with people. Three things caused many of these deaths: collisions with automobiles, hunters (of other animals) shooting when charged by a female grizzly bear with cubs nearby, and conservation managers killing bears that attacked livestock repeatedly. If you were a conservation manager, what steps might you take to minimize such encounters in Yellowstone?

For suggested answers, see Appendix A.

## CONCEPT 43.3

### Landscape and regional conservation help sustain biodiversity

Although conservation efforts historically focused on saving individual species, efforts today often seek to sustain the biodiversity of entire communities, ecosystems, and landscapes. Such a broad view requires applying not just the principles of community, ecosystem, and landscape ecology but aspects of

human population dynamics and economics as well. The goals of landscape ecology (see Chapter 40) include projecting future patterns of landscape use and making biodiversity conservation part of land-use planning.

## Landscape Structure and Biodiversity

The biodiversity of a given landscape is in large part a function of the structure of the landscape. Understanding landscape structure is critically important in conservation because many species use more than one kind of ecosystem, and many live on the borders between ecosystems.

### Fragmentation and Edges

The boundaries, or *edges*, between ecosystems—such as between a lake and the surrounding forest or between cropland and suburban housing tracts—are defining features of landscapes (**Figure 43.15**). An edge has its own set of physical conditions, which differ from those on either side of it. The soil surface of an edge between a forest patch and a burned area receives more sunlight and is usually hotter and drier than the forest interior, but it is cooler and wetter than the soil surface in the burned area.

Some organisms thrive in edge communities because they gain resources from both adjacent areas. The ruffed grouse (*Bonasa umbellus*) is a bird that needs forest habitat for nesting, winter food, and shelter, but it also needs forest openings with dense shrubs and herbs for summer food.

Ecosystems in which edges arise from human alterations often have reduced biodiversity and a preponderance of edge-adapted species. For example, white-tailed deer thrive in edge habitats, where they can browse on woody shrubs; deer populations often expand when forests are logged and more edges are generated. The brown-headed cowbird (*Molothrus ater*) is

an edge-adapted species that lays its eggs in the nests of other birds, often migratory songbirds. Cowbirds need forests, where they can parasitize the nests of other birds, and open fields, where they forage on seeds and insects. Consequently, their populations are growing where forests are being cut and fragmented, creating more edge habitat and open land. Increasing cowbird parasitism and habitat loss are correlated with declining populations of several of the cowbird's host species.

The influence of fragmentation on the structure of communities has been explored since 1979 in the long-term Biological Dynamics of Forest Fragments Project. Located in the heart of the Amazon River basin, the study area consists of isolated fragments of tropical rain forest separated from surrounding continuous forest by distances of 80–1,000 m (**Figure 43.16**). Numerous researchers working on this project have clearly documented the effects of this fragmentation on organisms ranging from bryophytes to beetles to birds. They have consistently found that species adapted to forest interiors show the greatest declines when patches are the smallest, suggesting that landscapes dominated by small fragments will support fewer species.

### Corridors That Connect Habitat Fragments

In fragmented habitats, the presence of a **movement corridor**, a narrow strip or series of small clumps of habitat connecting otherwise isolated patches, can be extremely important for conserving biodiversity. Riparian habitats often serve as corridors, and in some nations, government policy prohibits altering these habitats. In areas of heavy human use, artificial corridors are sometimes constructed. Bridges or tunnels, for instance, can reduce the number of animals killed trying to cross highways (**Figure 43.17**).

Movement corridors can also promote dispersal and reduce inbreeding in declining populations. Corridors have been

▲ **Figure 43.15** Edges between ecosystems. Grasslands give way to forest ecosystems in Yellowstone National Park.

▲ **Figure 43.16** Amazon rain forest fragments created as part of the Biological Dynamics of Forest Fragments Project.

▲ **Figure 43.17 An artificial corridor.** This bridge in Banff National Park, Canada, helps animals cross a human-created barrier.

shown to increase the exchange of individuals among populations of many organisms, including butterflies, voles, and aquatic plants. Corridors are especially important to species that migrate between different habitats seasonally. However, a corridor can also be harmful—for example, by allowing the spread of disease. In a 2003 study, a scientist at the University of Zaragoza, Spain, showed that habitat corridors facilitate the movement of disease-carrying ticks among forest patches in northern Spain. All the effects of corridors are not yet understood, and their impact is an area of active research in conservation biology.

## Establishing Protected Areas

Conservation biologists are applying their understanding of landscape dynamics in establishing protected areas to slow biodiversity loss. Currently, governments have set aside about 7% of the world's land in various forms of reserves. Choosing where to place nature reserves and how to design them poses many challenges. Should the reserve be managed to minimize the risks of fire and predation to a threatened species? Or should the reserve be left as natural as possible, with such processes as fires ignited by lightning allowed to play out on their own? This is just one of the debates that arise among people who share an interest in the health of national parks and other protected areas.

## Preserving Biodiversity Hot Spots

In deciding which areas are of highest conservation priority, biologists often focus on hot spots of biodiversity. A **biodiversity hot spot** is a relatively small area with numerous endemic species (species found nowhere else in the world) and a large number of endangered and threatened species (**Figure 43.18**). Nearly 30% of all bird species can be found in hot spots that make up only about 2% of Earth's land area. Together,

the “hottest” of the terrestrial biodiversity hot spots total less than 1.5% of Earth's land but are home to more than a third of all species of plants, amphibians, reptiles (including birds), and mammals. Aquatic ecosystems also have hot spots, such as coral reefs and certain river systems.

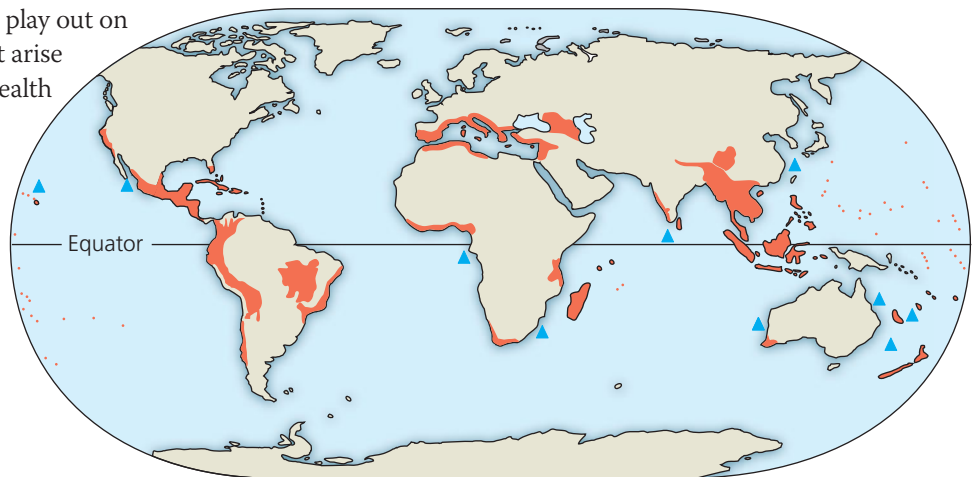

Biodiversity hot spots are good choices for nature reserves, but identifying them is not always simple. One problem is that a hot spot for one taxonomic group, such as butterflies, may not be a hot spot for some other taxonomic group, such as birds. Designating an area as a biodiversity hot spot is often biased toward saving vertebrates and plants, with less attention paid to invertebrates and microorganisms. Some biologists are also concerned that the hot-spot strategy places too much emphasis on such a small fraction of Earth's surface.

Global change makes the task of preserving hot spots even more challenging because the conditions that favor a particular community may not be found in the same location in the future. The biodiversity hot spot in the southwest corner of Australia (see Figure 43.18) holds thousands of species of endemic plants and numerous endemic vertebrates. Researchers recently concluded that between 5% and 25% of the plant species they examined may become extinct by 2080 because the plants will be unable to tolerate the increased dryness predicted for this region.

## Philosophy of Nature Reserves

Nature reserves are biodiversity islands in a sea of habitat degraded by human activity. Protected “islands” are not isolated from their surroundings, however, and the nonequilibrium model (see Chapter 41) applies to nature reserves as well as to the larger landscapes around them.

An earlier policy—that protected areas should be set aside to remain unchanged forever—was based on the concept that ecosystems are balanced, self-regulating units. However, disturbance is common in all ecosystems (see Chapter 41), and management policies that ignore natural disturbances or attempt to prevent them have generally failed. For instance, setting aside an area of a fire-dependent community, such as a

© 2000 Macmillan Publishers Ltd.

▲ **Figure 43.18 Earth's terrestrial (■) and marine (▲) biodiversity hot spots.**

portion of a tallgrass prairie, chaparral, or dry pine forest, with the intention of saving it is unrealistic if periodic burning is excluded. Without the dominant disturbance, the fire-adapted species are usually outcompeted and biodiversity is reduced.

An important conservation question is whether to create numerous small reserves or fewer large reserves. Small, unconnected reserves may slow the spread of disease between populations. One argument for large reserves is that large, far-ranging animals with low-density populations, such as the grizzly bear, require extensive habitats. Large reserves also have proportionately smaller perimeters than small reserves and are therefore less affected by edges.

As conservation biologists have learned more about the requirements for achieving minimum viable populations for endangered species, they have realized that most national parks and other reserves are far too small. The area needed for the long-term survival of the Yellowstone grizzly bear population, for instance, is more than ten times the combined area of Yellowstone and Grand Teton National Parks (Figure 43.19). Areas of private and public land surrounding reserves will likely have to contribute to biodiversity conservation.

### Zoned Reserves

Several nations have adopted a zoned reserve approach to landscape management. A **zoned reserve** is an extensive region that includes relatively undisturbed areas surrounded by areas that have been changed by human activity and are used for economic gain. The key challenge of the zoned reserve

approach is to develop a social and economic climate in the surrounding lands that is compatible with the long-term viability of the protected core. These surrounding areas continue to support human activities, but regulations prevent the types of extensive alterations likely to harm the protected area. As a result, the surrounding habitats serve as buffer zones against further intrusion into the undisturbed area.

The small Central American nation of Costa Rica has become a world leader in establishing zoned reserves (Figure 43.20). An agreement initiated in 1987 reduced Costa Rica's international debt in return for land preservation there. The agreement resulted in eight zoned reserves, called "conservation areas," that contain designated national park land. Costa Rica is making progress toward managing its zoned reserves, and the buffer zones provide a steady, lasting supply of forest products, water, and hydroelectric power while also supporting sustainable agriculture and tourism, both of which employ local people.

Although marine ecosystems have also been heavily affected by human exploitation, reserves in the ocean are far less common than reserves on land. Many fish populations around the world have collapsed as increasingly sophisticated equipment puts nearly all potential fishing grounds within human reach. In response, scientists at the University of York, England, have proposed establishing marine reserves around the world that would be off limits to fishing. They present strong evidence that a patchwork of marine reserves can serve as a means of both increasing fish populations within the reserves and improving fishing success in nearby areas. Their proposed system is a modern application of a centuries-old practice in the Fiji Islands in which some areas have historically remained closed to fishing—a traditional example of the zoned reserve concept.

▲ **Figure 43.19 Biotic boundaries for grizzly bears in Yellowstone and Grand Teton National Parks.** The biotic boundaries (solid and dashed red lines) surround the areas needed to support minimum viable populations of 50 and 500 bears. Even the smaller of these areas is larger than the two parks.

▲ **Figure 43.20 Zoned reserves in Costa Rica.** Boundaries of the zoned reserves are indicated by black outlines.

▲ **Figure 43.21** A diver measuring coral in the Florida Keys National Marine Sanctuary.

The United States adopted such a system in creating a set of 13 national marine sanctuaries, including the Florida Keys National Marine Sanctuary, which was established in 1990 (**Figure 43.21**). Populations of marine organisms, including fishes and lobsters, recovered quickly after harvests were banned in the 9,500-km<sup>2</sup> reserve. Larger and more abundant fish now produce larvae that help repopulate reefs and improve fishing outside the sanctuary. The increased marine life within the sanctuary also makes it a favorite for recreational divers, increasing the economic value of this zoned reserve.

#### CONCEPT CHECK 43.3

1. What is a biodiversity hot spot?
2. How do zoned reserves provide economic incentives for long-term conservation of protected areas?
3. **WHAT IF?** Suppose a developer proposes to clear-cut a forest that serves as a corridor between two parks. To compensate, the developer also proposes to add the same area of forest to one of the parks. As a professional ecologist, how might you argue for retaining the corridor?

For suggested answers, see Appendix A.

## CONCEPT 43.4

### Earth is changing rapidly as a result of human actions

As we've discussed, landscape and regional conservation help protect habitats and preserve species. However, environmental changes that result from human activities are creating new challenges. As a consequence of human-caused climate change, for example, the place where a vulnerable species is found today may not be the same as the one needed for preservation in the future. What would happen if *many* habitats on

Earth changed so quickly that the locations of preserves today were unsuitable for their species in 10, 50, or 100 years? Such a scenario is increasingly likely.

The rest of this section describes three types of environmental change that threaten biodiversity: nutrient enrichment, toxin accumulation, and climate change. The impacts of these and other changes are evident not just in human-dominated ecosystems, such as cities and farms, but also in the most remote ecosystems on Earth.

### Nutrient Enrichment

Human activity often removes nutrients from one part of the biosphere and adds them to another. Someone eating strawberries in Washington, DC, consumes nutrients that only days before were in the soil in California; a short time later, some of these nutrients will be in the Potomac River, having passed through the person's digestive system and a local sewage treatment facility.

Farming is an example of how human activities are altering the environment through the enrichment of nutrients. After vegetation is cleared from an area, the existing reserve of nutrients in the soil is sufficient to grow crops for only a brief period because a substantial fraction of these nutrients is exported from the area in crop biomass. For this reason, farmers typically add fertilizers to increase crop yields.

Nitrogen is the main nutrient element lost through agriculture (see Figure 42.13). Plowing mixes the soil and speeds up decomposition of organic matter, releasing nitrogen that is then removed when crops are harvested. Applied fertilizers make up for the loss of usable nitrogen from agricultural ecosystems. However, without plants to take up nitrates from the soil, the nitrates are likely to be leached from the ecosystem (see Figure 42.14). Recent studies indicate that human activities have more than doubled Earth's supply of fixed nitrogen available to primary producers.

A problem arises when the nutrient level in an ecosystem exceeds the **critical load**, the amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity. For example, nitrogenous minerals in the soil that exceed the critical load eventually leach into groundwater or run off into freshwater and marine ecosystems, sometimes contaminating water supplies and killing fish. Nitrate concentrations in groundwater are increasing in most agricultural regions, sometimes reaching levels that are unsafe for drinking.

Many rivers contaminated with nitrates and ammonium from agricultural runoff and sewage drain into the Atlantic Ocean, with the highest inputs coming from northern Europe and the central United States. The Mississippi River carries nitrogen pollution to the Gulf of Mexico, fueling a phytoplankton bloom each summer. When the phytoplankton die, their decomposition by oxygen-using organisms creates an extensive "dead zone" of low oxygen concentrations along the Gulf coast

▲ **Figure 43.22** A phytoplankton bloom arising from nitrogen pollution in the Mississippi basin that leads to a dead zone. In this satellite image from 2004, red and orange represent high concentrations of phytoplankton in the Gulf of Mexico.

(Figure 43.22). Fish and other marine animals disappear from some of the most economically important waters in the United States. To reduce the size of the dead zone, farmers have begun using fertilizers more efficiently, and managers are restoring wetlands in the Mississippi watershed, two changes stimulated by the results of ecosystem experiments.

Nutrient runoff can also lead to the eutrophication of lakes (see Concept 42.2). The bloom and subsequent die-off of algae and cyanobacteria and the ensuing depletion of oxygen are similar to what occurs in a marine dead zone. Such conditions threaten the survival of organisms. For example, eutrophication of Lake Erie coupled with overfishing wiped out commercially important fishes such as blue pike, whitefish, and lake trout by the 1960s. Since then, tighter regulations on the dumping of sewage and other wastes into the lake have enabled some fish populations to rebound, but many native species of fish and invertebrates have not recovered.

## Toxins in the Environment

Human activities release an immense variety of toxic chemicals, including thousands of synthetic compounds previously unknown in nature, with little regard for the ecological consequences. Organisms acquire toxic substances from the environment along with nutrients and water. Some of the poisons are metabolized or excreted, but others accumulate in specific tissues, often fat. One of the reasons accumulated toxins are particularly harmful is that they become more concentrated in successive trophic levels of a food web. This phenomenon, called **biological magnification**, occurs because the biomass at any given trophic level is produced from a much larger biomass ingested from the level below (see Concept 42.3). Thus, top-level carnivores tend to be most severely affected by toxic compounds in the environment.

One class of industrially synthesized compounds that have demonstrated biological magnification are the chlorinated hydrocarbons, which include the industrial chemicals called PCBs (polychlorinated biphenyls) and many pesticides, such as DDT. Current research implicates many of these compounds in endocrine system disruption in a large number of animal

▲ **Figure 43.23** Biological magnification of PCBs in a Great Lakes food web.

species, including humans. Biological magnification of PCBs has been found in the food web of the Great Lakes, where the concentration of PCBs in herring gull eggs, at the top of the food web, is nearly 5,000 times that in phytoplankton, at the base of the food web (Figure 43.23).

An infamous case of biological magnification that harmed top-level carnivores involved DDT, a chemical used to control insects such as mosquitoes and agricultural pests. In the decade after World War II, the use of DDT grew rapidly; its ecological consequences were not yet fully understood. By the 1950s, scientists were learning that DDT persists in the environment and is transported by water to areas far from where it is applied. One of the first signs that DDT was a serious environmental problem was a decline in the populations of pelicans, ospreys, and eagles, birds that feed at the top of food webs. The accumulation of DDT (and DDE, a product of its breakdown) in the tissues of these birds interfered with the deposition of calcium in their eggshells. When the birds tried to incubate their eggs, the weight of the parents broke the shells of affected eggs, resulting in catastrophic declines in the birds' reproduction rates. Rachel Carson's book *Silent Spring* helped bring the problem to public attention in the 1960s (Figure 43.24), and DDT was banned in the United States in 1971. A dramatic recovery in populations of the affected bird species followed.

► **Figure 43.24**

**Rachel Carson.**

Through her writing and her testimony before the U.S. Congress, biologist and author Rachel Carson helped promote a new environmental ethic. Her efforts led to a ban on DDT use in the United States and stronger controls on the use of other chemicals.

In countries throughout much of the tropics, DDT is still used to control the mosquitoes that spread malaria and other diseases. Societies there face a trade-off between saving human lives and protecting other species. The best approach seems to be to apply DDT sparingly and to couple its use with mosquito netting and other low-technology solutions. The complicated history of DDT illustrates the importance of understanding the ecological connections between diseases and communities (see Concept 41.5).

Pharmaceuticals make up another group of toxins in the environment, one that is a growing concern among ecologists. The use of over-the-counter and prescription drugs has risen in recent years, particularly in industrialized nations. People who consume such products excrete residual chemicals in their waste and may also dispose of unused drugs improperly, such as in their toilets or sinks. Drugs that are not broken down in sewage treatment plants may then enter rivers and lakes with the material discharged from these plants. Growth-promoting drugs given to farm animals can also enter rivers and lakes with agricultural runoff. As a consequence, many pharmaceuticals are spreading in low concentrations across the world's freshwater ecosystems (**Figure 43.25**).

▲ **Figure 43.25** Sources and movements of pharmaceuticals in the environment.

Among the pharmaceuticals that ecologists are studying are the sex steroids, including forms of estrogen used for birth control. Some fish species are so sensitive to certain estrogens that concentrations of a few parts per trillion in their water can alter sexual differentiation and shift the female-to-male sex ratio toward females. Researchers in Ontario, Canada, conducted a seven-year experiment in which they applied the synthetic estrogen used in contraceptives to a lake in very low concentrations (5–6 ng/L). They found that chronic exposure of the fathead minnow (*Pimephales promelas*) to the estrogen led to feminization of males and a near extinction of the species from the lake.

Many toxins cannot be degraded by microorganisms and persist in the environment for years or even decades. In other cases, chemicals released into the environment may be relatively harmless but are converted to more toxic products by reaction with other substances, by exposure to light, or by the metabolism of microorganisms. Mercury, a by-product of plastic production and coal-fired power generation, has been routinely expelled into rivers and the sea in an insoluble form. Bacteria in the bottom mud convert the waste to methylmercury ( $\text{CH}_3\text{Hg}^+$ ), an extremely toxic water-soluble compound that accumulates in the tissues of organisms, including humans who consume fish from the contaminated waters.

## Greenhouse Gases and Climate Change

Human activities release a variety of gaseous waste products. People once thought that the vast atmosphere could absorb these materials indefinitely, but we now know that such additions can cause fundamental changes to the atmosphere and to its interactions with the rest of the biosphere. In this section, we'll examine how increasing concentrations of carbon dioxide and other greenhouse gases may affect species and ecosystems.

Since the Industrial Revolution, the concentration of  $\text{CO}_2$  in the atmosphere has been increasing as a result of the burning of fossil fuels and deforestation. Scientists estimate that the average  $\text{CO}_2$  concentration in the atmosphere before 1850 was about 274 ppm. In 1958, a monitoring station began taking very accurate measurements on Hawaii's Mauna Loa peak, a location far from cities and high enough for the atmosphere to be well mixed. At that time, the  $\text{CO}_2$  concentration was 316 ppm (**Figure 43.26**). Today, it exceeds 390 ppm, an increase of more than 40% since the mid-19th century. In the **Scientific Skills Exercise**, you can graph and interpret changes in  $\text{CO}_2$  concentration that occur during the course of a year and over longer periods.

The marked increase in the concentration of atmospheric  $\text{CO}_2$  over the last 150 years concerns scientists because

► **Figure 43.26 Increase in atmospheric carbon dioxide concentration at Mauna Loa, Hawaii, and average global temperatures.**

Aside from normal seasonal fluctuations, the CO<sub>2</sub> concentration (blue curve) has increased steadily from 1958 to 2011. Though average global temperatures (red curve) fluctuated a great deal over the same period, there is a clear warming trend.

## Scientific Skills Exercise

### Graphing Cyclic Data

**How Does the Atmospheric CO<sub>2</sub> Concentration Change During a Year and from Decade to Decade?** The blue curve in Figure 43.26 shows how the concentration of CO<sub>2</sub> in Earth's atmosphere has changed over a span of more than 50 years. For each year in that span, two data points are plotted, one in May and one in November. A more detailed picture of the change in CO<sub>2</sub> concentration can be obtained by looking at measurements made at more frequent intervals. In this exercise, you'll graph monthly CO<sub>2</sub> concentrations for three years over three decades.

**Data from the Study** The data in the table below are average CO<sub>2</sub> concentrations (in parts per million) at the Mauna Loa monitoring station for each month in 1990, 2000, and 2010.

Month	1990	2000	2010
January	353.79	369.25	388.45
February	354.88	369.50	389.82
March	355.65	370.56	391.08
April	356.27	371.82	392.46
May	359.29	371.51	392.95
June	356.32	371.71	392.06
July	354.88	369.85	390.13
August	352.89	368.20	388.15
September	351.28	366.91	386.80
October	351.59	366.91	387.18
November	353.05	366.99	388.59
December	354.27	369.67	389.68

### Interpret the Data

- Plot the data for all three years on one graph. Select a type of graph that is appropriate for these data, and choose a vertical-axis scale that allows you to clearly see the patterns of CO<sub>2</sub> concentration changes, both during each year and from decade to decade. (For additional information about graphs, see the Scientific Skills Review in Appendix F and in the Study Area in MasteringBiology.)
- Within each year, what is the pattern of change in CO<sub>2</sub> concentration? Why does this pattern occur?
- The measurements taken at Mauna Loa represent average atmospheric CO<sub>2</sub> concentrations for the Northern Hemisphere. Suppose you could measure CO<sub>2</sub> concentrations under similar conditions in the Southern Hemisphere. What pattern would you expect to see in those measurements over the course of a year? Explain.
- In addition to the changes within each year, what changes in CO<sub>2</sub> concentration occurred between 1990 and 2010? Calculate the average CO<sub>2</sub> concentration for the 12 months of each year. By what percentage did this average change from 1990 to 2000 and from 1990 to 2010?

**Data from** National Oceanic & Atmospheric Administration, Earth System Research Laboratory, Global Monitoring Division

 A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

of its link to increased global temperature. Much of the solar radiation that strikes the planet is reflected back into space. Although CO<sub>2</sub>, methane, water vapor, and other gases in the atmosphere are transparent to visible light, they intercept and absorb much of the infrared radiation Earth emits, re-reflecting some of it back toward Earth. This process retains some of the solar heat. If it were not for this **greenhouse effect**, the average air temperature at Earth's surface would be a frigid  $-18^{\circ}\text{C}$  ( $-0.4^{\circ}\text{F}$ ), and most life as we know it could not exist.

For more than a century, scientists have studied how greenhouse gases warm Earth and how fossil fuel burning could contribute to the warming. Most scientists are convinced that such warming is already occurring and will increase rapidly this century (see Figure 43.26). Global models predict that by the end of the 21st century, the atmospheric CO<sub>2</sub> concentration will have more than doubled, increasing average global temperature by about  $3^{\circ}\text{C}$  ( $5^{\circ}\text{F}$ ).

Supporting these models is a correlation between CO<sub>2</sub> levels and temperatures in prehistoric times. One way climatologists estimate past CO<sub>2</sub> concentrations is to measure CO<sub>2</sub> levels in bubbles trapped in glacial ice, some of which are 700,000 years old. Prehistoric temperatures are inferred by several methods, including analysis of past vegetation based on fossils and the chemical isotopes in sediments and corals. An increase of only  $1.3^{\circ}\text{C}$  would make the world warmer than at any time in the past 100,000 years. A warming trend would also alter the geographic distribution of precipitation, likely making agricultural areas of the central United States much drier, for example.

The ecosystems where the largest warming has *already* occurred are those in the far north, particularly northern coniferous forests and tundra. As snow and ice melt and uncover darker, more absorptive surfaces, these systems reflect less radiation back to the atmosphere and warm further. Arctic sea ice in the summer of 2007 covered the smallest area on record. Climate models suggest that there may be no summer ice there within a few decades, decreasing habitat for polar bears, seals, and seabirds. Higher temperatures also increase the likelihood of fires. In boreal forests of western North America and Russia, fires have burned twice the usual area in recent decades.

### Range Shifts and Climate Change

Many organisms, especially plants that cannot disperse rapidly over long distances, may not be able to survive the rapid climate change projected to result from global warming. Furthermore, many habitats today are more fragmented than ever (see Concept 43.3), further limiting the ability of many organisms to migrate.

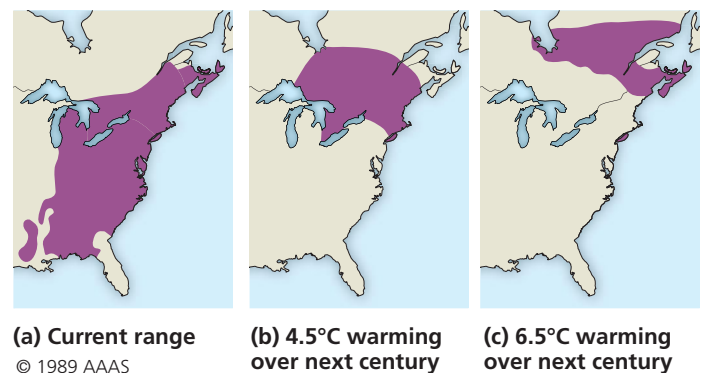

One way to predict the possible effects of future climate change on geographic ranges is to look back at the changes that have occurred in temperate regions since the last ice age ended. Until about 16,000 years ago, continental glaciers covered much of North America and Eurasia. As the climate

warmed and the glaciers retreated, tree distributions expanded northward. A detailed record of these changes is captured in fossil pollen deposited in lakes and ponds. (Recall from Chapter 26 that wind and animals sometimes disperse pollen and seeds over great distances.) If researchers can determine the climatic limits of current distributions of organisms, they can make predictions about how those distributions may change with continued climatic warming.

A fundamental question when applying this approach to plants is whether seeds can disperse quickly enough to sustain the range shift of each species as climate changes. Fossil pollen shows that species with winged seeds that disperse relatively far from a parent tree, such as the sugar maple (*Acer saccharum*), expanded rapidly into the northeastern United States and Canada after the last ice age ended. In contrast, the northward range expansion of the eastern hemlock (*Tsuga canadensis*), whose seeds lack wings, was delayed nearly 2,500 years compared with the shift in suitable habitat.

Will plants and other species be able to keep up with the much more rapid warming projected for this century? Ecologists have attempted to answer this question for the American beech (*Fagus grandifolia*). Their models predict that the northern limit of the beech's range may move 700–900 km northward in the next century, and its southern range limit will shift even more. The current and predicted geographic ranges of this species under two different climate-change scenarios are illustrated in **Figure 43.27**. If these predictions are even approximately correct, the beech's range must shift 7–9 km northward per year to keep pace with the warming climate. However, since the end of the last ice age, the beech has moved at a rate of only 0.2 km per year. Without human help in moving to new habitats, species such as the American beech may have much smaller ranges or even become extinct.

Changes in the distributions of species are already evident in many well-studied groups of terrestrial, marine, and freshwater organisms, consistent with the signature of a warmer world. In Europe, for instance, the northern range limits of

**▲ Figure 43.27** Current range and predicted range for the American beech under two climate-change scenarios.

**?** The predicted range in each scenario is based on climate factors alone. What other factors might alter the distribution of this species?

22 of 35 butterfly species studied had shifted farther north by 35–240 km over the time periods for which records exist, in some cases beginning in 1900. Other research shows that a Pacific diatom, *Neodenticula seminae*, recently has colonized the Atlantic Ocean for the first time in 800,000 years. As Arctic sea ice has receded in the past decade, the increased flow of water from the Pacific has swept these diatoms around Canada and into the Atlantic, where they quickly became established.

### Climate Change Solutions

We will need a variety of approaches to slow global warming and climate change in general. Quick progress can be made by using energy more efficiently and by replacing fossil fuels with renewable solar and wind power and, more controversially, with nuclear power. Today, coal, gasoline, wood, and other organic fuels remain central to industrialized societies and cannot be burned without releasing CO<sub>2</sub>. Stabilizing CO<sub>2</sub> emissions will require concerted international effort and changes in both personal lifestyles and industrial processes.

Another important approach to slowing global warming is to reduce deforestation around the world, particularly in the tropics. Deforestation currently accounts for about 12% of greenhouse gas emissions. Recent research shows that paying countries *not* to cut forests could decrease the rate of deforestation by half within 10 to 20 years. Reduced deforestation would not only slow the buildup of greenhouse gases in our atmosphere but sustain native forests and preserve biodiversity, a positive outcome for all.

#### CONCEPT CHECK 43.4

1. How can the addition of excess mineral nutrients to a lake threaten its fish population?
2. **MAKE CONNECTIONS** There are vast stores of organic matter in the soils of northern coniferous forests and tundra around the world. Suggest an explanation for why scientists who study global warming are closely monitoring these stores (see Figure 42.12).

For suggested answers, see Appendix A.

## CONCEPT 43.5

### The human population is no longer growing exponentially but is still increasing rapidly

Global environmental problems, such as climate change, arise from the intersection of two factors. One is the growing amount of goods and resources that each of us consumes. The other is the increasing size of the human population, which has grown at an unprecedented rate in the last few centuries. No population can grow indefinitely, however. In this section,

we'll apply ecological concepts to the specific case of the human population.

### The Global Human Population

The exponential growth model (see Figure 40.19) approximates the human population explosion over the last four centuries (**Figure 43.28**). Ours is a singular case; no other population of large animals has likely ever sustained so much growth for so long. The human population increased relatively slowly until about 1650, at which time approximately 500 million people inhabited Earth. Our population doubled to 1 billion within the next two centuries, doubled again to 2 billion by 1930, and doubled still again by 1975 to more than 4 billion. The global population is now more than 7 billion and is increasing by about 78 million each year. At this rate, it takes only about four years to add the equivalent of another United States to the world population. Ecologists predict a population of 8.1–10.6 billion people on Earth by the year 2050.

Though the global population is still growing, the *rate* of growth did begin to slow during the 1960s (**Figure 43.29**). The annual rate of increase in the global population peaked at 2.2% in 1962 but had declined to 1.1% by 2011. Current models project a continued decline in the annual growth rate to roughly 0.5% by 2050, a rate that would still add 45 million more people per year if the population climbs to a projected 9 billion. The reduction in growth rate over the past four decades shows that the human population has departed from true exponential growth, which assumes a constant rate. This departure is the result of fundamental changes in population dynamics due to diseases, including AIDS, and to voluntary population control.

The growth rates of individual nations vary with their degree of industrialization. In industrialized nations, populations are

▲ **Figure 43.28 Human population growth (data as of 2011).** The global human population has grown almost continuously throughout history, but it skyrocketed after the Industrial Revolution. The rate of population growth has slowed in recent decades, mainly as a result of decreased birth rates throughout the world.

▲ **Figure 43.29 Annual percent increase in the global human population (data as of 2011).** The sharp dip in the 1960s is due mainly to a famine in China in which about 60 million people died.

near equilibrium, with growth rates of about 0.1% per year and reproductive rates near the replacement level (total fertility rate = 2.1 children per female). In countries such as Canada, Germany, Japan, and the United Kingdom, total reproductive rates are in fact *below* replacement. These populations will eventually decline if there is no immigration and if the birth rate does not change. In fact, the population is already declining in many eastern and central European countries.

In contrast, most of the current global population growth of 1.1% per year is concentrated in less industrialized nations, where about 80% of the world's people now live. Countries such as Afghanistan, Uganda, and Jordan had populations that grew by more than 3% *per year* between 2005 and 2010. Although death rates have declined rapidly since 1950 in many less industrialized countries, birth rates have declined substantially in only some of them. The fall in birth rate has been most dramatic in China. Largely because of the Chinese government's strict one-child policy, the expected total fertility rate (children per woman per lifetime) decreased from 5.9 in 1970 to 1.6 in 2011. The transition to lower birth rates has also been rapid in some African countries, though birth rates remain high in most of sub-Saharan Africa. In India, birth rates have fallen more slowly.

A unique feature of human population growth is our ability to control family sizes using family planning and voluntary contraception. Social change and the rising educational and career aspirations of women in many cultures encourage women to delay marriage and postpone reproduction. Delayed reproduction helps to decrease population growth rates and to

move a society toward zero population growth under conditions of low birth rates and low death rates. However, there is a great deal of disagreement as to how much support should be provided for global family planning efforts.

## Global Carrying Capacity

No ecological question is more important than the future size of the human population. The projected worldwide population size depends on assumptions about future changes in birth and death rates. As we noted earlier, population ecologists project a global population of approximately 8.1–10.6 billion people in 2050. In other words, without some catastrophe, an estimated 1–4 billion people will be added to the population in the next four decades because of the momentum of population growth. But just how many humans can the biosphere support? Will the world be overpopulated in 2050? Is it *already* overpopulated?

### Estimates of Carrying Capacity

Estimates of the human carrying capacity of Earth have varied from less than 1 billion to more than 1,000 billion (1 trillion), with an average of 10–15 billion. Carrying capacity is difficult to estimate, and scientists use different methods to produce their estimates. Some current researchers use curves like that produced by the logistic equation (see Figure 40.19) to predict the future maximum of the human population. Others generalize from existing “maximum” population density and multiply this number by the area of habitable land. Still others base their estimates on a single limiting factor, such as food, and consider variables such as the amount of available farmland, the average yield of crops, the prevalent diet—vegetarian or meat based—and the number of calories needed per person per day.

### Limits on Human Population Size

A more comprehensive approach to estimating the carrying capacity of Earth is to recognize that humans have multiple constraints: We need food, water, fuel, building materials, and other resources, such as clothing and transportation. The **ecological footprint** concept summarizes the aggregate land and water area required by each person, city, or nation to produce all the resources it consumes and to absorb all the waste it generates. One way to estimate the ecological footprint of the entire human population is to add up all the ecologically productive land on the planet and divide by the population. This calculation yields approximately 2 ha per person (1 ha = 2.47 acres). Reserving some land for parks and conservation means reducing this allotment to 1.7 ha per person—the benchmark for comparing actual ecological footprints. Anyone who consumes resources that require more than 1.7 ha to produce is said to be using an unsustainable share of Earth's resources. A typical ecological footprint for a person in the United States is about 10 ha.

Ecologists sometimes calculate ecological footprints using other currencies besides land area, such as energy use. Average energy use differs greatly in developed and developing nations (**Figure 43.30**). A typical person in the United States, Canada, or Norway consumes roughly 30 times the energy that a person in central Africa does. Moreover, fossil fuels, such as oil, coal, and natural gas, are the source of 80% or more of the energy used in most developed nations. This unsustainable reliance on fossil fuels is changing Earth's climate and increasing the amount of waste that each of us produces. Ultimately, the combination of resource use per person and population density determines our global ecological footprint.

How many people our planet can sustain depends on the quality of life each of us enjoys and the distribution of wealth across people and nations, topics of great concern and political debate. Unlike other organisms, we can decide whether zero population growth will be attained through social changes based on human choices or, instead, through increased mortality due to resource limitation, plagues, war, and environmental degradation.

#### CONCEPT CHECK 43.5

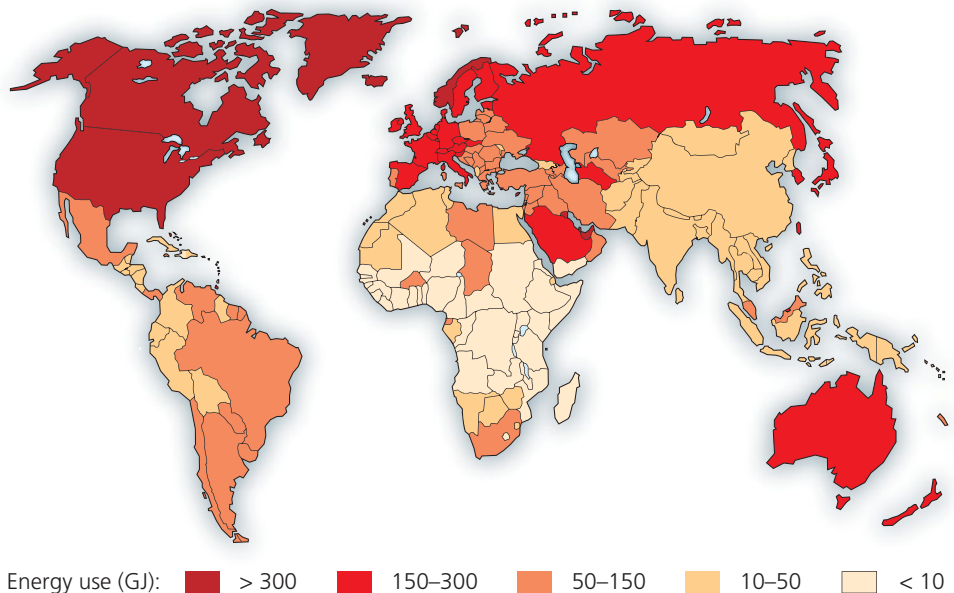

1. How has the growth of Earth's human population changed in recent decades? Answer in terms of growth rate and the number of people added each year.
2. **WHAT IF?** What choices can you make to influence your own ecological footprint?

For suggested answers, see Appendix A.

## CONCEPT 43.6

### Sustainable development can improve human lives while conserving biodiversity

With the loss and fragmentation of habitats, changes in Earth's physical environment and climate, and increasing human population, we face difficult trade-offs in managing the world's resources. Preserving all habitat patches isn't feasible, so biologists must help societies set conservation priorities by identifying which habitat patches are most crucial. Ideally, implementing these priorities should also improve the quality of life for local people. Ecologists use the concept of *sustainability* as a tool to establish long-term conservation priorities.

**▲ Figure 43.30 Annual per capita energy use around the world.** A gigajoule (GJ) equals  $10^9$  J. For comparison, leaving a 100-watt light bulb on continuously for one year would use 3.15 GJ.

### Sustainable Development

We need to understand the interconnections of the biosphere if we are to protect species from extinction and improve the quality of human life. To this end, many nations, scientific societies, and other groups have embraced the concept of **sustainable development**, economic development that meets the needs of people today without limiting the ability of future generations to meet their needs.

Achieving sustainable development is an ambitious goal. To sustain ecosystem processes and stem the loss of biodiversity, we must connect life science with the social sciences, economics, and the humanities. We must also reassess our personal values. As you learned in Concept 43.5, those of us living in developed nations have a larger ecological footprint than do people living in developing nations. By including the long-term costs of consumption in profit-and-loss calculations, we can learn to value the natural processes that sustain us. The following case study illustrates how the combination of scientific and personal efforts can make a significant difference in creating a truly sustainable world.

#### Case Study: Sustainable Development in Costa Rica

The success of conservation in Costa Rica that we discussed in Concept 43.3 has required a partnership between the national government, nongovernment organizations (NGOs), and private citizens. Many nature reserves established by individuals have been recognized by the government as national wildlife reserves and given significant tax benefits. However, conservation and restoration of biodiversity make up only one facet of sustainable development; the other key facet is improving the human condition.

How have the living conditions of the Costa Rican people changed as the country has pursued its conservation goals? Two of the most fundamental indicators of living conditions are infant mortality rate and life expectancy. From 1930 to 2010, the infant mortality rate in Costa Rica declined from 170 to 9 per 1,000 live births; over the same period, life expectancy increased from about 43 years to 79 years. Another indicator of living conditions is the literacy rate, which was 96% in 2011, compared to 97% in the United States. Such statistics show that living conditions in Costa Rica have improved greatly over the period in which the country has dedicated itself to conservation and restoration. While this result does not prove that conservation *causes* an improvement in human welfare, we can say with certainty that development in Costa Rica has attended to both nature *and* people.

## The Future of the Biosphere

Our modern lives are very different from those of early humans, who hunted and gathered to survive. Their reverence for the natural world is evident in the early murals of wildlife they painted on cave walls (**Figure 43.31a**) and in the stylized visions of life they sculpted from bone and ivory (**Figure 43.31b**).

Our lives reflect remnants of our ancestral attachment to nature and the diversity of life—the concept of *biophilia* that was introduced early in this chapter. We evolved in natural environments rich in biodiversity, and we still have an affinity for such settings (**Figure 43.31c, d**). E. O. Wilson makes the case that our biophilia is innate, an evolutionary product of natural selection acting on a brainy species whose survival depended on a close connection to the environment and a practical appreciation of plants and animals.

Our appreciation of life guides the field of biology today. We celebrate life by deciphering the genetic code that makes each species unique. We embrace life by using fossils and DNA to chronicle evolution through time. We preserve life through our efforts to classify and protect the millions of species on Earth. We respect life by using nature responsibly and reverently to improve human welfare.

Biology is the scientific expression of our desire to know nature. We are most likely to protect what we appreciate, and we are most likely to appreciate what we understand. By learning about the processes and diversity of life, we also become more aware of ourselves and our place in the biosphere. We hope this book has served you well in this lifelong adventure.

### CONCEPT CHECK 43.6

1. What is meant by the term *sustainable development*?
2. How might biophilia inspire us to conserve species and restore ecosystems?
3. **WHAT IF?** Suppose a new fishery is discovered, and you are put in charge of developing it sustainably. What ecological data might you want on the fish population? What criteria would you apply for the fishery's development?

For suggested answers, see Appendix A.

(a) Detail of animals in a 17,000-year-old cave painting, Lascaux, France

(b) A 30,000-year-old ivory carving of a water bird, found in Germany

(c) Nature lovers on a wildlife-watching expedition

(d) A young biologist holding a songbird

▲ **Figure 43.31** Biophilia, past and present.

# 43 Chapter Review

## SUMMARY OF KEY CONCEPTS

### CONCEPT 43.1

#### Human activities threaten Earth's biodiversity (pp. 883–888)

- Biodiversity can be considered at three main levels:

- Our biophilia enables us to recognize the value of biodiversity for its own sake. Other species also provide humans with food, fiber, medicines, and **ecosystem services**.
- Four major threats to biodiversity are habitat loss, **introduced species**, overharvesting, and global change.

? Give at least three examples of key ecosystem services that nature provides for people.

### CONCEPT 43.2

#### Population conservation focuses on population size, genetic diversity, and critical habitat (pp. 888–891)

- When a population drops below a **minimum viable population (MVP)** size, its loss of genetic variation due to nonrandom mating and genetic drift can trap it in an **extinction vortex**.
- The declining-population approach focuses on the environmental factors that cause decline, regardless of absolute population size. It follows a step-by-step conservation strategy.
- Conserving species often requires resolving conflicts between the habitat needs of **endangered species** and human demands.

? Why is the minimum viable population size smaller for a population that is more genetically diverse than it is for a less genetically diverse population?

### CONCEPT 43.3

#### Landscape and regional conservation help sustain biodiversity (pp. 891–895)

- The structure of a landscape can strongly influence biodiversity. As habitat fragmentation increases and edges become more extensive, biodiversity tends to decrease. **Movement corridors** can promote dispersal and help sustain populations.
- Biodiversity hot spots** are also hot spots of extinction and thus prime candidates for protection. Sustaining biodiversity in parks and reserves requires management to ensure that human activities in the surrounding landscape do not harm the protected habitats. The **zoned reserve** model recognizes that conservation efforts often involve working in landscapes that are greatly affected by human activity.

? Give two examples that show how habitat fragmentation can harm species in the long term.

### CONCEPT 43.4

#### Earth is changing rapidly as a result of human actions (pp. 895–900)

- Agriculture removes plant nutrients from ecosystems, so large supplements are usually required. The nutrients in fertilizer can pollute groundwater and surface water, where they can stimulate excess algal growth (eutrophication).
- The release of toxic wastes has polluted the environment with harmful substances that often persist for long periods and become increasingly concentrated in successively higher trophic levels of food webs (**biological magnification**).
- Because of the burning of wood and fossil fuels and other human activities, the atmospheric concentration of CO<sub>2</sub> and other greenhouse gases has been steadily increasing. The ultimate effects include significant global warming and other changes in climate.

? In the face of biological magnification of toxins, is it healthier to feed at a lower or higher trophic level? Explain.

### CONCEPT 43.5

#### The human population is no longer growing exponentially but is still increasing rapidly (pp. 900–902)

- Since about 1650, the global human population has grown exponentially, but within the last 50 years, the rate of growth has fallen by half. While some nations' populations are growing rapidly, those of others are stable or declining in size.
- The carrying capacity of Earth for humans is uncertain. **Ecological footprint** is the aggregate land and water area needed to produce all the resources a person or group of people consume and to absorb all of their wastes. It is one measure of how close we are to the carrying capacity of Earth. With a world population of more than 7 billion people, we are already using many resources in an unsustainable manner.

? How are we humans different from other species in being able to "choose" a carrying capacity?

**CONCEPT** 43.6**Sustainable development can improve human lives while conserving biodiversity (pp. 902–903)**

- The goal of the Sustainable Biosphere Initiative is to acquire the ecological information needed for the development, management, and conservation of Earth's resources.
- Costa Rica's success in conserving tropical biodiversity has involved a partnership between the government, other organizations, and private citizens. Human living conditions in Costa Rica have improved along with ecological conservation.
- By learning about biological processes and the diversity of life, we become more aware of our close connection to the environment and the value of other organisms that share it.

**?** *Why is sustainability such an important goal for conservation biologists?*

**TEST YOUR UNDERSTANDING****Level 1: Knowledge/Comprehension**

1. One characteristic that distinguishes a population in an extinction vortex from most other populations is that
  - a. its habitat is fragmented.
  - b. it is a rare, top-level predator.
  - c. its effective population size is much lower than its total population size.
  - d. its genetic diversity is very low.
  - e. it is not well adapted to edge conditions.
2. The main cause of the increase in the amount of CO<sub>2</sub> in Earth's atmosphere over the past 150 years is
  - a. increased worldwide primary production.
  - b. increased worldwide standing crop.
  - c. an increase in the amount of infrared radiation absorbed by the atmosphere.
  - d. the burning of larger amounts of wood and fossil fuels.
  - e. additional respiration by the rapidly growing human population.
3. What is the single greatest threat to biodiversity?
  - a. overharvesting of commercially important species
  - b. introduced species that compete with native species
  - c. pollution of Earth's air, water, and soil
  - d. disruption of trophic relationships as more and more prey species become extinct
  - e. habitat alteration, fragmentation, and destruction

**Level 2: Application/Analysis**

4. Which of the following is a consequence of biological magnification?
  - a. Toxic chemicals in the environment pose greater risk to top-level predators than to primary consumers.
  - b. Populations of top-level predators are generally smaller than populations of primary consumers.
  - c. The biomass of producers in an ecosystem is generally higher than the biomass of primary consumers.
  - d. Only a small portion of the energy captured by producers is transferred to consumers.
  - e. The amount of biomass in the producer level of an ecosystem decreases if the producer turnover time increases.
5. Which of the following strategies would most rapidly increase the genetic diversity of a population in an extinction vortex?
  - a. Capture all remaining individuals in the population for captive breeding followed by reintroduction to the wild.
  - b. Establish a reserve that protects the population's habitat.

- c. Introduce new individuals transported from other populations of the same species.
  - d. Sterilize the least fit individuals in the population.
  - e. Control populations of the endangered population's predators and competitors.
6. Of the following statements about protected areas that have been established to preserve biodiversity, which one is *not* correct?
    - a. About 25% of Earth's land area is now protected.
    - b. National parks are one of many types of protected areas.
    - c. Most protected areas are too small to protect species.
    - d. Management of a protected area should be coordinated with management of the land surrounding the area.
    - e. It is especially important to protect biodiversity hot spots.

**Level 3: Synthesis/Evaluation**

7. **DRAW IT** Using Figure 43.26 as a starting point, extend the *x*-axis to the year 2100. Then extend the CO<sub>2</sub> curve, assuming that the CO<sub>2</sub> concentration continues to rise as fast as it did from 1974 to 2011. What will be the approximate CO<sub>2</sub> concentration in 2100? What ecological factors and human decisions will influence the actual rise in CO<sub>2</sub> concentration? How might additional scientific data help societies predict this value?
8. **SCIENTIFIC INQUIRY**  
**DRAW IT** Suppose that you are managing a forest reserve, and one of your goals is to protect local populations of woodland birds from parasitism by the brown-headed cowbird. You know that female cowbirds usually do not venture more than about 100 m into a forest and that nest parasitism is reduced when woodland birds nest away from forest edges. The reserve you manage extends about 6,000 m from east to west and 1,000 m from north to south. It is surrounded by a deforested pasture on the west, an agricultural field for 500 m in the southwest corner, and intact forest everywhere else. You must build a road, 10 m by 1,000 m, from the north to the south side of the reserve and construct a maintenance building that will take up 100 m<sup>2</sup> in the reserve. Draw a map of the reserve, showing where you would put the road and the building to minimize cowbird intrusion along edges. Explain your reasoning.
9. **FOCUS ON EVOLUTION**  
One factor favoring rapid population growth by an introduced species is the absence of the predators, parasites, and pathogens that controlled its population in the region where it evolved. In a short essay (100–150 words), explain how evolution by natural selection would influence the rate at which native predators, parasites, and pathogens in a region of introduction attack an introduced species.
10. **FOCUS ON INTERACTIONS**  
In a short essay (100–150 words), identify the factor or factors that you think may ultimately be most important in regulating the human population, and explain your reasoning.

*For selected answers, see Appendix A.*

# Appendix A Answers

**NOTE:** Answers to Scientific Skills Exercises and essay questions are available for instructors in the Instructor Resources area of MasteringBiology.

## Chapter 1

### Figure Questions

**Figure 1.4** Possible answers include the match between the shape of the hummingbird's beak and the flower from which it obtains nectar; the streamlined shape of the bird's body and ability to fold up its legs for efficient flight; the color and appearance of the flower, which attract the hummingbird. **Figure 1.19** The resident mice might have a more reddish coat color. Both beach and mainland mice would probably suffer higher predation rates in the new habitat than in their native environments. However, the dark mainland mice might be expected to stand out less against the background, so might have a lower predation rate than the beach mice.

### Concept Check 1.1

**1.** Examples: A molecule consists of *atoms* bonded together. Each organelle has an orderly arrangement of *molecules*. Photosynthetic plant cells contain *organelles* called chloroplasts. A tissue consists of a group of similar *cells*. Organs such as the heart are constructed from several *tissues*. A complex multicellular organism, such as a plant, has several types of *organs*, such as leaves and roots. A population is a set of *organisms* of the same species. A community consists of *populations* of the various species inhabiting a specific area. An ecosystem consists of a biological *community* along with the nonliving factors important to life, such as air, soil, and water. The biosphere is made up of all of Earth's *ecosystems*. **2.** (a) Organization: Structure and function are correlated. (b) Organization: The cell is an organism's basic unit of structure and function, and Information: Life's processes involve the expression and transmission of genetic information. (c) Energy and Matter: Life requires transfer and transformation of energy, and Interactions: Organisms interact with other organisms and with the physical environment. **3.** Some possible answers: *Organization:* The ability of a human heart to pump blood requires an intact heart; it is not a capability of any of the heart's tissues or cells working alone. *Information:* Human eye color is determined by the combination of genes inherited from the two parents. *Energy and Matter:* A plant, such as a grass, absorbs energy from the sun and transforms it into molecules that act as stored fuel. Animals can eat parts of the plant and use the food for energy to carry out their activities. *Interactions:* A mouse eats food, such as nuts or grasses, and deposits some of the food material as feces and urine. Construction of a nest rearranges the physical environment and may hasten degradation of some of its components. The mouse may also act as food for a predator. *Evolution:* All plants have chloroplasts, indicating their descent from a common ancestor.

### Concept Check 1.2

**1.** An address pinpoints a location by tracking from broader to narrower categories—a state, city, zip, street, and building number. This is analogous to the groups-subordinate-to-groups structure of biological taxonomy. **2.** The naturally occurring heritable variation in a population is “edited” by natural selection because individuals with heritable traits better suited to the environment survive and reproduce more successfully than others. Over time, better-suited individuals persist and their percentage in the population increases, while less suited individuals become less prevalent—a type of population editing. **3.**

### Concept Check 1.3

**1.1** Inductive reasoning derives generalizations from specific cases; deductive reasoning predicts specific outcomes from general premises. **2.** The coloration pattern of the mice. **3.** A scientific theory is usually more general than a hypothesis and substantiated by a much greater amount of evidence. Natural selection is an explanatory idea that applies to all kinds of organisms and is supported by vast amounts of evidence of various kinds. **4.** Science aims to understand natural phenomena and how they work, while technology involves application of scientific discoveries for a particular purpose or to solve a specific problem.

### Summary of Key Concepts Questions

**1.1** Finger movements rely on the coordination of the many structural components of the hand (muscles, nerves, bones, etc.), each of which is composed of elements from lower levels of biological organization (cells, molecules). The development of the hand relies on the genetic information encoded in chromosomes found in cells throughout the body. To power the finger movements that result in a text message, muscle and nerve cells require chemical energy that they transform in powering muscle contraction or in propagating nerve impulses. Finally, all of the anatomical and physiological features that allow the activity of texting are the outcome of a process of natural selection that resulted in the evolution of hands and of the mental facilities for use of language. **1.2** Ancestors of the beach mouse may have exhibited variations in their coat color. Because of the prevalence of visual predators, the better camouflaged (lighter) mice may have survived longer and been able to produce more offspring. Over time,

a higher and higher proportion of individuals in the population would have had the adaptation of lighter fur that acted to camouflage the mouse. **1.3** Inductive reasoning is used in forming hypotheses, while deductive reasoning leads to predictions that are used to test hypotheses.

### Test Your Understanding

**1. b 2. c 3. b 4. c 5. c 6. d**

**7.** Your figure should show the following: (1) For the biosphere, Earth with an arrow coming out of a tropical ocean; (2) for the ecosystem, a distant view of a coral reef; (3) for the community, a collection of reef animals and algae, with corals, fishes, some seaweed, and any other organisms you can think of; (4) for the population, a group of fish of the same species; (5) for the organism, one fish from your population; (6) for the organ, the fish's stomach, and for the organ system, the whole digestive tract (see Chapter 33 for help); (7) for a tissue, a group of similar cells from the stomach; (8) for a cell, one cell from the tissue, showing its nucleus and a few other organelles; (9) for an organelle, the nucleus, where most of the cell's DNA is located; and (10) for a molecule, a DNA double helix. Your sketches can be very rough!

## Chapter 2

### Figure Questions

**Figure 2.6** Atomic number = 12; 12 protons, 12 electrons; 3 electron shells; 2 valence electrons. **Figure 2.15** The plant is submerged in water ( $H_2O$ ), in which the  $CO_2$  is dissolved. The sun's energy is used to make sugar, which is found in the plant and can act as food for the plant itself, as well as for animals that eat the plant. The oxygen ( $O_2$ ) is present in the bubbles. **Figure 2.16** One possible answer:

**Figure 2.20** Without hydrogen bonds, water would behave like other small molecules, and the solid phase (ice) would be denser than liquid water. The ice would sink to the bottom and would no longer insulate the body of water. All the water would eventually freeze because the average annual temperature at the South Pole is  $-50^\circ C$ . The shrimp could not survive. **Figure 2.21** Heating the solution would cause the water to evaporate faster than it is evaporating at room temperature. At a certain point, there wouldn't be enough water molecules to dissolve the salt ions. The salt would start coming out of solution and re-forming crystals. Eventually, all the water would evaporate, leaving behind a pile of salt like the original pile. **Figure 2.24** By causing the loss of coral reefs, a decrease in the ocean's carbonate concentration would have a ripple effect on noncalcifying organisms. Some of these organisms depend on the reef structure for protection, while others feed on species associated with reefs.

### Concept Check 2.1

**1.** Yes, because an organism requires trace elements, even though only in small amounts. **2.** A person with an iron deficiency will probably show fatigue and other effects of a low oxygen level in the blood. (The condition is called anemia and can also result from too few red blood cells or abnormal hemoglobin.)

### Concept Check 2.2

**1.**  $^{15}N$  **2.** 9 electrons; two electron shells; 1 electron is needed to fill the valence shell. **3.** The elements in a row all have the same number of electron shells. In a column, all the elements have the same number of electrons in their valence shells.

### Concept Check 2.3

**1.** Each carbon atom has only three covalent bonds instead of the required four. **2.** The attraction between oppositely charged ions, forming ionic bonds. **3.** If you could synthesize molecules that mimic these shapes, you might be able to treat diseases or conditions caused by the inability of affected individuals to synthesize such molecules.

### Concept Check 2.4

**1.** At equilibrium, the forward and reverse reactions occur at the same rate. **2.**  $C_6H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O + \text{Energy}$ . Glucose and oxygen react to form carbon dioxide and water, releasing energy. We breathe in oxygen because we need it for this reaction to occur, and we breathe out carbon dioxide because it is a product of this reaction. (This reaction is called cellular respiration, and you will learn more about it in Chapter 7.)

**Concept Check 2.5**

1. Hydrogen bonds hold neighboring water molecules together. This cohesion helps the chain of water molecules move upward against gravity in water-conducting cells as water evaporates from the leaves. Adhesion between water molecules and the walls of the water-conducting cells also helps counter gravity. 2. As water freezes, it expands because water molecules move farther apart in forming ice crystals. When there is water in a crevice of a boulder, expansion due to freezing may crack the boulder. 3. A liter of blood would contain  $7.8 \times 10^{13}$  molecules of ghrelin ( $1.3 \times 10^{-10}$  moles per liter  $\times 6.02 \times 10^{23}$  molecules per mole). 4.  $10^5$ , or 100,000. 5. The covalent bonds of water molecules would not be polar, and water molecules would not form hydrogen bonds with each other.

**Summary of Key Concepts Questions**

2.1 Iodine (part of a thyroid hormone) and iron (part of hemoglobin in blood) are both trace elements, required in minute quantities. Calcium and phosphorus (components of bones and teeth) are needed by the body in much greater quantities.

2.2

Both neon and argon are unreactive because they have completed valence shells. They do not have unpaired electrons that could participate in chemical bonds. 2.3 Electrons are shared equally between the two atoms in a nonpolar covalent bond. In a polar covalent bond, the electrons are drawn closer to the more electronegative atom. In the formation of ions, one or more electrons are completely transferred from one atom to a much more electronegative atom. 2.4 The concentration of products would increase as the added reactants were converted to products. Eventually, an equilibrium would again be reached in which the forward and reverse reactions were proceeding at the same rate and the relative concentrations of reactants and products returned to where they were before the addition of more reactants. 2.5 The polar covalent bonds of a water molecule allow it to form hydrogen bonds with other water molecules and other polar molecules as well. The sticking together of water molecules, called cohesion, and the sticking of water to other molecules, called adhesion, help water rise from the roots of plants to their leaves, among other biological benefits. Hydrogen bonding between water molecules is responsible for water's high specific heat (resistance to temperature change), which helps moderate temperature on Earth. Hydrogen bonding is also responsible for water's high heat of vaporization, which makes water useful for evaporative cooling. A lattice of stable hydrogen bonds in ice makes it less dense than liquid water, so that it floats, creating an insulating surface on bodies of water that allows organisms to live underneath. Finally, the polarity of water molecules resulting from their polar covalent bonds makes water an excellent solvent; polar and ionic atoms and molecules that are needed for life can exist in a dissolved state and participate in chemical reactions.

**Test Your Understanding**

1. b   2. d   3. d   4. e   5. c   6. c   7. e   8. e  
9.

**Chapter 3****Figure Questions**  
**Figure 3.8**

Note that the oxygen on carbon 5 lost its proton and that the oxygen on carbon 2, which used to be the carbonyl oxygen, gained a proton. Four carbons are in the fructose ring, and two are not. (The latter two carbons are attached to carbons 2 and 5, which are in the ring.) The fructose ring differs from the glucose ring, which has five carbons in the ring and one that is not. (Note that the orientation of this fructose molecule is flipped relative to that of the one in Figure 3.9.)

**Figure 3.9****Figure 3.14****Figure 3.18**

**Figure 3.22** The R group of glutamic acid is acidic and hydrophilic, whereas that of valine is nonpolar and hydrophobic. Therefore, it is unlikely that valine can participate in the same intramolecular interactions that glutamic acid can. A change in these interactions would be expected to cause a disruption of molecular structure. **Figure 3.24** The spirals are  $\alpha$  helices.

**Concept Check 3.1**

1. Both consist largely of hydrocarbon chains. 2. It has both an amino group ( $-\text{NH}_2$ ), which makes it an amine, and a carboxyl group ( $-\text{COOH}$ ), which makes it a carboxylic acid. 3. A chemical group that can act as a base (by picking up  $\text{H}^+$ ) has been replaced with a group that can act as an acid, increasing the acidic properties of the molecule. The shape of the molecule would also change, likely changing the molecules with which it can interact.

**Concept Check 3.2**

1. Nine, with one water molecule required to hydrolyze each connected pair of monomers. 2. The amino acids in the fish protein must be released in hydrolysis reactions and incorporated into other proteins in dehydration reactions.

**Concept Check 3.3**

1.  $\text{C}_3\text{H}_6\text{O}_3$ . 2.  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ . 3. The antibiotic treatment is likely to have killed the cellulose-digesting prokaryotes in the cow's stomach. The absence of these prokaryotes would hamper the cow's ability to obtain energy from food and could lead to weight loss and possibly death. Thus, prokaryotic species are reintroduced, in appropriate combinations, in the gut culture given to treated cows.

**Concept Check 3.4**

1. Both have a glycerol molecule attached to fatty acids. The glycerol of a fat has three fatty acids attached, whereas the glycerol of a phospholipid is attached to two fatty acids and one phosphate group. 2. Human sex hormones are steroids, a type of hydrophobic compound. 3. The oil droplet membrane could consist of a single layer of phospholipids rather than a bilayer, because an arrangement in which the hydrophobic tails of the membrane phospholipids were in contact with the hydrocarbon regions of the oil molecules would be more stable.

**Concept Check 3.5**

1. The function of a protein is a consequence of its specific shape, which is lost when a protein becomes denatured. 2. Secondary structure involves hydrogen bonds between atoms of the polypeptide backbone. Tertiary structure involves interactions between atoms of the side chains of the amino acid monomers. 3. These are all nonpolar amino acids, so you would expect this region to be located in the interior of the folded polypeptide, where it would not contact the aqueous environment inside the cell.

## Concept Check 3.6

1.

2.

3. a.

b.

## Summary of Key Concepts Questions

**3.1** The methyl group is nonpolar and not reactive. The other six groups are called functional groups and can participate in chemical reactions. Except for the sulfhydryl group, these functional groups are hydrophilic; they increase the solubility of organic compounds in water. **3.2** The polymers of carbohydrates, proteins, and nucleic acids are built from three different types of monomers: monosaccharides, amino acids, and nucleotides, respectively. **3.3** Both starch and cellulose are polymers of glucose, but the glucose monomers are in the  $\alpha$  configuration in starch and the  $\beta$  configuration in cellulose. The glycosidic linkages thus have different geometries, giving the polymers different shapes and thus different properties. Starch is an energy-storage compound in plants; cellulose is a structural component of plant cell walls. Humans can hydrolyze starch to provide energy but cannot hydrolyze cellulose. Cellulose aids in the passage of food through the digestive tract. **3.4** Lipids are not polymers because they do not exist as a chain of linked monomers. They are not considered macromolecules because they do not reach the giant size of many polysaccharides, proteins, and nucleic acids. **3.5** A polypeptide, which may consist of hundreds of amino acids in a specific sequence (primary structure), has regions of coils and pleats (secondary structure), which are then folded into irregular contortions (tertiary structure) and may be non-covalently associated with other polypeptides (quaternary structure). The linear order of amino acids, with the varying properties of their side chains (R groups), determines what secondary and tertiary structures will form to produce a protein. The resulting unique three-dimensional shapes of proteins are key to their specific and diverse functions. **3.6** The complementary base pairing of the two strands of DNA makes possible the precise replication of DNA every time a cell divides, ensuring that genetic information is faithfully transmitted. In some types of RNA, complementary base pairing enables RNA molecules to assume specific three-dimensional shapes that facilitate diverse functions.

## Test Your Understanding

1. b 2. d 3. d 4. b 5. a 6. d 7. c

	Monomers or Components	Polymer or larger molecule	Type of linkage
Carbohydrates	Monosaccharides	Polysaccharides	Glycosidic linkages
Lipids	Fatty acids	Triacylglycerols	Ester linkages
Proteins	Amino acids	Polypeptides	Peptide bonds
Nucleic acids	Nucleotides	Polynucleotides	Phosphodiester linkages

## Chapter 4

### Figure Questions

**Figure 4.5** A phospholipid is a lipid, consisting of a glycerol molecule joined to two fatty acids and one phosphate group. Together, the glycerol and phosphate end of the phospholipid form the "head," which is hydrophilic, while the hydrocarbon chains on the fatty acids form hydrophobic "tails." The presence in a single molecule of both a hydrophilic and a hydrophobic region makes the molecule ideal as the main building block of a membrane. **Figure 4.8** The DNA in a chromosome dictates synthesis of a messenger RNA (mRNA) molecule, which then moves out to the cytoplasm. There, the information is used for the production, on ribosomes, of proteins that carry out cellular functions. **Figure 4.9** Any of the bound ribosomes (attached to the endoplasmic reticulum) could be circled, because any could be making a protein that will be secreted.

### Figure 4.22

Each centriole has 9 sets of 3 microtubules, so the entire centrosome (two centrioles) has 54 microtubules. Each microtubule consists of a helical array of tubulin dimers (as shown in Table 4.1).

### Figure 4.23

The two central microtubules terminate above the basal body, so they aren't present at the level of the cross section through the basal body, indicated by the lower red rectangle in (a).

### Concept Check 4.1

**1.** Stains used for light microscopy are colored molecules that bind to cell components, affecting the light passing through, while stains used for electron microscopy involve heavy metals that affect the beams of electrons. **2.** (a) Light microscope, (b) scanning electron microscope

### Concept Check 4.2

**1.** See Figure 4.7.

**2.**

This cell would have the same volume as the large cell in column 2 and the collection of small cells in column 3 but proportionally more surface area than that in column 2 and less than that in column 3. Thus, the surface-to-volume ratio should be greater

than 1.2 but less than 6. To obtain the surface area, add the area of the six sides (the top, bottom, sides, and ends):  $125 + 125 + 125 + 125 + 1 + 1 = 502$ . The surface-to-volume ratio equals 502 divided by a volume of 125, or 4.0.

#### Concept Check 4.3

**1.** Ribosomes in the cytoplasm translate the genetic message, carried from the DNA in the nucleus by mRNA, into a polypeptide chain. **2.** Nucleoli consist of DNA and the ribosomal RNA (rRNA) made according to its instructions, as well as proteins imported from the cytoplasm. Together, the rRNA and proteins are assembled into large and small ribosomal subunits. (These are exported through nuclear pores to the cytoplasm, where they will participate in polypeptide synthesis.) **3.** Each chromosome consists of one long DNA molecule attached to numerous protein molecules, a combination called chromatin. The chromosomes are “condensing” as their thin strands of chromatin coil up to form shorter, thicker structures.

#### Concept Check 4.4

**1.** The primary distinction between rough and smooth ER is the presence of bound ribosomes on the rough ER. Both types of ER make phospholipids, but membrane proteins and secretory proteins are all produced on the ribosomes of the rough ER. The smooth ER also functions in detoxification, carbohydrate metabolism, and storage of calcium ions. **2.** Transport vesicles move membranes and substances they enclose between other components of the endomembrane system. **3.** The mRNA is synthesized in the nucleus and then passes out through a nuclear pore to be translated on a bound ribosome, attached to the rough ER. The protein is synthesized into the lumen of the ER and perhaps modified there. A transport vesicle carries the protein to the Golgi apparatus. After further modification in the Golgi, another transport vesicle carries it back to the ER, where it will perform its cellular function.

#### Concept Check 4.5

**1.** Both organelles are involved in energy transformation, mitochondria in cellular respiration and chloroplasts in photosynthesis. They both have multiple membranes that separate their interiors into compartments. In both organelles, the innermost membranes—cristae, or infoldings of the inner membrane, in mitochondria, and the thylakoid membranes in chloroplasts—have large surface areas with embedded enzymes that carry out their main functions. **2.** Yes. Plant cells are able to make their own sugar by photosynthesis, but mitochondria in these eukaryotic cells are the organelles that are able to generate energy from sugars, a function required in all cells. **3.** Mitochondria and chloroplasts are not derived from the ER, nor are they connected physically or via transport vesicles to organelles of the endomembrane system. Mitochondria and chloroplasts are structurally quite different from vesicles derived from the ER, which are bounded by a single membrane.

#### Concept Check 4.6

**1.** Dynein arms, powered by ATP, move neighboring doublets of microtubules relative to each other. Because they are anchored within the organelle and with respect to one another, the doublets bend instead of sliding past each other. Synchronized bending of the nine microtubule doublets brings about bending of both structures. **2.** Such individuals have defects in the microtubule-based movement of cilia and flagella. Thus, the sperm can't move because of malfunctioning or nonexistent flagella, and the airways are compromised because cilia that line the trachea malfunction or don't exist, and so mucus can't be cleared from the lungs.

#### Concept Check 4.7

**1.** One obvious difference is the presence of direct cytoplasmic connections between cells of plants (plasmodesmata) and animals (gap junctions). These connections result in the cytoplasm being continuous between adjacent cells. **2.** The cell would not be able to function properly and would probably soon die, as the cell wall or ECM must be permeable to allow the exchange of matter between the cell and its external environment. Molecules involved in energy production and use must be allowed entry, as well as those that provide information about the cell's environment. Other molecules, such as products synthesized by the cell for export and the by-products of cellular respiration, must be allowed to exit. **3.** The parts of the protein that face aqueous regions would be expected to have polar or charged (hydrophilic) amino acids, while the parts that go through the membrane would be expected to have nonpolar (hydrophobic) amino acids. You would predict polar or charged amino acids at each end (tail), in the region of the cytoplasmic loop, and in the regions of the two extracellular loops. You would predict nonpolar amino acids in the four regions inside the membrane between the tails and loops.

#### Summary of Key Concepts Questions

**4.1** Both light and electron microscopy allow cells to be studied visually, thus helping us understand internal cellular structure and the arrangement of cell components. Cell fractionation techniques separate out different groups of cell components, which can then be analyzed biochemically to determine their function. Performing microscopy on cell fractions helps to correlate the biochemical function of the cell with the cell component responsible. **4.2** The separation of different functions in different organelles has several advantages. Reactants and enzymes can be concentrated in one area instead of spread throughout the cell. Reactions that require specific conditions, such as a lower pH, can be compartmentalized. And enzymes for specific reactions may be embedded in the membranes that enclose or partition an organelle. **4.3** The nucleus contains the genetic material of the cell in the form of DNA, which codes for messenger RNA, which in turn provides instructions for the synthesis of proteins (including the proteins that make up part of the ribosomes). DNA also codes for ribosomal RNA, which is combined with proteins in the nucleolus into the subunits of ribosomes. Within the cytoplasm, ribosomes join with mRNA to build polypeptides, using the genetic information in the mRNA. **4.4** Transport vesicles move proteins and membrane synthesized by the rough ER to the Golgi for further processing and then to the plasma membrane, lysosomes, or other locations in the cell, including back to the ER. **4.5** According to the endosymbiont theory, mitochondria originated from an oxygen-using prokaryotic cell that was engulfed by an ancestral eukaryotic

cell. Over time, the host and endosymbiont evolved into a single unicellular organism. Chloroplasts originated when at least one of these mitochondria-containing eukaryotic cells engulfed and then retained a photosynthetic prokaryote. **4.6** Inside the cell, motor proteins interact with components of the cytoskeleton to move cellular parts. Motor proteins may “walk” vesicles along microtubules. The movement of cytoplasm within a cell involves interactions of the motor protein myosin and microfilaments (actin filaments). Whole cells can be moved by the rapid bending of flagella or cilia, which is caused by the motor-protein-powered sliding of microtubules within these structures. Some cells move by amoeboid movement, which involves interactions of microfilaments with myosin. Interactions of motor proteins and microfilaments in muscle cells can propel multicellular organisms. **4.7** A plant cell wall is primarily composed of microfibrils of cellulose embedded in other polysaccharides and proteins. The ECM of animal cells is primarily composed of the glycoproteins collagen and fibronectin, as well as other protein fibers. These fibers are embedded in a network of carbohydrate-rich proteoglycans. A plant cell wall provides structural support for the cell and, collectively, for the plant body. In addition to giving support, the ECM of an animal cell allows for communication of environmental changes into the cell.

## Chapter 5

### Figure Questions Figure 5.3

The hydrophilic portion is in contact with an aqueous environment (cytosol or extracellular fluid), and the hydrophobic portion is in contact with the hydrophobic portions of other phospholipids in the interior of the bilayer. **Figure 5.4** You couldn't rule out movement of proteins within membranes of the same species. You might propose that the membrane lipids and proteins from one species weren't able to mingle with those from the other species because of some incompatibility. **Figure 5.7** A transmembrane protein like the dimer in (c) might change its shape upon binding to a particular ECM molecule. The new shape might enable the interior portion of the protein to bind to a second, cytoplasmic protein that would relay the message to the inside of the cell, as shown in (f).

#### Figure 5.8

The protein would contact the extracellular fluid. **Figure 5.10** The orange dye would be evenly distributed throughout the solution on both sides of the membrane. The solution levels would not be affected because the orange dye can diffuse through the membrane and equalize its concentration. Thus, no additional osmosis would take place in either direction. **Figure 5.15** The diamond solutes are moving into the cell (down), and the round solutes are moving out of the cell (up); both are moving against their concentration gradient. **Figure 5.23** The testosterone molecule is hydrophobic and can therefore pass directly through the lipid bilayer of the plasma membrane into the cell. (Hydrophilic molecules cannot do this.) **Figure 5.24** The active form of protein kinase 1

**Concept Check 5.1**

1. They are on the inner side of the transport vesicle membrane. 2. The grasses living in the cooler region would be expected to have more unsaturated fatty acids in their membranes because those fatty acids remain fluid at lower temperatures. The grasses living immediately adjacent to the hot springs would be expected to have more saturated fatty acids, which would allow the fatty acids to “stack” more closely, making the membranes less fluid and therefore helping them to stay intact at higher temperatures. (Cholesterol could not moderate the effects of temperature on membrane fluidity in this case because it is not found in appreciable quantities in plant cell membranes.)

**Concept Check 5.2**

1.  $O_2$  and  $CO_2$  are both small, nonpolar molecules that can easily pass through the hydrophobic interior of a membrane. 2. Water is a polar molecule, so it cannot pass very rapidly through the hydrophobic region in the middle of a phospholipid bilayer. 3. The hydronium ion is charged, while glycerol is not. Charge is probably more significant than size as a basis for exclusion by the aquaporin channel.

**Concept Check 5.3**

1.  $CO_2$  is a nonpolar molecule that can diffuse through the plasma membrane. As long as it diffuses away so that the concentration remains low outside the cell, other  $CO_2$  molecules will continue to exit the cell in this way. (This is the opposite of the case for  $O_2$ , described in this section.) 2. The water is hypotonic to the plant cells, so the plant cells take up water. Thus, the cells of the vegetable remain turgid, and the vegetable (for example, lettuce or spinach) remains crisp and does not wilt. 3. The *Paramecium caudatum*'s contractile vacuole becomes less active. The vacuole pumps out excess water that accumulates in the cell; this accumulation occurs only in a hypotonic environment.

**Concept Check 5.4**

1. The pump uses ATP. To establish a voltage, ions have to be pumped against their gradients, which requires energy. 2. Each ion is being transported against its electrochemical gradient. If either ion were transported down its electrochemical gradient, this process *would* be considered cotransport. 3. The internal environment of a lysosome is acidic, so it has a higher concentration of  $H^+$  than does the cytosol. Therefore, you might expect the membrane of the lysosome to have a proton pump such as that shown in Figure 5.16 to pump  $H^+$  into the lysosome.

**Concept Check 5.5**

1. Exocytosis. When a transport vesicle fuses with the plasma membrane, the vesicle membrane becomes part of the plasma membrane.

2.

3. The glycoprotein would be synthesized in the ER lumen, move through the Golgi apparatus, and then travel in a vesicle to the plasma membrane, where it would undergo exocytosis and become part of the ECM.

**Concept Check 5.6**

1. The secretion of neurotransmitter molecules at a synapse is an example of local signaling. The electrical signal that travels along a very long nerve cell and is passed to the next nerve cell can be considered an example of long-distance signaling. (Note, however, that local signaling at the synapse between two cells is necessary for the signal to pass from one cell to the next.) 2. Protein phosphatases reverse the effects of the kinases. 3. At each step in a cascade of sequential activations, one molecule or ion may activate numerous molecules functioning in the next step.

**Summary of Key Concepts Questions**

**5.1** Plasma membranes define the cell by separating the cellular components from the external environment. This allows conditions inside cells to be controlled by membrane proteins, which regulate entry and exit of molecules and even cell function (see Figure 5.7). The processes of life can be carried out inside the controlled environment of the cell, so membranes are crucial. In eukaryotes, membranes also function to subdivide the cytoplasm into different compartments where distinct processes can occur, even under differing conditions such as pH. **5.2** Aquaporins are channel proteins that greatly increase the permeability of a membrane to water molecules, which are polar and therefore do not readily diffuse through the hydrophobic interior of the membrane. **5.3** There will be a net diffusion of water out of a cell into a hypertonic solution. The free water concentration is higher inside the cell than in the solution (where many water molecules are not free, but are clustered around the higher concentration of solute particles). **5.4** One of the solutes moved by the cotransporter is actively transported against its concentration gradient. The energy for this transport comes from the concentration gradient of the other solute, which was established by an electrogenic pump that used energy (usually provided by ATP) to transport the other solute across the membrane. **5.5** Receptor-mediated endocytosis. In this process, specific molecules bind to receptors on the plasma membrane in a region where a coated pit develops. The cell can acquire bulk quantities of those specific molecules when the coated pit forms a vesicle and carries the bound molecules into the cell. **5.6** A cell is able to respond to a hormone only if it has a receptor protein on the cell surface or inside the cell that can bind to the hormone. The response to a hormone depends on the specific cellular activity that a signal transduction pathway triggers within the cell. The response can vary for different types of cells.

**Test Your Understanding**

1. b 2. a 3. c 4. b 5. d 6. b

**Chapter 6****Figure Questions**

**Figure 6.9** The R group of glutamine (Gln, or Q) is like that of glutamic acid (Glu, or E), except it has an amino group ( $-NH_2$ ) in place of a hydroxyl group ( $-OH$ ), so Gln is drawn as a Glu with an attached  $-NH_2$ .

**Figure 6.12****Figure 6.16****Concept Check 6.1**

1. The second law is the trend toward randomization, or increasing entropy. When the concentrations of a substance on both sides of a membrane are equal, the distribution is more random than when they are unequal. Diffusion of a substance to a region where it is initially less concentrated increases entropy, making it an energetically favorable (spontaneous) process as described by the second law. (This explains the process seen in Figure 5.9.) 2. The apple has potential energy in its position hanging on the tree, and the sugars and other nutrients it contains have chemical energy. The apple has kinetic energy as it falls from the tree to the ground. Finally, when the apple is digested and its molecules broken down, some of the chemical energy is used to do work, and the rest is lost as thermal energy.

**Concept Check 6.2**

1. Cellular respiration is a spontaneous and exergonic process. The energy released from glucose is used to do work in the cell or is lost as heat. 2. The reaction is exergonic because it releases energy—in this case, in the form of light. (This is a nonbiological version of the bioluminescence seen in Figure 6.1.)

**Concept Check 6.3**

1. ATP usually transfers energy to endergonic processes by phosphorylating (adding phosphate groups to) other molecules. (Exergonic processes phosphorylate ADP to regenerate ATP.) 2. A set of coupled reactions can transform the first combination into the second. Since this is an exergonic process overall,  $\Delta G$  is negative and the first combination must have more free energy (see Figure 6.9). 3. Active transport: The solute is being transported against its concentration gradient, which requires energy, provided by ATP hydrolysis.

**Concept Check 6.4**

1. A spontaneous reaction is a reaction that is exergonic. However, if it has a high activation energy that is rarely attained, the rate of the reaction may be low. 2. Only the specific substrate(s) will fit properly into the active site of an enzyme, the part of the enzyme that carries out catalysis. 3. In the presence of malonate, increase the concentration of the normal substrate (succinate) and see whether the rate of reaction increases. If it does, malonate is a competitive inhibitor.

**Concept Check 6.5**

1. The activator binds in such a way that it stabilizes the active form of an enzyme, whereas the inhibitor stabilizes the inactive form.

**Summary of Key Concepts Questions**

**6.1** The process of “ordering” a cell’s structure is accompanied by an increase in the entropy, or disorder, of the universe. For example, an animal cell takes in highly ordered organic molecules as the source of matter and energy used to build and maintain its structures. In the same process, however, the cell releases heat and the simple molecules of carbon dioxide and water to the surroundings. The increase in entropy of the latter process offsets the entropy decrease in the former. **6.2** Spontaneous reactions supply the energy to perform cellular work. **6.3** The free energy released from the hydrolysis of ATP may drive endergonic reactions through the transfer of a phosphate group to a reactant molecule, forming a more reactive phosphorylated intermediate. ATP hydrolysis also powers the mechanical and transport work of a cell, often by powering shape changes in the relevant motor proteins. Cellular respiration, the catabolic breakdown of glucose, provides the energy for the endergonic regeneration of ATP from ADP and  $P_i$ . **6.4** Activation energy barriers prevent the complex molecules of the cell, which are rich in free energy, from spontaneously breaking down to less ordered, more stable molecules. Enzymes permit a regulated metabolism by binding to specific substrates and forming enzyme-substrate complexes that selectively lower the  $E_A$  for the chemical reactions in a cell. **6.5** A cell tightly regulates its metabolic pathways in response to fluctuating needs for energy and materials. The binding of activators or inhibitors to regulatory sites on allosteric enzymes stabilizes either the active or

inactive form of the subunits. For example, the binding of ATP to a catabolic enzyme in a cell with excess ATP would inhibit that pathway. Such types of feedback inhibition preserve chemical resources within a cell. If ATP supplies are depleted, binding of ADP to the regulatory site of catabolic enzymes will activate that pathway.

### Test Your Understanding

1. b 2. c 3. b 4. a 5. c 6. e 7. c

8.

- A. The substrate molecules are entering the cells, so no product is made yet.  
B. There is sufficient substrate, so the reaction is proceeding at a maximum rate.  
C. As the substrate is used up, the rate decreases (the slope is less steep).  
D. The line is flat because no new substrate remains and thus no new product appears.

## Chapter 7

### Figure Questions

**Figure 7.7** Because there is no external source of energy for the reaction, it must be exergonic, and the reactants must be at a higher energy level than the products.

**Figure 7.14** At first, some ATP could be made, since electron transport could proceed as far as complex III, and a small  $H^+$  gradient could be built up. Soon, however, no more electrons could be passed to complex III because it could not be reoxidized by passing its electrons to complex IV. **Figure 7.15** First, there are 2 NADH from the oxidation of pyruvate plus 6 NADH from the citric acid cycle (CAC);  $8 \text{ NADH} \times 2.5 \text{ ATP/NADH} = 20 \text{ ATP}$ . Second, there are 2  $FADH_2$  from the CAC;  $2 \text{ FADH}_2 \times 1.5 \text{ ATP/FADH}_2 = 3 \text{ ATP}$ . Third, the 2 NADH from glycolysis enter the mitochondrion through one of two types of shuttle. They pass their electrons either to 2 FAD, which become  $FADH_2$  and result in 3 ATP, or to 2  $NAD^+$ , which become NADH and result in 5 ATP. Thus,  $20 + 3 + 3 = 26 \text{ ATP}$  or  $20 + 3 + 5 = 28 \text{ ATP}$  from all NADH and  $FADH_2$ .

### Concept Check 7.1

- Both processes include glycolysis, the citric acid cycle, and oxidative phosphorylation. In aerobic respiration, the final electron acceptor is molecular oxygen ( $O_2$ ); in anaerobic respiration, the final electron acceptor is a different substance.
- Substrate-level phosphorylation, which occurs during glycolysis and the citric acid cycle, involves the direct transfer of a phosphate group from an organic substrate to ADP by an enzyme. Oxidative phosphorylation occurs during the third stage of cellular respiration, which is called oxidative phosphorylation. In this process, the synthesis of ATP from ADP and inorganic phosphate ( $P_i$ ) is powered by the redox reactions of the electron transport chain.
- $C_4H_6O_5$  would be oxidized, and  $NAD^+$  would be reduced.

### Concept Check 7.2

- $NAD^+$  acts as the oxidizing agent in step 6, accepting electrons from glyceraldehyde 3-phosphate, which thus acts as the reducing agent.

### Concept Check 7.3

- NADH and  $FADH_2$ ; they will donate electrons to the electron transport chain.
- $CO_2$  is released from the pyruvate that is the end product of glycolysis, and  $CO_2$  is also released during the citric acid cycle.

### Concept Check 7.4

- Oxidative phosphorylation would eventually stop entirely, resulting in no ATP production by this process. Without oxygen to “pull” electrons down the electron transport chain,  $H^+$  would not be pumped into the mitochondrion’s intermembrane space and chemiosmosis would not occur.
- Decreasing the pH means the addition of  $H^+$ . This would establish a proton gradient even without the function of the electron transport chain, and we would expect ATP synthase to function and synthesize ATP. (In fact, it was experiments like this that provided support for chemiosmosis as an energy-coupling mechanism.)
- One of the components of the electron transport chain, ubiquinone (Q), must be able to diffuse within the membrane. It could not do so if the membrane were locked rigidly into place.

### Concept Check 7.5

- A derivative of pyruvate, such as acetaldehyde during alcohol fermentation, or pyruvate itself during lactic acid fermentation; oxygen during aerobic respiration
- The cell would need to consume glucose at a rate about 16 times the consumption rate in the aerobic environment (2 ATP are generated by fermentation versus up to 32 ATP by cellular respiration).

### Concept Check 7.6

- The fat is much more reduced; it has many  $-CH_2-$  units, and in all these bonds the electrons are equally shared. The electrons present in a carbohydrate molecule are already somewhat oxidized (shared unequally in bonds), as quite a few of them are bound to oxygen.
- When you consume more food than necessary for metabolic processes, your body synthesizes fat as a way of storing energy for later use.
- When oxygen is present, the fatty acid chains containing most of the energy of a fat

are oxidized and fed into the citric acid cycle and the electron transport chain. During intense exercise, however, oxygen is scarce in muscle cells, so ATP must be generated by glycolysis alone. A very small part of the fat molecule, the glycerol backbone, can be oxidized via glycolysis, but the amount of energy released by this portion is insignificant compared with that released by the fatty acid chains. (This is why moderate exercise, staying below 70% maximum heart rate, is better for burning fat—because enough oxygen remains available to the muscles.)

### Summary of Key Concepts Questions

**7.1** Most of the ATP produced in cellular respiration comes from oxidative phosphorylation, in which the energy released from redox reactions in an electron transport chain is used to produce ATP. In substrate-level phosphorylation, an enzyme directly transfers a phosphate group to ADP from an intermediate substrate. All ATP production in glycolysis occurs by substrate-level phosphorylation; this form of ATP production also occurs at one step in the citric acid cycle. **7.2** The oxidation of the three-carbon sugar glyceraldehyde 3-phosphate yields energy. In this oxidation, electrons and  $H^+$  are transferred to  $NAD^+$ , forming NADH, and a phosphate group is attached to the oxidized substrate. ATP is then formed by substrate-level phosphorylation when this phosphate group is transferred to ADP. **7.3** The release of six molecules of  $CO_2$  represents the complete oxidation of glucose. During the processing of two pyruvates to acetyl CoA, the fully oxidized carboxyl group ( $-COO^-$ ) is given off as  $CO_2$ . The remaining four carbons are released as  $CO_2$  in the citric acid cycle as citrate is oxidized back to oxaloacetate. **7.4** The flow of  $H^+$  through the ATP synthase complex causes the rotor and attached rod to rotate, exposing catalytic sites in the knob portion that produce ATP from ADP and  $P_i$ . ATP synthases are found in the inner mitochondrial membrane, the plasma membrane of prokaryotes, and membranes within chloroplasts. **7.5** Anaerobic respiration yields more ATP. The 2 ATP produced by substrate-level phosphorylation in glycolysis represent the total energy yield of fermentation. NADH passes its “high-energy” electrons to pyruvate or a derivative of pyruvate, recycling  $NAD^+$  and allowing glycolysis to continue. Anaerobic respiration uses an electron transport chain to capture the energy of the electrons in NADH via a series of redox reactions; ultimately, the electrons are transferred to an electronegative molecule other than oxygen. Also, additional molecules of NADH are produced in anaerobic respiration as pyruvate is oxidized. **7.6** The ATP produced by catabolic pathways is used to drive anabolic pathways. Also, many of the intermediates of glycolysis and the citric acid cycle are used in the biosynthesis of a cell’s molecules.

### Test Your Understanding

1. d 2. c 3. c 4. a 5. e 6. a 7. b

8.

## Chapter 8

### Figure Questions

**Figure 8.9** Red, but not violet-blue, wavelengths would pass through the filter, so the bacteria would not congregate where the violet-blue light normally comes through. Therefore, the left “peak” of bacteria would not be present, but the right peak would be observed because the red wavelengths passing through the filter would be used for photosynthesis.

### Figure 8.17

Three carbon atoms enter the cycle, one by one, as individual  $CO_2$  molecules and leave the cycle in one three-carbon molecule (G3P) per three turns of the cycle.

### Concept Check 8.1

- $CO_2$  enters the leaves via stomata, and water enters the plant via roots and is carried to the leaves through veins.
- Using  $^{18}O$ , a heavy isotope of oxygen, as a label, researchers were able to confirm van Niel’s hypothesis that the oxygen produced during photosynthesis originates in water, not in carbon dioxide.
- The light reactions could not keep producing NADPH and ATP without the  $NADP^+$ , ADP, and  $P_i$  that the Calvin cycle generates. The two cycles are interdependent.

### Concept Check 8.2

1. Green, because green light is mostly transmitted and reflected—not absorbed—by photosynthetic pigments. 2. Water ( $\text{H}_2\text{O}$ ) is the initial electron donor;  $\text{NADP}^+$  accepts electrons at the end of the electron transport chain, becoming reduced to NADPH. 3. The rate of ATP synthesis would slow and eventually stop. Because the added compound would not allow a proton gradient to build up across the membrane, ATP synthase could not catalyze ATP production.

### Concept Check 8.3

1. The amount of energy and reducing power required to form a molecule determines the amount of potential energy that molecule stores. Glucose is a valuable energy source because it is highly reduced, storing lots of potential energy in its electrons. To reduce  $\text{CO}_2$  to glucose, a large amount of energy and reducing power are required in the form of large numbers of ATP and NADPH molecules, respectively. 2. The light reactions require ADP and  $\text{NADP}^+$ , which would not be formed in sufficient quantities from ATP and NADPH if the Calvin cycle stopped. 3. Photorespiration decreases photosynthetic output by adding oxygen, instead of carbon dioxide, to the Calvin cycle.

### Summary of Key Concepts Questions

8.1  $\text{CO}_2$  and  $\text{H}_2\text{O}$  are the products of respiration; they are the reactants in photosynthesis. In respiration, glucose is oxidized to  $\text{CO}_2$  as electrons are passed through an electron transfer chain from glucose to  $\text{O}_2$ , producing  $\text{H}_2\text{O}$ . In photosynthesis,  $\text{H}_2\text{O}$  is the source of electrons, which are energized by light, temporarily stored in NADPH, and used to reduce  $\text{CO}_2$  to carbohydrate. 8.2 The action spectrum of photosynthesis shows that some wavelengths of light that are not absorbed by chlorophyll *a* are still effective at promoting photosynthesis. The light-harvesting complexes of photosystems contain accessory pigments, such as chlorophyll *b* and carotenoids, which absorb different wavelengths and pass the energy to chlorophyll *a*, broadening the spectrum of light useful for photosynthesis.

8.3

In the reduction phase of the Calvin cycle, ATP phosphorylates a three-carbon compound, and NADPH then reduces this compound to G3P. ATP is also used in the regeneration phase, when five molecules of G3P are converted to three molecules of the five-carbon compound RuBP. Rubisco catalyzes the first step of carbon fixation—the addition of  $\text{CO}_2$  to RuBP.

### Test Your Understanding

1. d 2. b 3. c 4. d 5. c 6. b 7. d 8. 6; 18; 12 9.

The ATP would end up outside the thylakoid. The thylakoids were able to make ATP in the dark because the researchers set up an artificial proton concentration gradient across the thylakoid membrane; thus, the light reactions were not necessary to establish the  $\text{H}^+$  gradient required for ATP synthesis by ATP synthase.

## Chapter 9

### Figure Questions

Figure 9.4

Circling the other chromatid instead would also be correct. **Figure 9.5** The chromosome has four chromatid arms. **Figure 9.7** 12; 2; 2; 1 **Figure 9.8**

**Figure 9.9** The mark would have moved toward the nearer pole. The lengths of fluorescent microtubules between that pole and the mark would have decreased, while the lengths between the chromosomes and the mark would have remained the same.

**Figure 9.14** In both cases, the  $\text{G}_1$  nucleus would have remained in  $\text{G}_1$  until the time it normally would have entered the S phase. Chromosome condensation and spindle formation would not have occurred until the S and  $\text{G}_2$  phases had been completed.

**Figure 9.16** The cell would divide under conditions where it was inappropriate to do so. If the daughter cells and their descendants also ignored the checkpoint and divided, there would soon be an abnormal mass of cells. (This type of inappropriate cell division can contribute to the development of cancer.) **Figure 9.17** The cells in the vessel with PDGF would not be able to respond to the growth factor signal and thus would not divide. The culture would resemble the culture without the added PDGF.

### Concept Check 9.1

1. 2 2. 39; 39; 78

### Concept Check 9.2

1. 6 chromosomes, duplicated; 12 chromatids 2. Following mitosis, cytokinesis results in two genetically identical daughter cells in both plant cells and animal cells. However, the mechanism of dividing the cytoplasm is different in animals and plants. In an animal cell, cytokinesis occurs by cleavage, which divides the parent cell in two with a contractile ring of actin filaments. In a plant cell, a cell plate forms in the middle of the cell and grows until its membrane fuses with the plasma membrane of the parent cell. A new cell wall grows inside the cell plate. 3. They elongate the cell during anaphase. 4. From the end of S phase in interphase through the end of metaphase in mitosis

### Concept Check 9.3

1. The nucleus on the right was originally in the  $\text{G}_1$  phase; therefore, it had not yet duplicated its chromosome. The nucleus on the left was in the M phase, so it had already duplicated its chromosome. 2. Most body cells are in a nondividing state called  $\text{G}_0$ . 3. Both types of tumors consist of abnormal cells, but their characteristics are different. A benign tumor stays at the original site and can usually be surgically removed; the cells have some genetic and cellular changes from normal, non-tumor cells. Cancer cells from a malignant tumor have more significant genetic and cellular changes, can spread from the original site by metastasis, and may impair the functions of one or more organs. 4. The cells might divide even in the absence of PDGF. In addition, they would not stop when the surface of the culture vessel was covered; they would continue to divide, piling on top of one another.

### Summary of Key Concepts Questions

9.1 The DNA of a eukaryotic cell is packaged into structures called *chromosomes*. Each chromosome is a long molecule of DNA, which carries hundreds to thousands of genes, with associated proteins that maintain chromosome structure and help control gene activity. This DNA-protein complex is called *chromatin*. The chromatin of each chromosome is long and thin when the cell is not dividing. Prior to cell division, each chromosome is duplicated, and the resulting sister *chromatids* are attached to each other by proteins at the centromeres and, for many species, all along their lengths (sister chromatid cohesion). 9.2 Chromosomes exist as single DNA molecules in  $\text{G}_1$  of interphase and in anaphase and telophase of mitosis. During S phase, DNA replication produces sister chromatids, which persist during  $\text{G}_2$  of interphase and through prophase, prometaphase, and metaphase of mitosis. 9.3 Checkpoints allow cellular surveillance mechanisms to determine whether the cell is prepared to go to the next stage. Internal and external signals move a cell past these checkpoints. The  $\text{G}_1$  checkpoint, called the "restriction point" in mammalian cells, determines whether a cell will complete the cell cycle and divide or switch into the  $\text{G}_0$  phase. The signals to pass this checkpoint often are external—such as growth factors. Regulation of the cell cycle is carried out by a molecular system, including kinases and proteins called cyclins. The signal to pass the M phase checkpoint is not activated until all chromosomes are attached to kinetochore fibers and are aligned at the metaphase plate. Only then will sister chromatid separation occur.

## Test Your Understanding

Only one cell is indicated for each stage, but other correct answers are also present in this micrograph.

7.

## Chapter 10

## Figure Questions

**Figure 10.4** The haploid number,  $n$ , is 3; a set is always haploid; two sets; two sets.  
**Figure 10.7**

(A short strand of DNA is shown here for simplicity, but each chromosome or chromatid contains a very long coiled and folded DNA molecule.) **Figure 10.8** If the two cells in Figure 9.7 underwent another round of mitosis, each of the four resulting cells would have six chromosomes, while the four cells resulting from meiosis in Figure 10.8 each have three chromosomes. In mitosis, DNA replication (and thus chromosome duplication) precedes each prophase, ensuring that daughter cells have the same number of chromosomes as the parent cell. In meiosis, in contrast, DNA replication occurs only before prophase I (not before prophase II). Thus, in two rounds of mitosis, the chromosomes duplicate twice and divide twice, while in meiosis, the chromosomes duplicate once and divide twice. **Figure 10.9** Yes. Each of the six chromosomes (three per cell) shown in telophase I has one nonrecombinant chromatid and one recombinant chromatid. Therefore, eight possible sets of chromosomes can be generated for the cell on the left and eight for the cell on the right. See metaphase II in Figure 10.8; note that the chromosomes can line up in different arrangements.

## Concept Check 10.1

1. Parents pass genes to their offspring; the genes program cells to make specific enzymes and other proteins, whose cumulative action produces an individual's inherited traits. 2. Such organisms reproduce by mitosis, which generates offspring whose genomes are exact copies of the parent's genome (without taking mutation into account). 3. She should clone it. Cross-breeding it with another plant would generate offspring that have additional variation, which she no longer desires, now that she has obtained her ideal orchid.

## Concept Check 10.2

1. Each of the six chromosomes is duplicated, so each contains two DNA double helices. Therefore, there are 12 DNA molecules in the cell. 2. In meiosis, the chromosome count is reduced from diploid to haploid; the union of two haploid gametes in fertilization restores the diploid chromosome count. 3. The haploid number ( $n$ ) is 7; the diploid number ( $2n$ ) is 14. 4. This organism has the life cycle shown in Figure 10.6c. Therefore, it must be a fungus or a protist, perhaps an alga.

## Concept Check 10.3

1. The chromosomes are similar in that each is composed of two sister chromatids, and the individual chromosomes are positioned similarly at the metaphase plate. The chromosomes differ in that in a mitotically dividing cell, sister chromatids of each chromosome are genetically identical, but in a meiotically dividing cell, sister chromatids are genetically distinct because of crossing over in meiosis I. Moreover, the chromosomes in metaphase of mitosis can be a diploid set or a haploid set, but the chromosomes in metaphase of meiosis II always consist of a haploid set. 2. If crossing over did not occur, the two homologs would not be associated in any way. This might result in incorrect arrangement of homologs during metaphase I and ultimately in formation of gametes with an abnormal number of chromosomes.

## Concept Check 10.4

1. Mutations in a gene lead to the different versions (alleles) of that gene. 2. If the segments of the maternal and paternal chromatids that undergo crossing over are genetically identical and thus have the same two alleles for every gene, then the recombinant chromosomes will be genetically equivalent to the parental chromosomes. Crossing over contributes to genetic variation only when it involves the rearrangement of different alleles.

## Summary of Key Concepts Questions

**10.1** Genes program specific traits, and offspring inherit genes from each parent, accounting for similarities in their appearance to one or the other parent. Humans reproduce sexually, which ensures new combinations of genes (and thus traits) in the offspring. Consequently, the offspring are not clones of their parents (which would be the case if humans reproduced asexually). **10.2** Animals and plants both reproduce sexually, alternating meiosis with fertilization. Both have haploid gametes that unite to form a diploid zygote, which then goes on to divide mitotically, forming a diploid multicellular organism. In animals, haploid cells become gametes and don't undergo mitosis, while in plants, the haploid cells resulting from meiosis undergo mitosis to form a haploid multicellular organism, the gametophyte. This organism then goes on to generate haploid gametes. (In plants such as trees, the gametophyte is quite reduced in size and not obvious to the casual observer.) **10.3** At the end of meiosis I, the two members of a homologous pair end up in different cells, so they cannot pair up and undergo crossing over. **10.4** First, during independent assortment in metaphase I, each pair of homologous chromosomes lines up independent of every other pair at the metaphase plate, so a daughter cell of meiosis I randomly inherits either a maternal or paternal chromosome. Second, due to crossing over, each chromosome is not exclusively maternal or paternal, but includes regions at the ends of the chromatid from a nonsister chromatid (a chromatid of the other homolog). (The nonsister segment can also be in an internal region of the chromatid if a second crossover occurs beyond the first one before the end of the chromatid.) This provides much additional diversity in the form of new combinations of alleles. Third, random fertilization ensures even more variation, since any sperm of a large number containing many possible genetic combinations can fertilize any egg of a similarly large number of possible combinations.

## Test Your Understanding

1. a 2. b 3. d 4. c 5. d

6. (a)

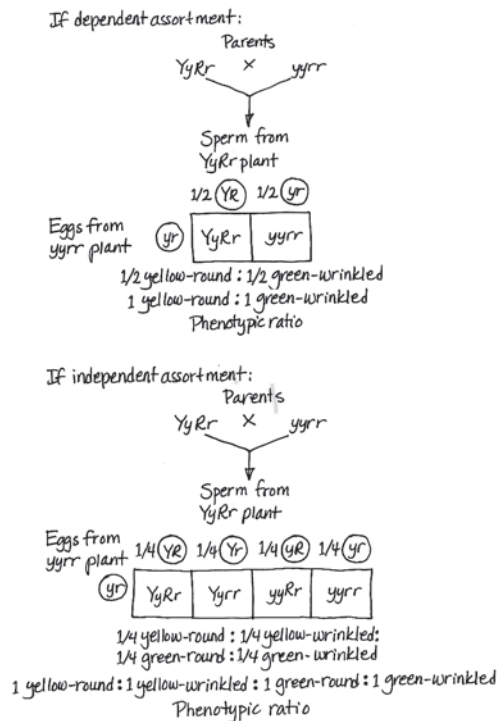

(b) Metaphase I (c) A haploid set is made up of one long, one medium, and one short chromosome. In this diagram, the haploid set going to each side of the cell is either blue or red, except for small segments of the other color due to crossing over. A diploid set is made up of all red and blue chromosomes together.

7. This cell must be undergoing meiosis because homologous chromosomes are associated with each other at the metaphase plate; this does not occur in mitosis.

## Chapter 11

### Figure Questions

**Figure 11.3** All offspring would have purple flowers. (The ratio would be one purple to zero white.) The P generation plants are true-breeding, so mating two purple-flowered plants produces the same result as self-pollination: All the offspring have the same trait. **Figure 11.8**

Yes, this cross would also have allowed Mendel to make different predictions for the two hypotheses, thereby allowing him to distinguish the correct one. **Figure 11.10** Your classmate would probably point out that the  $F_1$  generation hybrids show an intermediate phenotype between those of the homozygous parents, which supports the blending hypothesis. You could respond that crossing the  $F_1$  hybrids results in the re-appearance of the white phenotype, rather than identical pink offspring, which fails to support the idea of traits blending during inheritance. **Figure 11.11** Both the  $I^A$  and  $I^B$  alleles are dominant to the  $i$  allele, which is recessive and results in no attached carbohydrate. The  $I^A$  and  $I^B$  alleles are codominant; both are expressed in the phenotype of  $I^A I^B$  heterozygotes, who have type AB blood. **Figure 11.15** In the Punnett square, two of the three individuals with normal coloration are carriers, so the probability is  $2/3$ . (Note that you must take into account everything you know when you calculate probability: You know she is not  $aa$ , so there are only three possible genotypes to consider.)

### Concept Check 11.1

- There are 423 round peas and 133 wrinkled peas, a ratio of 3.18:1, or roughly 3:1.
- According to the law of independent assortment, 25 plants ( $1/16$  of the offspring) are

predicted to be  $aatt$ , or recessive for both characters. The actual result is likely to differ slightly from this value.

Parents:  $AaTt \times AaTt$

Sperm from  $AaTt$  plant:  $AT, At, aT, at$

Eggs from  $AaTt$  plant:  $AT, At, aT, at$

$AT$	$AATT$	$AATt$	$AaTT$	$AaTt$
$At$	$AATt$	$Aatt$	$AaTt$	$Aa tt$
$aT$	$AaTT$	$AaTt$	$aaTT$	$aaTt$
$at$	$AaTt$	$Aa tt$	$aaTt$	$aatt$

3. The plant could make eight different gametes ( $YRI, YRi, YrI, Yri, yRI, yRi, yri$ , and  $yri$ ). To fit all the possible gametes in a self-pollination, a Punnett square would need 8 rows and 8 columns. It would have spaces for the 64 possible unions of gametes in the offspring. 4. Self-pollination is sexual reproduction because meiosis is involved in forming gametes, which unite during fertilization. As a result, the offspring in self-pollination are genetically different from the parent.

### Concept Check 11.2

1.  $1/2$  homozygous dominant ( $AA$ ), 0 homozygous recessive ( $aa$ ), and  $1/2$  heterozygous ( $Aa$ ) 2.  $1/4 BBDD; 1/4 BbDD; 1/4 BBdd; 1/4 Bbdd$  3. The genotypes that fulfill this condition are  $ppyyIi, ppYyii, Ppyyii, ppYYii$ , and  $ppyyii$ . Use the multiplication rule to find the probability of getting each genotype, and then use the addition rule to find the overall probability of meeting the conditions of this problem:

$$\begin{array}{lcl}
 ppyyIi & 1/2 (\text{probability of } pp) \times 1/4 (yy) \times 1/2 (Ii) & = 1/16 \\
 ppYyii & 1/2 (pp) \times 1/2 (Yy) \times 1/2 (ii) & = 1/16 \\
 Ppyyii & 1/2 (Pp) \times 1/4 (yy) \times 1/2 (ii) & = 1/16 \\
 ppYyii & 1/2 (pp) \times 1/4 (Yy) \times 1/2 (ii) & = 1/16 \\
 ppyyii & 1/2 (pp) \times 1/4 (yy) \times 1/2 (ii) & = 1/16 \\
 \hline
 \text{Fraction predicted to have at least} & & = 6/16 \text{ or } 3/8 \\
 \text{two recessive traits} & & 
 \end{array}$$

### Concept Check 11.3

1. Incomplete dominance describes the relationship between two alleles of a single gene, whereas epistasis relates to the genetic relationship between two genes (and the respective alleles of each). 2. Half of the children would be expected to have type A blood and half type B blood. 3. The black and white alleles are incompletely dominant, with heterozygotes being gray in color. A cross between a gray rooster and a black hen should yield approximately equal numbers of gray and black offspring.

### Concept Check 11.4

1.  $1/9$  (Since cystic fibrosis is caused by a recessive allele, Beth and Tom's siblings who have CF must be homozygous recessive. Therefore, each parent must be a carrier of the recessive allele. Since neither Beth nor Tom has CF, this means they each have a  $2/3$  chance of being a carrier. If they are both carriers, there is a  $1/4$  chance that they will have a child with CF.  $2/3 \times 2/3 \times 1/4 = 1/9$ ); 0 (Both Beth and Tom would have to be carriers to produce a child with the disease.) 2. In the monohybrid cross involving flower color, the ratio is 3.15 purple : 1 white, while in the human family in the pedigree, the ratio in the third generation is 1 free : 1 attached earlobe. The difference is due to the small sample size (two offspring) in the human family. If the second-generation couple in this pedigree were able to have 929 offspring as in the pea plant cross, the ratio would likely be closer to 3:1. (Note that none of the pea plant crosses in Table 11.1 yielded exactly a 3:1 ratio.)

### Summary of Key Concepts Questions

**11.1** Alternative versions of genes, called alleles, are passed from parent to offspring during sexual reproduction. In a cross between purple- and white-flowered homozygous parents, the  $F_1$  offspring are all heterozygous, each inheriting a purple allele from one parent and a white allele from the other. Because the purple allele is dominant, it determines the phenotype of all  $F_1$  offspring to be purple, while the expression of the recessive white allele is masked. Only in the  $F_2$  generation is it possible for a white allele to exist in a homozygous state, which causes the white trait to be expressed.

**11.2**

Sperm:  $1/2 Y, 1/2 y$

Eggs:  $1/2 Y, 1/2 y$

$Y$	$YY$	$Yy$
$y$	$Yy$	$yy$

3/4 yellow  
1/4 green

Sperm:  $1/2 R, 1/2 r$

Eggs:  $1/2 R, 1/2 r$

$R$	$RR$	$Rr$
$r$	$Rr$	$rr$

3/4 round  
1/4 wrinkled

$3/4 \text{ yellow} \times 3/4 \text{ round} = 9/16 \text{ yellow-round}$   
 $3/4 \text{ yellow} \times 1/4 \text{ wrinkled} = 3/16 \text{ yellow-wrinkled}$   
 $1/4 \text{ green} \times 3/4 \text{ round} = 3/16 \text{ green-round}$   
 $1/4 \text{ green} \times 1/4 \text{ wrinkled} = 1/16 \text{ green-wrinkled}$   
 $= 9 \text{ yellow-round} : 3 \text{ yellow-wrinkled} : 3 \text{ green-round} : 1 \text{ green-wrinkled}$

**11.3** The ABO blood group is an example of multiple alleles because this single gene has more than two alleles ( $I^A$ ,  $I^B$ , and  $i$ ). Two of the alleles,  $I^A$  and  $I^B$ , exhibit codominance, since both carbohydrates (A and B) are present when these two alleles exist together in a genotype.  $I^A$  and  $I^B$  each exhibit complete dominance over the  $i$  allele. This situation is not an example of incomplete dominance because each allele affects the phenotype in a distinguishable way, so the result is not intermediate between the two phenotypes. Because this situation involves a single gene, it is not an example of epistasis or polygenic inheritance. **11.4** The chance of the fourth child having cystic fibrosis is  $1/4$ , as it was for each of the other children, because each birth is an independent event. We already know that both parents are carriers, so whether their first three children are carriers or not has no bearing on the probability that their next child will have the disease. The parents' genotypes provide the only relevant information.

### Test Your Understanding

1. Gene, l; Allele, e; Character, g; Trait, b; Dominant allele, j; Recessive allele, a; Genotype, k; Phenotype, h; Homozygous, c; Heterozygous, f; Testcross, i; Monohybrid cross, d  
2.

3. Man  $I^A i$ ; woman  $I^B i$ ; child  $ii$ . Genotypes for future children are predicted to be  $1/4 I^A I^B$ ,  $1/4 I^A i$ ,  $1/4 I^B i$ ,  $1/4 ii$ . **4.**  $1/2$  **5.** A cross of  $Ii \times ii$  would yield offspring with a genotypic ratio of  $1 Ii : 1 ii$  (2:2 is an equivalent answer) and a phenotypic ratio of 1 inflated : 1 constricted (2:2 is equivalent).

6. (a)  $1/64$ ; (b)  $1/64$ ; (c)  $1/8$ ; (d)  $1/32$  **7.** Albino ( $b$ ) is a recessive trait; black ( $B$ ) is dominant. First cross: parents  $BB \times bb$ ; gametes  $B$  and  $b$ ; offspring all  $Bb$  (black coat). The black guinea pig in the second cross is a heterozygote. Second cross: parents  $Bb \times bb$ ; gametes  $1/2 B$  and  $1/2 b$  (heterozygous parent) and  $b$ ; offspring  $1/2 Bb$  (black) and  $1/2 bb$  (white). **8.** Parental cross is  $AAC^R C^R \times aaC^W C^W$ .  $F_1$  genotype is  $AaC^R C^W$ , phenotype is all axial-pink.  $F_2$  genotypes are  $1 AAC^R C^R : 2 AAC^R C^W : 1 AAC^W C^W : 2 AaC^R C^R : 4 AaC^R C^W : 2 AaC^W C^W : 1 aaC^R C^R : 2 aaC^R C^W : 1 aaC^W C^W$ .  $F_2$  phenotypes are 3 axial-red : 6 axial-pink : 3 axial-white : 1 terminal-red : 2 terminal-pink : 1 terminal-white. **9.** (a)  $PPLl \times PPLl$ ,  $PPLl \times PpLl$ , or  $PpLl \times PpLl$ ; (b)  $pPll \times ppLl$ ; (c)  $PPLL \times$  any of the 9 possible genotypes or  $PpLl \times PpLl$ ; (d)  $PpLl \times PpLl$ ; (e)  $PpLl \times PpLl$  **10.** (a)  $3/4 \times 3/4 \times 3/4 = 27/64$ ; (b)  $1 - 27/64 = 37/64$ ; (c)  $1/4 \times 1/4 \times 1/4 = 1/64$ ; (d)  $1 - 1/64 = 63/64$  **11.** (a)  $1/256$ ; (b)  $1/16$ ; (c)  $1/256$ ; (d)  $1/64$ ; (e)  $1/128$  **12.** (a) 1; (b)  $1/32$ ; (c)  $1/8$ ; (d)  $1/2$  **13.**  $1/9$  **14.** 25%, or  $1/4$ , will be cross-eyed; all (100%) of the cross-eyed offspring will also be white. **15.** Matings of the original mutant cat with true-breeding noncurl cats will produce both curl and noncurl  $F_1$  offspring if the curl allele is dominant, but only noncurl offspring if the curl allele is recessive. Whether the curl trait is dominant or recessive, you would obtain some true-breeding offspring homozygous for the curl allele from matings between the  $F_1$  cats resulting from the original curl  $\times$  noncurl crosses. If dominant, you wouldn't be able to tell truebreeding, homozygous offspring from heterozygotes without further crosses. You will know that cats are true-breeding when curl  $\times$  curl matings produce only curl offspring for several generations. As it turns out, the allele that causes curled ears is dominant. **16.**  $1/16$  **17.** The dominant allele  $I$  is epistatic to the  $P/p$  locus, and thus the genotypic ratio for the  $F_1$  generation will be  $9 I-P- \text{ (colorless)} : 3 I-pp \text{ (colorless)} : 3 iiP- \text{ (purple)} : 1 iipp \text{ (red)}$ . Overall, the phenotypic ratio is 12 colorless : 3 purple : 1 red. **18.** Recessive. All affected individuals (Arlene, Tom, Wilma, and Carla) are homozygous recessive  $aa$ . George is  $Aa$ , since

some of his children with Arlene are affected. Sam, Ann, Daniel, and Alan are each  $Aa$ , since they are all unaffected children with one affected parent. Michael also is  $Aa$ , since he has an affected child (Carla) with his heterozygous wife Ann. Sandra, Tina, and Christopher can each have either the  $AA$  or  $Aa$  genotype. **19.**  $1/6$  **20.**  $9 B-A- \text{ (agouti)} : 3 B-aa \text{ (black)} : 3 bbA- \text{ (white)} : 1 bbaa \text{ (white)}$ . Overall, 9 agouti : 3 black : 4 white.

## Chapter 12

### Figure Questions

**Figure 12.2** The ratio would be 1 yellow-round : 1 green-round : 1 yellow-wrinkled : 1 green-wrinkled. **Figure 12.4** About  $3/4$  of the  $F_2$  offspring would have red eyes and about  $1/4$  would have white eyes. About half of the white-eyed flies would be female and half would be male; similarly, about half of the red-eyed flies would be female and half would be male. **Figure 12.7** All the males would be color-blind, and all the females would be carriers. **Figure 12.9** The two largest classes would still be the parental-type offspring (offspring with the phenotypes of the true-breeding P generation flies), but now they would be gray-vestigial and black-normal because those were the specific allele combinations in the P generation. **Figure 12.10** The two chromosomes below, left, are like the two chromosomes inherited by the  $F_1$  female, one from each P generation fly. They are passed by the  $F_1$  female intact to the offspring and thus could be called "parental" chromosomes. The other two chromosomes result from crossing over during meiosis in the  $F_1$  female. Because they have combinations of alleles not seen in either of the  $F_1$  female's chromosomes, they can be called "recombinant" chromosomes. (Note that in this example, the alleles on the recombinant chromosomes,  $b^+ vg^+$  and  $b vg$ , are the allele combinations that were on the parental chromosomes in the cross shown in Figures 12.9 and 12.10. The basis for calling them parental chromosomes is the combination of alleles that was present on the P generation chromosomes.)

### Concept Check 12.1

1. The law of segregation relates to the inheritance of alleles for a single character. The law of independent assortment of alleles relates to the inheritance of alleles for two characters. **2.** The physical basis for the law of segregation is the separation of homologs in anaphase I. The physical basis for the law of independent assortment is the alternative arrangements of all the homologous chromosome pairs in metaphase I. **3.** To show the mutant phenotype, a male needs to possess only one mutant allele. If this gene had been on a pair of autosomes, both alleles would have had to be mutant for an individual to show the recessive mutant phenotype, a much less probable situation.

### Concept Check 12.2

1. Because the gene for this eye-color character is located on the X chromosome, all female offspring will be red-eyed and heterozygous ( $X^{w+} X^w$ ); all male offspring will inherit a Y chromosome from the father and be white-eyed ( $X^w Y$ ). **2.**  $1/4$  ( $1/2$  chance that the child will inherit a Y chromosome from the father and be male  $\times 1/2$  chance that he will inherit the X carrying the disease allele from his mother); if the child is a boy, there is a  $1/2$  chance he will have the disease; a female will have zero chance (but  $1/2$  chance of being a carrier). **3.** With a disorder caused by a dominant allele, there is no such thing as a "carrier," since those with the allele have the disorder. Because the allele is dominant, the females lose any "advantage" in having two X chromosomes, since one disorder-associated allele is sufficient to result in the disorder. All fathers who have the dominant allele will pass it along to all their daughters, who will also have the disorder. A mother who has the allele (and thus the disorder) will pass it to half of her sons and half of her daughters.

### Concept Check 12.3

1. Crossing over during meiosis I in the heterozygous parent produces some gametes with recombinant genotypes for the two genes. Offspring with a recombinant phenotype arise from fertilization of the recombinant gametes by homozygous recessive gametes from the double-mutant parent. **2.** In each case, the alleles contributed by the female parent (in the egg) determine the phenotype of the offspring because the male in this cross contributes only recessive alleles. **3.** No. The order could be  $A-C-B$  or  $C-A-B$ . To determine which possibility is correct, you need to know the recombination frequency between  $B$  and  $C$ .

### Concept Check 12.4

1. In meiosis, a combined 14-21 chromosome behaves as one chromosome. If a gamete receives the combined 14-21 chromosome and a normal copy of chromosome 21, trisomy 21 will result when this gamete combines with a normal gamete during fertilization. **2.** No. The child can be either  $I^A I^A$  or  $I^A ii$ . A sperm of genotype  $I^A I^A$  could result from nondisjunction in the father during meiosis II, while an egg with the genotype  $ii$  could result from nondisjunction in the mother during either meiosis I or meiosis II. **3.** Activation of this gene could lead to the production of too much of this kinase. If the kinase is involved in a signaling pathway that triggers cell division, too much of it could trigger unrestricted cell division, which in turn could contribute to the development of a cancer (in this case, a cancer of one type of white blood cell). **4.** The inactivation of two X chromosomes in XXX women would leave them with one genetically active X, as in women with the normal number of chromosomes. Microscopy should reveal two Barr bodies in XXX women.

## Summary of Key Concepts Questions

**12.1** Because the sex chromosomes are different from each other and because they determine the sex of the offspring, Morgan could use the sex of the offspring as a phenotypic characteristic to follow the parental chromosomes. (He could also have followed them under a microscope, as the X and Y chromosomes look different.) At the same time, he could record eye color to follow the eye-color alleles.

**12.2** Males have only one X chromosome, along with a Y chromosome, while females have two X chromosomes. The Y chromosome has very few genes on it, while the X has about 1,000. When a recessive X-linked allele that causes a disorder is inherited by a male on the X from his mother, there isn't a second allele present on the Y (males are hemizygous), so the male has the disorder. Because females have two X chromosomes, they must inherit two recessive alleles in order to have the disorder, a rarer occurrence. **12.3** Crossing over results in new combinations of alleles. Crossing over is a random occurrence, and the more distance there is between two genes, the more chances there are for crossing over to occur, leading to a new combination of alleles. **12.4** In inversions and reciprocal translocations, the same genetic material is present in the same relative amount but just organized differently. In aneuploidy, duplications, and deletions, the balance of genetic material is upset, as large segments are either missing or present in more than one copy. Apparently, this type of imbalance is very damaging to the organism. (Although it isn't lethal in the developing embryo, the reciprocal translocation that produces the Philadelphia chromosome can lead to a form of cancer by altering the expression of important genes.)

## Test Your Understanding

**1.** 0;  $\frac{1}{2}$ ;  $\frac{1}{16}$  **2.** Recessive; if the disorder were dominant, it would affect at least one parent of a child born with the disorder. The disorder's inheritance is sex-linked because it is seen only in boys. For a girl to have the disorder, she would have to inherit recessive alleles from *both* parents. This would be very rare, since males with the recessive allele on their X chromosome die in their early teens. **3.** Between *T* and *A*, 12%; between *A* and *S*, 5% **4.** Between *T* and *S*, 18%; sequence of genes is *T*–*A*–*S*. **5.**  $\frac{1}{4}$  for each daughter ( $\frac{1}{2}$  chance that the child will be female  $\times$   $\frac{1}{2}$  chance of a homozygous recessive genotype);  $\frac{1}{2}$  for first son **6.** About one-third of the distance from the vestigial-wing locus to the brown-eye locus **7.** 6%; wild-type heterozygous for normal wings and red eyes  $\times$  recessive homozygous for vestigial wings and purple eyes **8.** Fifty percent of the offspring will show phenotypes resulting from crossovers. These results would be the same as those from a cross where *A* and *B* were *not* on the same chromosome. Further crosses involving other genes on the same chromosome would reveal the genetic linkage and map distances. **9.** 450 each of blue-oval and white-round (parentals) and 50 each of blue-round and white-oval (recombinants)

## Chapter 13

### Figure Questions

**Figure 13.2** The living S cells found in the blood sample were able to reproduce to yield more S cells, indicating that the S trait is a permanent, heritable change, rather than just a one-time use of the dead S cells' capsules. **Figure 13.4** The radioactivity would have been found in the pellet when proteins were labeled (batch 1) because proteins would have had to enter the bacterial cells to program them with genetic instructions. It's hard for us to imagine now, but the DNA might have played a structural role that allowed some of the proteins to be injected while it remained outside the bacterial cell (resulting in no radioactivity in the pellet in batch 2).

**Figure 13.11** The tube from the first replication would look the same, with a middle band of hybrid  $^{15}\text{N}$ – $^{14}\text{N}$  DNA, but the second tube would not have the upper band of two light blue strands. Instead, it would have a bottom band of two dark blue strands, like the bottom band in the result predicted after one replication in the conservative model. **Figure 13.13** In the bubble at the top of the micrograph in (b), arrows should be drawn pointing left and right to indicate the two replication forks. **Figure 13.14** Looking at any of the DNA strands, we see that one end is called the 5' end and the other the 3' end. If we proceed from the 5' end to the 3' end on the left-most strand, for example, we list the components in this order: phosphate group  $\rightarrow$  5' C of the sugar  $\rightarrow$  3' C  $\rightarrow$  phosphate  $\rightarrow$  5' C  $\rightarrow$  3' C. Going in the opposite direction on the same strand, the components proceed in the reverse order: 3' C  $\rightarrow$  5' C  $\rightarrow$  phosphate. Thus, the two directions are distinguishable, which is what we mean when we say that the strands have directionality. (Review Figure 13.5 if necessary.)

Figure 13.17

Figure 13.23

### Concept Check 13.1

**1.** You can't tell which end is the 5' end. You need to know which end has a phosphate group on the 5' carbon (the 5' end) or which end has an —OH group on the 3' carbon (the 3' end). **2.** He was expecting that the mouse injected with the mixture of heat-killed S cells and living R cells would survive, since neither type of cell alone would kill the mouse.

### Concept Check 13.2

**1.** Complementary base pairing ensures that the two daughter molecules are exact copies of the parental molecule. When the two strands of the parental molecule separate, each serves as a template on which nucleotides are arranged, by the base-pairing rules, into new complementary strands.

**2.**

Protein	Function
Helicase	Unwinds parental double helix at replication forks
Single-strand binding protein	Binds to and stabilizes single-stranded DNA until it can be used as a template
Topoisomerase	Relieves "overwinding" strain ahead of replication forks by breaking, swiveling, and rejoining DNA strands
Primase	Synthesizes an RNA primer at 5' end of leading strand and at 5' end of each Okazaki fragment of lagging strand
DNA pol III	Using parental DNA as a template, synthesizes new DNA strand by covalently adding nucleotides to 3' end of a preexisting DNA strand or RNA primer
DNA pol I	Removes RNA nucleotides of primer from 5' end and replaces them with DNA nucleotides
DNA ligase	Joins 3' end of DNA that replaces primer to rest of leading strand and joins Okazaki fragments of lagging strand

**3.** In the cell cycle, DNA synthesis occurs during the S phase, between the  $G_1$  and  $G_2$  phases of interphase. DNA replication is therefore complete before the mitotic phase begins.

### Concept Check 13.3

**1.** A nucleosome is made up of eight histone proteins, two each of four different types, around which DNA is wound. Linker DNA runs from one nucleosome to the next. **2.** Euchromatin is chromatin that becomes less compacted during interphase and is accessible to the cellular machinery responsible for gene activity. Heterochromatin, on the other hand, remains quite condensed during interphase and contains genes that are largely inaccessible to this machinery.

### Concept Check 13.4

**1.** The covalent sugar-phosphate bonds of the DNA strands **2.** Yes, *PvuI* will cut the molecule (at the position indicated by the dashed red line).

**3.** Cloning requires joining two pieces of DNA—a cloning vector, such as a bacterial plasmid, and a gene or DNA fragment from another source. Both pieces must be cut with the same restriction enzyme, creating sticky ends that will base-pair with complementary ends on other fragments. (The sugar-phosphate backbones will then be ligated together.) In DNA sequencing, primers base-pair to the template, allowing DNA synthesis to start, and then nucleotides are added to the growing strand based on complementarity of base pairing. In PCR, the primers must base-pair with their target sequences in the DNA mixture, locating one specific region among many, and complementary base pairing is the basis for the building of the new strand during the extension step.

## Summary of Key Concepts Questions

**13.1** Each strand in the double helix has polarity, the end with a phosphate group on the 5' carbon of the sugar being called the 5' end, and the end with an —OH group on the 3' carbon of the sugar being called the 3' end. The two strands run in opposite directions, so each end of the molecule has both a 5' and a 3' end. This arrangement is called "antiparallel." If the strands were parallel, they would both run 5' → 3' in the same direction, so an end of the molecule would have either two 5' ends or two 3' ends. **13.2** On both the leading and lagging strands, DNA polymerase adds onto the 3' end of an RNA primer synthesized by primase, synthesizing DNA in the 5' → 3' direction. Because the parental strands are antiparallel, however, only on the leading strand does synthesis proceed continuously into the replication fork. The lagging strand is synthesized bit by bit in the direction away from the fork as a series of shorter Okazaki fragments, which are later joined together by DNA ligase. Each fragment is initiated by synthesis of an RNA primer by primase as soon as a given stretch of single-stranded template strand is opened up. Although both strands are synthesized at the same rate, synthesis of the lagging strand is delayed because initiation of each fragment begins only when sufficient template strand is available. **13.3** Most of the chromatin in an interphase nucleus is uncondensed. Much is present as the 30-nm fiber, with some in the form of the 10-nm fiber and some as looped domains of the 30-nm fiber. (These different levels of chromatin packing may reflect differences in gene expression occurring in these regions.) Also, a small percentage of the chromatin, such as that at the centromeres and telomeres, is highly condensed heterochromatin. **13.4** A plasmid vector and a source of foreign DNA to be cloned are both cut with the same restriction enzyme, generating restriction fragments with sticky ends. These fragments are mixed together, ligated, and reintroduced into bacterial cells, which can then make many copies of the foreign DNA or its product.

## Test Your Understanding

1. c 2. c 3. b 4. d 5. c 6. c 7. d 8. b 9. a

**10.** Like histones, the *E. coli* proteins would be expected to contain many basic (positively charged) amino acids, such as lysine and arginine, which can form weak bonds with the negatively charged phosphate groups on the sugar-phosphate backbone of the DNA molecule.

**11.**

## Chapter 14

### Figure Questions

**Figure 14.2** The mutant would not grow in the absence of arginine. **Figure 14.5** The mRNA sequence (5'-UGGUUUGGCUCA-3') is the same as the nontemplate DNA strand sequence (5'-TGGTTTGGCTCA-3'), except there is U in the mRNA and T in the DNA. **Figure 14.8** The processes are similar in that polymerases form polynucleotides complementary to an antiparallel DNA template strand. In replication, however, both strands act as templates, whereas in transcription, only one DNA strand acts as a template. **Figure 14.9** The RNA polymerase would bind directly to the promoter, rather than depending on the previous binding of other factors. **Figure 14.23** The mRNA on the right (the longest one) started being transcribed first. The ribosome at the top, closest to the DNA, started translating first and thus has the longest polypeptide.

### Concept Check 14.1

1. Recessive 2. A polypeptide made up of 10 Gly (glycine) amino acids 3.

"Template sequence" (from nontemplate sequence in problem, written 3' → 5'):

3'-ACGACTGAA-5'

mRNA sequence: 5'-UGCUGACUU-3'

Translated: Cys-STOP-Leu

(Remember that the mRNA is antiparallel to the DNA strand.) A protein translated from the nontemplate sequence would have a completely different amino acid sequence and would most likely be nonfunctional. (It would also be shorter because of the stop signal shown in the mRNA sequence above—and possibly others earlier in the mRNA sequence.)

### Concept Check 14.2

1. The promoter is the region of DNA to which RNA polymerase binds to begin transcription, and it is at the upstream end of the gene (transcription unit). 2. In a bacterial cell, RNA polymerase recognizes the gene's promoter and binds to it. In a eukaryotic cell, transcription factors mediate the binding of RNA polymerase to the promoter. In both cases, sequences in the promoter bind precisely to the RNA polymerase, so the enzyme is in the right location and orientation. 3. The transcription

factor that recognizes the TATA sequence would be unable to bind, so RNA polymerase could not bind, and transcription of that gene probably would not occur.

### Concept Check 14.3

1. Due to alternative splicing of exons, each gene can result in multiple different mRNAs and can thus direct synthesis of multiple different proteins. 2. In editing a video, segments are cut out and discarded (like introns), and the remaining segments are joined together (like exons) so that the regions of joining ("splicing") are not noticeable. 3. Once the mRNA has exited the nucleus, the cap prevents it from being degraded by hydrolytic enzymes and facilitates its attachment to ribosomes. If the cap were removed from all mRNAs, the cell would no longer be able to synthesize any proteins and would probably die.

### Concept Check 14.4

1. First, each aminoacyl-tRNA synthetase specifically recognizes a single amino acid and attaches it only to an appropriate tRNA. Second, a tRNA charged with its specific amino acid binds only to an mRNA codon for that amino acid. 2. The structure and function of the ribosome seem to depend more on the rRNAs than on the ribosomal proteins. Because it is single-stranded, an RNA molecule can hydrogen-bond with itself and with other RNA molecules. RNA molecules make up the interface between the two ribosomal subunits, so presumably RNA-RNA binding helps hold the ribosome together. The binding site for mRNA in the ribosome includes rRNA that can bind the mRNA. Also, complementary bonding within an RNA molecule allows it to assume a particular three-dimensional shape and, along with the RNA's functional groups, presumably enables rRNA to catalyze peptide bond formation during translation. 3. A signal peptide on the leading end of the polypeptide being synthesized is recognized by a signal-recognition particle that brings the ribosome to the ER membrane. There the ribosome attaches and continues to synthesize the polypeptide, depositing it in the ER lumen. 4. Because of wobble, the tRNA could bind to either 5'-GCA-3' or 5'-GCG-3', both of which code for alanine (Ala). Alanine would be attached to the tRNA.

### Concept Check 14.5

1. In the mRNA, the reading frame downstream from the deletion is shifted, leading to a long string of incorrect amino acids in the polypeptide, and in most cases, a stop codon will arise, leading to premature termination. The polypeptide will most likely be nonfunctional. 2. Heterozygous individuals, said to have sickle-cell trait, have a copy each of the wild-type allele and the sickle-cell allele. Both alleles will be expressed, so these individuals will have both normal and sickle-cell hemoglobin molecules. Apparently, having a mix of the two forms of  $\beta$ -globin has no effect under most conditions, but during prolonged periods of low blood oxygen (such as at higher altitudes), these individuals can show some signs of sickle-cell disease.

3.

Normal DNA sequence

(template strand is on top): 3'-TACTTGTCCGATATC-5'  
5'-ATGAACAGGCTATAG-3'

mRNA sequence: 5'-AUGAACAGGCUAUAG-3'

Amino acid sequence: Met-Asn-Arg-Leu-STOP

Mutated DNA sequence

(template strand is on top): 3'-TACTTGTCCAATATC-5'  
5'-ATGAACAGGTTATAG-3'

mRNA sequence: 5'-AUGAACAGGUUAUAG-3'

Amino acid sequence: Met-Asn-Arg-Leu-STOP

No effect: The amino acid sequence is Met-Asn-Arg-Leu both before and after the mutation because the mRNA codons 5'-CUA-3' and 5'-UUA-3' both code for Leu. (The fifth codon is a stop codon.)

## Summary of Key Concepts Questions

**14.1** A gene contains genetic information in the form of a nucleotide sequence. The gene is first transcribed into an RNA molecule, and a messenger RNA molecule is ultimately translated into a polypeptide. The polypeptide makes up part or all of a protein, which performs a function in the cell and contributes to the phenotype of the organism. **14.2** Both bacterial and eukaryotic genes have promoters, regions where RNA polymerase ultimately binds and begins transcription. In bacteria, RNA polymerase binds directly to the promoter; in eukaryotes, transcription factors bind first to the

promoter, and then RNA polymerase binds to the transcription factors and promoter together. **14.3** Both the 5' cap and the poly-A tail help the mRNA exit from the nucleus and then, in the cytoplasm, help ensure mRNA stability and allow it to bind to ribosomes. **14.4** tRNAs function as translators between the nucleotide-based language of mRNA and the amino-acid-based language of polypeptides. A tRNA carries a specific amino acid, and the anticodon on the tRNA is complementary to the codon on the mRNA that codes for that amino acid. In the ribosome, the tRNA binds to the A site, where the polypeptide being synthesized is joined to the new amino acid, which becomes the new (C-terminal) end of the polypeptide. Next, the tRNA moves to the P site. When the next amino acid is added via transfer of the polypeptide to the new tRNA, the now empty tRNA moves to the E site, where it exits the ribosome. **14.5** When a nucleotide base is altered chemically, its base-pairing characteristics may be changed. When that happens, an incorrect nucleotide is likely to be incorporated into the complementary strand during the next replication of the DNA, and successive rounds of replication will perpetuate the mutation. Once the gene is transcribed, the mutated codon may code for a different amino acid that inhibits or changes the function of a protein. If the chemical change in the base is detected and repaired by the DNA repair system before the next replication, no mutation will result.

### Test Your Understanding

1. b 2. d 3. a 4. a 5. b 6. d 7. e  
8.

Type of RNA	Functions
Messenger RNA (mRNA)	Carries information specifying amino acid sequences of proteins from DNA to ribosomes
Transfer RNA (tRNA)	Serves as translator molecule in protein synthesis; translates mRNA codons into amino acids
Ribosomal RNA (rRNA)	Plays catalytic (ribozyme) roles and structural roles in ribosomes
Primary transcript	Is a precursor to mRNA, rRNA, or tRNA, before being processed; some intron RNA acts as a ribozyme, catalyzing its own splicing
Small RNAs in spliceosome	Play structural and catalytic roles in spliceosomes, the complexes of protein and RNA that splice pre-mRNA

## Chapter 15

### Figure Questions

**Figure 15.3** As the concentration of tryptophan in the cell falls, eventually there will be none bound to repressor molecules, which will then take on their inactive shapes and dissociate from the operator, allowing transcription of the operon to resume. The enzymes for tryptophan synthesis will be made, and they will begin to synthesize tryptophan again in the cell. **Figure 15.11** The albumin gene enhancer has the three control elements colored yellow, gray, and red. The sequences in the liver and lens cells would be identical, since the cells are in the same organism.

### Concept Check 15.1

1. Binding by the *trp* corepressor (tryptophan) activates the *trp* repressor, shutting off transcription of the *trp* operon; binding by the *lac* inducer (allolactose) inactivates the *lac* repressor, leading to transcription of the *lac* operon. 2. When glucose is scarce, cAMP is bound to CAP and CAP is bound to the promoter, favoring the binding of RNA polymerase. However, in the absence of lactose, the repressor is bound to the operator, blocking RNA polymerase binding to the promoter. Therefore, the operon genes are not transcribed. 3. The cell would continuously produce  $\beta$ -galactosidase and the two other enzymes for lactose utilization, even in the absence of lactose, thus wasting cell resources.

### Concept Check 15.2

1. Histone acetylation is generally associated with gene expression, while DNA methylation is generally associated with lack of expression. 2. General transcription factors function in assembling the transcription initiation complex at the promoters for all genes. Specific transcription factors bind to control elements associated with a particular gene and, once bound, either increase (activators) or decrease (repressors) transcription of that gene. 3. The three genes should have some similar or identical sequences in the control elements of their enhancers. Because of this similarity, the same specific transcription factors in muscle cells could bind to the enhancers of all three genes and stimulate their expression coordinately.

### Concept Check 15.3

1. The mRNA would persist and be translated into the cell division-promoting protein, and the cell would probably divide. If the intact miRNA is necessary for inhibition of cell division, then division of this cell might be inappropriate. Uncontrolled cell division could lead to formation of a mass of cells (tumor) that prevents proper functioning of the organism and could contribute to the development of cancer. 2. The *XIST* RNA is transcribed from the *XIST* gene on the X chromosome that will be inactivated. It then binds to that chromosome and induces heterochromatin formation. A likely model is that the *XIST* RNA somehow recruits chromatin modification enzymes that lead to formation of heterochromatin.

### Concept Check 15.4

1. In RT-PCR, the primers must base-pair with their target sequences in the DNA mixture, locating one specific region among many. In microarray analysis, the labeled probe binds only to the specific target sequence owing to complementary nucleic acid hybridization (DNA-DNA hybridization). 2. As a researcher interested in cancer development, you would want to study genes represented by spots that are green or red because these are genes for which the expression level differs between the two types of tissues. Some of these genes may be expressed differently as a result of cancer, but others might play a role in causing cancer.

### Summary of Key Concepts Questions

**15.1** A corepressor and an inducer are both small molecules that bind to the repressor protein in an operon, causing the repressor to change shape. In the case of a corepressor (like tryptophan), this shape change allows the repressor to bind to the operator, blocking transcription. In contrast, an inducer causes the repressor to dissociate from the operator, allowing transcription to begin. **15.2** The chromatin must not be tightly condensed because it must be accessible to transcription factors. The appropriate specific transcription factors (activators) must bind to the control elements in the enhancer of the gene, while repressors must not be bound. The DNA must be bent by a bending protein so the activators can contact the mediator proteins and form a complex with general transcription factors at the promoter. Then RNA polymerase must bind and begin transcription. **15.3** miRNAs do not "code" for the amino acids of a protein—they are never translated. Each miRNA associates with a group of proteins to form a complex. Binding of the complex to an mRNA with a complementary sequence causes that mRNA to be degraded or blocks its translation. This is considered gene regulation because it controls the amount of a particular mRNA that can be translated into a functional protein. **15.4** The genes that are expressed in a given tissue or cell type determine the proteins (and ncRNAs) that are the basis of the structure and functions of that tissue or cell type. Understanding which groups of interacting genes establish particular structures and allow certain functions will help us learn how the parts of an organism form and are maintained and help us treat diseases that occur when faulty gene expression leads to malfunctioning tissues.

### Test Your Understanding

1. d 2. a 3. c 4. d 5. e 6. b  
7. (a)

The purple, blue, and red activator proteins would be present.

Only gene 4 would be transcribed.

(c) In nerve cells, the orange, blue, green, and black activators would have to be present, thus activating transcription of genes 1, 2, and 4. In skin cells, the red, black, purple, and blue activators would have to be present, thus activating genes 3 and 5.

## Chapter 16

### Figure Questions

**Figure 16.4** Even if the mutant MyoD protein couldn't activate the *myoD* gene, it could still turn on genes for the other proteins in the pathway (other transcription factors, which would turn on the genes for muscle-specific proteins, for example). Therefore, some differentiation would occur. But unless there were other activators that could compensate for the loss of the MyoD protein's activation of the *myoD* gene, the cell would not be able to maintain its differentiated state. **Figure 16.10** Normal Bicoid protein would be made in the anterior end and compensate for the presence of mutant *bicoid* mRNA put into the egg by the mother. Development should be normal, with a head present. (This is what was observed.) **Figure 16.11** None of the eggs with the transplanted nuclei from the four-cell embryo at the upper left would have developed into a tadpole. Also, the resulting samples might include only some of the tissues of a tadpole. The tissues that develop might differ from treatment to treatment, depending on which of the four nuclei was transplanted. (This assumes that there was some way to tell the four cells apart, as one can in some frog species.)

**Concept Check 16.1**

1. Cells undergo differentiation during embryonic development, becoming different from each other. Therefore, in the adult organism, there are many highly specialized cell types. 2. By binding to a receptor on the receiving cell's surface and triggering a signal transduction pathway involving intracellular molecules such as second messengers and transcription factors that affect gene expression. 3. Because their products, made and deposited into the egg by the mother, determine the head and tail ends, as well as the back and belly, of the embryo (and eventually the adult fly).

**Concept Check 16.2**

1. The state of chromatin modification in the nucleus from the intestinal cell was undoubtedly less similar to that of a nucleus from a fertilized egg, explaining why many fewer of these nuclei were able to be reprogrammed. In contrast, the chromatin in a nucleus from a cell at the four-cell stage would have been much more like that of a nucleus in a fertilized egg and therefore much more easily programmed to direct development. 2. No, primarily because of subtle (and perhaps not so subtle) differences in their environments. 3. A technique would have to be worked out for turning a human iPS cell into a pancreatic cell (probably by inducing expression of pancreas-specific regulatory genes in the cell).

**Concept Check 16.3**

1. Apoptosis is signaled by p53 protein when a cell has extensive DNA damage, so apoptosis plays a protective role in eliminating a cell that might contribute to cancer. If mutations in the genes in the apoptotic pathway blocked apoptosis, a cell with such damage could continue to divide and might lead to tumor formation. 2. When an individual has inherited an oncogene or a mutant allele of a tumor-suppressor gene. 3. A cancer-causing mutation in a proto-oncogene usually makes the gene product overactive, whereas a cancer-causing mutation in a tumor-suppressor gene usually makes the gene product nonfunctional.

**Summary of Key Concepts Questions**

**16.1** The first process involves cytoplasmic determinants, including mRNAs and proteins, placed into specific locations in the egg by the mother. The cells that are formed from different regions in the egg during early cell divisions will have different proteins in them, which will direct different programs of gene expression. The second process involves how the cells respond to signaling molecules secreted by neighboring cells. The signaling pathways in the responding cells lead to different patterns of gene expression. The coordination of these two processes results in each cell following a unique pathway in the developing embryo. **16.2** Cloning a mouse involves transplanting a nucleus from a differentiated mouse cell into a mouse egg cell that has had its own nucleus removed. Activating the egg cell and promoting its development into an embryo in a surrogate mother results in a mouse that is genetically identical to the mouse that donated the nucleus. In this case, the differentiated nucleus has been reprogrammed by factors in the egg cytoplasm. Mouse ES cells are generated from inner cells in mouse blastocysts, so in this case the cells are "naturally" reprogrammed by the process of reproduction and development. (Cloned mouse embryos can also be used as a source of ES cells.) iPS cells can be generated without the use of embryos from a differentiated adult mouse cell by adding certain transcription factors into the cell. In this case, the transcription factors are reprogramming the cells to become pluripotent. **16.3** The protein product of a proto-oncogene is usually involved in a pathway that stimulates cell division. The protein product of a tumor-suppressor gene is usually involved in a pathway that inhibits cell division.

**Test Your Understanding**

1. a 2. a 3. d 4. c 5. b

**Chapter 17****Figure Questions**

**Figure 17.3** Top vertical arrow: Infection. Left upper arrow: Replication. Right upper arrow: Transcription. Right middle arrow: Translation. Lower left and right arrows: Self-assembly. Bottom middle arrow: Exit. **Figure 17.7** There are many steps that could be interfered with: binding of the virus to the cell, reverse transcriptase function, integration into the host cell chromosome, genome synthesis (in this case, transcription of RNA from the integrated provirus), assembly of the virus inside the cell, and budding of the virus. (Many of these, if not all, are targets of actual medical strategies to block progress of the infection in HIV-infected people.)

**Concept Check 17.1**

1. TMV consists of one molecule of RNA surrounded by a helical array of proteins. The influenza virus has eight molecules of RNA, each surrounded by a helical array of proteins, similar to the arrangement of the single RNA molecule in TMV. Another difference between the viruses is that the influenza virus has an outer envelope and TMV does not. 2. The T2 phages were an excellent choice for use in the Hershey-Chase experiment because they consist of only DNA surrounded by a protein coat, and DNA and protein were the two candidates for macromolecules that carried genetic information. Hershey and Chase were able to radioactively label each type of molecule alone and follow it during separate infections of *E. coli* cells with T2. Only the DNA entered the bacterial cell during infection, and only labeled DNA showed up in some of the progeny phage. Hershey and Chase concluded that the DNA must carry the genetic information necessary for the phage to reprogram the cell and produce progeny phages.

**Concept Check 17.2**

1. Lytic phages can only carry out lysis of the host cell, whereas lysogenic phages may either lyse the host cell or integrate into the host chromosome. In the latter case, the viral DNA (prophage) is simply replicated along with the host chromosome. Under certain conditions, a prophage may exit the host chromosome and initiate a lytic cycle. 2. Both the viral RNA polymerase and the cellular RNA polymerase in Figure 14.10 synthesize an RNA molecule complementary to a template strand. However, the cellular RNA polymerase in Figure 14.10 uses one of the strands of the DNA double helix as a template, whereas the viral RNA polymerase uses the RNA of the viral genome as a template.

3. Because it synthesizes DNA from its RNA genome. This is the reverse ("retro") of the usual DNA → RNA information flow.

**Concept Check 17.3**

1. Mutations can lead to a new strain of a virus that can no longer be effectively fought by the immune system, even if an animal had been exposed to the original strain; a virus can jump from one species to a new host; and a rare virus can spread if a host population becomes less isolated. 2. In horizontal transmission, a plant is infected from an external source of the virus, which can enter through a break in the plant's epidermis due to damage by herbivores. In vertical transmission, a plant inherits viruses from its parent either via infected seeds (sexual reproduction) or via an infected cutting (asexual reproduction). 3. Humans are not within the host range of TMV, so they can't be infected by the virus.

**Summary of Key Concepts Questions**

**17.1** Viruses are generally considered nonliving because they are not capable of replicating outside of a host cell. To replicate, they depend completely on host enzymes and resources. **17.2** Single-stranded RNA viruses require an RNA polymerase that can make RNA using an RNA template. (Cellular RNA polymerases make RNA using a DNA template.) Retroviruses require reverse transcriptases to make DNA using an RNA template. (Once the first DNA strand has been made, the same enzyme can promote synthesis of the second DNA strand.) **17.3** The mutation rate of RNA viruses is higher than that of DNA viruses because RNA polymerase has no proofreading function, so errors in replication are not corrected. Their higher mutation rate means that RNA viruses change faster than DNA viruses, allowing them to have an altered host range and to evade immune defenses in possible hosts.

**Test Your Understanding**

1. c 2. d 3. c 4. d 5. b

6. As shown in the sketch, the viral genome would be translated into capsid proteins and envelope glycoproteins directly, rather than after a complementary RNA copy was made. A complementary RNA strand would still be made, however, that could be used as a template for many new copies of the viral genome.

**Chapter 18****Figure Questions**

**Figure 18.2** In stage 2 of this figure, the order of the fragments relative to each other is not known and will be determined later by computer. The unordered nature of the fragments is reflected by their scattered arrangement in the diagram. **Figure 18.7** The transposon would be cut out of the DNA at the original site rather than copied, so the figure would show the original stretch of DNA without the transposon after the mobile transposon had been cut out. **Figure 18.9** The RNA transcripts extending from the DNA in each transcription unit are shorter on the left and longer on the right. This means that RNA polymerase must be starting on the left end of the unit and moving toward the right.

**Figure 18.12**

**Figure 18.13** Pseudogenes are nonfunctional. They could have arisen by any mutations in the second copy that made the gene product unable to function. Examples would be base changes that introduce stop codons in the sequence, alter amino acids, or change a region of the gene promoter so that the gene can no longer be expressed. **Figure 18.14** Let's say a transposable element (TE) existed in the intron to the left of the indicated EGF exon in the EGF gene, and the same TE was present in the intron to the right of the indicated F exon in the fibronectin gene. During meiotic recombination, these TEs could cause nonsister chromatids on homologous chromosomes to pair up incorrectly, as seen in Figure 18.12. One gene might end up with an F exon next to an EGF exon. Further mistakes in pairing over many generations might result in these two exons being separated from the rest of the gene and placed next to a single or duplicated K exon. In general, the presence of repeated sequences in introns and between genes facilitates these processes because it allows incorrect pairing of nonsister chromatids, leading to novel exon combinations.

#### Concept Check 18.1

1. In the whole-genome shotgun approach, short fragments generated by multiple restriction enzymes are cloned and sequenced and then ordered by computer programs that identify overlapping regions. In this way, a composite sequence is obtained.

#### Concept Check 18.2

1. The Internet allows centralization of databases such as GenBank and software resources such as BLAST, making them freely accessible. Having all the data in a central database, easily accessible on the Internet, minimizes the possibility of errors and of researchers working with different data. It streamlines the process of science, since all researchers are able to use the same software programs, rather than each having to obtain their own, possibly different, software. It speeds up dissemination of data and ensures as much as possible that errors are corrected in a timely fashion. These are just a few answers; you can probably think of more. 2. Cancer is a disease caused by multiple factors. To focus on a single gene or a single defect would ignore other factors that may influence the cancer and even the behavior of the single gene being studied. The systems approach, because it takes into account many factors at the same time, is more likely to lead to an understanding of the causes and most useful treatments for cancer. 3. Some of the transcribed region is accounted for by introns. The rest is transcribed into noncoding RNAs, including small RNAs, such as microRNAs (miRNAs). These RNAs help regulate gene expression by blocking translation, causing degradation of mRNA, binding to the promoter and repressing transcription, or causing remodeling of chromatin structure. The functions of the remainder are not yet known.

#### Concept Check 18.3

1. Alternative splicing of RNA transcripts from a gene and post-translational processing of polypeptides. 2. The total number of completed genomes is found by clicking on "Complete Projects" under "Isolate Genomes"; the numbers of completed genomes for each domain are at the top of this page. The number of genomes "in progress" is visible if you click on "Incomplete Projects" under "Isolate Genomes" on the home page; the number is broken down by domains and also by the status of the project. (Note: Back at the home page, you can click on "Phylogenetic" under "Genome Distribution" to see how the numbers of sequenced genomes are distributed among phylogenetic groups at the phylum level. Note the number of Chordate genomes near the bottom of the table.) 3. Prokaryotes are generally smaller cells than eukaryotic cells, and they reproduce by binary fission. The evolutionary process involved is natural selection for more quickly reproducing cells: The faster they can replicate their DNA and divide, the more likely they will be able to dominate a population of prokaryotes. The less DNA they have to replicate, then, the faster they will reproduce.

#### Concept Check 18.4

1. The number of genes is higher in mammals, and the amount of noncoding DNA is greater. Also, the presence of introns in mammalian genes makes them larger, on average, than prokaryotic genes. 2. The copy-and-paste transposon mechanism and retrotransposition. 3. In the rRNA gene family, identical transcription units for the three different RNA products are present in long, tandemly repeated arrays. The large number of copies of the rRNA genes enables organisms to produce the rRNA for enough ribosomes to carry out active protein synthesis, and the single transcription unit ensures that the relative amounts of the different rRNA molecules produced are correct. Each globin gene family consists of a relatively small number of nonidentical genes. The differences in the globin proteins encoded by these genes result in production of hemoglobin molecules adapted to particular developmental stages of the organism.

#### Concept Check 18.5

1. If meiosis is faulty, two copies of the entire genome can end up in a single cell. Errors in crossing over during meiosis can lead to one segment being duplicated while another is deleted. During DNA replication, slippage backward along the template strand can result in segment duplication. 2. For either gene, a mistake in crossing over during meiosis could have occurred between the two copies of that gene, such that one ended up with a duplicated exon. This could have happened several times, resulting in the multiple copies of a particular exon in each gene. 3. Homologous transposable elements scattered throughout the genome provide sites where recombination can occur between different chromosomes. Movement of these elements into coding or regulatory sequences may change expression of genes. Transposable elements also can carry genes with them, leading to dispersion of genes and in some cases different patterns of expression. Transport of an exon during transposition and its insertion into a gene may add a new functional domain to the originally encoded protein, a type of exon shuffling. (For any of these changes to be heritable, they must happen in germ cells, cells that will give rise to gametes.)

#### Concept Check 18.6

1. Because both humans and macaques are primates, their genomes are expected to be more similar than the macaque and mouse genomes are. The mouse lineage diverged from the primate lineage before the human and macaque lineages diverged. 2. Homeotic genes differ in their *nonhomeobox* sequences, which determine the

interactions of homeotic gene products with other transcription factors and hence which genes are regulated by the homeotic genes. These nonhomeobox sequences differ in the two organisms, as do the expression patterns of the homeobox genes.

#### Summary of Key Concepts Questions

**18.1** One focus of the Human Genome Project was to improve sequencing technology in order to speed up the process. During the project, many advances in sequencing technology allowed faster reactions, which were therefore less expensive. **18.2** The most significant finding was that more than 90% of the human genomic region studied was transcribed, which suggested that the transcribed RNA (and thus the DNA from which it was produced) was performing some unknown functions. The project has been expanded to include other species because to determine the functions of these transcribed DNA elements, it is necessary to carry out this type of analysis on the genomes of species that can be used in laboratory experiments. **18.3** (a) In general, bacteria and archaea have smaller genomes, lower numbers of genes, and higher gene density than eukaryotes. (b) Among eukaryotes, there is no apparent systematic relationship between genome size and phenotype. The number of genes is often lower than would be expected from the size of the genome—in other words, the gene density is often lower in larger genomes. (Humans are an example.) **18.4** Transposable elements can move from place to place in the genome, and some of these sequences make a new copy of themselves when they do so. Thus, it is not surprising that they make up a significant percentage of the genome, and this percentage might be expected to increase over evolutionary time. **18.5** Chromosomal rearrangements within a species lead to some individuals having different chromosomal arrangements. Each of these individuals could still undergo meiosis and produce gametes, and fertilization involving gametes with different chromosomal arrangements could result in viable offspring. However, during meiosis in the offspring, the maternal and paternal chromosomes might not be able to pair up, causing gametes with incomplete sets of chromosomes to form. Most often, when zygotes are produced from such gametes, they do not survive. Ultimately, a new species could form if two different chromosomal arrangements became prevalent within a population and individuals could mate successfully only with other individuals having the same arrangement. **18.6** Comparing the genomes of closely related species can reveal information about more recent evolutionary events, perhaps events that resulted in the distinguishing characteristics of the species. Comparing the genomes of very distantly related species can tell us about evolutionary events that occurred a very long time ago. For example, genes that are shared between distantly related species must have arisen before those species diverged.

5. ATETI...PKSSD...TSSIT...NARRD  
6. VTETI...PKSSD...TSSIT...NARRD

(a) Lines 1, 3, and 5 are the C, G, R species. (b) See the underlined amino acids in Line 4. (Line 4 is the human sequence.) (c) Line 6 is the orangutan sequence. (d) There is one amino acid difference between the mouse (the E on line 2) and the C, G, R species (which have a D in that position). There are three amino acid differences between the mouse and the human. (The E, T, and N in the mouse sequence are instead D, N, and S, respectively, in the human sequence.) (e) Because only one amino acid difference arose during the 60–100 million years since the mouse and C, G, R species diverged, it is somewhat surprising that two additional amino acid differences resulted during the 6 million years since chimpanzees and humans diverged. This indicates that the *FOXP2* gene has been evolving faster in the human lineage than in the lineages of other primates.

## Chapter 19

#### Figure Questions

**Figure 19.6** The cactus-eater is more closely related to the seed-eater; Figure 1.16 shows that they share a more recent common ancestor (a seed-eater) than the cactus-eater shares with the insect-eater. **Figure 19.9** The common ancestor lived more than 5.5 million years ago. **Figure 19.13** The colors and body forms of these mantids allow them to blend into their surroundings, providing an example of how organisms are well matched to life in their environments. The mantids also share features with one another (and with all other mantids), such as six legs, grasping forelimbs, and large eyes. These shared features illustrate another key observation about life: the unity of life that results from descent from a common ancestor. Over time, as these mantids diverged from a common ancestor, they accumulated different adaptations that made them well suited for life in their different environments. Eventually, these differences became large enough that new species were formed, thus contributing to the great diversity of life. **Figure 19.14** These results show that being reared from the egg stage on one plant species or the other did not result in the adult having a beak length appropriate for that host; instead, adult beak lengths were determined primarily by the population from which the eggs were obtained. Because an egg from a balloon vine population likely had long-beaked parents, while an egg from a goldenrain tree population likely had short-beaked parents, these results indicate that beak length is an inherited trait. **Figure 19.20** Hind limb structure changed first. *Rodhocetus* lacked flukes, but its pelvic bones and hind limbs had changed substantially from how those bones were shaped and arranged in *Pakicetus*. For example, in *Rodhocetus*, the pelvis

and hind limbs appear to be oriented for paddling, whereas they were oriented for walking in *Pakicetus*.

### Concept Check 19.1

1. Hutton and Lyell proposed that geologic events in the past were caused by the same processes operating today, at the same gradual rate. This principle suggested that Earth must be much older than a few thousand years, the age that was widely accepted at that time. Hutton and Lyell's ideas also stimulated Darwin to reason that the slow accumulation of small changes could ultimately produce the profound changes documented in the fossil record. In this context, the age of Earth was important to Darwin, because unless Earth was very old, he could not envision how there would have been enough time for evolution to occur. 2. By these criteria, Cuvier's explanation of the fossil record and Lamarck's hypothesis of evolution are both scientific. Cuvier thought that species did not evolve over time. He also suggested that sudden, catastrophic events caused extinctions in particular areas. These assertions can be tested against the fossil record, and his assertion that species do not evolve has been falsified. With respect to Lamarck, his principle of use and disuse can be used to make testable predictions for fossils of groups such as whale ancestors as they adapted to a new habitat. Lamarck's principle of use and disuse and his associated principle of the inheritance of acquired characteristics can also be tested directly in living organisms; these principles have been falsified.

### Concept Check 19.2

1. Organisms share characteristics (the unity of life) because they share common ancestors; the great diversity of life occurs because new species have repeatedly formed when descendant organisms gradually adapted to different environments, becoming different from their ancestors. 2. The fossil mammal species (or its ancestors) would most likely have colonized the Andes from within South America, whereas ancestors of mammals currently found in African mountains would most likely have colonized those mountains from other parts of Africa. As a result, the Andes fossil species would share a more recent common ancestor with South American mammals than with mammals in Africa. Thus, for many of its traits, the fossil mammal species would probably more closely resemble mammals that live in South American jungles than mammals that live on African mountains. It is also possible, however, that the fossil mammal species could resemble the African mountain mammals because similar environments selected for similar adaptations (even though they were only distantly related to one another). 3. As long as the white phenotype (encoded by the genotype *pp*) continues to be favored by natural selection, the frequency of the *p* allele will likely increase over time in the population. If the proportion of white individuals increases relative to purple individuals, the frequency of the recessive *p* allele will also increase relative to that of the *P* allele, which only appears in purple individuals (some of whom also carry a *p* allele).

### Concept Check 19.3

1. An environmental factor such as a drug does not create new traits, such as drug resistance, but rather selects for traits among those that are already present in the population. 2. (a) Despite their different functions, the forelimbs of different mammals are structurally similar because they all represent modifications of a structure found in the common ancestor. (b) This is a case of convergent evolution. The similarities between the sugar glider and flying squirrel indicate that similar environments selected for similar adaptations despite different ancestry. 3. At the time that dinosaurs originated, Earth's landmasses formed a single large continent, Pangaea. Because many dinosaurs were large and mobile, it is likely that early members of these groups lived on many different parts of Pangaea. When Pangaea broke apart, fossils of these organisms would have moved with the rocks in which they were deposited. As a result, we would predict that fossils of early dinosaurs would have a broad geographic distribution (this prediction has been upheld).

### Summary of Key Concepts Questions

19.1 Darwin thought that descent with modification occurred as a gradual, step-like process. The age of Earth was important to him because if Earth were only a few thousand years old (as conventional wisdom suggested), there wouldn't have been sufficient time for major evolutionary change. 19.2 All species have the potential to overreproduce—that is, to produce more offspring than can be supported by the environment. This ensures that there will be what Darwin called a “struggle for existence” in which many of the offspring are eaten, starved, diseased, or unable to reproduce for a variety of other reasons. Members of a population exhibit a range of heritable variations, some of which make it likely that their bearers will leave more offspring than other individuals (for example, the bearer may escape predators more effectively or be more tolerant of the physical conditions of the environment). Over time, natural selection resulting from factors such as predators, lack of food, or the physical conditions of the environment can increase the proportion of individuals with favorable traits in a population (evolutionary adaptation). 19.3 The hypothesis that cetaceans originated from a terrestrial mammal and are closely related to even-toed ungulates is supported by several lines of evidence. For example, fossils document that early cetaceans had hind limbs, as expected for organisms that descended from a land mammal; these fossils also show that cetacean hind limbs became reduced over time. Other fossils show that early cetaceans had a type of ankle bone that is otherwise found only in even-toed ungulates, providing strong evidence that even-toed ungulates are the land mammals to which cetaceans are most closely related. DNA sequence data also indicate that even-toed ungulates are the land mammals to which cetaceans are most closely related.

### Test Your Understanding

1. b 2. d 3. d 4. c 5. a  
6. (a)

(b) The rapid rise in the percentage of mosquitoes resistant to DDT was most likely caused by natural selection in which mosquitoes resistant to DDT could survive and reproduce while other mosquitoes could not. (c) In India—where DDT resistance first appeared—natural selection would have caused the frequency of resistant mosquitoes to increase over time. If resistant mosquitoes then migrated from India (for example, transported by wind or in planes, trains, or ships) to other parts of the world, the frequency of DDT resistance would increase there as well.

## Chapter 20

### Figure Questions

Figure 20.5 The new version (shown below) does not alter any of the evolutionary relationships shown in Figure 20.5. For example, B and C remain sister taxa, taxon A is still as closely related to taxon B as it is to taxon C, and so on.

Figure 20.6 Unknown 1b (a portion of sample 1) and Unknowns 9–13 all would have to be located on the branch of the tree that currently leads to Minke (Southern Hemisphere) and Unknowns 1a and 2–8. Figure 20.9 There are four possible bases (A, C, G, T) at each nucleotide position. If the base at each position depends on chance, not common descent, we would expect roughly one out of four (25%) of them to be the same. Figure 20.11 You should have circled the frog, turtle, and leopard lineages, along with their most recent common ancestor. Figure 20.12 The zebrafish lineage; of the five vertebrate lineages shown, its branch is the longest. Figure 20.15 The lizard and snake lineage is the most basal taxon shown (closest to the root of the tree). Among the descendants of the common ancestor indicated by the blue dot, the crocodilian lineage is the most basal. Figure 20.18 The molecular clock indicates that the divergence time is roughly 45–50 million years. Figure 20.20 This tree indicates that the sequences of rRNA and other genes in mitochondria are most closely related to those of proteobacteria, while the sequences of chloroplast genes are most closely related to those of cyanobacteria. These gene sequence relationships are what would be predicted from the endosymbiont theory illustrated in Figure 4.16, which posits that both mitochondria and chloroplasts originated as engulfed prokaryotic cells.

### Concept Check 20.1

1. We are classified the same from the domain level to the class level; both the leopard and human are mammals. Leopards belong to order Carnivora, whereas humans do not. 2. The branching pattern of the tree indicates that the badger and the wolf share a common ancestor that is more recent than the ancestor that these two animals share with the leopard. 3. The tree in (c) shows a different pattern of evolutionary relationships. In (c), C and B are sister taxa, whereas C and D are sister taxa in (a) and (b). 4.

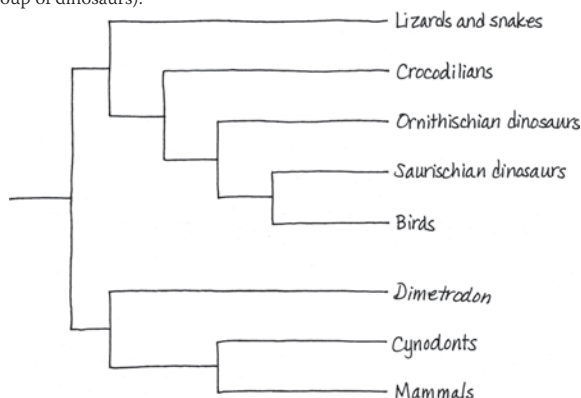

**Concept Check 20.2**

1. (a) Analogy, since porcupines and cacti are not closely related and since most other animals and plants do not have similar structures; (b) homology, since cats and humans are both mammals and have homologous forelimbs, of which the hand and paw are the lower part; (c) analogy, since owls and hornets are not closely related and since the structure of their wings is very different. 2. Species 2 and 3 are more likely to be closely related. Small genetic changes (as between species 2 and 3) can produce divergent physical appearances, but if many genes have diverged greatly (as in species 1 and 2), then the lineages have probably been separate for a long time.

**Concept Check 20.3**

1. No; hair is a shared ancestral character common to all mammals and thus is not helpful in distinguishing different mammalian subgroups. 2. The principle of maximum parsimony states that the hypothesis about nature we investigate first should be the simplest explanation found to be consistent with the facts. Actual evolutionary relationships may differ from those inferred by parsimony owing to complicating factors such as convergent evolution. 3. The traditional classification provides a poor match to evolutionary history, thus violating the basic principle of cladistics—that classification should be based on common descent. Both birds and mammals originated from groups traditionally designated as reptiles, making reptiles (as traditionally delineated) a paraphyletic group. These problems can be addressed by removing *Dimetrodon* and cynodonts from the reptiles and by regarding birds as a group of reptiles (specifically, as a group of dinosaurs).

**Concept Check 20.4**

1. A molecular clock is a method of estimating the actual time of evolutionary events based on numbers of base changes in genes that are related by descent. It is based on the assumption that the regions of genomes being compared evolve at constant rates. 2. There are many portions of the genome that do not code for genes; mutations that alter the sequence of bases in these regions could accumulate without affecting an organism's fitness. Even in coding regions of the genome, some mutations may not have a critical effect on genes or proteins. 3. The gene (or genes) used for the molecular clock may have evolved more slowly in these two taxa than in the species used to calibrate the clock; as a result, the clock would underestimate the time at which the taxa diverged from each other.

**Concept Check 20.5**

1. The kingdom Monera included bacteria and archaea, but we now know that these organisms are in separate domains. Kingdoms are subsets of domains, so a single kingdom (like Monera) that includes taxa from different domains is not valid. 2. Because of horizontal gene transfer, some genes in eukaryotes are more closely related to bacteria, while others are more closely related to archaea; thus, depending on which genes are used, phylogenetic trees constructed from DNA data can yield conflicting results. 3.

The fossil record indicates that prokaryotes originated long before eukaryotes. This suggests that the third tree, in which the eukaryotic lineage diverged first, is not accurate and hence is not likely to receive support from genetic data.

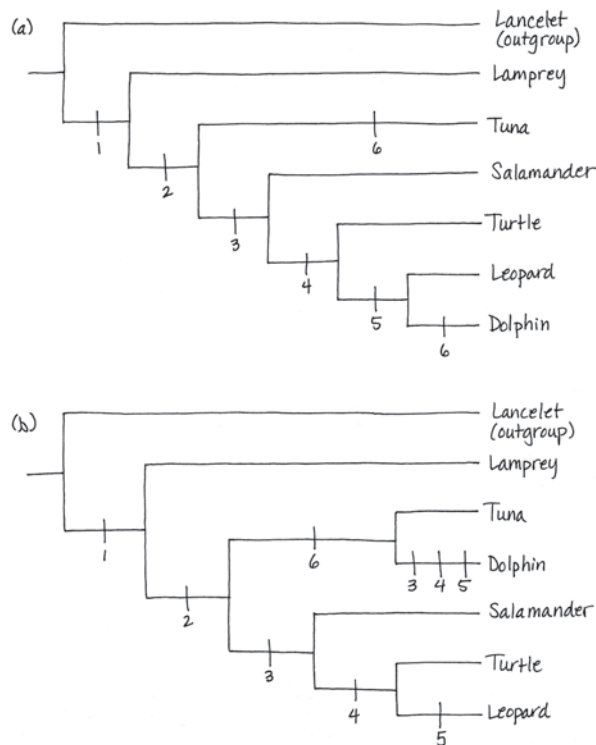

**Summary of Key Concepts Questions**

**20.1** The fact that humans and chimpanzees are sister species indicates that we share a more recent common ancestor with chimpanzees than we do with any other living primate species. But that does not mean that humans evolved from chimpanzees, or vice versa; instead, it indicates that both humans and chimpanzees are descendants of that common ancestor. **20.2** Homologous characters result from shared ancestry. As organisms diverge over time, some of their homologous characters will also diverge. The homologous characters of organisms that diverged long ago typically differ more than do the homologous characters of organisms that diverged more recently. As a result, differences in homologous characters can be used to infer phylogeny. In contrast, analogous characters result from convergent evolution, not shared ancestry, and hence can give misleading estimates of phylogeny. **20.3** All features of organisms arose at some point in the history of life. In the group in which a new feature first arose, that feature is a shared derived character that is unique to that clade. The group in which each shared derived character first appeared can be determined, and the resulting nested

pattern can be used to infer evolutionary history. **20.4** A key assumption of molecular clocks is that nucleotide substitutions occur at fixed rates, and hence the number of nucleotide differences between two DNA sequences is proportional to the time since the sequences diverged from each other. Some limitations of molecular clocks: No gene marks time with complete precision; natural selection can favor certain DNA changes over others; nucleotide substitution rates can change over long periods of time (causing molecular-clock estimates of when events in the distant past occurred to be highly uncertain); and the same gene can evolve at different rates in different organisms. **20.5** Genetic data indicated that many prokaryotes differed as much from each other as they did from eukaryotes. This indicated that organisms should be grouped into three “super-kingdoms,” or domains (Archaea, Bacteria, Eukarya). These data also indicated that the previous kingdom Monera (which had contained all the prokaryotes) did not make biological sense and should be abandoned. Later genetic and morphological data also indicated that the former kingdom Protista (which had primarily contained single-celled organisms) should be abandoned because some protists are more closely related to plants, fungi, or animals than they are to other protists.

**Test Your Understanding**

1. a 2. d 3. b 4. d 5. d 6. c 7. d 8.

(c) The tree in (a) requires seven evolutionary changes, while the tree in (b) requires nine evolutionary changes. Thus, the tree in (a) is more parsimonious, since it requires fewer evolutionary changes.

**Chapter 21****Figure Questions**

**Figure 21.4** The genetic code is redundant, meaning that more than one codon can specify the same amino acid. As a result, a substitution at a particular site in a coding region of the *Adh* gene might change the codon but not the translated amino acid and thus not the resulting protein encoded by the gene. One way an insertion in an exon would not affect the gene produced is if it occurs in an untranslated region of the exon. This is the case for the insertion at location 1,703. **Figure 21.8** The predicted frequencies are 36%  $C^R C^R$ , 48%  $C^R C^W$ , and 16%  $C^W C^W$ . **Figure 21.13** Directional selection. Goldenrain tree has smaller fruit than does the native host, balloon vine. Thus, in soapberry bug populations feeding on goldenrain tree, bugs with shorter beaks had an advantage, resulting in directional selection for shorter beak length. **Figure 21.16** Crossing a single female's eggs with both an SC and an LC male's sperm allowed the researchers to directly compare the effects of the males' contribution to the next generation, since both batches of offspring had the same maternal contribution. This isolation of the male's impact enabled researchers to draw conclusions about differences in genetic “quality” between the SC and LC males. **Figure 21.18** The researchers measured the percentage of successfully reproducing adults in the breeding population that had each phenotype. This approach of determining which phenotype was favored by selection assumes that reproduction was a sufficient indicator of relative fitness (as opposed to counting the number of eggs laid or offspring hatched, for example) and that mouth phenotype was the driving factor determining the fish's ability to reproduce.

**Concept Check 21.1**

1. Within a population, genetic differences among individuals provide the raw material on which natural selection and other mechanisms can act. Without such differences, allele frequencies could not change over time—and hence the population could not

evolve. **2.** Many mutations occur in somatic cells, which do not produce gametes and so are lost when the organism dies. Of mutations that do occur in cell lines that produce gametes, many do not have a phenotypic effect on which natural selection can act. Others have a harmful effect and are thus unlikely to increase in frequency because they decrease the reproductive success of their bearers. **3.** Its genetic variation (whether measured at the level of the gene or at the level of nucleotide sequences) would probably drop over time. During meiosis, crossing over and the independent assortment of chromosomes produce many new combinations of alleles. In addition, a population contains a vast number of possible mating combinations, and fertilization brings together the gametes of individuals with different genetic backgrounds. Thus, via crossing over, independent assortment of chromosomes, and fertilization, sexual reproduction reshuffles alleles into fresh combinations each generation. Without sexual reproduction, the rate of forming new combinations of alleles would be vastly reduced, causing the overall amount of genetic variation to drop.

#### Concept Check 21.2

**1.** Each individual has two alleles, so the total number of alleles is 1,400. To calculate the frequency of allele *A*, note that each of the 85 individuals of genotype *AA* has two *A* alleles, each of the 320 individuals of genotype *Aa* has one *A* allele, and each of the 295 individuals of genotype *aa* has zero *A* alleles. Thus, the frequency (*p*) of allele *A* is

$$p = \frac{(2 \times 85) + (1 \times 320) + (0 \times 295)}{1,400} = 0.35$$

There are only two alleles (*A* and *a*) in our population, so the frequency of allele *a* must be  $q = 1 - p = 0.65$ . **2.** Because the frequency of allele *a* is 0.45, the frequency of allele *A* must be 0.55. Thus, the expected genotype frequencies are  $p^2 = 0.3025$  for genotype *AA*,  $2pq = 0.495$  for genotype *Aa*, and  $q^2 = 0.2025$  for genotype *aa*. **3.** There are 120 individuals in the population, so there are 240 alleles. Of these, there are 124 *V* alleles—32 from the 16 *VV* individuals and 92 from the 92 *Vv* individuals. Thus, the frequency of the *V* allele is  $p = 124/240 = 0.52$ ; hence, the frequency of the *v* allele is  $q = 0.48$ . Based on the Hardy-Weinberg equation, if the population were not evolving, the frequency of genotype *VV* should be  $p^2 = 0.52 \times 0.52 = 0.27$ ; the frequency of genotype *Vv* should be  $2pq = 2 \times 0.52 \times 0.48 = 0.5$ ; and the frequency of genotype *vv* should be  $q^2 = 0.48 \times 0.48 = 0.23$ . In a population of 120 individuals, these expected genotype frequencies lead us to predict that there would be 32 *VV* individuals ( $0.27 \times 120$ ), 60 *Vv* individuals ( $0.5 \times 120$ ), and 28 *vv* individuals ( $0.23 \times 120$ ). The actual numbers for the population (16 *VV*, 92 *Vv*, 12 *vv*) deviate from these expectations (fewer homozygotes and more heterozygotes than expected). This indicates that the population is not in Hardy-Weinberg equilibrium and hence may be evolving at this locus.

#### Concept Check 21.3

**1.** Natural selection is more “predictable” in that it alters allele frequencies in a non-random way: It tends to increase the frequency of alleles that increase the organism’s reproductive success in its environment and decrease the frequency of alleles that decrease the organism’s reproductive success. Alleles subject to genetic drift increase or decrease in frequency by chance alone, whether or not they are advantageous. **2.** Genetic drift results from chance events that cause allele frequencies to fluctuate at random from generation to generation; within a population, this process tends to decrease genetic variation over time. Gene flow is the transfer of alleles between populations, a process that can introduce new alleles to a population and hence may increase its genetic variation (albeit slightly, since rates of gene flow are often low). **3.** Selection is not important at this locus; furthermore, the populations are not small, and hence the effects of genetic drift should not be pronounced. Gene flow is occurring via the movement of pollen and seeds. Thus, allele and genotype frequencies in these populations should become more similar over time as a result of gene flow.

#### Concept Check 21.4

**1.** Zero, because fitness includes reproductive contribution to the next generation, and a sterile mule cannot produce offspring. **2.** Although both gene flow and genetic drift can increase the frequency of advantageous alleles in a population, they can also decrease the frequency of advantageous alleles or increase the frequency of harmful alleles. Only natural selection consistently results in an increase in the frequency of alleles that enhance survival or reproduction. Thus, natural selection is the only mechanism that consistently leads to adaptive evolution. **3.** The three modes of natural selection (directional, stabilizing, and disruptive) are defined in terms of the selective advantage of different phenotypes, not different genotypes. Thus, the type of selection represented by heterozygote advantage depends on the phenotype of the heterozygotes. In this question, because heterozygous individuals have a more extreme phenotype than either homozygote, heterozygote advantage represents directional selection. **4.** Under prolonged low-oxygen conditions, some of the red blood cells of a heterozygote may sickle, leading to harmful effects (see Figure 3.22). This does not occur in individuals with two normal hemoglobin alleles, suggesting that there may be selection against heterozygotes in malaria-free regions (where heterozygote advantage does not occur). However, since heterozygotes are healthy under most conditions, selection against them is unlikely to be strong.

#### Summary of Key Concepts Questions

**21.1** Much of the nucleotide variability at a genetic locus occurs within introns. Nucleotide variation at these sites typically does not affect the phenotype because introns do not code for the protein product of the gene. (Note to students: In certain circumstances, it is possible that a change in an intron could affect RNA splicing and ultimately have some phenotypic effect on the organism, but such mechanisms are not covered in this introductory text.) There are also many variable nucleotide sites within exons. However, most of the variable sites within exons reflect changes to the DNA sequence that do not change the sequence of amino acids encoded by the gene (and hence may not affect the phenotype). **21.2** No, this is not an example of circular reasoning. Calculating *p* and *q* from observed genotype frequencies does not imply

that those genotype frequencies must be in Hardy-Weinberg equilibrium. Consider a population that has 195 individuals of genotype *AA*, 10 of genotype *Aa*, and 195 of genotype *aa*. Calculating *p* and *q* from these values yields  $p = q = 0.5$ . Using the Hardy-Weinberg equation, the predicted equilibrium frequencies are  $p^2 = 0.25$  for genotype *AA*,  $2pq = 0.5$  for genotype *Aa*, and  $q^2 = 0.25$  for genotype *aa*. Since there are 400 individuals in the population, these predicted genotype frequencies indicate that there should be 100 *AA* individuals, 200 *Aa* individuals, and 100 *aa* individuals—numbers that differ greatly from the values that we used to calculate *p* and *q*. **21.3** It is unlikely that two such populations would evolve in similar ways. Since their environments are very different, the alleles favored by natural selection would probably differ between the two populations. Although genetic drift may have important effects in each of these small populations, drift causes unpredictable changes in allele frequencies, so it is unlikely that drift would cause the populations to evolve in similar ways. Both populations are geographically isolated, suggesting that little gene flow would occur between them (again making it less likely that they would evolve in similar ways). **21.4** Compared to males, it is likely that the females of such species would be larger, more colorful, endowed with more elaborate ornamentation (for example, a large morphological feature such as the peacock’s tail), and more apt to engage in behaviors intended to attract mates or prevent other members of their sex from obtaining mates.

#### Test Your Understanding

1. e 2. c 3. e 4. b 5. a 6. d

7. The frequency of the *lap<sup>94</sup>* allele increases as one moves from southwest to northeast across Long Island Sound.

A hypothesis that explains the shape of the graph and accounts for the observations stated in the question is that the frequency of the *lap<sup>94</sup>* allele at different sites results from an interaction between selection and gene flow. Under this hypothesis, in the southwest portion of the Sound, salinity is relatively low, and selection against the *lap<sup>94</sup>* allele is strong. Moving toward the northeast and into the open ocean, where salinity is relatively high, selection favors a high frequency of the *lap<sup>94</sup>* allele. However, because mussel larvae disperse long distances, gene flow prevents the *lap<sup>94</sup>* allele from becoming fixed in the open ocean or from declining to zero in the southwestern portion of Long Island Sound.

## Chapter 22

### Figure Questions

**Figure 22.8** If this had not been done, the strong preference of “starch flies” and “maltose flies” to mate with like-adapted flies could have occurred simply because the flies could detect (for example, by sense of smell) what their potential mates had eaten as larvae—and they preferred to mate with flies that had a similar smell to their own. **Figure 22.10** In murky waters where females distinguish colors poorly, females of each species might mate often with males of the other species. Hence, since hybrids between these species are viable and fertile, the gene pools of the two species could become more similar over time. **Figure 22.11** The graph suggests there has been gene flow of some fire-bellied toad alleles into the range of the yellow-bellied toad. Otherwise, all individuals located to the left of the hybrid zone portion of the graph would have allele frequencies very close to 1. **Figure 22.12** Because the populations had only just begun to diverge from one another at this point in the process, it is likely that any existing barriers to reproduction would weaken over time. **Figure 22.16** Over time, the chromosomes of the experimental hybrids came to resemble those of *H. anomalus*. This occurred even though conditions in the laboratory differed greatly from conditions in the field, where *H. anomalus* is found, suggesting that selection for laboratory conditions was not strong. Thus, it is unlikely that the observed rise in the fertility of the experimental hybrids was due to selection for life under laboratory conditions. **Figure 22.17** The presence of *M. cardinalis* plants that carry the *M. lewisii* *yup* allele would make it more likely that bumblebees would transfer pollen between the two monkey flower species. As a result, we would expect the number of hybrid offspring to increase.

**Concept Check 22.1**

1. (a) All except the biological species concept can be applied to both asexual and sexual species because they define species on the basis of characteristics other than the ability to reproduce. In contrast, the biological species concept can be applied only to sexual species. (b) The easiest species concept to apply in the field would be the morphological species concept because it is based only on the appearance of the organism. Additional information about its ecological habits, evolutionary history, and reproduction are not required. 2. Because these birds live in fairly similar environments and can breed successfully in captivity, the reproductive barrier in nature is probably prezygotic; given the species' differences in habitat preference, this barrier could result from habitat isolation.

**Concept Check 22.2**

1. In allopatric speciation, a new species forms while in geographic isolation from its parent species; in sympatric speciation, a new species forms in the absence of geographic isolation. Geographic isolation greatly reduces gene flow between populations, whereas ongoing gene flow is more likely in sympatric populations. As a result, sympatric speciation is less common than allopatric speciation. 2. Gene flow between subsets of a population that live in the same area can be reduced in a variety of ways. In some species—especially plants—changes in chromosome number can block gene flow and establish reproductive isolation in a single generation. Gene flow can also be reduced in sympatric populations by habitat differentiation (as seen in the apple maggot fly, *Rhagoletis*) and sexual selection (as seen in Lake Victoria cichlids). 3. Allopatric speciation would be less likely to occur on a nearby island than on an isolated island of the same size. The reason we expect this result is that continued gene flow between mainland populations and those on a nearby island reduces the chance that enough genetic divergence will take place for allopatric speciation to occur. 4. If all of the homologs failed to separate during anaphase I of meiosis, some gametes would end up with an extra set of chromosomes (and others would end up with no chromosomes). If a gamete with an extra set of chromosomes fused with a normal gamete, a triploid would result; if two gametes with an extra set of chromosomes fused with each other, a tetraploid would result.

**Concept Check 22.3**

1. Hybrid zones are regions in which members of different species meet and mate, producing some offspring of mixed ancestry. Such regions can be viewed as “natural laboratories” in which to study speciation because scientists can directly observe factors that cause (or fail to cause) reproductive isolation. 2. (a) If hybrids consistently survived and reproduced poorly compared with the offspring of intraspecific matings, reinforcement could occur. If it did, natural selection could cause prezygotic barriers to reproduction between the parent species to strengthen over time, decreasing the production of unfit hybrids and leading to a completion of the speciation process. (b) If hybrid offspring survived and reproduced as well as the offspring of intraspecific matings, indiscriminate mating between the parent species would lead to the production of large numbers of hybrid offspring. As these hybrids mated with each other and with members of both parent species, the gene pools of the parent species could fuse over time, reversing the speciation process.

**Concept Check 22.4**

1. The time between speciation events includes (1) the length of time that it takes for populations of a newly formed species to begin diverging reproductively from one another and (2) the time it takes for speciation to be complete once this divergence begins. Although speciation can occur rapidly once populations have begun to diverge from one another, it may take millions of years for that divergence to begin. 2. Investigators transferred alleles at the *yup* locus (which influences flower color) from each parent species to the other. *M. lewisii* plants with an *M. cardinalis* *yup* allele received many more visits from hummingbirds than usual; hummingbirds usually pollinate *M. cardinalis* but avoid *M. lewisii*. Similarly, *M. cardinalis* plants with an *M. lewisii* *yup* allele received many more visits from bumblebees than usual; bumblebees usually pollinate *M. lewisii* and avoid *M. cardinalis*. Thus, alleles at the *yup* locus can influence pollinator choice, which in these species provides the primary barrier to interspecific mating. Nevertheless, the experiment does not prove that the *yup* locus alone controls barriers to reproduction between *M. lewisii* and *M. cardinalis*; other genes might enhance the effect of the *yup* locus (by modifying flower color) or cause entirely different barriers to reproduction (for example, gametic isolation or a post-zygotic barrier). 3. Crossing over. If crossing over did not occur, each chromosome in an experimental hybrid would remain as in the  $F_1$  generation: composed entirely of DNA from one parent species or the other.

**Summary of Key Concepts Questions**

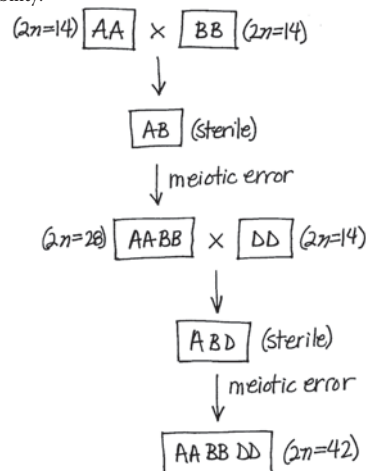

22.1 According to the biological species concept, a species is a group of populations whose members interbreed and produce viable, fertile offspring; thus, gene flow occurs between populations of a species. In contrast, members of different species do not interbreed, and hence no gene flow occurs between their populations. Overall, then, in the biological species concept, species can be viewed as designated by the absence of gene flow—making gene flow of central importance to the biological species concept. 22.2 Sympatric speciation can be promoted by factors such as polyploidy, habitat shifts, and sexual selection, all of which can reduce gene flow between the subpopulations of a larger population. But such factors can also occur in allopatric populations and hence can also promote allopatric speciation. 22.3 If the hybrids are selected against, the hybrid zone could persist if individuals from the parent species regularly travel into the zone, where they mate to produce hybrid offspring. If hybrids are not selected against, there is no cost to the continued production of hybrids, and large numbers of hybrid offspring may be produced. Natural selection for life in different environments may keep the gene pools of the two parent species distinct, thus preventing the loss (by fusion) of the parent species and once again causing the hybrid zone to be stable over time. 22.4 As the goatsbeard plant, Bahamas mosquitofish, and apple maggot fly illustrate, speciation continues to happen today. A new species

can begin to form whenever gene flow is reduced between populations of the parent species. Such reductions in gene flow can occur in many ways: A new, geographically isolated population may be founded by a few colonists; some members of the parent species may begin to utilize a new habitat; and sexual selection may isolate formerly connected populations or subpopulations. These and many other such events are happening today.

**Test Your Understanding**

1. b 2. c 3. c 4. a 5. e 6. d

7. Here is one possibility:

**Chapter 23****Figure Questions**

**Figure 23.5** There are two speciation events and two extinctions in lineage A, while there are three speciation events and no extinctions in lineage B. **Figure 23.8** The Australian plate's current direction of movement is roughly similar to the northeasterly direction that the continent traveled over the past 65 million years.

**Figure 23.10** The blue curve is for marine animal families. Families often contain many species, and if even one of those species survives, the family would not become extinct. Hence, we would expect the percentage of families that became extinct to be lower than the percentage of species that became extinct. **Figure 23.17** In this bat, the ratio of the length of the longest set of hand and finger bones to the length of the radius is approximately equal to 2. Although answers will vary from person to person, the corresponding ratio is typically less than 1 in humans. **Figure 23.20** The coding sequence of the *Pitx1* gene would differ between the marine and lake populations, but patterns of gene expression would not.

**Concept Check 23.1**

1. 22,920 years (four half-lives:  $5,730 \times 4$ ) 2. The fossil record shows that different groups of organisms dominated life on Earth at different points in time and that many organisms once alive are now extinct; specific examples can be found in Figure 23.2. The fossil record also indicates that new groups of organisms can arise via the gradual modification of previously existing organisms, as illustrated by fossils that document the origin of mammals from their cynodont ancestors. 3. Because uranium-238 has a half-life of 4.5 billion years, the x-axis would be relabeled (in billions of years) as 4.5, 9, 13.5, and 18. 4. A fossil record of life today would include many organisms with hard body parts (such as vertebrates and many marine invertebrates), but might not include some species we are very familiar with, such as those that have small geographic ranges and/or small population sizes (for example, endangered species such as the giant panda, tiger, and several rhinoceros species). 5. The discovery of such a (hypothetical) fossil organism would indicate that aspects of our current understanding of the origin of mammals are not correct because mammals are thought to have originated much more recently (see Figure 23.4). For example, such a discovery could suggest that the dates of previous fossil discoveries are not correct or that the lineages shown in Figure 23.4 shared features with mammals but were not their direct ancestors. Such a discovery would also suggest that radical changes in multiple aspects of the skeletal structure of organisms could arise suddenly—an idea that is not supported by the known fossil record.

**Concept Check 23.2**

1. Continental drift alters the physical geography and climate of Earth, as well as the extent to which organisms are geographically isolated. Because these factors affect extinction and speciation rates, continental drift has a major impact on life on Earth. 2. In each of the five mass extinctions documented in the fossil record, 50% or more of marine species became extinct, as did large numbers of terrestrial species. As a result, a mass extinction alters the course of evolution dramatically, removing many evolutionary lineages and reducing the diversity of life on Earth for millions of years. A mass extinction can also change ecological communities by changing the types of organisms that live in them. 3. Mass extinctions; major evolutionary innovations; the diversification of another group of organisms (which can provide new sources of food); migration to new locations where few competitor species exist. 4. In theory, fossils of both common and rare species would be present right up to the time of the catastrophic event, then disappear. Reality is more complicated because the fossil record is not perfect. So the most recent fossil for a species might be a million years

before the mass extinction—even though the species did not become extinct *until* the mass extinction. This complication is especially likely for rare species because so few of their fossils will form and be discovered. Hence, for many rare species, the fossil record would not document that the species was alive immediately before the extinction (even if it was).

### Concept Check 23.3

1. Heterochrony can cause a variety of morphological changes. For example, if the onset of sexual maturity changes, a retention of juvenile characteristics (paedomorphosis) may result. Paedomorphosis can be caused by small genetic changes that result in large changes in morphology, as seen in the axolotl salamander. 2. In animal embryos, *Hox* genes influence the development of structures such as limbs and feeding appendages. As a result, changes in these genes—or in the regulation of these genes—are likely to have major effects on morphology. 3. From genetics, we know that gene regulation is altered by how well transcription factors bind to noncoding DNA sequences called control elements. Thus, if changes in morphology are often caused by changes in gene regulation, portions of noncoding DNA that contain control elements are likely to be strongly affected by natural selection.

### Concept Check 23.4

1. Complex structures do not evolve all at once, but in increments, with natural selection selecting for adaptive variants of the earlier versions. 2. Although the myxoma virus is highly lethal, initially some of the rabbits are resistant (0.2% of infected rabbits are not killed). Thus, assuming resistance is an inherited trait, we would expect the rabbit population to show a trend for increased resistance to the virus. We would also expect the virus to show an evolutionary trend toward reduced lethality. We would expect this trend because a rabbit infected with a less lethal virus would be more likely to live long enough for a mosquito to bite it and hence potentially transmit the virus to another rabbit. (A virus that kills its rabbit host before a mosquito transmits the virus to another rabbit dies with its host.)

### Summary of Key Concepts Questions

**23.1** One challenge is that organisms do not use radioisotopes that have long half-lives to build their bones or shells. As a result, fossils older than 75,000 years cannot be dated directly. Fossils are often found in sedimentary rock, but those rocks typically contain sediments of different ages, again posing a challenge when trying to date old fossils. To circumvent these challenges, geologists date layers of volcanic rock that surround old fossils and that contain radioisotopes with long half-lives. This approach provides minimum and maximum estimates for the ages of fossils sandwiched between two layers of volcanic rock. **23.2** The broad evolutionary changes documented by the fossil record reflect the rise and fall of major groups of organisms. In turn, the rise or fall of any particular group results from a balance between speciation and extinction rates: A group increases in size when the rate at which its members produce new species is greater than the rate at which its member species are lost to extinction, while a group shrinks in size if extinction rates are greater than speciation rates. **23.3** A change in the sequence or regulation of a developmental gene can produce major morphological changes. In some cases, such morphological changes may enable organisms to perform new functions or live in new environments—thus potentially leading to an adaptive radiation and the formation of a new group of organisms. **23.4** Evolutionary change results from interactions between organisms and their current environments. No goal is involved in this process. As environments change over time, the features of organisms favored by natural selection may also change. When this happens, what once may have seemed like a “goal” of evolution (for example, improvements in the function of a feature previously favored by natural selection) may cease to be beneficial or may even be harmful.

### Test Your Understanding

1. e 2. b 3. d 4. c 5. b 6. The synapsid clade. *Dimetrodon* and mammals share a common ancestor that was a synapsid; hence, both *Dimetrodon* and mammals are synapsids. Although mammals are also therapsids, *Dimetrodon* is not a therapsid because it diverged from the mammal evolutionary lineage before the origin of the first therapsids.

## Chapter 24

### Figure Questions

**Figure 24.3** Proteins are almost always composed of the same 20 amino acids shown in Figure 3.17. However, many other amino acids could potentially form in this or any other experiment. For example, any molecule that had a different R group than those listed in Figure 3.17 (yet still contained an  $\alpha$  carbon, an amino group, and a carboxyl group) would be an amino acid—yet it would not be one of the 20 amino acids commonly found in nature today. **Figure 24.14** It is likely that the expression or sequence of genes that affect glucose metabolism may have changed; genes for metabolic processes no longer needed by the cell also may have changed.

**Figure 24.15** Transduction results in horizontal gene transfer when the host and recipient cells are members of different species. **Figure 24.18** Eukarya

**Figure 24.20** Thermophiles live in very hot environments, so it is likely that their enzymes can continue to function normally at much higher temperatures than do the enzymes of other organisms. At low temperatures, however, the enzymes of thermophiles may not function as well as the enzymes of other organisms.

**Figure 24.22** From the graph, plant uptake can be estimated as 0.7, 0.6, and 0.95 mg  $K^+$  for strains 1, 2, and 3, respectively. These values average to 0.75 mg  $K^+$ . If bacteria had no effect, the average plant uptake of potassium for strains 1, 2, and 3 should be close to 0.5 mg  $K^+$ , the value observed for plants grown in bacteria-free soil.

### Concept Check 24.1

1. The hypothesis that conditions on early Earth could have permitted the synthesis of organic molecules from inorganic ingredients. 2. In contrast to random mingling of molecules in an open solution, segregation of molecular systems by the membranes of protocells could concentrate organic molecules, assisting biochemical reactions.

3. The earliest prokaryotic fossils are of stromatolites that lived in shallow marine environments 3.5 billion years ago. By 3.1 billion years ago, stromatolites had diversified into two different morphological types, and by 2.8 billion years ago, they had expanded to live in salty lakes as well as marine environments. Fossils of individual prokaryotic cells have also been found, the earliest dating to 3.4 billion years ago. By 2.5 billion years ago, diverse communities of photosynthetic cyanobacteria lived in the oceans. These cyanobacteria released oxygen to Earth's atmosphere during the water-splitting step of photosynthesis. As a result, the composition of the atmosphere changed and many prokaryotic groups were driven to extinction—thus altering the course of evolution. 4. Today, genetic information usually flows from DNA to RNA, as when the DNA sequence of a gene is used as a template to synthesize the mRNA encoding a particular protein. However, the life cycle of retroviruses such as HIV shows that genetic information can flow in the reverse direction (from RNA to DNA). In these viruses, the enzyme reverse transcriptase uses RNA as a template for DNA synthesis, suggesting that a similar enzyme could have played a key role in the transition from an RNA world to a DNA world.

### Concept Check 24.2

1. Prokaryotic cells lack the complex compartmentalization associated with the membrane-enclosed organelles of eukaryotic cells. Prokaryotic genomes have much less DNA than eukaryotic genomes, and most of this DNA is contained in a single ring-shaped chromosome located in the nucleoid rather than within a true membrane-enclosed nucleus. In addition, many prokaryotes also have plasmids, small ring-shaped DNA molecules containing a few genes. 2. A phototroph derives its energy from light, while a chemotroph gets its energy from chemical sources. An autotroph derives its carbon from  $CO_2$ ,  $HCO_3^-$ , or related compounds, while a heterotroph gets its carbon from organic nutrients such as glucose. Thus, there are four nutritional modes: photoautotrophic, photoheterotrophic (unique to prokaryotes), chemoautotrophic (unique to prokaryotes), and chemoheterotrophic. 3. Plastids such as chloroplasts are thought to have evolved from an endosymbiotic photosynthetic prokaryote. More specifically, the phylogenetic tree shown in Figure 20.20 indicates that plastids are closely related to cyanobacteria. Hence, we can hypothesize that the thylakoid membranes of chloroplasts resemble those of cyanobacteria because chloroplasts evolved from an endosymbiotic cyanobacterium. 4. If humans could fix nitrogen, we could build proteins using atmospheric  $N_2$  and hence would not need to eat high-protein foods such as meat, fish, or soy. Our diet would, however, need to include a source of carbon, along with minerals and water. Thus, a typical meal might consist of carbohydrates as a carbon source, along with fruits and vegetables to provide essential minerals (and additional carbon).

### Concept Check 24.3

1. Prokaryotes can have extremely large population sizes, in part because they often have short generation times. The large number of individuals in prokaryotic populations makes it likely that in each generation there will be many individuals that have new mutations at any particular gene, thereby adding considerable genetic diversity to the population. 2. In transformation, naked, foreign DNA from the environment is taken up by a bacterial cell. In transduction, phages carry bacterial genes from one bacterial cell to another. In conjugation, a bacterial cell directly transfers plasmid or chromosomal DNA to another cell via a mating bridge that temporarily connects the two cells. 3. The population that includes individuals capable of conjugation would probably be more successful, since some of its members could form recombinant cells whose new gene combinations might be advantageous in a novel environment. 4. Yes. Genes for antibiotic resistance could be transferred (by transformation, transduction, or conjugation) from the nonpathogenic bacterium to a pathogenic bacterium; this could make the pathogen an even greater threat to human health. In general, transformation, transduction, and conjugation tend to increase the spread of resistance genes.

### Concept Check 24.4

1. Molecular systematic studies indicate that organisms once classified as bacteria are more closely related to eukaryotes and belong in a domain of their own: Archaea. Such studies have also shown that horizontal gene transfer is common and plays an important role in the evolution of prokaryotes. 2. By not requiring that organisms be cultured in the laboratory, metagenomic studies have revealed an immense diversity of previously unknown prokaryotic species. Over time, the ongoing discovery of new species by metagenomic analyses may alter our understanding of prokaryotic phylogeny greatly. 3. At present, all known methanogens are archaea in the clade Euryarchaeota; this suggests that this unique metabolic pathway probably arose in ancestral species within Euryarchaeota. Since Bacteria and Archaea have been separate evolutionary lineages for billions of years, the discovery of a methanogen from the domain Bacteria would suggest that adaptations that enabled the use of  $CO_2$  to oxidize  $H_2$  may have evolved twice—once in Archaea (within Euryarchaeota) and once in Bacteria. (It is also possible that a newly discovered bacterial methanogen could have acquired the genes for this metabolic pathway by horizontal gene transfer from a methanogen in domain Archaea. However, horizontal gene transfer is not a likely explanation because of the large number of genes involved and because gene transfers between species in different domains are rare.)

### Concept Check 24.5

1. Although prokaryotes are small, their large numbers and metabolic abilities enable them to play key roles in ecosystems by decomposing wastes, recycling chemicals, and affecting the concentrations of nutrients available to other organisms. Prokaryotes also play a key role in ecological interactions such as mutualism and parasitism. 2. No. If the poison is secreted as an exotoxin, live bacteria could be transmitted to another person. But the same is true if the poison is an endotoxin—only in this case, the live bacteria that are transmitted may be descendants of the (now-dead) bacteria that produced the poison. 3. Cyanobacteria produce oxygen when water is split in the light reactions of photosynthesis. The Calvin cycle incorporates  $CO_2$  from the air into organic molecules, which are then converted to sugars. 4. Some of the many

different species of prokaryotes that live in the human gut compete with one another for resources (from the food that you eat). Because different prokaryotic species have different adaptations, a change in diet may alter which species can grow most rapidly, thus altering species abundance.

### Summary of Key Concepts Questions

**24.1** Particles of montmorillonite clay may have provided surfaces on which organic molecules became concentrated and hence were more likely to react with one another. Montmorillonite clay particles may also have facilitated the transport of key molecules, such as short strands of RNA, into vesicles. These vesicles can form spontaneously from simple precursor molecules, “reproduce” and “grow” on their own, and maintain internal concentrations of molecules that differ from those in the surrounding environment. These features of vesicles represent key steps in the emergence of protocells and (ultimately) the first living cells. **24.2** Specific structural features that enable prokaryotes to thrive in diverse environments include their cell walls (which provide shape and protection), flagella (which function in directed movement), and ability to form capsules or endospores (both of which can protect against adverse environmental conditions). Prokaryotes also have an exceptionally broad range of metabolic adaptations, enabling them to thrive in many different environments.

**24.3** Many prokaryotic species can reproduce extremely rapidly, and their populations can number in the trillions. As a result, even though mutations are rare, every day many offspring are produced that have new mutations at particular gene loci. In addition, even though prokaryotes reproduce asexually and hence the vast majority of offspring are genetically identical to their parent, the genetic variation of their populations can be increased by transduction, transformation, and conjugation. Each of these (nonreproductive) processes can increase genetic variation by transferring DNA from one cell to another—even among cells that are of different species. **24.4** Molecular data have revealed that prokaryotes form two domains (Bacteria and Archaea), and they have elucidated relationships among major groups of prokaryotes. Molecular data have also allowed researchers to sample genes directly from the environment; using such genes to construct phylogenies has led to the discovery of major new groups of prokaryotes. **24.5** Prokaryotes play key roles in the chemical cycles on which life depends. For example, prokaryotes are important decomposers, breaking down corpses and waste materials, thereby releasing nutrients to the environment, where they can be used by other organisms. Prokaryotes also convert inorganic compounds to forms that other organisms can use. With respect to their ecological interactions, many prokaryotes form life-sustaining mutualisms with other species. For example, human well-being depends on our associations with mutualistic prokaryotes, such as the many species that live in our intestines and digest food that we cannot. In some cases, such as hydrothermal vent communities, the metabolic activities of prokaryotes provide an energy source on which hundreds of other species depend; in the absence of the prokaryotes, the community collapses.

### Test Your Understanding

1. d 2. c 3. e 4. b 5. d 6. e 7. a

(b) Some *Rhizobium* strains are much more effective at promoting plant growth than other *Rhizobium* strains; the most ineffective strains have little positive effect (plant growth with these strains differs little from plant growth in the absence of *Rhizobium*). The ineffective strains may transfer relatively little nitrogen to their plant host, limiting plant growth.

## Chapter 25

### Figure Questions

**Figure 25.4** Four. The first (and primary) genome is the DNA located in the chlorarachniophyte nucleus. A chlorarachniophyte also contains remnants of a green alga's nuclear DNA, located in the nucleomorph. Finally, mitochondria and chloroplasts contain DNA from the (different) bacteria from which they evolved. These two prokaryotic genomes comprise the third and fourth genomes contained within a chlorarachniophyte.

**Figure 25.7** As described in observations 1 and 2, choanoflagellates and several groups of animals have collar cells. Since collar cells have never been observed in plants, fungi, or non-choanoflagellate protists, this suggests that choanoflagellates may be more closely related to animals than to other eukaryotes. If choanoflagellates are more closely related to animals than to any other group of eukaryotes, choanoflagellates and animals should share other traits that are not found in other eukaryotes. The data described in observation 3 are consistent with this prediction. **Figure 25.9** Based on the age of the oldest taxonomically resolved fossil eukaryote, a red alga that lived 1.2 billion years ago, we can conclude that the

supergroups must have begun to diverge no later than 1.2 billion years ago. **Figure 25.21** If the assumption is correct, then their results indicate that the fusion of the genes for DHFR and TS may be a derived trait shared by members of three supergroups of eukaryotes (Excavata, the SAR clade, and Archaeplastida). However, if the assumption is not correct, the presence or absence of the gene fusion may tell little about phylogenetic history. For example, if the genes fused multiple times, groups could share the trait because of convergent evolution rather than common descent. If instead the genes were secondarily split, a group with such a split could be placed (incorrectly) in Unikonta rather than its correct placement in one of the other three supergroups. **Figure 25.26** The apicoplast is a modified plastid and hence was derived from a cyanobacterium. Thus, the metabolic pathway that the apicoplast uses to synthesize this essential chemical would likely differ from pathways found in humans—and hence drugs that target this pathway would probably not harm humans.

### Concept Check 25.1

**1.** The earliest fossil eukaryotes date to 1.8 billion years ago. By 1.3 billion years ago, the fossil record documents a moderate diversity of unicellular and simple multicellular eukaryotes, some of which had asymmetric forms indicating the presence of a well-developed cytoskeleton. Fossil organisms that lived from 1.3 billion to 635 million years ago include those with complex multicellularity, sexual life cycles, and eukaryotic photosynthesis. Large, multicellular eukaryotes first appeared about 600 million years ago. **2.** Eukaryotes are considered “combination” organisms because some of their genes and cellular characteristics are derived from archaea, while others are derived from bacteria. Strong evidence shows that eukaryotes acquired mitochondria after a host cell (either an archaean or a cell with archaeal ancestors) first engulfed and then formed an endosymbiotic association with an alpha proteobacterium. Similarly, chloroplasts in red and green algae appear to have descended from a photosynthetic cyanobacterium that was engulfed by an ancient heterotrophic eukaryote. Secondary endosymbiosis also played an important role: Various protist lineages acquired plastids by engulfing unicellular red or green algae. **3.** Photosynthetic eukaryotes are descended from the endosymbiotic event that gave rise to plastids. Thus, such a discovery would suggest that eukaryotic photosynthesis arose at least twice, in two separate endosymbiotic events in which a cyanobacterium was engulfed by a heterotrophic eukaryote.

### Concept Check 25.2

**1.** Morphologically, choanoflagellates are almost indistinguishable from the collar cells of sponges, a basal animal lineage. Other animals also have collar cells, whereas such cells have never been observed in fungi, plants, or protists other than choanoflagellates. Finally, DNA sequence comparisons indicate that choanoflagellates are the sister group of animals. **2.** The evolution of proteins that attach animal cells to one another was a key step in the origin of multicellularity in animals. Choanoflagellates encode many of the domains found in one such group of animal attachment proteins, the cadherins. Other eukaryotes do not encode these domains; thus, animal cadherin proteins appear to have descended from proteins found in choanoflagellates. Evidence for modification is also clear: As seen in Figure 25.8, the protein domains found in animal cadherins differ in type, number, and location from those found in the ancestral choanoflagellate protein. **3.** Multicellularity originated independently in *Volvox*, plants, and fungi. Since each of these groups arose from different single-celled ancestors, it is likely that their cell-to-cell attachments form using different molecules. (Data from recent molecular studies are consistent with this prediction.)

### Concept Check 25.3

**1.** Many members of the supergroup Excavata have unique cytoskeletal features, and some have an “excavated” feeding groove on one side of their cells; two major clades of excavates are characterized by having reduced mitochondria. The SAR supergroup contains three large clades—stramenopiles, alveolates, and rhizarians—which collectively include diatoms and other key photosynthetic species, protists that move using cilia, and amoebas with threadlike pseudopodia. The supergroup Archaeplastida contains clades that descended from a protist ancestor that engulfed a cyanobacterium, including red algae, green algae, and land plants. Finally, the supergroup Unikonta includes a large clade of amoebas that have lobe- or tube-shaped pseudopodia, as well as animals, fungi, and their close protist relatives. **2.** During photosynthesis, aerobic algae produce  $O_2$  and use  $CO_2$ .  $O_2$  is produced as a by-product of the light reactions, while  $CO_2$  is used as an input to the Calvin cycle (the end products of which are sugars). Aerobic algae also perform cellular respiration, which uses  $O_2$  as an input and produces  $CO_2$  as a waste product. **3.** Since the unknown protist is more closely related to diplomonads than to euglenozoans, it must have originated after the diplomonads and parabasalids diverged from the euglenozoans. In addition, since the unknown species has fully functional mitochondria—yet both diplomonads and parabasalids do not—it is likely that the unknown species originated *before* the last common ancestor of the diplomonads and parabasalids.

### Concept Check 25.4

**1.** Because photosynthetic protists constitute the base of aquatic food webs, many aquatic organisms depend on them for food, either directly or indirectly. (In addition, a substantial percentage of the oxygen produced by photosynthesis is made by photosynthetic protists.) **2.** Protists form mutualistic and parasitic associations with other organisms. Examples include photosynthetic dinoflagellates that form a mutualistic symbiosis with coral polyps; parabasalids that form a mutualistic symbiosis with termites; and the stramenopile *Phytophthora ramorum*, a parasite of oak trees. **3.** Corals depend on their dinoflagellate symbionts for nourishment, so coral bleaching would probably cause the corals to die. As the corals died, less food would be available for fishes and other species that eat coral. As a result, populations of these species might decline, and that, in turn, might cause populations of their predators to decline.

### Summary of Key Concepts Questions

**25.1** All eukaryotes have mitochondria or remnants of these organelles, but not all eukaryotes have plastids. **25.2** Two such examples are described in this chapter: the evolution of multicellularity in *Volvox* and the evolution of multicellularity in animals. In each case, structures or genes present in unicellular ancestors were co-opted and used

for new purposes in the multicellular lineage. In *Volvox*, cells are attached to one another using proteins that are homologous to proteins in the inner cell wall of their unicellular ancestor, *Chlamydomonas*. Likewise, in animals the cadherin proteins that function in cell attachment represent modified versions of proteins that served other purposes in their unicellular, choanoflagellate ancestors. **25.3** Kingdom Protista has been abandoned because some protists are more closely related to plants, fungi, or animals than they are to other protists. In addition, in the early 1990s many biologists hypothesized that a collection of eukaryotes that seemed to lack mitochondria represented the oldest lineage of living eukaryotes. That hypothesis, known as the “amitochondriate hypothesis,” has also been abandoned for two reasons: Species previously thought to lack mitochondria have since been shown to have reduced mitochondria, and DNA sequence data have shown that some of these organisms are not closely related to one another. Finally, morphological studies and DNA sequence analyses suggest that the vast diversity of eukaryotes alive today can be grouped into four very large clades, the eukaryotic “supergroups.”

**25.4** Sample response: Ecologically important protists include photosynthetic dinoflagellates that provide essential sources of energy to their symbiotic partners, the corals that build coral reefs. Other important protistan symbionts include those that enable termites to digest wood and *Plasmodium*, the pathogen that causes malaria. Photosynthetic protists such as diatoms are among the most important producers in aquatic communities; as such, many other species in aquatic environments depend on them for food.

### Test Your Understanding

1. a 2. e 3. d 4. b 5. c 6. d

7. The two approaches differ in the evolutionary changes they may bring about. A strain of *Wolbachia* that confers resistance to infection by *Plasmodium* and does not harm mosquitoes would spread rapidly through the mosquito population. In this case, natural selection would favor any *Plasmodium* individuals that could overcome the resistance to infection conferred by *Wolbachia*. If insecticides are used, mosquitoes that are resistant to the insecticide would be favored by natural selection. Hence, use of *Wolbachia* could cause evolution in *Plasmodium* populations, while using insecticides could cause evolution in mosquito populations.

9.

Pathogens that share a relatively recent common ancestor with humans will likely also share metabolic and structural characteristics with humans. Because drugs target the pathogen's metabolism or structure, developing drugs that harm the pathogen but not the patient should be most difficult for pathogens with which we share the most recent evolutionary history. Working backward in time, we can use the phylogenetic tree to determine the order in which humans shared a common ancestor with pathogens in different taxa. This process leads to the prediction that it should be hardest to develop drugs to combat animal pathogens, followed by choanoflagellate pathogens, fungal and nucleariid pathogens, amoebozoans, other protists, and finally prokaryotes.

## Chapter 26

### Figure Questions

**Figure 26.6** The life cycle in Figure 10.6b has alternation of generations; the others do not. Unlike the animal life cycle (Figure 10.6a), in alternation of generations, meiosis produces spores, not gametes. These spores then divide repeatedly by mitosis, ultimately forming a multicellular haploid individual that produces gametes. There is no multicellular haploid stage in the animal life cycle. An alternation of generations life cycle also has a multicellular diploid stage, whereas the life cycle shown in Figure 10.6c does not. **Figure 26.10** DNA from each of these mushrooms would be identical if each mushroom is part of a single hyphal network, as could well be the case.

**Figure 26.20** It contains cells from three generations: (1) the current sporophyte (cells of ploidy  $2n$ , found in the seed coat and in the megasporangium remnant that surrounds the spore wall); (2) the female gametophyte (cells of ploidy  $n$ , found in the food supply); and (3) the sporophyte of the next generation (cells of ploidy  $2n$ , found in the embryo). **Figure 26.24** All taxa in this tree are vascular plants; you should have circled the lycophytes, the earliest-diverging group of vascular plants.

**Figure 26.28** Two possible controls would be  $E-P-$  and  $E+P-$ . Results from an  $E-P-$  control could be compared with results from the  $E-P+$  experiment, and results from an  $E+P-$  control could be compared with results from the  $E+P+$  experiment. Together, these two comparisons would indicate whether the addition of the pathogen causes an increase in leaf mortality. Results from an  $E-P-$  experiment could also be compared with results from the second control ( $E+P-$ ) to determine whether adding the endophytes has a negative effect on the plant.

### Concept Check 26.1

1. Land plants share some key traits only with charophytes, including rings of cellulose-synthesizing complexes and similarity in sperm structure. Comparisons of nuclear and chloroplast genes also indicate that charophytes are the closest living relatives of land plants. 2. Possible answers include: spore walls toughened by sporopollenin (protects against harsh environmental conditions); multicellular, dependent embryos (provides nutrients and protection to the developing embryo); cuticle (reduces water loss); stomata (supports photosynthesis by allowing the exchange of  $CO_2$  and  $O_2$  between the outside air and the plant body; stomata close during dry conditions, reducing water loss) 3. The earliest fossil evidence of land plants comes from spores that date to 470 million years ago. These spores had a chemical composition similar to that in plant spores but different from the spores of other organisms; the walls of these spores also had structural features found only in spore walls of certain land plants. Larger plant structures appear in the fossil record by 425 million years ago. By 400 million years ago, fossil evidence shows that a diverse assemblage of plants lived on land; collectively, these plants had key traits not found in their algal ancestors, such as specialized tissues for water transport, stomata, and branched sporophytes. 4. The multicellular diploid stage of the life cycle would not produce gametes. Instead, both males and females would produce haploid spores by meiosis. These spores would give rise to multicellular male and female haploid stages—a major change from the single-celled haploid stages (sperm and eggs) that we actually have. The multicellular haploid stages would produce gametes and reproduce sexually. An individual at the multicellular haploid stage of the human life cycle might look like us, or it might look completely different.

### Concept Check 26.2

1. Both a fungus and a human are heterotrophs. Many fungi digest their food externally by secreting enzymes into the food and then absorbing the small molecules that result from digestion. Other fungi absorb such small molecules directly from their environment. In contrast, humans (and most other animals) ingest relatively large pieces of food and digest the food within their bodies. 2. Mycorrhizae form extensive networks of hyphae through the soil, enabling nutrients to be absorbed more efficiently than a plant can do on its own; this is true today, and similar associations were probably very important for the earliest land plants (which lacked roots). Evidence for the antiquity of mycorrhizal associations includes fossils showing arbuscular mycorrhizae in the early land plant *Aglaophyton* and molecular results showing that genes required for the formation of mycorrhizae are present in liverworts and other basal plant lineages. 3. Carbon that enters the plant through stomata is fixed into sugar through photosynthesis. Some of these sugars are absorbed by the fungus that partners with the plant to form mycorrhizae; others are transported within the plant body and used in the plant. Thus, the carbon may be deposited in either the body of the plant or the body of the fungus.

### Concept Check 26.3

1. Both seedless vascular plants and bryophytes have flagellated sperm that require moisture for fertilization; this shared similarity poses challenges for these species in arid regions. With respect to key differences, seedless vascular plants have lignified, well-developed vascular tissue, a trait that enables the sporophyte to grow tall and that has transformed life on Earth (via the formation of forests). Seedless vascular plants also have true leaves and roots, which, when compared with bryophytes, provide increased surface area for photosynthesis and improve their ability to extract nutrients from soil. 2. Land plants, vascular plants, and seed plants are monophyletic because each of these groups includes the common ancestor of the group and all of the descendants of that common ancestor. The other two categories of plants, the nonvascular plants and the seedless vascular plants, are paraphyletic: These groups do not include all of the descendants of the group's most recent common ancestor. 3. The phylogeny in Figure 26.16 shows that while monilophytes and lycophytes are all seedless vascular plants, monilophytes share a more recent common ancestor with seed plants than with lycophytes. Therefore, we would expect key traits that arose after monilophytes diverged from lycophytes but before monilophytes diverged from seed plants should be found in the most recent common ancestor of monilophytes and seed plants. The concept of descent with modification indicates that key traits found in the common ancestor of monilophytes and seed plants would likely also be found in that ancestor's descendants, the monilophytes and the seed plants.

### Concept Check 26.4

1. The reduced gametophytes of seed plants are nurtured by sporophytes and protected from stress, such as drought conditions and UV radiation. Pollen grains, with walls containing sporopollenin, provide protection during transport by wind or animals; because the sperm-producing male gametophytes are contained within pollen grains, the sperm of seed plants do not require water to reach the eggs. The ovule has a layer of tissue called integument that protects the female gametophyte as it develops from a megaspore. When mature, the ovule forms a seed, which has a thick layer of protective tissue, the seed coat. Seeds also contain a stored supply of food, which provides nourishment for growth after dormancy is broken and the embryo emerges as a seedling. 2. Darwin was troubled by the relatively sudden and geographically widespread appearance of angiosperms in the fossil record. Fossil evidence shows that angiosperms arose and began to diversify over a period of 20–30 million years, a less rapid event than was suggested by the fossils known during Darwin's lifetime. Fossil discoveries have also uncovered extinct lineages of woody seed plants that may have been closely related to angiosperms; one such group, the Bennettitales, had flowerlike structures that may have been pollinated by insects. Phylogenetic analyses have identified *Amborella* as the most basal angiosperm lineage; *Amborella* is woody, and hence its basal position supports the

conclusion (from fossils) that the angiosperm common ancestor was likely woody.

**3. No.** Their sister clade relationship indicates that these two groups share a more recent common ancestor with each other than they do with other plant groups—but that does not necessarily mean that they originated at the same time. Indeed, while fossil evidence indicates that gymnosperms originated at least 305 million years ago, this does not mean that angiosperms are that old—only that the most recent common ancestor of gymnosperms and angiosperms must be that old.

#### Concept Check 26.5

**1.** Lichens, symbiotic associations between fungi and photosynthetic microorganisms (algae or cyanobacteria), break down bare rock surfaces by physically penetrating and chemically altering them. This influences the formation of soil and enables a succession of plants to grow. Plants also affect the formation of soil: Their roots hold soil in place, and leaf litter and other decaying plant parts add nutrients to the soil. Plants also affect the composition of Earth's atmosphere by releasing oxygen to the air and by their impact on the atmospheric concentration of  $\text{CO}_2$ . **2.** Mutualistic fungi absorb nutrients from their host organism but reciprocate by providing benefits to the host. Important examples include mycorrhizal associations with plant roots (in which fungal hyphae increase the efficiency with which the plant can absorb nutrients such as phosphorus from the soil) and symbiotic endophytes (fungi that live within leaves or other plant parts and provide the plant with benefits such as increased resistance to disease or increased tolerance of heat, drought, or heavy metals). Parasitic fungi also absorb nutrients from host cells but provide no benefits in return. Examples include the ascomycete fungus *Cryphonectria parasitica* (which causes chestnut blight, a disease that has virtually eliminated the once-common chestnut tree from forests of the north-eastern United States). **3.** You should have circled steps that represent light energy absorption, photosynthesis, consumers eating producers, uptake of nutrients by plants, and decomposition. **4.** By focusing on cases in which a radial clade shared an immediate common ancestor with a bilateral clade, the researchers could control for effects of time; that is, each radial clade had the same amount of time over which new species could form as did the bilateral clade to which it was compared. As a result, differences in the number of species between the two clades could be attributed to flower shape (rather than to differences in the length of time over which new species could form).

#### Summary of Key Concepts Questions

**26.1** The earliest fossil evidence of land plants comes from spores that date to 470 million years ago. These spores have a chemical composition that matches that found in the spores of extant plants, yet differs from the spores of other organisms. Furthermore, the structure of the walls these spores is only found in the spores of certain land plants (liverworts). Finally, similar spores dating to 450 million years ago have been found embedded in plant cuticle material. **26.2** The body of a multicellular fungus typically consists of thin filaments called hyphae. These filaments form an interwoven mass (mycelium) that penetrates the substrate on which the fungus grows and feeds. Because the individual filaments are thin, the surface-to-volume ratio of the mycelium is maximized, making nutrient absorption highly efficient. Furthermore, fungi that form mycorrhizal associations with plant roots have specialized hyphae (called haustoria) through which they can exchange nutrients with their host plant. The high efficiency with which fungal filaments absorb nutrients, together with the ability of mycorrhizae to exchange nutrients through haustoria, may have provided early land plants (which lacked roots) with greater access to soil nutrients—thus aiding the colonization of land by plants. **26.3** Lignified vascular tissue provided the strength needed to support a tall plant against gravity, as well as a means to transport water and nutrients to plant parts located high above ground. Roots were another key trait, anchoring the plant to the ground and providing additional structural support for plants that grew tall. Tall plants could shade shorter plants, thereby outcompeting them for light. Because the spores of a tall plant disperse farther than the spores of a short plant, it is also likely that tall plants could colonize new habitats more rapidly than short plants. **26.4** The Bennettitales is one of several groups of fossil seed plants that are thought to be more closely related to extant angiosperms than to extant gymnosperms. All of the species in the Bennettitales and other such fossil seed plants were woody. The earliest-diverging lineage of extant angiosperms (*Amborella*) is also woody. The fact that both the seed plant ancestors of angiosperms and the most basal taxon of extant angiosperms were woody suggests that the angiosperm common ancestor was woody. **26.5** During photosynthesis, plants convert light energy to the chemical energy of food; that chemical energy supports all life on land, either directly (as when an herbivore eats a plant) or indirectly (as when a predator eats an herbivore that ate a plant). Large animals, such as vertebrate herbivores and their predators, could not survive on land in the absence of land plants, so the presence of plants on land has enabled the myriad biotic interactions that occur among large animal species today. Similarly, plants extract nutrients from the soil and capture carbon (in the form of  $\text{CO}_2$ ) from the air; as a result, those nutrients become available to terrestrial animals. Fungi also play an essential role in increasing the availability of nutrients to other terrestrial organisms. As decomposers, fungi break down the bodies of dead organisms, thereby recycling chemical nutrients to the physical environment. If plants and fungi had not colonized land, photosynthesis and decomposition would still occur—but all terrestrial life would be microbial, and hence biotic interactions among terrestrial organisms would occur on a much smaller scale than they do today.

#### Test Your Understanding

- 1.** b **2.** e **3.** a. diploid; b. haploid; c. haploid; d. diploid; e. haploid **4.** a **5.** c **6.** e **7.**

8.

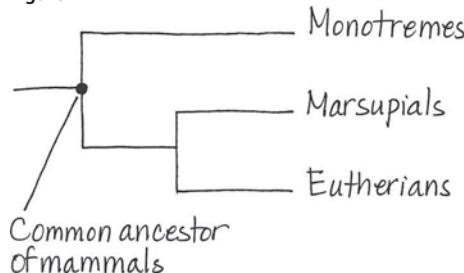

As indicated by the raw data and bar graph, grass plants with endophytes (E+) produced more new shoots and had greater biomass than did grass plants that lacked endophytes (E-). These differences were especially pronounced at the highest soil temperature, where E- grass plants produced no new shoots and had a biomass of zero (indicating they were dead).

## Chapter 27

### Figure Questions

**Figure 27.5** You should have circled the node, shown in the tree diagram at approximately 580 million years ago (mya), that leads to the echinoderm/chordate lineage and to the lineage that gave rise to brachiopods, annelids, molluscs, and arthropods. Although the 580 mya date is estimated, this common ancestor must be at least as old as any of its descendants. Since fossil molluscs date to about 560 mya, the common ancestor represented by the circled branch point must be at least 560 million years old. **Figure 27.10** Cnidaria is the sister phylum in this figure. **Figure 27.12** Such a result would be consistent with the *Ubx* and *abd-A Hox* genes having played a major role in the evolution of increased body segment diversity in arthropods. However, by itself, such a result would simply show that the presence of the *Ubx* and *abd-A Hox* genes was correlated with an increase in body segment diversity in arthropods; it would not provide direct experimental evidence that the acquisition of the *Ubx* and *abd-A* genes caused an increase in arthropod body segment diversity. **Figure 27.23** Sometime between 380 mya and 340 mya. We can infer this because amphibians must have originated after the most recent common ancestor of *Tulerpeton* and living tetrapods (and that ancestor originated 380 mya), but no later than the date of the earliest known fossils of amphibians (shown in the figure as 340 mya). **Figure 27.26** Crocodilians. Among extant amniotes, crocodilians are the sister group of birds. Hence, it is likely that DNA sequences in birds are more similar to those in crocodilians than they are to those of more distantly related amniotes.

### Figure 27.27

**Figure 27.32** Since the cod are adapting to the pressure of fishing by reproducing at younger ages, their overall number of offspring will be lower. This may cause the population to decline as time goes on, thereby further reducing the population's ability to recover.

### Concept Check 27.1

**1.** The earliest fossil evidence of animal life comes from fossilized steroids indicative of sponges that date to 710 million years ago (mya). This fossil biochemical evidence is consistent with molecular clock results indicating that animals originated 770 mya, sponges originated 700 mya, and cnidarians originated 680 mya. The oldest fossils of large animals date to about 560 mya; these fossils are of sponges, cnidarians, and molluscs. Thus, by 560 mya at the latest, the two early-diverging animal groups, sponges and cnidarians, had diverged from other animal groups. **2.** We cannot infer whether extant animals originated before or after extant choanoflagellates. If correct, the date provided for the most recent common ancestor of choanoflagellates and animals would indicate that extant animals originated sometime within the last 900 million years. Fossil biochemical evidence indicates that extant animals (in particular, sponges) originated 710 million years ago. Assuming that this evidence accurately indicates the presence of sponges, we could conclude only that extant animals originated sometime between 900 and 710 million years ago.

### Concept Check 27.2

**1.** The "Cambrian explosion" refers to a relatively short interval of time (535–525 million years ago) during which large forms of many present-day animal phyla first appear.

in the fossil record. The evolutionary changes that occurred during this time, such as the appearance of large predators and well-defended prey, were important because they set the stage for many of the key events in the history of life over the last 500 million years. **2.** Following such a change, predators that were best able to kill or catch these well-defended prey might leave more offspring than would other (less capable) predators. As a result, evolution by natural selection in the predator population would likely improve the ability of the predators to eat these prey. If that took place, prey individuals with new defensive adaptations would be favored by natural selection, potentially leading to further changes in predator populations, and so on.

#### Concept Check 27.3

**1.** A body plan is a set of morphological and developmental traits, integrated into a functional whole (the living animal). One key feature is the type of symmetry (or absence of symmetry): Sponges lack symmetry, some animals exhibit radial symmetry, and others are bilaterally symmetric. Another key feature is the way tissues are organized. Sponges and a few other animal groups lack true tissues; the tissues of cnidarians and ctenophores originate from two embryonic germ layers, while the tissues of most animals (bilaterians) originate from three germ layers. A third feature found in most bilaterians is a body cavity, a fluid- or air-filled space located between the digestive tract and the outer body wall. **2.** The phylogeny in Figure 27.10 indicates that all animals share a common ancestor; that sponges are basal animals; that Eumetazoa is a clade of animals with true tissues; and that most phyla belong to the clade Bilateria. As for whether the Cambrian explosion consists of three explosions, note that the phylogeny in Figure 27.10 indicates that molluscs are members of Lophotrochozoa, one of the three main groups of bilaterians (the others being Deuterostomia and Ecdysozoa). As discussed in Concept 27.2, the fossil record shows that molluscs were present tens of millions of years before the Cambrian explosion. Thus, long before the Cambrian explosion, the lophotrochozoan clade had formed and was evolving independently of the evolutionary lineages leading to Deuterostomia and Ecdysozoa. Based on the phylogeny in Figure 27.10, we can also conclude that the lineages leading to Deuterostomia and Ecdysozoa were independent of one another before the Cambrian explosion. Since the lineages leading to the three main clades of bilaterians were evolving independently of one another prior to the Cambrian explosion, that explosion could be viewed as consisting of three “explosions,” not one. **3.** During the time period covered by this question, a broad range of invertebrate phyla diversified in marine environments. Invertebrates in one of these phyla—Chordata—gave rise to early vertebrates, and those early vertebrates diversified further into two lineages of jawless vertebrates and three lineages of jawed vertebrates. One lineage of jawed vertebrates would ultimately give rise to the tetrapods, the vertebrate lineage that colonized land. But the other lineages of jawed vertebrates—along with the many lineages of invertebrates—continued to diversify in aquatic environments, making it hard to argue that the evolutionary changes that took place were directed toward the origin of terrestrial vertebrates.

#### Concept Check 27.4

**1.** The arthropod exoskeleton, which had already evolved in the ocean, allows terrestrial species to retain water and support their bodies on land. Wings allow insects to disperse quickly to new habitats and to find food and mates. The tracheal system allows for efficient gas exchange despite the presence of an exoskeleton. **2.** Descent with modification—the process by which organisms gradually accumulate differences from their ancestors—occurred in the colonization of land by plants as well as the colonization of land by animals. The modifications over time, however, were more extensive in plants than in animals. This was because land plants arose from a small alga with few features that were suitable for life on land. Animals, in contrast, colonized land repeatedly; in each of these events, the animals that colonized land already had a complete digestive tract and well-developed skeletal, muscle, and nerve systems. **3.** The egg came first. The amniotic egg, which all reptiles (including chickens) and all mammals have, arose more than 310 million years ago, long before the first chicken.

#### Concept Check 27.5

**1.** The oceans had cloudy waters and low oxygen levels for more than a billion years after the origin of eukaryotes; throughout this time, cyanobacteria were the dominant producers. By the early Cambrian period, the ocean waters were clearer and had higher oxygen levels; in addition, cyanobacteria were less abundant and algae had become the dominant producers. By removing large quantities of cyanobacteria, early filter-feeding animals would have made the waters less cloudy, a change that favored algae (which require more light for photosynthesis than do cyanobacteria). By about 530 million years ago, a variety of large animals were present, leading to dramatic changes in feeding relationships as formidable predators pursued well-defended prey. **2.** Before animals colonized land, terrestrial communities had a simple structure, the main elements of which consisted of producers (early land plants) and decomposers. The colonization of land by animals introduced new types of biotic interactions that involved herbivorous animals that ate plants, detritivores such as millipedes that consumed decaying organic matter, and predators. **3.** Gene flow occurs more readily between nearby than between distant populations; hence, we would predict that gene flow would be higher in the original population than in the remnant populations. And since genetic drift has more pronounced effects in small populations, we would predict that the role of genetic drift would be more pronounced in the remnant populations. Finally, since genetic drift can lead to the fixation of harmful alleles, we would predict that the risk of extinction would be higher in the remnant populations than in the original populations.

#### Summary of Key Concepts Questions

**27.1** Sponge choanocyte cells are similar morphologically to the cells of choanoflagellates; DNA sequences of sponges and choanoflagellates are also very similar. These observations are consistent with the hypothesis that animals descended from a lineage of single-celled eukaryotes similar to present-day choanoflagellates. **27.2** Current hypotheses about the cause of the Cambrian explosion include new predator-prey relationships, an increase in atmospheric oxygen, and an increase in developmental flexibility provided by the origin of *Hox* genes and other genetic changes.

**27.4** The major derived characteristic of the amniotes is the amniotic egg, which contains four specialized membranes: the amnion, the chorion, the yolk sac, and the allantois. The amniotic egg provides protection to the embryo and allows the embryo to develop on land, eliminating the necessity of a watery environment for reproduction. As a result, the amniotes were able to expand into a wider range of terrestrial habitats than were earlier-diverging tetrapod groups (including the amphibians).

**27.5** As organisms interact over time with other organisms and the physical environment, their populations can evolve. The activities of animals have altered the physical structure (for example, the water clarity) of the ocean and fundamentally changed biotic interactions in the sea and on land—thus potentially causing evolutionary change in a wide range of species. Examples include the effects animals have had on evolutionary radiations in parasites and plants, as well as the ongoing evolutionary changes that are taking place in populations that humans hunt for sport or food.

#### Test Your Understanding

1. b 2. e 3. d 4. a 5. c 6. b

**7.** (a) Because brain size tends to increase consistently in such lineages, we can conclude that natural selection favored the evolution of larger brains and hence that the benefits outweighed the costs. (b) As long as the benefits of brains that are large relative to body size are greater than the costs, large brains can evolve. Natural selection might favor the evolution of brains that are large relative to body size because such brains confer an advantage in obtaining mates and/or an advantage in survival. (c)

Adult mortality tends to be lower in birds with larger brains.

**8.** The circled clade should include birds, the two dinosaur lineages, and the common ancestor of the dinosaurs. The phylogeny shows that dinosaurs other than birds are nested between crocodilians and birds. Since crocodilians and birds differ with respect to whether they are endothermic, we cannot use phylogenetic bracketing to predict whether dinosaurs other than birds were endothermic (or not). However, we can conclude that the dinosaur that gave rise to birds was endothermic, as are all birds.

## Chapter 28

### Figure Questions

**Figure 28.12** Every root epidermal cell would develop a root hair. **Figure 28.18** Pith and cortex are defined, respectively, as ground tissue that is internal and ground tissue that is external to vascular tissue. Since vascular bundles of monocot stems are scattered throughout the ground tissue, there is no clear distinction between internal and external relative to the vascular tissue. **Figure 28.19** The vascular cambium produces growth that increases the diameter of a stem or root. The tissues that are exterior to the vascular cambium cannot keep pace with the growth because their cells no longer divide. As a result, these tissues rupture.

### Concept Check 28.1

**1.** The vascular tissue system connects leaves and roots, allowing sugars to move from leaves to roots in the phloem and allowing water and minerals to move to the leaves

in the xylem. **2.** To get sufficient energy from photosynthesis, we would need lots of surface area exposed to the sun. This large surface-to-volume ratio, however, would create a new problem—evaporative water loss. We would have to be permanently connected to a water source—the soil, also our source of minerals. In short, we would probably look and behave very much like plants. **3.** As plant cells enlarge, they typically form a huge central vacuole that contains a dilute watery sap. Central vacuoles enable plant cells to become large with only a minimal investment of new cytoplasm. The orientation of the cellulose microfibrils in plant cell walls affects the growth pattern of cells.

#### Concept Check 28.2

**1.** Primary growth arises from apical meristems and involves production and elongation of organs. Secondary growth arises from lateral meristems and adds to the girth of roots and stems. **2.** The largest, oldest leaves would be lowest on the shoot. Since they would probably be heavily shaded, they would not photosynthesize much regardless of their size. **3.** No, the carrot roots will probably be smaller at the end of the second year because the food stored in the root will be used to produce flowers, fruit, and seeds.

#### Concept Check 28.3

**1.** In roots, primary growth occurs in three successive stages, moving away from the tip of the root: the zones of cell division, elongation, and differentiation. In shoots, it occurs at the tip of apical buds, with leaf primordia arising along the sides of an apical meristem. Most growth in length occurs in older internodes below the shoot tip. **2.** No. Because vertically oriented leaves, such as maize, can capture light equally on both sides of the leaf, you would expect them to have mesophyll cells that are not differentiated into palisade and spongy layers. This is typically the case. Also, vertical leaves usually have stomata on both leaf surfaces. **3.** Root hairs are cellular extensions that increase the surface area of the root epidermis, thereby enhancing the absorption of minerals and water. Microvilli are extensions that increase the absorption of nutrients by increasing the surface area of the gut.

#### Concept Check 28.4

**1.** The sign will still be 2 m above the ground because this part of the tree is no longer growing in length (primary growth); it is now growing only in thickness (secondary growth). **2.** Since there is little temperature variation in the tropics, the growth rings of a tree from the tropics would be difficult to discern unless the tree came from an area that had pronounced wet and dry seasons. **3.** The tree would die slowly. Girdling removes an entire ring of secondary phloem (part of the bark), completely preventing transport of sugars and starches from the shoots to the roots. After several weeks, the roots would have used all of their stored carbohydrate reserves and would die.

#### Summary of Key Concepts Questions

**28.1** Here are a few examples: The cuticle of leaves and stems protects these structures from desiccation. Collenchyma and sclerenchyma cells have thick walls that provide support for plants. Strong, branching root systems help anchor the plant in the soil. **28.2** All plant organs and tissues are ultimately derived from meristematic activity. **28.3** Lateral roots emerge from the pericycle and destroy plant cells as they emerge. In stems, branches arise from axillary buds and do not destroy any cells. **28.4** With the evolution of secondary growth, plants were able to grow taller and shade competitors.

#### Test Your Understanding

1. c 2. c 3. c 4. e 5. d 6.

## Chapter 29

### Figure Questions

**Figure 29.3** The leaves are being produced in a counterclockwise spiral.

**Figure 29.5** A proton pump inhibitor would depolarize the membrane potential because less  $H^+$  would be pumped out across the plasma membrane. The immediate effect of an inhibitor of the  $H^+$ /sucrose cotransporter would be to hyperpolarize the membrane potential because less  $H^+$  would be leaking back into the cell through these cotransporters. An inhibitor of the  $H^+$ /NO<sub>3</sub><sup>-</sup> cotransporter would have no effect on the membrane potential because the simultaneous cotransport of a positively charged ion and a negatively charged ion has no net effect on charge difference across the membrane. An inhibitor of the  $K^+$  ion channels would decrease the membrane potential because additional positively charged ions would not be accumulating outside the cell. **Table 29.1** Plants may contain more than 50 elements, but only a few are essential for the plant to complete its life cycle. The others, including fluorine, selenium and chromium, are present but not essential for the plant's

survival. **Figure 29.10** Anions. Because cations are bound to soil particles, they are less likely to be lost from the soil following heavy rains. **Figure 29.14** If phosphate were the only limiting mineral, then native tree growth would be less severely impacted by the reduction in mycorrhizal associations caused by garlic mustard. Consequently, the competitive advantage of garlic mustard would be reduced by the addition of phosphate to the soil. **Figure 29.16** The Casparian strip blocks water and minerals from moving between endodermal cells or moving around an endodermal cell via the cell's wall. Therefore, water and minerals must pass through an endodermal cell's plasma membrane.

#### Concept Check 29.1

**1.** Vascular plants must transport minerals and water absorbed by the roots to all the other parts of the plant. They must also transport sugars from sites of production to sites of use. **2.** Many features of plant architecture affect self-shading, including leaf arrangement and the orientations of stems and leaves. **3.** Increased stem elongation would raise the plant's upper leaves. Erect leaves and reduced lateral branching would make the plant less subject to shading by the encroaching neighbors.

#### Concept Check 29.2

**1.** The cell's  $\Psi_p$  is 0.7 MPa. In a solution with a  $\Psi$  of -0.4 MPa, the cell's  $\Psi_p$  at equilibrium would be 0.3 MPa. **2.** The cells would still adjust to changes in their osmotic environment, but their responses would be slower. Although aquaporins do not affect the water potential gradient across membranes, they allow for more rapid osmotic adjustments. **3.** The protoplasts would burst. Because the cytoplasm has many dissolved solutes, water would enter the protoplast continuously without reaching equilibrium. (When present, the cell wall prevents rupturing by excessive expansion of the protoplast.)

#### Concept Check 29.3

**1.** No. Even though macronutrients are required in greater amounts, all essential elements are necessary for the plant to complete its life cycle. **2.** No. The fact that the addition of an element results in an increase in the growth rate of a plant does not mean that the element is strictly required for the plant to complete its life cycle. **3.** Waterlogging displaces air from the soil, leading to low O<sub>2</sub> conditions. Such conditions promote the anaerobic process of alcoholic fermentation in plants, the end product of which is ethanol.

#### Concept Check 29.4

**1.** The rhizosphere is a narrow zone in the soil immediately adjacent to living roots. This zone is especially rich in both organic and inorganic nutrients and has a microbial population that is many times greater than the bulk of the soil. **2.** Soil bacteria and mycorrhizae enhance plant nutrition by making certain minerals more available to plants. For example, many types of soil bacteria are involved in the nitrogen cycle, and the hyphae of mycorrhizae provide a large surface area for the absorption of nutrients, particularly phosphate ions. **3.** Saturating rainfall may deplete the soil of oxygen. A lack of soil oxygen would inhibit nitrogen fixation by the soybean root nodules and decrease the nitrogen available to the plant. Alternatively, heavy rain may leach nitrate from the soil. A symptom of nitrogen deficiency is yellowing of older leaves.

#### Concept Check 29.5

**1.** The endodermis regulates the passage of water-soluble solutes by requiring all such molecules to cross a selectively permeable membrane. Presumably, the inhibitor never reaches the plant's photosynthetic cells. **2.** Perhaps greater root mass helps compensate for the lower water permeability of the plasma membranes. **3.** The Casparian strip and tight junctions both prevent movement of fluid between cells.

#### Concept Check 29.6

**1.** The activation of the proton pumps of stomatal cells would cause the guard cells to take up  $K^+$ . The increased turgor of the guard cells would lock the stomata open and lead to extreme evaporation from the leaf. **2.** After the flowers are cut, transpiration from any leaves and from the petals (which are modified leaves) will continue to draw water up the xylem. If cut flowers are transferred directly to a vase, air pockets in xylem vessels prevent delivery of water from the vase to the flowers. Cutting stems again underwater, a few centimeters from the original cut, will sever the xylem above the air pocket. The water droplets prevent another air pocket from forming while placing the flowers in a vase. **3.** Water molecules are in constant motion, traveling at different rates. The average speed of these particles depends on the water's temperature. If water molecules gain enough energy, the most energetic molecules near the liquid's surface will impart sufficient speed, and therefore sufficient kinetic energy, to cause water molecules to propel away from the liquid in the form of gaseous molecules or, more simply, as water vapor. As the particles with the highest kinetic energy levels evaporate, the average kinetic energy of the remaining liquid decreases. Because a liquid's temperature is directly related to the average kinetic energy of its molecules, the liquid cools as it evaporates.

#### Concept Check 29.7

**1.** The main sugar sources are fully grown leaves (by photosynthesis) and fully developed storage organs (by breakdown of starch). Roots, buds, stems, expanding leaves, and fruits are powerful sugar sinks because they are actively growing. A storage organ may be a sugar sink in the summer when accumulating carbohydrates, but a sugar source in the spring when breaking down starch into sugar for growing shoot tips. **2.** Positive pressure in the sieve-tube elements of the phloem requires active transport. Most long-distance transport in the xylem depends on bulk flow driven by negative pressure potential generated ultimately by the evaporation of water from the leaf and does not require living cells. **3.** The spiral slash prevents optimal bulk flow of the phloem sap to the root sinks. Therefore, more phloem sap can move from the source leaves to the fruit sinks, making them sweeter.

#### Summary of Key Concepts Questions

**29.1** Plants with tall shoots and elevated leaf canopies generally had an advantage over shorter competitors. A consequence of the selective pressure for tall shoots was the

further separation of leaves from roots. This separation created problems for the transport of materials between root and shoot systems. Plants with xylem cells were more successful at supplying their shoot systems with soil resources (water and minerals). Similarly, those with phloem cells were more successful at supplying sugar sinks with carbohydrates. **29.2** Xylem sap is pulled up the plant by transpiration much more often than it is pushed up the plant by root pressure. **29.3** No, plants can complete their life cycle when grown hydroponically, that is, in aerated salt solutions containing the proper ratios of all the minerals needed by plants. **29.4** No, some parasitic plants obtain their energy by siphoning off carbon nutrients from other organisms. **29.5** Hydrogen bonds are necessary for the cohesion of water molecules to each other and for the adhesion of water to other materials, such as cell walls. Both adhesion and cohesion of water molecules are involved in the ascent of xylem sap under conditions of negative pressure. **29.6** Although stomata account for most of the water lost from plants, they are necessary for exchange of gases—for example, for the uptake of carbon dioxide needed for photosynthesis. **29.7** Although the movement of phloem sap depends on bulk flow, the pressure gradient that drives phloem transport depends on the osmotic uptake of water in response to the loading of sugars into sieve-tube elements at sugar sources. Phloem loading depends on  $H^+$  cotransport processes that ultimately depend on  $H^+$  gradients established by active  $H^+$  pumping.

## Chapter 30

### Figure Questions

**Figure 30.3** Another example of a homeotic gene mutation is the mutation in a *Hox* gene that causes legs to form in place of antennae in *Drosophila* (depicted in Figure 16.8). **Figure 30.4** The flower would consist of nothing but carpels. **Figure 30.9** In addition to having a single cotyledon, monocots generally have leaves with parallel leaf venation, scattered vascular tissue in their stems, a fibrous root system, pollen grains with only one opening, and floral organs in multiples of three. In contrast, eudicots have two cotyledons and generally netlike leaf venation, vascular tissue in a ring, taproots, pollen grains with three openings, and floral organs in multiples of four or five. **Figure 30.10** Beans use a hypocotyl hook to push through the soil. The delicate leaves and shoot apical meristem are also protected by being sandwiched between two large cotyledons. The coleoptile of maize seedlings helps protect the emerging leaves.

#### Concept Check 30.1

1. Long styles help to weed out pollen grains that are genetically inferior and not capable of successfully growing long pollen tubes. 2. Hypothetically, tepals could arise if *B* gene activity was present in all three of the outer whorls of the flower. 3. No. The haploid (gametophyte) generation of plants is multicellular and arises from spores. The haploid phase of the animal life cycle is a single-celled gamete (egg or sperm) that arises directly from meiosis. There are no spores.

#### Concept Check 30.2

1. Flowering plants can avoid self-fertilization by being dioecious, by having different flowers with reproductive parts of different lengths, or by self-incompatibility. 2. Asexually propagated crops lack genetic diversity. Genetically diverse populations are less likely to become extinct in the face of an epidemic because there is a greater likelihood that a few individuals in the population are resistant. 3. In the short term, selfing may be advantageous in a population that is so dispersed and sparse that pollen delivery is unreliable. In the long term, however, selfing is an evolutionary dead end because it leads to a loss of genetic diversity that may preclude adaptive evolution.

#### Concept Check 30.3

1. Traditional breeding and genetic engineering both involve artificial selection for desired traits. However, genetic engineering techniques facilitate faster gene transfer and are not limited to transferring genes between closely related varieties or species. 2. *Bt* maize suffers less insect damage; therefore, *Bt* maize plants are less likely to be infected by fumonisin-producing fungi that infect plants through wounds. 3. In such species, engineering the transgene into the chloroplast DNA would not prevent its escape in pollen; such a method requires that the chloroplast DNA be found only in the egg. An entirely different method of preventing transgene escape would therefore be needed, such as male sterility, apomixis, or self-pollinating closed flowers.

#### Summary of Key Concepts Questions

**30.1** After pollination, a flower typically changes into a fruit. The petals, sepals, and stamens typically fall off the flower. The stigma of the pistil withers and the ovary begins to swell. The ovules (embryonic seeds) inside the ovary begin to mature. **30.2** Asexual reproduction can be advantageous in a stable environment because individual plants that are well suited to that environment pass on all their genes to offspring. Also, asexual reproduction generally results in offspring that are less fragile

than the seedlings produced by sexual reproduction. However, sexual reproduction offers the advantage of dispersal of tough seeds. Moreover, sexual reproduction produces genetic variety, which may be advantageous in an unstable environment. The likelihood is better that at least one offspring of sexual reproduction will survive in a changed environment. **30.3** “Golden Rice” has been engineered to produce more vitamin A, thereby raising the nutritional value of rice. A protoxin gene from a soil bacterium has been engineered into *Bt* maize. This protoxin is lethal to invertebrates but harmless to vertebrates. *Bt* crops require less pesticide spraying and have lower levels of fungal infection. Genetic engineering has increased the nutritional value of cassava by boosting the amount of iron and beta-carotene (a vitamin A precursor) and almost eliminating cyanide-producing chemicals from the roots.

## Chapter 31

### Figure Questions

**Figure 31.2** To determine which wavelengths of light are most effective in phototropism, you could use a glass prism to split white light into its component colors and see which colors cause the quickest bending (the answer is blue; see Figure 31.12).

**Figure 31.3** More auxin would move down the side without the TIBA-containing agar bead, causing greater elongation on this side and, consequently, bending of the coleoptile toward the side with the bead. **Figure 31.4** No. Polar auxin transport depends on the distribution of auxin transport proteins at the basal ends of cells.

**Figure 31.13** Yes. The white light, which contains red light, would stimulate seed germination in all treatments. **Figure 31.17** The short-day plant would not flower. The long-day plant would flower. **Figure 31.18** If this were true, florigen would be an inhibitor of flowering, not an inducer.

#### Concept Check 31.1

1. Fusicoccin's ability to cause an increase in plasma  $H^+$  pump activity would have an auxin-like effect and promote stem cell elongation. 2. The plant will exhibit a constitutive triple response. Because the kinase that normally prevents the triple response is dysfunctional, the plant will undergo the triple response regardless of whether ethylene is present or the ethylene receptor is functional. 3. Since ethylene often stimulates its own synthesis, it is under positive-feedback regulation.

#### Concept Check 31.2

1. Not necessarily. Many environmental factors, such as temperature and light, change over a 24-hour period in the field. To determine whether the enzyme is under circadian control, a scientist would have to demonstrate that its activity oscillates even when environmental conditions are held constant. 2. It is impossible to say. To establish that this species is a short-day plant, it would be necessary to establish the critical night length for flowering and that this species only flowers when the night is longer than the critical night length. 3. According to the action spectrum of photosynthesis, red and blue light are the most effective in photosynthesis. Thus, it is not surprising that plants assess their light environment using blue- and red-light-absorbing photoreceptors.

#### Concept Check 31.3

1. A plant that overproduces ABA would undergo less evaporative cooling because its stomata would not open as widely. 2. Plants close to the aisles may be more subject to mechanical stresses caused by passing workers and air currents. The plants nearer to the center of the bench may also be taller as a result of shading and less evaporative stress. 3. No. Because root caps are involved in sensing gravity, roots that have their root caps removed are almost completely insensitive to gravity.

#### Concept Check 31.4

1. Some insects increase plants' productivity by eating harmful insects or aiding in pollination. 2. Mechanical damage breaches a plant's first line of defense against infection, its protective dermal tissue. 3. Perhaps the breeze blows away a volatile defense compound that the plants produce.

#### Summary of Key Concepts Questions

**31.1** Yes, there is truth to the old adage that one bad apple spoils the whole bunch. Ethylene, a gaseous hormone that stimulates ripening, is produced by damaged, infected, or overripe fruits. Ethylene can diffuse to healthy fruit in the “bunch” and stimulate their rapid ripening. **31.2** Plant physiologists proposed the existence of a floral-promoting factor (florigen) based on the fact that a plant induced to flower could induce flowering in a second plant to which it was grafted, even though the second plant was not in an environment that would normally induce flowering in that species. **31.3** Plants subjected to drought stress are often more resistant to freezing stress because the two types of stress are quite similar. Freezing of water in the extracellular spaces causes free water concentrations outside the cell to decrease. This, in turn, causes free water to leave the cell by osmosis, leading to the dehydration of

cytoplasm, much like what is seen in drought stress. **31.4** Chewing insects make plants more susceptible to pathogen invasion by disrupting the waxy cuticle of shoots, thereby creating an opening for infection. Moreover, substances released from damaged cells can serve as nutrients for the invading pathogens.

### Test Your Understanding

1. e 2. c 3. d 4. b 5. b 6. c  
7.

## Chapter 32

### Figure Questions

**Figure 32.4** The air conditioner would form a second control circuit, cooling the house when air temperature exceeded the set point. Such opposing, or antagonistic, pairs of control circuits increase the effectiveness of a homeostatic mechanism.

**Figure 32.20** You would expect to find these cells lining tubules where they pass through the renal medulla. Because the extracellular fluid of the renal medulla has a very high osmolarity, production of solutes by tubule cells in this region keeps intracellular osmolarity high, with the result that these cells maintain normal volume.

**Figure 32.21** Furosemide increases urine volume. The absence of ion transport in the ascending limb that results from this drug leaves the filtrate too concentrated for substantial volume reduction in the distal tubule and collecting duct.

### Concept Check 32.1

1. No; an animal's internal environment fluctuates within a normal range or around set points. Homeostasis is a dynamic state. Furthermore, there are sometimes programmed changes in set points, such as those resulting in radical increases in hormone levels at particular times in development. 2. In thermoregulation, the product of the pathway (a change in temperature) decreases pathway activity by reducing the stimulus. In an enzyme-catalyzed biosynthetic process, the product of the pathway (in this case, isoleucine) inhibits the pathway that generated it. 3. The ice water would cool tissues in your head, including blood that would then circulate throughout your body. This effect would accelerate the return to a normal body temperature. If, however, the ice water reached the ear drum and cooled the blood vessel that supplies the hypothalamus, the hypothalamic thermostat would respond by inhibiting sweating and constricting blood vessels in the skin, slowing cooling elsewhere in the body.

### Concept Check 32.2

1. Yes, the response can differ if the pathway regulated by the receptor is different in the two cell types. 2. If the function of the pathway is to provide a transient response, a short-lived stimulus would be less dependent on negative feedback. 3. Epinephrine in animals and auxin in plants act as hormones that trigger specific cellular responses that vary among different tissues of the organism.

### Concept Check 32.3

1. Filtration produces a fluid for exchange processes that is free of cells and large molecules, which are of benefit to the animal and could not readily be reabsorbed. 2. Because uric acid is largely insoluble in water, it can be excreted as a semisolid paste, thereby reducing an animal's water loss. 3. Without a layer of insulating fur, the camel must use the cooling effect of evaporative water loss to maintain body temperature, thus linking thermoregulation and osmoregulation.

### Concept Check 32.4

1. The consumption of a large amount of water in a very short period of time, coupled with an absence of solute intake, can reduce sodium levels in the blood below tolerable levels. This condition, called hyponatremia, leads to disorientation and, sometimes, respiratory distress. It has occurred in some marathon runners who drink water rather than sports drinks. (It has also caused the death of a fraternity pledge as a consequence of a water hazing ritual and the death of a contestant in a water-drinking competition.) 2. The kidney medulla would absorb less water; consequently, the drug would increase the amount of water lost in the urine. 3. A decline in blood pressure in the afferent arteriole would reduce the force driving water and solutes across the membranes of glomerular capillaries and would therefore reduce the filtration rate.

### Summary of Key Concepts Questions

**32.1** Heat exchange across the skin is a primary mechanism for the regulation of body core temperature, with the result that the skin is cooler than the body core.

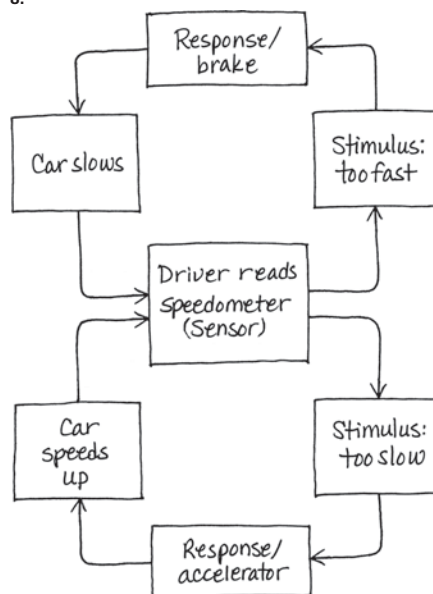

**32.2** Because receptors for water-soluble hormones are located on the cell surface, facing the extracellular space, injecting the hormone into the cytoplasm would not trigger a response.

Waste Attribute	Ammonia	Urea	Uric Acid
Toxicity	High	Very low	Low
Energy content	Low	Moderate	High
Water loss in excretion	High	Moderate	Low

**32.4** Both types of nephrons have proximal tubules that can reabsorb nutrients, but only juxtamedullary nephrons have loops of Henle that extend deep into the renal medulla. As a result, only kidneys containing juxtamedullary nephrons can produce urine that is more concentrated than the blood.

### Test Your Understanding

1. b 2. c 3. a 4. b 5. d 6. d 7. b  
8.

## Chapter 33

### Figure Questions

**Figure 33.10** Since enzymes are proteins, and proteins are hydrolyzed in the small intestine, the digestive enzymes in that compartment need to be resistant to enzymatic cleavage other than the cleavage required to activate them. **Figure 33.11** None.

Since digestion is completed in the small intestine, tapeworms simply absorb pre-digested nutrients through their large body surface. **Figure 33.18** The transport of nutrients across membranes and the synthesis of RNA and protein are coupled to ATP hydrolysis. These processes proceed spontaneously because there is an overall drop in free energy, with the excess energy given off as heat. Similarly, less than half of the free energy in glucose is captured in the coupled reactions of cellular respiration. The remainder of the energy is released as heat. **Figure 33.19** Both insulin and glucagon are involved in negative-feedback circuits.

### Concept Check 33.1

1. The only essential amino acids are those that an animal cannot synthesize from other molecules. 2. Many vitamins serve as enzyme cofactors, which, like enzymes themselves, are unchanged by the chemical reactions in which they participate. Therefore, only very small amounts of vitamins are needed. 3. To identify the essential nutrient missing from an animal's diet, a researcher could supplement the diet with individual nutrients and determine which nutrient eliminates the signs of malnutrition.

### Concept Check 33.2

1. A gastrovascular cavity is a digestive pouch with a single opening that functions in both ingestion and elimination; an alimentary canal is a digestive tube with a separate mouth and anus at opposite ends. 2. As long as nutrients are within the cavity of the alimentary canal, they are in a compartment that is continuous with the outside environment via the mouth and anus and have not yet crossed a membrane to enter the body. 3. Just as food remains outside the body in a digestive tract, gasoline moves from the fuel tank to the engine, and waste products exit through the exhaust without ever entering the passenger compartment of the automobile. In addition, gasoline, like food, is broken down in a specialized compartment, so that the rest of the automobile (or body) is protected from disassembly. In both cases, high-energy fuels are consumed, complex molecules are broken down into simpler ones, and waste products are eliminated.

### Concept Check 33.3

1. By peristalsis, which can squeeze food through the esophagus even without the help of gravity. 2. Because parietal cells in the stomach pump hydrogen ions to produce HCl, a proton pump inhibitor reduces the acidity of chyme and thus the irritation

that occurs when chyme enters the esophagus. **3.** Proteins would be denatured and digested into peptides. Further digestion, to individual amino acids, would require enzymatic secretions found in the small intestine. No digestion of carbohydrates or lipids would occur.

#### Concept Check 33.4

**1.** The increased time for transit through the alimentary canal allows for more extensive processing, and the increased surface of the canal area provides greater opportunity for absorption. **2.** A mammal's digestive system provides mutualistic microbes with an environment that is protected against other microbes by saliva and gastric juice, that is held at a constant temperature conducive to enzyme action, and that provides a steady source of nutrients. **3.** For the yogurt treatment to be effective, the bacteria from yogurt would have to establish a mutualistic relationship with the small intestine, where disaccharides are broken down and sugars are absorbed. Conditions in the small intestine are likely to be very different from those in a yogurt culture. The bacteria might be killed before they reach the small intestine, or they might not be able to grow there in sufficient numbers to aid in digestion.

#### Concept Check 33.5

**1.** Over the long term, the body stores excess calories in fat, whether those calories come from fat, carbohydrate, or protein in food. **2.** Since each gram of the mouse requires more calories than each gram of the elephant, the metabolic rate *per gram* must be higher in the mouse than in the elephant. **3.** Since patients with type 2 diabetes produce insulin but fail to maintain normal glucose levels, you might predict that there could be mutations in the genes for the insulin receptor or the signal transduction pathway it activates. Such mutations have in fact been found in type 2 patients.

#### Summary of Key Concepts Questions

**33.1** Since the cofactor is necessary in all animals, those animals that do not require it in their diet must be able to synthesize it from other organic molecules. **33.2** A liquid diet containing glucose, amino acids, and other building blocks could be ingested and absorbed without the need for mechanical or chemical digestion. **33.3** The small intestine has a much larger surface area than the stomach. **33.4** The assortment of teeth in our mouth and the short length of our cecum suggest that our ancestors' digestive systems were not specialized for digesting plant material. **33.5** When mealtime arrives, nervous inputs from the brain signal the stomach to prepare to digest food through secretions and churning.

## Chapter 34

### Figure Questions

**Figure 34.8** Each feature of the ECG recording, such as the sharp upward spike, occurs once per cardiac cycle. Using the *x*-axis to measure the time in seconds between successive spikes and dividing that number into 60 would yield the heart rate as the number of cycles per minute. **Figure 34.21** The reduction in surface tension results from the presence of surfactant. Therefore, for all the infants that had died of RDS, you would expect the amount of surfactant to be near zero. For infants that had died of other causes, you would expect the amount of surfactant to be near zero for weights less than 1,200 g but much greater than zero for weights above 1,200 g.

**Figure 34.23** Breathing at a rate greater than that needed to meet metabolic demand (hyperventilation) would lower blood  $\text{CO}_2$  levels. Sensors in major blood vessels and the medulla would signal the breathing control centers to decrease the rate of contraction of the diaphragm and rib muscles, decreasing the breathing rate and restoring normal  $\text{CO}_2$  levels in the blood and other tissues. **Figure 34.24** The resulting increase in tidal volume would enhance ventilation within the lungs, increasing  $\text{P}_{\text{O}_2}$  and decreasing  $\text{P}_{\text{CO}_2}$  in the alveoli.

#### Concept Check 34.1

**1.** In both an open circulatory system and a fountain, fluid is pumped through a tube and then returns to the pump after collecting in a pool. **2.** The ability to shut off blood supply to the lungs when the animal is submerged. **3.** The  $\text{O}_2$  content would be abnormally low because some oxygen-depleted blood returned to the right atrium from the systemic circuit would mix with the oxygen-rich blood in the left atrium.

#### Concept Check 34.2

**1.** The pulmonary veins carry blood that has just passed through capillary beds in the lungs, where it accumulated  $\text{O}_2$ . The venae cavae carry blood that has just passed through capillary beds in the rest of the body, where it lost  $\text{O}_2$  to the tissues. **2.** The delay allows the atria to empty completely, filling ventricles fully before they contract. **3.** The heart, like any other muscle, becomes stronger through regular exercise. You would expect a stronger heart to have a greater stroke volume, which would allow for the decrease in heart rate.

#### Concept Check 34.3

**1.** The large total cross-sectional area of the capillaries. **2.** An increase in blood pressure and cardiac output combined with the diversion of more blood to the skeletal muscles would increase the capacity for action by increasing the rate of blood circulation and delivering more  $\text{O}_2$  and nutrients to the skeletal muscles. **3.** Additional hearts could be used to improve blood return from the legs. However, it might be difficult to coordinate the activity of multiple hearts and to maintain adequate blood flow to hearts far from the gas exchange organs.

#### Concept Check 34.4

**1.** An increase in the number of white blood cells (leukocytes) may indicate that the person is combating an infection. **2.** Clotting factors do not initiate clotting but are essential steps in the clotting process. Also, the clots that form a thrombus typically result from an inflammatory response to an atherosclerotic plaque, not from clotting at a wound site. **3.** The chest pain results from inadequate blood flow in coronary arteries. Vasodilation promoted by nitric oxide from nitroglycerin increases blood flow, providing the heart muscle with additional oxygen and thus relieving the pain.

#### Concept Check 34.5

**1.** Their interior position helps them stay moist. If the respiratory surfaces of lungs extended out into the terrestrial environment, they would quickly dry out, and diffusion of  $\text{O}_2$  and  $\text{CO}_2$  across these surfaces would stop. **2.** Earthworms need to keep their skin moist for gas exchange, but they need air outside this moist layer. If they stay in their waterlogged tunnels after a heavy rain, they will suffocate because they cannot get as much  $\text{O}_2$  from water as from air. **3.** In the extremities of some vertebrates, blood flows in opposite directions in neighboring veins and arteries; this countercurrent arrangement maximizes the recapture of heat from blood leaving the body core in arteries, which is important for thermoregulation in cold environments. Similarly, in the gills of fish, water passes over the gills in the direction opposite to that of blood flowing through the gill capillaries, maximizing the extraction of oxygen from the water along the length of the exchange surface.

#### Concept Check 34.6

**1.** An increase in blood  $\text{CO}_2$  concentration causes an increase in the rate of  $\text{CO}_2$  diffusion into the cerebrospinal fluid, where the  $\text{CO}_2$  combines with water to form carbonic acid. Dissociation of carbonic acid releases hydrogen ions, decreasing the pH of the cerebrospinal fluid. **2.** Increased heart rate increases the rate at which  $\text{CO}_2$ -rich blood is delivered to the lungs, where  $\text{CO}_2$  is removed. **3.** A hole would allow air to enter the space between the inner and outer layers of the double membrane, resulting in a condition called a pneumothorax. The two layers would no longer stick together, and the lung on the side with the hole would collapse and cease functioning.

#### Concept Check 34.7

**1.** The direction of net diffusion is determined by the difference in partial pressure. Net diffusion of gases occurs from a region of higher partial pressure to a region of lower partial pressure. **2.** The Bohr shift causes hemoglobin to release more  $\text{O}_2$  at a lower pH, such as found in the vicinity of tissues with high rates of cellular respiration and  $\text{CO}_2$  release. **3.** The doctor is assuming that the rapid breathing is the body's response to low blood pH. Metabolic acidosis, the lowering of blood pH, can have many causes, including complications of certain types of diabetes, shock (extremely low blood pressure), and poisoning.

#### Summary of Key Concepts Questions

**34.1** In a closed circulatory system, an ATP-driven muscular pump generally moves fluids in one direction on a scale of millimeters to meters. Exchange between cells and their environment relies on diffusion, which involves random movements of molecules. Concentration gradients of molecules across exchange surfaces can drive rapid net diffusion on a scale of 1 mm or less. **34.2** Replacement of a defective valve should increase stroke volume. A lower heart rate would therefore be sufficient to maintain the same cardiac output. **34.3** Blood pressure in the arm would fall by 25 to 30 mm Hg, the same difference as is normally seen between your heart and your brain.

**34.4** One microliter of blood contains about 5 million erythrocytes and 5,000 leukocytes, so leukocytes make up only about 0.1% of the cells in the absence of infection.

**34.5** Because  $\text{CO}_2$  is such a small fraction of atmospheric gas (0.29 mm Hg/760 mm Hg, or less than 0.04%), the partial pressure gradient of  $\text{CO}_2$  between the respiratory surface and the environment always strongly favors the release of  $\text{CO}_2$  to the atmosphere. **34.6** Because the lungs do not empty completely with each breath, incoming and outgoing air mix, resulting in a lower  $\text{P}_{\text{O}_2}$  in the lungs than in the air that enters the body during inspiration. **34.7** An enzyme speeds up a reaction without changing the equilibrium and without being consumed. Similarly, a respiratory pigment speeds up the movement of gases in the body without changing the equilibrium and without being consumed.

1. c 2. b 3. d 4. c 5. a 6. a 7. a

## Chapter 35

### Figure Questions

**Figure 35.4** Cell-surface TLRs recognize pathogens identifiable by surface molecules, whereas TLRs in vesicles recognize pathogens identifiable by internal molecules after the pathogens are broken down. **Figure 35.7** Part of the enzyme or antigen receptor provides a structural “backbone” that maintains overall shape, while interaction occurs at a surface with a close fit to the substrate or antigen. The combined effect of multiple noncovalent interactions at the active site or binding site is a high-affinity interaction of tremendous specificity. **Figure 35.10** After gene rearrangement, a lymphocyte and its daughter cells make a single version of the antigen receptor. In contrast, alternative splicing is not heritable and can give rise to diverse gene products in a single cell. **Figure 35.15** These receptors enable memory cells to present antigen on their cell surface to a helper T cell. This presentation of antigen is required to activate memory cells in a secondary immune response. **Figure 35.16** Primary response: arrows extending from Antigen (1st exposure), Antigen-presenting cell, Helper T cell, B cell, Plasma cells, Cytotoxic T cell, and Active cytotoxic T cells; secondary response: arrows extending from Antigen (2nd exposure), Memory helper T cells, Memory B cells, and Memory cytotoxic T cells

### Concept Check 35.1

1. Because pus contains white blood cells, fluid, and cell debris, it indicates an active and at least partially successful inflammatory response against invading microbes. 2. Whereas the ligand for the TLR receptor is a foreign molecule, the ligand for many signal transduction pathways is a molecule produced by the animal itself. 3. Bacteria with a human host would likely grow optimally at normal human body temperature or, if fever were often induced, at a temperature a few degrees higher.

### Concept Check 35.2

1. See Figure 35.6. The transmembrane regions lie within the C regions, which also form the disulfide bridges. In contrast, the antigen-binding sites are in the V regions. 2. Generating memory cells ensures both that a receptor specific for a particular epitope will be present and that there will be more lymphocytes with this specificity than in a host that had never encountered the antigen. 3. If each B cell produced two different light and heavy chains for its antigen receptor, different combinations would make four different receptors. If any one was self-reactive, the lymphocyte would be eliminated in the generation of self-tolerance. For this reason, many more B cells would be eliminated, and those that could respond to a foreign antigen would be less effective at doing so due to the variety of receptors (and antibodies) they express.

### Concept Check 35.3

1. Myasthenia gravis is considered an autoimmune disease because the immune system produces antibodies against self molecules (certain receptors on muscle cells). 2. A child lacking a thymus would have no functional T cells. Without helper T cells to help activate B cells, the child would be unable to produce antibodies against extracellular bacteria. Furthermore, without cytotoxic T cells or helper T cells, the child's immune system would be unable to kill virus-infected cells. 3. If the handler developed immunity to proteins in the antivenin, another injection could provoke a severe immune response. The handler's immune system might also now produce antibodies that could neutralize the venom in the absence of antivenin.

### Summary of Key Concepts Questions

35.1 Lysozyme in saliva destroys bacterial cell walls; the viscosity of mucus helps trap bacteria; acidic pH in the stomach kills many bacteria; and the tight packing of cells lining the gut provides a physical barrier to infection. 35.2 Sufficient numbers of cells to mediate an innate immune response are always present, whereas an adaptive response requires selection and proliferation of an initially very small cell population specific for the infecting pathogen. 35.3 No. Immunological memory after a natural infection and immunological memory after immunization are very similar. There may be minor differences in the particular antigens that can be recognized in a subsequent infection.

### Test Your Understanding

8. One possible answer:

## Chapter 36

### Figure Questions

**Figure 36.10** The analysis would be informative because the polar bodies contain all of the maternal chromosomes that don't end up in the mature egg. For example, finding two copies of the disease gene in the polar bodies would indicate its absence in the egg. This method of genetic testing is sometimes carried out when oocytes collected from a female are fertilized with sperm in a laboratory dish.

### Concept Check 36.1

1. Internal fertilization allows the sperm to reach the egg without either gamete drying out. 2. No. Owing to random assortment of chromosomes during meiosis, the offspring may receive the same copy or different copies of a particular parental chromosome from the sperm and the egg. Furthermore, genetic recombination during meiosis will result in reassortment of genes between pairs of parental chromosomes. 3. Both fragmentation and budding in animals have direct counterparts in the asexual reproduction of plants.

### Concept Check 36.2

1. Both have a haploid DNA content and very little cytoplasm. However, the early spermatid will develop into a functional gamete, whereas a polar body is a by-product of oocyte production. 2. Spermatogenesis occurs normally only when the testicles are cooler than the rest of the body. Extensive use of a hot tub (or of very tight-fitting underwear) can cause a decrease in sperm quality and number. 3. Like the uterus of an insect, the ovary of a plant is the site of fertilization. Unlike the plant ovary, the uterus is not the site of egg production, which occurs in the insect ovary. In addition, the fertilized insect egg is expelled from the uterus, whereas the plant embryo develops within a seed in the ovary. 4. The only effect of sealing off each vas deferens is an absence of sperm in the ejaculate. Sexual response and ejaculate volume are unchanged. The cutting and sealing off of these ducts, a *vasectomy*, is a common surgical procedure for men who do not wish to produce any (more) offspring.

### Concept Check 36.3

1. In both females and males, FSH encourages the growth of cells that support and nourish developing gametes (follicle cells in females and Sertoli cells in males), and LH stimulates the production of sex hormones that promote gametogenesis (estrogens, primarily estradiol, in females and androgens, especially testosterone, in males). 2. In estrous cycles, which occur in most female mammals, the endometrium is reabsorbed (rather than shed) if fertilization does not occur. Estrous cycles often occur just one or a few times a year, and the female is usually receptive to copulation only during the period around ovulation. Menstrual cycles are about four weeks in length, do not restrict receptivity to copulation to a particular interval, and are found only in humans and some other primates. 3. The combination of estradiol and progesterone would have a negative-feedback effect on the hypothalamus, blocking release of GnRH. This would interfere with LH secretion by the pituitary, thus preventing ovulation. This is in fact one basis of action of the most common hormonal contraceptives.

### Concept Check 36.4

1. Fertilization occurs in one of the two oviducts. 2. Mesoderm. Skin is derived from ectoderm, and the lining of many internal organs is endodermal in origin. 3. The menstrual cycle would be unaffected because it is controlled by hormones, which circulate in the bloodstream. However, the woman could not become pregnant naturally because the oviduct blockage would prevent sperm from reaching her eggs.

### Summary of Key Concepts Questions

36.1 Not necessarily. Because parthenogenesis involves meiosis, the mother would pass on to each offspring a random and therefore typically distinct combination of the chromosomes she inherited from her mother and father. 36.2 The small size and lack of cytoplasm characteristic of a sperm are adaptations well suited to its function as a delivery vehicle for DNA. The large size and rich cytoplasmic contents of eggs support the growth and development of the embryo. 36.3 Circulating anabolic steroids mimic the feedback regulation of testosterone, turning off pituitary signaling to the testes and thereby blocking the release of signals required for spermatogenesis. 36.4 The fertilization envelope forms after cortical granules release their contents outside the egg, causing the vitelline membrane to rise and harden. The fertilization envelope serves as a barrier to fertilization by more than one sperm.

### Test Your Understanding

1. d 2. a 3. a 4. c 5. a 6. b 7. c 8. d

9.

(c) The supply of stem cells would be used up and spermatogenesis would not be able to continue.

## Chapter 37

### Figure Questions

**Figure 37.7** Adding chloride channels would make the membrane potential less positive. Adding sodium or potassium channels would have no effect because sodium ions are already at equilibrium and there are no potassium ions present.

**Figure 37.10**

**Figure 37.15** The production and transmission of action potentials would be unaffected. However, action potentials arriving at chemical synapses would be unable to trigger release of neurotransmitter. Signaling at such synapses would thus be blocked.

### Concept Check 37.1

1. Axons and dendrites extend from the cell body and function in information flow. Dendrites transfer information to the cell body, whereas axons transmit information from the cell body. A typical neuron has multiple dendrites and one axon. 2. Sensors in your ear transmit information to your brain. There the activity of interneurons in processing centers enables you to recognize your name. In response, signals transmitted via motor neurons cause contraction of muscles that turn your neck. 3. Increased branching would allow control of a greater number of postsynaptic cells, enhancing coordination of responses to nervous system signals.

### Concept Check 37.2

1. Ions can flow against a chemical concentration gradient if there is an opposing electrical gradient of greater magnitude. 2. A decrease in permeability to  $K^+$ , an increase in permeability to  $Na^+$ , or both. 3. Charged dye molecules could equilibrate only if other charged molecules could also cross the membrane. If not, a membrane potential would develop that would counterbalance the chemical gradient.

### Concept Check 37.3

1. A graded potential has a magnitude that varies with stimulus strength, whereas an action potential has an all-or-none magnitude that is independent of stimulus strength. 2. Loss of the insulation provided by myelin sheaths leads to a disruption of action potential propagation along axons. Voltage-gated sodium channels are restricted to the nodes of Ranvier, and without the insulating effect of myelin, the inward current produced at one node during an action potential cannot depolarize the membrane to the threshold at the next node. 3. The maximum frequency would decrease because the refractory period would be extended.

### Concept Check 37.4

1. It can bind to different types of receptors, each triggering a specific response in postsynaptic cells. 2. These toxins would prolong the EPSPs that acetylcholine produces because the neurotransmitter would remain longer in the synaptic cleft. 3. Membrane depolarization, exocytosis, and membrane fusion

## Summary of Key Concepts Questions

**37.1** It would prevent information from being transmitted away from the cell body along the axon. **37.2** There are very few open sodium channels in a resting neuron, so the resting potential either would not change or would become slightly more negative (hyperpolarization). **37.3** Positive feedback is responsible for the rapid opening of many voltage-gated sodium channels, causing the rapid outflow of sodium ions responsible for the rising phase of the action potential. As the membrane potential becomes positive, voltage-gated potassium channels open in a form of negative feedback that helps bring about the falling phase of the action potential. **37.4** A given neurotransmitter can have many receptors that differ in their location and activity. Drugs that target receptor activity rather than neurotransmitter release or stability are therefore likely to exhibit greater specificity and potentially have fewer undesirable side effects.

## Test Your Understanding

1. c 2. c 3. c 4. b 5. a 6. e 7. The activity of the sodium-potassium pump is essential to maintain the resting potential. With the pump inactivated, the sodium and potassium concentration gradients would gradually disappear, resulting in a greatly reduced resting potential. 8. Since GABA is an inhibitory neurotransmitter in the CNS, this drug would be expected to decrease brain activity. A decrease in brain activity might be expected to slow down or reduce behavioral activity. Many sedative drugs act in this fashion. 9. As shown in this pair of drawings, a pair of action potentials would move outward in both directions from each electrode. (Action potentials are unidirectional only if they begin at one end of an axon.) However, because of the refractory period, the two action potentials between the electrodes both stop where they meet. Thus, only one action potential reaches the synaptic terminal.

## Chapter 38

### Figure Questions

**Figure 38.9** If the depolarization brings the membrane potential to or past threshold, it should initiate action potentials that cause dopamine release from the VTA neurons. This should mimic natural stimulation of the brain reward system, resulting in positive and perhaps pleasurable sensations. **Figure 38.10** Regions you would expect to be active regardless of the type of music played would include ones that are important for processing and interpreting sounds. **Figure 38.26** In step 4, the activity of phosphodiesterase can bring about signal amplification, because each enzyme molecule can cleave many molecules of cyclic GMP. In step 5, the  $Na^+$  channels can contribute to amplification, since large numbers of ions can cross the membrane through a single open channel.

### Concept Check 38.1

1. The sympathetic division would likely be activated. It mediates the “fight-or-flight” response in stressful situations. 2. Nerves contain bundles of axons, some that belong to motor neurons, which send signals outward from the CNS, and some that belong to sensory neurons, which bring signals into the CNS. Therefore, you would expect effects on both motor control and sensation.

### Concept Check 38.2

1. The cerebral cortex on the left side of the brain initiates voluntary movement of the right side of the body. 2. Alcohol diminishes function of the cerebellum. 3. A coma reflects a disruption in the cycles of sleep and arousal regulated by communication between the midbrain and pons and the cerebrum. You would expect this group to have damage to the midbrain, pons, cerebrum, or any part of the brain between these structures. Paralysis reflects an inability to carry out motor commands transmitted from the cerebrum to the spinal cord. You would expect this group to have damage to the portion of the CNS extending from the spinal cord up to but not including the midbrain and pons.

### Concept Check 38.3

1. There can be an increase in the number of synapses between the neurons or an increase in the strength of existing synaptic connections. 2. Broca’s area, which is active during the generation of speech, is located near the motor cortex, which controls skeletal muscles, including those in the face. Wernicke’s area, which is active when speech is heard, is located in the posterior part of the temporal lobe, which is involved in hearing. 3. Each cerebral hemisphere is specialized for different parts of this task—the right for face recognition and the left for language. Without an intact corpus callosum, neither hemisphere can take advantage of the other’s processing abilities.

### Concept Check 38.4

1. Electromagnetic receptors in general detect only external stimuli. Other sensory receptors, such as chemoreceptors or mechanoreceptors, can act as either internal or external sensors. 2. The capsaicin present in the peppers activates the thermoreceptor for high temperatures. In response to the perceived high temperature, the nervous system triggers sweating to achieve evaporative cooling. 3. The electrical stimulus would be perceived as if the sensory receptors that regulate that neuron had been

activated. For example, electrical stimulation of a sensory neuron that synapses with a thermoreceptor activated by menthol would likely be perceived as a local cooling.

### Concept Check 38.5

1. Otoliths in the utricle and saccule enable a mammal to detect its orientation with respect to gravity, providing information that is essential in environments where light cues are absent. 2. As a sound that changed gradually from a very low to a very high pitch. 3. The stapes and the other middle ear bones transmit vibrations from the tympanic membrane to the oval window. Fusion of these bones (as occurs in a disease called otosclerosis) would block this transmission and result in hearing loss.

### Concept Check 38.6

1. Planarians have ocelli that cannot form images but can sense the intensity and direction of light, providing enough information to enable the animals to find protection in shaded places. Flies have compound eyes that form images and excel at detecting movement. 2. In the light, the photoreceptors hyperpolarize, shutting off their release of the neurotransmitter glutamate. In response, the bipolar cells that are depolarized by glutamate hyperpolarize, and those that are hyperpolarized by glutamate depolarize. If the bipolar cells that hyperpolarize in the light release a neurotransmitter that inhibits ganglion cells, then those ganglion cells will generate more action potentials in the light. Similarly, if the bipolar cells that depolarize in the light release a neurotransmitter that excites ganglion cells, then those ganglion cells will also generate more action potentials in the light. 3. Absorption of light by retinal converts retinal from its *cis* isomer to its *trans* isomer, initiating the process of light detection. In contrast, a photon absorbed by chlorophyll does not bring about isomerization, but instead boosts an electron to a higher-energy orbital, initiating the electron flow that generates ATP and NADPH.

### Summary of Key Concepts Questions

38.1 Glia have diverse functions. For example, ependymal cells help circulate cerebrospinal fluid, which carries nutrients, hormones, and waste products. In contrast, astrocytes promote increased blood flow to active neurons and microglia defend against pathogens within the nervous system. 38.2 The midbrain coordinates visual reflexes; the cerebellum controls coordination of movement that depends on visual input; the thalamus serves as a routing center for visual information; and the cerebrum is essential for converting visual input to a visual image. 38.3 You would expect the right side of the body to be paralyzed because it is controlled by the left cerebral hemisphere, where language generation and interpretation are localized. 38.4 Nociceptors overlap with other classes of receptors in the type of stimulus they detect. They differ from other receptors only in how a particular stimulus is perceived. 38.5 Volume is encoded by the frequency of action potentials transmitted to the brain; pitch is encoded by which axons are transmitting action potentials. 38.6 The major difference is that neurons in the retina integrate information from multiple sensory receptors (photoreceptors) before transmitting information to the central nervous system.

### Test Your Understanding

1. d 2. c 3. a 4. b 5. e 6. c 7. d

## Chapter 39

### Figure Questions

**Figure 39.4** Hundreds of myosin heads participate in sliding each pair of thick and thin filaments past each other. Because cross-bridge formation and breakdown are not synchronized, many myosin heads are exerting force on the thin filaments at all times during muscle contraction. **Figure 39.8** By causing all of the motor neurons that control the muscle to generate action potentials at a rate high enough to produce tetanus in all of the muscle fibers. **Figure 39.15** The fixed action pattern based on the sign stimulus of a red belly ensures that the male will chase away any invading males of his species. By chasing away such males, the defender decreases the chance that another male will fertilize eggs laid in his nesting territory. **Figure 39.17** There should be no effect. Imprinting is an innate behavior that is carried out anew in each generation. Assuming that the nest was not disturbed, the offspring of the Lorenz followers would imprint on the mother goose. **Figure 39.18** Perhaps the wasp doesn't use visual cues. It might also be that wasps recognize objects native to their environment, but not foreign objects, such as the pinecones. Tinbergen addressed these ideas before carrying out the pinecone study. When he swept away the pebbles and sticks around the nest, the wasps could no longer find their nests. If he shifted the natural objects in their natural arrangement, the shift in the landmarks caused a shift in the site to which the wasps returned. Finally, if natural objects around the nest site were replaced with pinecones while the wasp was in the burrow, the wasp nevertheless found her way back to the nest site.

### Concept Check 39.1

1. In a skeletal muscle fiber,  $\text{Ca}^{2+}$  binds to the troponin complex, which moves tropomyosin away from the myosin-binding sites on actin and allows cross-bridges to form. In a smooth muscle cell,  $\text{Ca}^{2+}$  binds to calmodulin, which activates an enzyme that phosphorylates the myosin head and thus enables cross-bridge formation. 2. *Rigor mortis*, a Latin phrase meaning "stiffness of death," results from the complete depletion of ATP in skeletal muscle. Since ATP is required to release myosin from actin and to pump  $\text{Ca}^{2+}$  out of the cytosol, muscles become chronically contracted beginning about 3–4 hours after death. 3. A competitive inhibitor binds to the same site as the substrate for the enzyme. In contrast, the troponin and tropomyosin complex masks, but does not bind to, the myosin-binding sites on actin.

### Concept Check 39.2

1. Septa provide the divisions of the coelom that allow for peristalsis, a form of locomotion requiring independent control of different body segments. 2. The main

problem in swimming is drag; a fusiform body minimizes drag. The main problem in flying is overcoming gravity; wings shaped like airfoils provide lift, and adaptations such as air-filled bones reduce body mass. 3. When you grasp the sides of the chair, you are using a contraction of the triceps to keep your arms extended against the pull of gravity on your body. As you lower yourself slowly into the chair, you gradually decrease the number of motor units in the triceps that are contracted. Contracting your biceps would jerk you down, since you would no longer be opposing gravity.

### Concept Check 39.3

1. The proximate explanation for this fixed action pattern might be that nudging and rolling are released by the sign stimulus of an object outside the nest, and the behavior is carried to completion once initiated. The ultimate explanation might be that ensuring that eggs remain in the nest increases the chance of producing healthy offspring. 2. In both cases, the detection of periodic variation in the environment results in a reproductive cycle timed to environmental conditions that optimize the opportunity for success.

### Concept Check 39.4

1. Natural selection would tend to favor convergence in color because a predator learning to associate a color with a sting would avoid all other individuals with that same color, regardless of species. 2. You might move objects around to establish an abstract rule, such as "past landmark A, the same distance as A is from the starting point," while maintaining a minimum of fixed metric relationships, that is, avoiding having the food directly adjacent to or a set distance from a landmark. As you might surmise, designing an informative experiment of this kind is not easy. 3. Learned behavior, just like innate behavior, can contribute to reproductive isolation and thus to speciation. For example, learned bird songs contribute to species recognition during courtship, thereby helping ensure that only members of the same species mate.

### Concept Check 39.5

1. Certainty of paternity is higher with external fertilization. 2. Balancing selection could maintain the two alleles at the *forager* locus if population density fluctuated from one generation to another. At times of low population density, the energy-conserving *sitter* larvae (carrying the *for<sup>s</sup>* allele) would be favored, while at higher population density, the more mobile *rover* larvae (*for<sup>R</sup>* allele) would have a selective advantage.

### Concept Check 39.6

1. Because this geographic variation corresponds to differences in prey availability between two garter snake habitats, it seems likely that snakes with characteristics enabling them to feed on the abundant prey in their locale would have had increased survival and reproductive success. In this way, natural selection would have resulted in the divergent foraging behaviors. 2. It is true for some but not all individuals. If a parent has more than one reproductive partner, the offspring of different partners will have a coefficient of relatedness less than 0.5. 3. The older individual cannot be the beneficiary because he or she cannot have extra offspring. However, the cost is low for an older individual performing the altruistic act because that individual has already reproduced (but perhaps is still caring for a child or grandchild). There can therefore be selection for an altruistic act by a postreproductive individual that benefits a young relative.

### Summary of Key Concepts Questions

39.1 Oxidative fibers rely mostly on aerobic respiration and have many mitochondria, a rich blood supply, and a large amount of myoglobin. Glycolytic fibers use glycolysis as their primary source of ATP. They have a larger diameter and less myoglobin than oxidative fibers and fatigue more readily. 39.2 In response to nervous system motor output, the formation and breakdown of cross-bridges between myosin heads and actin cause the thin and thick filaments to slide past each other within each sarcomere. Because the thick filaments are anchored in the center of the sarcomeres and the thin filaments are anchored at the ends of the sarcomeres, this sliding movement shortens the sarcomeres and the muscle fibers that contain them. Furthermore, because the fibers themselves are part of muscles anchored at each end to bones, this shortening results in the movement of bones, as in the bending of an elbow. 39.3 Circannual rhythms are typically based on the cycles of light and dark in the environment. As the global climate changes, animals that migrate in response to these rhythms may shift to a location before or after local environmental conditions are optimal for reproduction and survival. 39.4 Because many foods have a distinctive color, associating a color with food can provide a selective advantage in foraging. However, the environment of a pigeon is unlikely to differ in color when a threat is present. Consequently, there would be no selective forces favoring the ability to associate color with danger. 39.5 Because feeding the female is likely to improve her reproductive success, the genes from the sacrificed male are likely to appear in a greater number of progeny. 39.6 Yes. Kin selection does not require any recognition or awareness of relatedness.

### Test Your Understanding

## Chapter 40

### Figure Questions

**Figure 40.12** Some factors, such as fire, are relevant only for terrestrial systems. At first glance, water availability is primarily a terrestrial factor, too. However, species living along the intertidal zone of oceans or along the edge of lakes also suffer desiccation. Salinity stress is important for species in some aquatic and terrestrial systems. Oxygen availability is an important factor primarily for species in some aquatic systems and in soils and sediments. **Figure 40.13** When only urchins were removed, limpets may have increased in abundance and reduced seaweed cover somewhat (the difference between the purple and blue lines on the graph).

Figure 40.22

**Concept Check 40.1**

1. In the tropics, high temperatures evaporate water and cause warm, moist air to rise. The rising air cools and releases much of its water as rain over the tropics. The remaining dry air descends at approximately 30° north and south, causing deserts to occur in those regions. 2. Answers will vary by location but should be based on the information in Figure 40.9. How much your local area has been altered from its natural state will influence how much it reflects the expected characteristics of your biome, particularly the expected plants and animals. 3. Northern coniferous forest is likely to replace tundra along the boundary between these biomes. To see why, note that northern coniferous forest is adjacent to tundra throughout North America, northern Europe, and Asia (see Figure 40.7) and that the temperature range for northern coniferous forest is just above that for tundra (see Figure 40.8).

**Concept Check 40.2**

1. In the oceanic pelagic zone, the ocean bottom lies below the photic zone, so there is too little light to support benthic algae or rooted plants. 2. As explained in Concept 32.3, aquatic organisms either gain or lose water by osmosis if the osmolarity of their environment differs from their internal osmolarity. Water gain can cause cells to swell, and water loss can cause them to shrink. To avoid excessive changes in cell volume, organisms that live in estuaries must be able to compensate for both water gain (under freshwater conditions) and water loss (under saltwater conditions). 3. In a river below a dam, the fish are more likely to be species that prefer colder water. In summer, the deep layers of a reservoir are colder than the surface layers, so a river below a dam will be colder than an undammed river.

**Concept Check 40.3**

1. (a) Humans might transplant a species to a new area that it could not previously reach because of a geographic barrier. (b) Humans might eliminate a predator or herbivore species, such as sea urchins, from an area. 2. One test would be to build a fence around a plot of land in an area that has trees of that species, excluding all deer from the plot. You could then compare the abundance of tree seedlings inside and outside the fenced plot over time.

**Concept Check 40.4**

1.

A Type III survivorship curve is most likely because very few of the young probably survive. 2. The average number of female offspring is  $0.74 \times 3.01 = 2.23$ . 3. Male sticklebacks would likely have a uniform pattern of dispersion, with antagonistic interactions maintaining a relatively constant spacing between them.

**Concept Check 40.5**

1. Though  $r_{\max}$  is constant,  $N$ , the population size, is increasing. As  $r_{\max}$  is applied to an increasingly large  $N$ , population growth ( $r_{\max}N$ ) accelerates, producing the J-shaped curve. 2. When  $N$  (population size) is small, there are relatively few individuals producing offspring. When  $N$  is large, near the carrying capacity, the per capita growth rate is relatively small because it is limited by available resources. The steepest part of the logistic growth curve corresponds to a population with a number of reproducing individuals that is substantial but not yet near carrying capacity. 3. If a population becomes too crowded, the likelihood of disease and mortality may increase because of the effects of pathogens. Thus, pathogens can reduce the long-term carrying capacity of a population.

**Concept Check 40.6**

1. By preferentially investing in the eggs it lays in the nest, the peacock wrasse increases their probability of survival. The eggs it disperses widely and does not provide care for are less likely to survive but require a lower investment by the adults. (In a sense, the adults avoid the risk of placing all their eggs in one basket.) 2. If a parent's survival is compromised greatly by caring for young during times of stress, the animal's fitness may increase if it abandons its current offspring and survives to produce healthier offspring at a later time. 3. In negative feedback, the output, or product, of a process slows that process. In populations that have a density-dependent birth rate, such as dune fescue grass, an accumulation of product (more individuals, resulting in a higher population density) slows the process of population growth by decreasing the birth rate.

**Summary of Key Concepts Questions**

40.1 Because tundra is much cooler than deserts (see Figure 40.8), less water evaporates during the growing season and the tundra stays more moist. 40.2 An aphotic zone is most likely to be found in the deep waters of a lake, the oceanic pelagic zone, or the marine benthic zone. 40.3 You could make a flowchart that begins with abiotic limitations—first determining the physical and chemical conditions under which a species could survive—and then moves through the other factors listed in the flowchart. 40.4 Ecologists can potentially estimate birth rates by counting the number of young whales born each year, and they can estimate death rates by seeing how the number of adults changes each year. 40.5 There are many things you could do to increase the carrying capacity of the species, including increasing its food supply, protecting it from predators, and providing more sites for nesting or reproduction. 40.6 An example of a biotic factor would be disease caused by a pathogen; natural disasters, such as floods and storms, are examples of abiotic factors.

**Test Your Understanding**

1. e 2. a 3. a 4. c  
5.

Based on what you learned from Figure 40.13 and on the positive relationship you observed in the field between kelp abundance and otter density, you could hypothesize that otters lower sea urchin density, reducing feeding of the urchins on kelp.

6. c

**Chapter 41****Figure Questions**

Figure 41.3 Its realized and fundamental niches would be similar, unlike those of *Chthamalus*. Figure 41.4 The smallest beak depth observed for *G. fortis* on Santa Maria and San Cristóbal Islands is 10 mm. Therefore, the predicted beak length is  $10 \text{ mm} \times 1.12 = 11 \text{ mm}$ . Figure 41.15 The death of individuals of *Mytilus*, a dominant species, should open up space for other species and increase species richness even in the absence of *Pisaster*. Figure 41.22 Other factors not included in the model must contribute to the number of species.

**Concept Check 41.1**

1. Interspecific competition has negative effects on both species (−/−). In predation, the predator population benefits at the expense of the prey population (+/−). Mutualism is a symbiosis in which both species benefit (+/+). 2. One of the competing species will become locally extinct because of the greater reproductive success of the more efficient competitor. 3. By specializing in eating seeds of a single plant species, individuals of the two finch species may be less likely to come into contact in the separate habitats, reinforcing a reproductive barrier to hybridization.

**Concept Check 41.2**

1. Species richness, the number of species in the community, and relative abundance, the proportions of the community represented by the various species, both contribute to species diversity. Compared to a community with a very high proportion of one species, a community with a more even proportion of species is considered more diverse. 2. The food web in Figure 41.14 indicates that elephant seals eat fish and squid and are in turn eaten by smaller toothed whales and humans. 3. According to the bottom-up model, adding extra predators would have little effect on lower trophic levels, particularly grasses. If the top-, increased bobcat numbers would decrease raccoon numbers, increase snake numbers, decrease mouse numbers, and increase grass biomass.

**Concept Check 41.3**

1. High levels of disturbance are generally so disruptive that they eliminate many species from communities, leaving the community dominated by a few tolerant species.

Low levels of disturbance permit competitively dominant species to exclude other species from the community. Moderate levels of disturbance, however, can facilitate co-existence of a greater number of species in a community by preventing competitively dominant species from becoming abundant enough to eliminate other species from the community. **2.** Early successional species can facilitate the arrival of other species in many ways, including increasing the fertility or water-holding capacity of soils or providing shelter to seedlings from wind and intense sunlight. **3.** The absence of fire for 100 years would represent a change to a low level of disturbance. According to the intermediate disturbance hypothesis, this change should cause diversity to decline as competitively dominant species gained sufficient time to exclude less competitive species.

#### Concept Check 41.4

**1.** Ecologists propose that the greater species richness of tropical regions is the result of their longer evolutionary history and the greater solar energy input and water availability in tropical regions. **2.** Immigration of species to islands declines with distance from the mainland and increases with island area. Extinction of species is lower on larger islands and on less isolated islands. Since the number of species on islands is largely determined by the difference between rates of immigration and extinction, the number of species will be highest on large islands near the mainland and lowest on small islands far from the mainland. **3.** Because of their greater mobility, birds disperse to islands more often than snakes and lizards, so birds should have greater richness.

#### Concept Check 41.5

**1.** Pathogens are microorganisms or viruses that cause disease. **2.** To keep the rabies virus out, you could ban imports of all mammals, including pets. Potentially, you could also attempt to vaccinate all dogs in the British Isles against the virus. A more practical approach might be to quarantine all pets brought into the country that are potential carriers of the disease, the approach the British government actually takes.

#### Summary of Key Concepts Questions

**41.1** Competition: a fox and a bobcat competing for prey. Predation: an orca eating a sea otter. Herbivory: a bison grazing in a prairie. Parasitism: a parasitoid wasp that lays its eggs on a caterpillar. Mutualism: a fungus and an alga that make up a lichen. Commensalism: a remora attached to a whale. Facilitation: a flowering plant and its pollinator. **41.2** Not necessarily if the more species-rich community is dominated by only one or a few species. **41.3** Because of the presence of species initially, the disturbance would initiate secondary succession in spite of its severe appearance. **41.4** Glaciations have severely reduced diversity in northern temperate, boreal, and Arctic ecosystems, compared to tropical ecosystems. **41.5** A host is required to complete the pathogen's life cycle, but a vector is not. A vector is an intermediate species that merely transports a pathogen to its host.

#### Test Your Understanding

**1.** e **2.** c **3.** d **4.** Community 1:  $H = -(0.05 \ln 0.05 + 0.05 \ln 0.05 + 0.85 \ln 0.85 + 0.05 \ln 0.05) = 0.59$ . Community 2:  $H = -(0.30 \ln 0.30 + 0.40 \ln 0.40 + 0.30 \ln 0.30) = 1.1$ . Community 2 is more diverse. **5.** Crab numbers should increase, reducing the abundance of eelgrass.

## Chapter 42

### Figure Questions

**Figure 42.6** Wetlands, coral reefs, and coastal zones cover areas too small to be seen clearly on global maps. **Figure 42.7** If the new duck farms made nitrogen available in rich supply, as phosphorus already is, then adding extra nitrogen in the experiment would not increase phytoplankton density. **Figure 42.12** Water availability is probably another factor that varied across the sites. Such factors not included in the experimental design could make the results more difficult to interpret. Multiple factors can also change together in nature, so ecologists must be careful that the factor they are studying is actually causing the observed response and is not just correlated with it.

#### Concept Check 42.1

**1.** Energy passes through an ecosystem, entering as sunlight and leaving as heat. It is not recycled within the ecosystem. **2.** You would need to know how much biomass the wildebeests ate from your plot and how much nitrogen was contained in that biomass. You would also need to know how much nitrogen they deposited in urine or feces. **3.** The second law states that in any energy transfer or transformation, some of the energy is dissipated to the surroundings as heat. This "escape" of energy from an ecosystem is offset by the continuous influx of solar radiation.

#### Concept Check 42.2

**1.** Only a fraction of solar radiation strikes plants or algae, only a portion of that fraction is of wavelengths suitable for photosynthesis, and much energy is lost as a result of reflection or heating of plant tissue. **2.** By manipulating the level of the factors of interest, such as phosphorus availability or soil moisture, and measuring responses by primary producers. **3.** The enzyme rubisco, which catalyzes the first step in the Calvin cycle, is the most abundant protein on Earth. Photosynthetic organisms require considerable nitrogen to make rubisco. Phosphorus is also needed as a component of

several metabolites in the Calvin cycle and as a component of both ATP and NADPH (see Figure 8.17).

#### Concept Check 42.3

**1.** 20 J; **40%** **2.** Nicotine protects the plant from herbivores. **3.** Total net production =  $10,000 + 1,000 + 100 + 10 \text{ J} = 11,110 \text{ J}$ ; at steady state, this is the amount of energy theoretically available to detritivores.

#### Concept Check 42.4

**1.** For example, for the carbon cycle:

**2.** Removal of the trees stops nitrogen uptake from the soil, allowing nitrate to accumulate there. The nitrate is washed away by precipitation and enters the streams.

**3.** Most of the nutrients in a tropical rain forest are contained in the trees, so removing the trees by logging rapidly depletes nutrients from the ecosystem. The nutrients that remain in the soil are quickly carried away into streams and groundwater by the abundant precipitation.

#### Concept Check 42.5

**1.** The main goal is to restore degraded ecosystems to a more natural state. **2.** Bioremediation uses organisms, generally prokaryotes, fungi, or plants, to detoxify or remove pollutants from ecosystems. Biological augmentation uses organisms, such as nitrogen-fixing plants, to add essential materials to degraded ecosystems. **3.** The Kissimmee River project returns the flow of water to the original channel and restores natural flow, a self-sustaining outcome. Ecologists at the Maunagautari reserve will need to maintain the integrity of the fence indefinitely, an outcome that is not self-sustaining in the long term.

#### Summary of Key Concepts Questions

**42.1** Because energy conversions are inefficient, with some energy inevitably lost as heat, you would expect that a given mass of primary producers would support a smaller biomass of secondary producers. **42.2** For estimates of NEP, you need to measure the respiration of all organisms in an ecosystem, not just the respiration of primary producers. In a sample of ocean water, primary producers and other organisms are usually mixed together, making their respective respirations hard to separate. **42.3** Runners use much more energy in respiration when they are running than when they are sedentary, reducing their production efficiency. **42.4** Factors other than temperature, including a shortage of water and nutrients, slow decomposition in hot deserts. **42.5** If the topsoil and deeper soil are kept separate, you could return the deeper soil to the site first and then apply the more fertile topsoil to improve the success of revegetation and other restoration efforts.

#### Test Your Understanding

**1.** c **2.** b **3.** d **4.** d **5.** c **6.** e **7.** e **8.** e **9.**

Based on these global numbers, approximately 110 km³ of precipitation falls over land each year.

## Chapter 43

### Figure Questions

**Figure 43.4** You would need to know the complete range of the species and that it is missing across all of that range. You would also need to be certain that the species isn't hidden, as might be the case for an animal that is hibernating underground or a plant that is present in the form of seeds or spores. **Figure 43.12** Because the population of Illinois birds has a different genetic makeup than birds in other regions, you would want to maintain to the greatest extent possible the frequency of beneficial genes or alleles found only in that population. In restoration, preserving genetic diversity in a species is as important as increasing organism numbers. **Figure 43.14** The natural disturbance regime in this habitat includes frequent fires that clear undergrowth but do not kill mature pine trees. Without these fires, the undergrowth quickly fills in and the habitat becomes unsuitable for red-cockaded woodpeckers. **Figure 43.27** Dispersal limitations, the activities of people (such as a broad-scale conversion of forests to agriculture or selective harvesting), or many other factors (including those discussed in Concept 40.3)

**Concept Check 43.1**

1. In addition to species loss, the biodiversity crisis includes the loss of genetic diversity within populations and species and the degradation of entire ecosystems. 2. Habitat destruction, such as deforestation, channelizing of rivers, or conversion of natural ecosystems to agriculture or cities, deprives species of places to live. Introduced species, which are transported by humans to regions outside their native range, where they are not controlled by their natural pathogens or predators, often reduce the population sizes of native species through competition or predation. Overharvesting has reduced populations of plants and animals or driven them to extinction. Finally, global change is altering the environment to the extent that it reduces the capacity of Earth to sustain life. 3. If both populations breed separately, then gene flow between the populations would not occur and genetic differences between them would be greater. As a result, the loss of genetic diversity would be greater than if the populations interbred.

**Concept Check 43.2**

1. Reduced genetic variation decreases the capacity of a population to evolve in the face of change. 2. The effective population size,  $N_e$ , was  $4(15 \times 5)/(15 + 5) = 15$  birds. 3. Because millions of people use the greater Yellowstone ecosystem each year, it would be impossible to eliminate all contact between people and bears. Instead, you might try to reduce the kinds of encounters where bears are killed. You might recommend lower speed limits on roads in the park, adjust the timing or location of hunting seasons (where hunting is allowed outside the park) to minimize contact with mother bears and cubs, and provide financial incentives for livestock owners to try alternative means of protecting livestock, such as using guard dogs.

**Concept Check 43.3**

1. A small area supporting numerous endemic species as well as a large number of endangered and threatened species. 2. Zoned reserves may provide sustained supplies of forest products, water, hydroelectric power, educational opportunities, and income from tourism. 3. Habitat corridors can increase the rate of movement or dispersal of organisms between habitat patches and thus the rate of gene flow between subpopulations. They thus help prevent a decrease in fitness attributable to inbreeding. They can also minimize interactions between organisms and humans as the organisms disperse; in cases involving potential predators, such as bears or large cats, minimizing such interactions is desirable.

**Concept Check 43.4**

1. Adding nutrients causes population explosions of algae and the organisms that feed on them. Increased respiration by algae and consumers, including detritivores, depletes the lake's oxygen, which the fish require. 2. Because higher temperatures lead to faster decomposition, organic matter in these soils could be quickly decomposed to  $\text{CO}_2$ , speeding up global warming.

**Concept Check 43.5**

1. The growth rate of Earth's human population has dropped by half since the 1960s, from 2.2% in 1962 to 1.1% today. Nonetheless, growth has not slowed much because the smaller growth rate is counterbalanced by increased population size; the number of additional people on Earth each year remains enormous—approximately 78 million. 2. Each of us influences our ecological footprint by how we live—what we eat, how much energy we use, and the amount of waste we generate—as well as by how many children we have. Making choices that reduce our demand for resources makes our ecological footprint smaller.

**Concept Check 43.6**

1. Sustainable development is an approach to development that works toward the long-term prosperity of human societies and the ecosystems that support them, which requires linking the biological sciences with the social sciences, economics, and humanities. 2. Biophilia, our sense of connection to nature and all forms of life, may act as a significant motivation for the development of an environmental ethic that resolves not to allow species to become extinct or ecosystems to be destroyed. Such an ethic is necessary if we are to become more attentive and effective custodians of the environment. 3. At a minimum, you would want to know the size of the population and the average reproductive rate of its individuals. To develop the fishery sustainably, you would seek a harvest rate that maintains the population near its original size and maximizes its harvest in the long term rather than the short term.

**Summary of Key Concepts Questions**

43.1 Nature provides us with many beneficial services, including a supply of reliable, clean water, the production of food and fiber, and the dilution and detoxification of

our pollutants. 43.2 A more genetically diverse population is better able to withstand pressures from disease or environmental change, making it less likely to become extinct over a given period of time. 43.3 Habitat fragmentation can isolate populations, leading to inbreeding and genetic drift, and it can make populations more susceptible to local extinctions resulting from the effects of pathogens, parasites, or predators. 43.4 It's healthier to feed at a lower trophic level because biological magnification increases the concentration of toxins at higher levels. 43.5 We are unique in our potential ability to reduce global population through contraception and family planning. We also are capable of consciously choosing our diet and personal lifestyle, and these choices influence the number of people Earth can support. 43.6 One goal of conservation biology is to preserve as many species as possible. Sustainable approaches that maintain the quality of habitats are required for the long-term survival of organisms.

**Test Your Understanding**

1. d 2. d 3. e 4. a 5. c 6. a  
7.

Between 1974 and 2011, Earth's atmospheric  $\text{CO}_2$  concentration increased from approximately 330 ppm to 394 ppm. If this rate of increase of approximately 1.7 ppm/yr continues, the concentration in 2100 will be about 545 ppm. The actual rise in  $\text{CO}_2$  concentration could be larger or smaller, depending on Earth's human population, our per capita energy use, and the extent to which societies take steps to reduce  $\text{CO}_2$  emissions, including replacing fossil fuels with renewable or nuclear fuels. Additional scientific data will be important for many reasons, including determining how quickly greenhouse gases such as  $\text{CO}_2$  are removed from the atmosphere by the biosphere.

8.

To minimize the area of forest into which the cowbirds penetrate, you should locate the road along one edge of the reserve. Any other location would increase the area of affected habitat. Similarly, the maintenance building should be in a corner of the reserve to minimize the area susceptible to cowbirds.

# Appendix B Periodic Table of the Elements

Atomic number  
(number of protons) → 6  
Element symbol → C  
Atomic mass  
(number of protons plus  
number of neutrons averaged  
over all isotopes) → 12.01

Metals      Metalloids      Nonmetals

Representative elements

**Groups:** Elements in a vertical column have the same number of electrons in their valence (outer) shell and thus have similar chemical properties.

**Periods:** Each horizontal row contains elements with the same total number of electron shells. Across each period, elements are ordered by increasing atomic number.

Period number	1	2	Transition elements										13	14	15	16	17	18

	1 millisecond (ms or msec)	= $10^{-3}$ second		
Temperature	Degrees Celsius ( $^{\circ}\text{C}$ ) (0 K [Kelvin] = $-273.15^{\circ}\text{C}$ )		$^{\circ}\text{F} = \frac{9}{5}^{\circ}\text{C} + 32$	$^{\circ}\text{C} = \frac{5}{9} (^{\circ}\text{F} - 32)$

# Appendix D A Comparison of the Light Microscope and the Electron Microscope

## Light Microscope

In light microscopy, light is focused on a specimen by a glass condenser lens; the image is then magnified by an objective lens and an ocular lens, for projection on the eye, digital camera, digital video camera, or photographic film.

## Electron Microscope

In electron microscopy, a beam of electrons (top of the microscope) is used instead of light, and electromagnets are used instead of glass lenses. The electron beam is focused on the specimen by a condenser lens; the image is magnified by an objective lens and a projector lens for projection on a digital detector, fluorescent screen, or photographic film.

# Appendix E Classification of Life

This appendix presents a taxonomic classification for the major extant groups of organisms discussed in this text; not all phyla are included. The classification presented here is based on the three-domain system, which assigns the two major groups of prokaryotes, bacteria and archaea, to separate domains (with eukaryotes making up the third domain).

Various alternative classification schemes are discussed in Unit Four of the text. The taxonomic turmoil includes debates about the number and boundaries of kingdoms and about the alignment of the Linnaean classification hierarchy with the findings of modern cladistic analysis. In this review, asterisks (\*) indicate currently recognized phyla thought by some systematists to be paraphyletic.

## DOMAIN BACTERIA

- **Proteobacteria**
- **Chlamydia**
- **Spirochetes**
- **Cyanobacteria**
- **Gram-positive bacteria**

## DOMAIN ARCHAEA

- **Korarchaeota**
- **Euryarchaeota**
- **Crenarchaeota**
- **Nanoarchaeota**

## DOMAIN EUKARYA

In the phylogenetic hypothesis we present in Chapter 25, major clades of eukaryotes are grouped together in the four “supergroups” listed in blue type. Formerly, all the eukaryotes generally called protists were assigned to a single kingdom, Protista. However, advances in systematics have made it clear that some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom Protista has been abandoned.

### Excavata

- Diplomonadida (diplomonads)
- Parabasala (parabasalids)
- Euglenozoa (euglenozoans)
  - Kinetoplastida (kinetoplastids)
  - Euglenophyta (euglenids)

### The “SAR” clade

- Stramenopila (stramenopiles)
  - Bacillariophyta (diatoms)
  - Phaeophyta (brown algae)
- Alveolata (alveolates)
  - Dinoflagellata (dinoflagellates)
  - Apicomplexa (apicomplexans)
  - Ciliophora (ciliates)

- Rhizaria
  - Foraminifera (forams)
  - Cercozoa (cercozoans)

### Archaeplastida

- Rhodophyta (red algae)
- Chlorophyta (green algae: chlorophytes)
- Charophyta (green algae: charophytes)
- Plantae
  - Phylum Hepatophyta (liverworts)
  - Phylum Bryophyta (mosses)
  - Phylum Anthocerophyta (hornworts)
  - Phylum Lycopphyta (lycophytes)
  - Phylum Monilophyta (ferns, horsetails, whisk ferns)
  - Phylum Ginkgophyta (ginkgo)
  - Phylum Cycadophyta (cycads)
  - Phylum Gnetophyta (gnetophytes)
  - Phylum Coniferophyta (conifers)
  - Phylum Anthophyta (flowering plants)

Nonvascular plants (bryophytes)

Seedless vascular plants

Gymnosperms

Angiosperms

## DOMAIN EUKARYA, continued

### Unikonta

- Amoebozoa (amoebozoans)
  - Dictyostelida (cellular slime molds)
  - Entamoeba (entamoebas)
- Nucleariida (nucleariids)
- Fungi
  - \*Phylum Chytridiomycota (chytrids)
  - \*Phylum Zygomycota (zygomycetes)
  - Phylum Glomeromycota (glomeromycetes)
  - Phylum Ascomycota (sac fungi)
  - Phylum Basidiomycota (club fungi)

- Choanoflagellata (choanoflagellates)
- Animalia
  - Phylum Porifera (sponges)
  - Phylum Ctenophora (comb jellies)
  - Phylum Cnidaria (cnidarians)

### Lophotrochozoa (lophotrochozoans)

- Phylum Platyhelminthes (flatworms)
- Phylum Ectoprocta (ectoprocts)
- Phylum Brachiopoda (brachiopods)
- Phylum Rotifera (rotifers)
- Phylum Mollusca (molluscs)
- Phylum Annelida (segmented worms)

### Ecdysozoa (ecdysozoans)

- Phylum Nematoda (roundworms)
- Phylum Arthropoda (This survey groups arthropods into a single phylum, but some zoologists now split the arthropods into multiple phyla.)
  - Subphylum Chelicerata (horseshoe crabs, arachnids)
  - Subphylum Myriapoda (millipedes, centipedes)
  - Subphylum Hexapoda (insects, springtails)
  - Subphylum Crustacea (crustaceans)
- Phylum Onychophora (velvet worms)

### Deuterostomia (deuterostomes)

- Phylum Hemichordata (hemichordates)
- Phylum Echinodermata (echinoderms)
- Phylum Chordata (chordates)
  - Subphylum Cephalochordata (lancelets)
  - Subphylum Urochordata (tunicates)
  - Subphylum Craniata (craniates)
    - Myxini (hagfishes)
    - Petromyzontida (lampreys)
    - Chondrichthyes (sharks, rays, chimaeras)
    - Actinopterygii (ray-finned fishes)
    - Actinistia (coelacanths)
    - Dipnoi (lungfishes)
    - Amphibia (amphibians)
    - Reptilia (tuataras, lizards, snakes, turtles, crocodilians, birds)
    - Mammalia (mammals)

Vertebrates

# Appendix F Scientific Skills Review

## Graphs

Graphs provide a visual representation of numerical data. They may reveal patterns or trends in the data that are not easy to recognize in a table. A graph is a diagram that shows how one variable in a data set is related (or perhaps not related) to another variable. If one variable is dependent on the other, the dependent variable is typically plotted on the  $y$ -axis and the independent variable on the  $x$ -axis. Types of graphs that are frequently used in biology include scatter plots, line graphs, bar graphs, and histograms.

A **scatter plot** is used when the data for all variables are numerical and continuous. Each piece of data is represented by a point. In a **line graph**, each data point is connected to the next point in the data set with a straight line, as in the graph below.

Two or more data sets can be plotted on the same line graph to show how two dependent variables are related to the same independent variable.

In some scatter-plot graphs, a straight or curved line is drawn through the entire data set to show the general trend in the data. A straight line that mathematically fits the data best is called a *regression line*. Alternatively, a mathematical function that best fits the data may describe a curved line, often termed a *best-fit curve*.

A **bar graph** is a kind of graph in which the independent variable represents groups or nonnumerical categories and the values of the dependent variable(s) are shown by bars.

A variant of a bar graph called a **histogram** can be made for numeric data by first grouping, or “binning,” the variable plotted on the *x*-axis into intervals of equal width. The “bins” may be integers or ranges of numbers. In the histogram below, the intervals are 25 mg/dL wide. The height of each bar shows the percent (or alternatively, the number) of experimental subjects whose characteristics can be described by one of the intervals plotted on the *x*-axis.

# Glossary of Scientific Inquiry Terms

See Concept 1.3 for more discussion of the process of scientific inquiry.

- control group** In a controlled experiment, a set of subjects that lacks (or does not receive) the specific factor being tested. Ideally, the control group should be identical to the experimental group in other respects.
- deductive reasoning** A type of logic in which specific results are predicted from a general premise.
- dependent variable** In an experiment, a variable whose value is influenced by changes in another variable (the independent variable).
- experimental group** A set of subjects that has (or receives) the specific factor being tested in a controlled experiment.
- hypothesis** A testable explanation for a set of observations based on the available data and guided by inductive reasoning. A hypothesis is narrower in scope than a theory.

- independent variable** A variable whose value is manipulated or changed during an experiment to reveal possible effects on another variable (the dependent variable).
- inductive reasoning** A type of logic in which generalizations are based on a large number of specific observations.
- model** A physical or conceptual representation of a natural phenomenon.
- prediction** In deductive reasoning, a forecast that follows logically from a hypothesis. By testing predictions, experiments may allow certain hypotheses to be rejected.
- theory** An explanation that is broader in scope than a hypothesis, generates new hypotheses, and is supported by a large body of evidence.

## Chi-Square ( $\chi^2$ ) Distribution Table

To use the table, find the row that corresponds to the degrees of freedom in your data set. (The degrees of freedom is the number of categories of data minus 1.) Move along that row to the pair of values that your calculated  $\chi^2$  value lies between. Move up from those numbers to the probabilities at the top of the columns to find the probability range for your  $\chi^2$  value. A probability of 0.05 or less is generally considered significant. See the Scientific Skills Exercise in Chapter 12 for an example of how to use the chi-square test.

Degrees of Freedom (df)	Probability										
	0.95	0.90	0.80	0.70	0.50	0.30	0.20	0.10	0.05	0.01	0.001
1	0.004	0.02	0.06	0.15	0.45	1.07	1.64	2.71	3.84	6.64	10.83
2	0.10	0.21	0.45	0.71	1.39	2.41	3.22	4.61	5.99	9.21	13.82

# Glossary

## Pronunciation Key

Pronounce

ā	as in	ace
a/ah		ash
ch		chose
ē		meet
e/eh		bet
g		game
ī		ice
i		hit
ks		box
kw		quick
ng		song
ō		robe
o		ox
oy		boy
s		say
sh		shell
th		thin
ū		boot
u/uh		up
z		zoo

' = primary accent

' = secondary accent

**5' cap** A modified form of guanine nucleotide added onto the end of a pre-mRNA molecule.

**A site** One of a ribosome's three binding sites for tRNA during translation. The A site holds the tRNA carrying the next amino acid to be added to the polypeptide chain. (A stands for aminoacyl tRNA.)

**ABC hypothesis** A model of flower formation identifying three classes of organ identity genes that direct formation of the four types of floral organs.

**abiotic** (ā'-bī-ot'-ik) Nonliving; referring to the physical and chemical properties of an environment.

**abscisic acid (ABA)** (ab-sis'-ik) A plant hormone that slows growth, often antagonizing the actions of growth hormones. Two of its many effects are to promote seed dormancy and facilitate drought tolerance.

**absorption** The third stage of food processing in animals: the uptake of small nutrient molecules by an organism's body.

**absorption spectrum** The range of a pigment's ability to absorb various wavelengths of light; also a graph of such a range.

**accessory fruit** A fruit, or assemblage of fruits, in which the fleshy parts are derived largely or entirely from tissues other than the ovary.

**acetyl CoA** Acetyl coenzyme A; the entry compound for the citric acid cycle in cellular respiration, formed from a two-carbon fragment of pyruvate attached to a coenzyme.

**acetylcholine** (as'-uh-til-kō'-lĕn) One of the most common neurotransmitters; functions by binding to receptors and altering the permeability of the postsynaptic membrane to specific ions, either depolarizing or hyperpolarizing the membrane.

**acid** A substance that increases the hydrogen ion concentration of a solution.

**acrosome** (ak'-ruh-sōm) A vesicle in the tip of a sperm containing hydrolytic enzymes and other proteins that help the sperm reach the egg.

**actin** (ak'-tin) A globular protein that links into chains, two of which twist helically about each other, forming microfilaments (actin filaments) in muscle and other kinds of cells.

**action potential** An electrical signal that propagates (travels) along the membrane of a neuron or other excitable cell as a nongraded (all-or-none) depolarization.

**action spectrum** A graph that profiles the relative effectiveness of different wavelengths of radiation in driving a particular process.

**activation energy** The amount of energy that reactants must absorb before a chemical reaction will start; also called free energy of activation.

**activator** A protein that binds to DNA and stimulates gene transcription. In prokaryotes, activators bind in or near the promoter; in eukaryotes, activators generally bind to control elements in enhancers.

**active immunity** Long-lasting immunity conferred by the action of B cells and T cells and the resulting B and T memory cells specific for a pathogen. Active immunity can develop as a result of natural infection or immunization.

**active site** The specific region of an enzyme that binds the substrate and that forms the pocket in which catalysis occurs.

**active transport** The movement of a substance across a cell membrane against its concentration or electrochemical gradient, mediated by specific transport proteins and requiring an expenditure of energy.

**adaptation** Inherited characteristic of an organism that enhances its survival and reproduction in a specific environment.

**adaptive evolution** A process in which traits that enhance survival or reproduction tend to increase in frequency in a population over time.

**adaptive immunity** A vertebrate-specific defense that is mediated by B lymphocytes (B cells) and T lymphocytes (T cells) and that exhibits specificity, memory, and self-nonspecific recognition; also called acquired immunity.

**adaptive radiation** Period of evolutionary change in which groups of organisms form many new species whose adaptations allow them to fill different ecological roles in their communities.

**addition rule** A rule of probability stating that the probability of any one of two or more mutually exclusive events occurring can be determined by adding their individual probabilities.

**adenosine triphosphate** See ATP (adenosine triphosphate).

**adhesion** The clinging of one substance to another, such as water to plant cell walls, by means of hydrogen bonds.

**aerobic respiration** A catabolic pathway for organic molecules, using oxygen (O<sub>2</sub>) as the final electron acceptor in an electron transport chain and ultimately producing ATP. This is the most efficient catabolic pathway and is carried out in most eukaryotic cells and many prokaryotic organisms.

**aggregate fruit** A fruit derived from a single flower that has more than one carpel.

**AIDS (acquired immunodeficiency syndrome)** The symptoms and signs present during the late stages of HIV infection, defined by a specified reduction in the number of T cells and the appearance of characteristic secondary infections.

**alcohol fermentation** Glycolysis followed by the reduction of pyruvate to ethyl alcohol, regenerating NAD<sup>+</sup> and releasing carbon dioxide.

**aldosterone** (al-dos'-tuh-rōn) A steroid hormone that acts on tubules of the kidney to regulate the transport of sodium ions (Na<sup>+</sup>) and potassium ions (K<sup>+</sup>).

**alga** (plural, **algae**) Member of a diverse collection of photosynthetic protists that includes unicellular and multicellular forms. Algal species are included in three eukaryote supergroups (Excavata, "SAR" clade, and Archaeplastida).

**alimentary canal** (al'-uh-men'-tuh-rē) A complete digestive tract, consisting of a tube running between a mouth and an anus.

**allele** (uh-lē'-ul) Any of the alternative versions of a gene that may produce distinguishable phenotypic effects.

**allergen** An antigen that triggers an exaggerated immune response.

**allopatric speciation** (al'-uh-pat'-rik) The formation of new species in populations that are geographically isolated from one another.

**allopolyploid** (al'-ō-pol'-ē-ploid) A fertile individual that has more than two chromosome sets as a result of two different species interbreeding and combining their chromosomes.

**allosteric regulation** The binding of a regulatory molecule to a protein at one site that affects the function of the protein at a different site.

**alpha (α) helix** (al'-fuh hē'-liks) A coiled region constituting one form of the secondary structure of proteins, arising from a specific pattern of hydrogen bonding between atoms of the polypeptide backbone (not the side chains).

**alternation of generations** A life cycle in which there is both a multicellular diploid form, the sporophyte, and a multicellular haploid form, the gametophyte; characteristic of plants and some algae.

**alternative RNA splicing** A type of eukaryotic gene regulation at the RNA-processing level in which different mRNA molecules are produced from the same primary transcript, depending on which RNA segments are treated as exons and which as introns.

**altruism** (al'-trū-iz-um) Selflessness; behavior that reduces an individual's fitness while increasing the fitness of another individual.

**alveolates** (al-vē'-uh-lets) One of the three major subgroups for which the "SAR" eukaryotic supergroup is named. Alveolate protists have membrane-enclosed sacs (alveoli) located just under the plasma membrane.

**alveolus** (al-vē'-uh-lus) (plural, **alveoli**) One of the dead-end air sacs where gas exchange occurs in a mammalian lung.

**amino acid** (uh-mēn'-ō) An organic molecule possessing both a carboxyl and an amino group. Amino acids serve as the monomers of polypeptides.

**amino group** A chemical group consisting of a nitrogen atom bonded to two hydrogen atoms; can act as a base in solution, accepting a hydrogen ion and acquiring a charge of 1+.

**aminoacyl-tRNA synthetase** An enzyme that joins each amino acid to the appropriate tRNA.

**ammonia** A small, toxic molecule (NH<sub>3</sub>) produced by nitrogen fixation or as a metabolic waste product of protein and nucleic acid metabolism.

**amniote** (am'-nē-ōt) Member of a clade of tetrapods named for a key derived character, the amniotic egg, which contains specialized membranes, including the fluid-filled amnion, that protect the embryo. Amniotes include mammals as well as birds and other reptiles.

**amniotic egg** An egg that contains specialized membranes that function in protection, nourishment, and gas exchange. The amniotic egg was a major evolutionary innovation, allowing embryos to develop on land in a fluid-filled sac, thus reducing the dependence of tetrapods on water for reproduction.

**amoeba** (uh-mē'-buh) A member of one of several groups of unicellular eukaryotes that have pseudopodia.

**amoebocyte** (uh-mē'-buh-sīt') An amoeba-like cell that moves by pseudopodia and is found in most animals. Depending on the species, it may digest and distribute food, dispose of wastes, form skeletal fibers, fight infections, or change into other cell types.

**amoebozoan** (uh-mē'-buh-zō'-an) A protist in a clade that includes many species with lobe- or tube-shaped pseudopodia.

**amphibian** Member of the tetrapod class Amphibia, including salamanders, frogs, and caecilians.

**amphipathic** (am'-fē-path'-ik) Having both a hydrophilic region and a hydrophobic region.

**amplification** The strengthening of stimulus energy during transduction.

**amylase** (am'-uh-lās') An enzyme that hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose polymer from animals) into smaller polysaccharides and the disaccharide maltose.

**anabolic pathway** (an'-uh-bol'-ik) A metabolic pathway that consumes energy to synthesize a complex molecule from simpler molecules.

**anaerobic respiration** (an-er-ō'-bik) A catabolic pathway in which inorganic molecules other than oxygen accept electrons at the "downhill" end of electron transport chains.

**analogous** Having characteristics that are similar because of convergent evolution, not homology.

**analogy** (an-al'-uh-jē) Similarity between two species that is due to convergent evolution rather than to descent from a common ancestor with the same trait.

**anaphase** The fourth stage of mitosis, in which the chromatids of each chromosome have separated and the daughter chromosomes are moving to the poles of the cell.

**anatomy** The structure of an organism.

**anchorage dependence** The requirement that a cell must be attached to a substratum in order to initiate cell division.

**aneuploidy** (an'-yū-ploy'-dē) A chromosomal aberration in which one or more chromosomes are present in extra copies or are deficient in number.

**angiosperm** (an'-jē-ō-sperm) A flowering plant, which forms seeds inside a protective chamber called an ovary.

**angiotensin II** A peptide hormone that stimulates constriction of precapillary arterioles

and increases reabsorption of NaCl and water by the proximal tubules of the kidney, increasing blood pressure and volume.

**anion** (an'-i-on) A negatively charged ion.

**anterior** Pertaining to the front, or head, of a bilaterally symmetric animal.

**anterior pituitary** A portion of the pituitary that develops from non-neural tissue; consists of endocrine cells that synthesize and secrete several tropic and nontropic hormones.

**anther** In an angiosperm, the terminal pollen sac of a stamen, where pollen grains containing sperm-producing male gametophytes form.

**antibody** A protein secreted by plasma cells (differentiated B cells) that binds to a particular antigen; also called immunoglobulin. All antibodies have the same Y-shaped structure and in their monomer form consist of two identical heavy chains and two identical light chains.

**anticodon** (an'-ti-kō'-don) A nucleotide triplet at one end of a tRNA molecule that base-pairs with a particular complementary codon on an mRNA molecule.

**antidiuretic hormone (ADH)** (an'-tī-dī-yū-ret'-ik) A peptide hormone, also known as vasopressin, that promotes water retention by the kidneys. Produced in the hypothalamus and released from the posterior pituitary, ADH also functions in the brain.

**antigen** (an'-ti-jen) A substance that elicits an immune response by binding to receptors of B cells, antibodies, or T cells.

**antigen presentation** The process by which an MHC molecule binds to a fragment of an intracellular protein antigen and carries it to the cell surface, where it is displayed and can be recognized by a T cell.

**antigen receptor** The general term for a surface protein, located on B cells and T cells, that binds to antigens, initiating adaptive immune responses. The antigen receptors on B cells are called B cell receptors, and the antigen receptors on T cells are called T cell receptors.

**antigen-presenting cell** A cell that upon ingesting pathogens or internalizing pathogen proteins generates peptide fragments that are bound by class II MHC molecules and subsequently displayed on the cell surface to T cells. Macrophages, dendritic cells, and B cells are the primary antigen-presenting cells.

**antiparallel** Referring to the arrangement of the sugar-phosphate backbones in a DNA double helix (they run in opposite 5' → 3' directions).

**aphotic zone** (ā'-fō'-tik) The part of an ocean or lake beneath the photic zone, where light does not penetrate sufficiently for photosynthesis to occur.

**apical bud** (ā'-pik-ul) A bud at the tip of a plant stem; also called a terminal bud.

**apical dominance** (ă'-pik-ul) Tendency for growth to be concentrated at the tip of a plant shoot, because the apical bud partially inhibits axillary bud growth.

**apical meristem** (ă'-pik-ul mār'-uh-stem) Embryonic plant tissue in the tips of roots and buds of shoots. The dividing cells of an apical meristem enable the plant to grow in length.

**apicomplexan** (ap'-ē-kom-pleks'-un) A protist in a clade that includes many species that parasitize animals. Some apicomplexans cause human disease.

**apomixis** (ap'-uh-mik'-sis) The ability of some plant species to reproduce asexually through seeds without fertilization by a male gamete.

**apoplast** (ap'-ō-plast) Everything external to the plasma membrane of a plant cell, including cell walls, intercellular spaces, and the space within dead structures such as xylem vessels and tracheids.

**apoptosis** (ā-puh-tō'-sus) A type of programmed cell death that is brought about by activation of enzymes that break down many chemical components in the cell.

**aposematic coloration** (ap'-ō-si-mat'-ik) The bright warning coloration of many animals with effective physical or chemical defenses.

**appendix** A small, finger-like extension of the vertebrate cecum; contains a mass of white blood cells that contribute to immunity.

**aquaporin** A channel protein in the plasma membrane of a plant, animal, or microorganism cell that specifically facilitates osmosis, the diffusion of free water across the membrane.

**aqueous solution** (ă'-kwē-us) A solution in which water is the solvent.

**arbuscular mycorrhizae** (ar-bus'-kyū-lur mī'-kō-rī'-zē) Associations of a fungus with a plant root system in which the fungus causes the invagination of the host (plant) cells' plasma membranes.

**arbuscular mycorrhizal fungus** A symbiotic fungus whose hyphae grow through the cell wall of plant roots and extend into the root cell (enclosed in tubes formed by invagination of the root cell plasma membrane).

**Archaea** (ar'-kē'-uh) One of two prokaryotic domains, the other being Bacteria.

**Archaeplastida** (ar'-kē-plas'-tid-uh) One of four supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. This monophyletic group, which includes red algae, green algae, and land plants, descended from an ancient protist ancestor that engulfed a cyanobacterium. *See also* Excavata, "SAR" clade, and Unikonta.

**artery** A vessel that carries blood away from the heart to organs throughout the body.

**arthropod** A segmented, molting bilaterian animal with a hard exoskeleton and jointed

appendages. Familiar examples include insects, spiders, millipedes, and crabs.

**artificial selection** The selective breeding of domesticated plants and animals to encourage the occurrence of desirable traits.

**asexual reproduction** The generation of offspring from a single parent that occurs without the fusion of gametes (by budding, division of a single cell, or division of the entire organism into two or more parts). In most cases, the offspring are genetically identical to the parent.

**associative learning** The acquired ability to associate one environmental feature (such as a color) with another (such as danger).

**aster** A radial array of short microtubules that extends from each centrosome toward the plasma membrane in an animal cell undergoing mitosis.

**astrocyte** A glial cell with diverse functions, including providing structural support for neurons, regulating the interstitial environment, facilitating synaptic transmission, and assisting in regulating the blood supply to the brain.

**atherosclerosis** A cardiovascular disease in which fatty deposits called plaques develop in the inner walls of the arteries, obstructing the arteries and causing them to harden.

**atom** The smallest unit of matter that retains the properties of an element.

**atomic mass** The total mass of an atom, which is the mass in grams of 1 mole of the atom.

**atomic nucleus** An atom's dense central core, containing protons and neutrons.

**atomic number** The number of protons in the nucleus of an atom, unique for each element and designated by a subscript.

**ATP (adenosine triphosphate)** (a-den'-ō-sēn trī-fos'-fāt) An adenine-containing nucleoside triphosphate that releases free energy when its phosphate bonds are hydrolyzed. This energy is used to drive endergonic reactions in cells.

**ATP synthase** A complex of several membrane proteins that functions in chemiosmosis with adjacent electron transport chains, using the energy of a hydrogen ion (proton) concentration gradient to make ATP. ATP synthases are found in the inner mitochondrial membranes of eukaryotic cells and in the plasma membranes of prokaryotes.

**atrioventricular (AV) node** A region of specialized heart muscle tissue between the left and right atria where electrical impulses are delayed for about 0.1 second before spreading to both ventricles and causing them to contract.

**atrioventricular (AV) valve** A heart valve located between each atrium and ventricle that prevents a backflow of blood when the ventricle contracts.

**atrium** (ă'-trē-um) (plural, **atria**) A chamber of the vertebrate heart that receives blood

from the veins and transfers blood to a ventricle.

**autoimmune disease** An immunological disorder in which the immune system turns against self.

**autonomic nervous system** (ot'-ō-nom'-ik) An efferent branch of the vertebrate peripheral nervous system that regulates the internal environment; consists of the sympathetic, parasympathetic, and enteric divisions.

**autopolyploid** (ot'-ō-pol'-ē-ploid) An individual that has more than two chromosome sets that are all derived from a single species.

**autosome** (ot'-ō-sōm) A chromosome that is not directly involved in determining sex; not a sex chromosome.

**autotroph** (ot'-ō-trōf) An organism that obtains organic food molecules without eating other organisms or substances derived from other organisms. Autotrophs use energy from the sun or from oxidation of inorganic substances to make organic molecules from inorganic ones.

**auxin** (ōk'-sin) A term that primarily refers to indoleacetic acid (IAA), a natural plant hormone that has a variety of effects, including cell elongation, root formation, secondary growth, and fruit growth.

**avirulent** Describing a pathogen that can mildly harm, but not kill, the host.

**axillary bud** (ak'-sil-ār-ē) A structure that has the potential to form a lateral shoot, or branch. The bud appears in the angle formed between a leaf and a stem.

**axon** (ak'-son) A typically long extension, or process, of a neuron that carries nerve impulses away from the cell body toward target cells.

**B cells** The lymphocytes that complete their development in the bone marrow and become effector cells for the humoral immune response.

**Bacteria** One of two prokaryotic domains, the other being Archaea.

**bacteriophage** (bak-tēr'-ē-ō-fāj) A virus that infects bacteria; also called a phage.

**bacteroid** A form of the bacterium *Rhizobium* contained within the vesicles formed by the root cells of a root nodule.

**balancing selection** Natural selection that maintains two or more phenotypic forms in a population.

**bar graph** A graph in which the independent variable represents groups or nonnumerical categories. Each piece of data is represented by a bar, whose height (or length) represents the value of the independent variable for the group or category indicated.

**bark** All tissues external to the vascular cambium, consisting mainly of the secondary phloem and layers of periderm.

**Barr body** A dense object lying along the inside of the nuclear envelope in cells of

female mammals, representing a highly condensed, inactivated X chromosome.

**basal body** (bă'-sul) A eukaryotic cell structure consisting of a "9 + 0" arrangement of microtubule triplets. The basal body may organize the microtubule assembly of a cilium or flagellum and is structurally very similar to a centriole.

**basal taxon** In a specified group of organisms, a taxon whose evolutionary lineage diverged early in the history of the group.

**base** A substance that reduces the hydrogen ion concentration of a solution.

**Batesian mimicry** (băt'-zē-un mim'-uh-krē) A type of mimicry in which a harmless species looks like a species that is poisonous or otherwise harmful to predators.

**behavior** Individually, an action carried out by muscles or glands under control of the nervous system in response to a stimulus; collectively, the sum of an animal's responses to external and internal stimuli.

**behavioral ecology** The study of the evolution of and ecological basis for animal behavior.

**benign tumor** A mass of abnormal cells with specific genetic and cellular changes such that the cells are not capable of surviving at a new site and generally remain at the site of the tumor's origin.

**benthic zone** The bottom surface of an aquatic environment.

**benthos** (ben'-thōz) The communities of organisms living in the benthic zone of an aquatic biome.

**beta (β) pleated sheet** One form of the secondary structure of proteins in which the polypeptide chain folds back and forth. Two regions of the chain lie parallel to each other and are held together by hydrogen bonds between atoms of the polypeptide backbone (not the side chains).

**beta oxidation** A metabolic sequence that breaks fatty acids down to two-carbon fragments that enter the citric acid cycle as acetyl CoA.

**bicoid** A maternal effect gene that codes for a protein responsible for specifying the anterior end in *Drosophila melanogaster*.

**bilateral symmetry** Body symmetry in which a central longitudinal plane divides the body into two equal but opposite halves.

**bilaterian** (bi'-luh-ter'-ē-uhn) Member of a clade of animals with bilateral symmetry and three germ layers.

**bile** A mixture of substances that is produced in the liver and stored in the gallbladder; enables formation of fat droplets in water as an aid in the digestion and absorption of fats.

**binary fission** A method of asexual reproduction by "division in half." In prokaryotes, binary fission does not involve mitosis, but in single-celled eukaryotes that undergo binary fission, mitosis is part of the process.

**binomial** A common term for the two-part, latinized format for naming a species, consisting of the genus and specific epithet; also called a binomen.

**biodiversity hot spot** A relatively small area with numerous endemic species and a large number of endangered and threatened species.

**bioenergetics** (1) The overall flow and transformation of energy in an organism. (2) The study of how energy flows through organisms.

**biofilm** A surface-coating colony of one or more species of prokaryotes that engage in metabolic cooperation.

**biofuel** A fuel produced from biomass.

**biogenic amine** A neurotransmitter derived from an amino acid.

**biogeochemical cycle** Any of the various chemical cycles that involve both biotic and abiotic components of ecosystems.

**biogeography** The scientific study of the past and present geographic distributions of species.

**bioinformatics** The use of computers, software, and mathematical models to process and integrate biological information from large data sets.

**biological augmentation** An approach to restoration ecology that uses organisms to add essential materials to a degraded ecosystem.

**biological clock** An internal timekeeper that controls an organism's biological rhythms. The biological clock marks time with or without environmental cues but often requires signals from the environment to remain tuned to an appropriate period. *See also* circadian rhythm.

**biological magnification** A process in which retained substances become more concentrated at each higher trophic level in a food chain.

**biological species concept** Definition of a species as a group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but do not produce viable, fertile offspring with members of other such groups.

**biology** The scientific study of life.

**biomanipulation** An approach that applies the top-down model of community organization to alter ecosystem characteristics. For example, ecologists can prevent algal blooms and eutrophication by altering the density of higher-level consumers in lakes instead of by using chemical treatments.

**biomass** The total mass of organic matter comprising a group of organisms in a particular habitat.

**biome** (bi'-ōm) Any of the world's major ecosystem types, often classified according to the predominant vegetation for terrestrial biomes and the physical environment for aquatic biomes and characterized by

adaptations of organisms to that particular environment.

**bioremediation** The use of organisms to detoxify and restore polluted and degraded ecosystems.

**biosphere** The entire portion of Earth inhabited by life; the sum of all the planet's ecosystems.

**biotic** (bi-ot'-ik) Pertaining to the living factors—the organisms—in an environment.

**blade** (1) A leaflike structure of a seaweed that provides most of the surface area for photosynthesis. (2) The flattened portion of a typical leaf.

**blastocoel** (blas'-tuh-sēl) The fluid-filled cavity that forms in the center of a blastula.

**blastula** (blas'-tyū-luh) A hollow ball of cells that marks the end of the cleavage stage during early embryonic development in animals.

**blood** A connective tissue with a fluid matrix called plasma in which red blood cells, white blood cells, and cell fragments called platelets are suspended.

**blue-light photoreceptor** A type of light receptor in plants that initiates a variety of responses, including phototropism and slowing of hypocotyl elongation.

**body plan** In multicellular eukaryotes, a set of morphological and developmental traits that are integrated into a functional whole—the living organism.

**Bohr shift** A lowering of the affinity of hemoglobin for oxygen, caused by a drop in pH. It facilitates the release of oxygen from hemoglobin in the vicinity of active tissues.

**bolus** A lubricated ball of chewed food.

**bottleneck effect** Genetic drift that occurs when the size of a population is reduced, as by a natural disaster or human actions. Typically, the surviving population is no longer genetically representative of the original population.

**bottom-up model** A model of community organization in which mineral nutrients influence community organization by controlling plant or phytoplankton numbers, which in turn control herbivore numbers, which in turn control predator numbers.

**Bowman's capsule** (bō'-munz) A cup-shaped receptacle in the vertebrate kidney that is the initial, expanded segment of the nephron where filtrate enters from the blood.

**brain** Organ of the central nervous system where information is processed and integrated.

**brainstem** A collection of structures in the vertebrate brain, including the midbrain, the pons, and the medulla oblongata; functions in homeostasis, coordination of movement, and conduction of information to higher brain centers.

**branch point** The representation on a phylogenetic tree of the divergence of two

- or more taxa from a common ancestor. A branch point is usually shown as a dichotomy in which a branch representing the ancestral lineage splits (at the branch point) into two branches, one for each of the two descendant lineages.
- brassinosteroid** A steroid hormone in plants that has a variety of effects, including inducing cell elongation, retarding leaf abscission, and promoting xylem differentiation.
- breathing** Ventilation of the lungs through alternating inhalation and exhalation.
- bronchus** (brong'-kus) (plural, **bronchi**) One of a pair of breathing tubes that branch from the trachea into the lungs.
- brown alga** A multicellular, photosynthetic protist with a characteristic brown or olive color that results from carotenoids in its plastids. Most brown algae are marine, and some have a plantlike body.
- bryophyte** (bri'-uh-fit) An informal name for a moss, liverwort, or hornwort; a nonvascular plant that lives on land but lacks some of the terrestrial adaptations of vascular plants.
- buffer** A solution that contains a weak acid and its corresponding base. A buffer minimizes changes in pH when acids or bases are added to the solution.
- bulk feeder** An animal that eats relatively large pieces of food.
- bulk flow** The movement of a fluid due to a difference in pressure between two locations.
- C<sub>3</sub> plant** A plant that uses the Calvin cycle for the initial steps that incorporate CO<sub>2</sub> into organic material, forming a three-carbon compound as the first stable intermediate.
- C<sub>4</sub> plant** A plant in which the Calvin cycle is preceded by reactions that incorporate CO<sub>2</sub> into a four-carbon compound, the end product of which supplies CO<sub>2</sub> for the Calvin cycle.
- callus** A mass of dividing, undifferentiated cells growing in culture.
- calorie (cal)** The amount of heat energy required to raise the temperature of 1 g of water by 1°C; also the amount of heat energy that 1 g of water releases when it cools by 1°C. The Calorie (with a capital C), usually used to indicate the energy content of food, is a kilocalorie.
- Calvin cycle** The second of two major stages in photosynthesis (following the light reactions), involving fixation of atmospheric CO<sub>2</sub> and reduction of the fixed carbon into carbohydrate.
- CAM plant** A plant that uses crassulacean acid metabolism, an adaptation for photosynthesis in arid conditions. In this process, carbon dioxide entering open stomata during the night is converted to organic acids, which release CO<sub>2</sub> for the Calvin cycle during the day, when stomata are closed.
- Cambrian explosion** A relatively brief time in geologic history when many present-day phyla of animals first appeared in the fossil record. This burst of evolutionary change occurred about 535–525 million years ago and saw the emergence of the first large, hard-bodied animals.
- canopy** The uppermost layer of vegetation in a terrestrial biome.
- capillary** (kap'-il-âr'-ê) A microscopic blood vessel that penetrates the tissues and consists of a single layer of endothelial cells that allows exchange between the blood and interstitial fluid.
- capillary bed** A network of capillaries in a tissue or organ.
- capsid** The protein shell that encloses a viral genome. It may be rod-shaped, polyhedral, or more complex in shape.
- capsule** (1) In many prokaryotes, a dense and well-defined layer of polysaccharide or protein that surrounds the cell wall and is sticky, protecting the cell and enabling it to adhere to substrates or other cells. (2) The sporangium of a bryophyte (moss, liverwort, or hornwort).
- carbohydrate** (kar'-bô-hi'-drât) A sugar (monosaccharide) or one of its dimers (disaccharides) or polymers (polysaccharides).
- carbon fixation** The initial incorporation of carbon from CO<sub>2</sub> into an organic compound by an autotrophic organism (a plant, another photosynthetic organism, or a chemoautotrophic prokaryote).
- carbonyl group** (kar-buh-nêl') A chemical group present in aldehydes and ketones and consisting of a carbon atom double-bonded to an oxygen atom.
- carboxyl group** (kar-bok'-sil) A chemical group present in organic acids and consisting of a single carbon atom double-bonded to an oxygen atom and also bonded to a hydroxyl group.
- cardiac cycle** (kar'-dê-ak) The alternating contractions and relaxations of the heart.
- cardiac muscle** A type of striated muscle that forms the contractile wall of the heart. Its cells are joined by intercalated disks that relay the electrical signals underlying each heartbeat.
- cardiovascular system** A closed circulatory system with a heart and branching network of arteries, capillaries, and veins. The system is characteristic of vertebrates.
- carnivore** An animal that mainly eats other animals.
- carotenoid** (kuh-rot'-uh-noyd') An accessory pigment, either yellow or orange, in the chloroplasts of plants and in some prokaryotes. By absorbing wavelengths of light that chlorophyll cannot, carotenoids broaden the spectrum of colors that can drive photosynthesis.
- carpel** (kar'-pul) The ovule-producing reproductive organ of a flower, consisting of the stigma, style, and ovary.
- carrier** In genetics, an individual who is heterozygous at a given genetic locus for a recessively inherited disorder. The heterozygote is generally phenotypically normal for the disorder but can pass on the recessive allele to offspring.
- carrying capacity** The maximum population size that can be supported by the available resources, symbolized as *K*.
- Casparian strip** (ka-spâr'-ê-un) A water-impermeable ring of wax in the endodermal cells of plants that blocks the passive flow of water and solutes into the stele by way of cell walls.
- catabolic pathway** (kat'-uh-bol'-ik) A metabolic pathway that releases energy by breaking down complex molecules to simpler molecules.
- catalyst** (kat'-uh-list) A chemical agent that selectively increases the rate of a reaction without being consumed by the reaction.
- cation** (cat'-i'-on) A positively charged ion.
- cation exchange** A process in which positively charged minerals are made available to a plant when hydrogen ions in the soil displace mineral ions from the clay particles.
- cecum** (sê'-kum) (plural, **ceca**) The blind pouch forming one branch of the large intestine.
- cell body** The part of a neuron that houses the nucleus and most other organelles.
- cell cycle** An ordered sequence of events in the life of a cell, from its origin in the division of a parent cell until its own division into two. The eukaryotic cell cycle is composed of interphase (including G<sub>1</sub>, S, and G<sub>2</sub> subphases) and M phase (including mitosis and cytokinesis).
- cell cycle control system** A cyclically operating set of molecules in the eukaryotic cell that both triggers and coordinates key events in the cell cycle.
- cell division** The reproduction of cells.
- cell fractionation** The disruption of a cell and separation of its parts by centrifugation at successively higher speeds.
- cell plate** A membrane-bounded, flattened sac located at the midline of a dividing plant cell, inside which the new cell wall forms during cytokinesis.
- cell wall** A protective layer external to the plasma membrane in the cells of plants, prokaryotes, fungi, and some protists. Polysaccharides such as cellulose (in plants and some protists), chitin (in fungi), and peptidoglycan (in bacteria) are important structural components of cell walls.
- cell-mediated immune response** The branch of adaptive immunity that involves the activation of cytotoxic T cells, which defend against infected cells.
- cellular respiration** The catabolic pathways of aerobic and anaerobic respiration, which break down organic molecules and use an electron transport chain for the production of ATP.

**cellulose** (sel'-yū-lōs) A structural polysaccharide of plant cell walls, consisting of glucose monomers joined by  $\beta$  glycosidic linkages.

**central nervous system (CNS)** The portion of the nervous system where signal integration occurs; in vertebrate animals, the brain and spinal cord.

**central vacuole** In a mature plant cell, a large membranous sac with diverse roles in growth, storage, and sequestration of toxic substances.

**centriole** (sen'-trē-ōl) A structure in the centrosome of an animal cell composed of a cylinder of microtubule triplets arranged in a  $9 + 0$  pattern. A centrosome has a pair of centrioles.

**centromere** (sen'-trō-mēr) In a duplicated chromosome, the region on each sister chromatid where they are most closely attached to each other by proteins that bind to specific DNA sequences; this close attachment causes a constriction in the condensed chromosome. (An uncondensed, unduplicated chromosome has a single centromere, identified by its DNA sequence.)

**centrosome** (sen'-trō-sōm) A structure present in the cytoplasm of animal cells that functions as a microtubule-organizing center and is important during cell division. A centrosome has two centrioles.

**cerczoan** An amoeboid or flagellated protist that feeds with threadlike pseudopodia.

**cerebellum** (sār'-ruh-bel'-um) Part of the vertebrate hindbrain located dorsally; functions in unconscious coordination of movement and balance.

**cerebral cortex** (suh-rē'-brul) The surface of the cerebrum; the largest and most complex part of the mammalian brain, containing nerve cell bodies of the cerebrum; the part of the vertebrate brain most changed through evolution.

**cerebral hemisphere** The right or left side of the cerebrum.

**cerebrum** (suh-rē'-brum) The dorsal portion of the vertebrate forebrain, composed of right and left hemispheres; the integrating center for memory, learning, emotions, and other highly complex functions of the central nervous system.

**cervix** (ser'-viks) The neck of the uterus, which opens into the vagina.

**chaparral** A scrubland biome of dense, spiny evergreen shrubs found at midlatitudes along coasts where cold ocean currents circulate offshore; characterized by mild, rainy winters and long, hot, dry summers.

**character** An observable heritable feature that may vary among individuals.

**character displacement** The tendency for characteristics to be more divergent in sympatric populations of two species than in allopatric populations of the same two species.

**checkpoint** A control point in the cell cycle where stop and go-ahead signals can regulate the cycle.

**chemical bond** An attraction between two atoms, resulting from a sharing of outer-shell electrons or the presence of opposite charges on the atoms. The bonded atoms gain complete outer electron shells.

**chemical energy** Energy available in molecules for release in a chemical reaction; a form of potential energy.

**chemical equilibrium** In a chemical reaction, the state in which the rate of the forward reaction equals the rate of the reverse reaction, so that the relative concentrations of the reactants and products do not change with time.

**chemical reaction** The making and breaking of chemical bonds, leading to changes in the composition of matter.

**chemiosmosis** (kem'-ē-oz-mō'-sis) An energy-coupling mechanism that uses energy stored in the form of a hydrogen ion gradient across a membrane to drive cellular work, such as the synthesis of ATP. Under aerobic conditions, most ATP synthesis in cells occurs by chemiosmosis.

**chemoreceptor** A sensory receptor that responds to a chemical stimulus, such as a solute or an odorant.

**chiasma** (plural, **chiasmata**) (kī-az'-muh, kī-az'-muh-tuh) The X-shaped, microscopically visible region where crossing over has occurred earlier in prophase I between homologous nonsister chromatids. Chiasmata become visible after synapsis ends, with the two homologs remaining associated due to sister chromatid cohesion.

**chitin** (kī'-tin) A structural polysaccharide, consisting of amino sugar monomers, found in many fungal cell walls and in the exoskeletons of all arthropods.

**chlorophyll** (klōr'-ō-fil) A green pigment located in membranes within the chloroplasts of plants and algae and in the membranes of certain prokaryotes. Chlorophyll *a* participates directly in the light reactions, which convert solar energy to chemical energy.

**chlorophyll *a*** A photosynthetic pigment that participates directly in the light reactions, which convert solar energy to chemical energy.

**chlorophyll *b*** An accessory photosynthetic pigment that transfers energy to chlorophyll *a*.

**chloroplast** (klōr'-ō-plast) An organelle found in plants and photosynthetic protists that absorbs sunlight and uses it to drive the synthesis of organic compounds from carbon dioxide and water.

**choanocyte** (kō-an'-uh-sīt) A flagellated feeding cell found in sponges. Also called a collar cell, it has a collar-like ring that traps food particles around the base of its flagellum.

**cholesterol** (kō-les'-tuh-rol) A steroid that forms an essential component of animal cell membranes and acts as a precursor molecule for the synthesis of other biologically important steroids, such as many hormones.

**chondrichthyan** (kon-drik'-thē-an) Member of the class Chondrichthyes, vertebrates with skeletons made mostly of cartilage, such as sharks and rays.

**chordate** Member of the phylum Chordata, animals that at some point during their development have a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.

**chromatin** (krō'-muh-tin) The complex of DNA and proteins that makes up eukaryotic chromosomes. When the cell is not dividing, chromatin exists in its dispersed form, as a mass of very long, thin fibers that are not visible with a light microscope.

**chromosome** (krō'-muh-sōm) A cellular structure consisting of one DNA molecule and associated protein molecules. (In some contexts, such as genome sequencing, the term may refer to the DNA alone.) A eukaryotic cell typically has multiple, linear chromosomes, which are located in the nucleus. A prokaryotic cell often has a single, circular chromosome, which is found in the nucleoid, a region that is not enclosed by a membrane. *See also* chromatin.

**chromosome theory of inheritance** A basic principle in biology stating that genes are located at specific positions (loci) on chromosomes and that the behavior of chromosomes during meiosis accounts for inheritance patterns.

**chylomicron** (kī'-lō-mī'-kron) A lipid transport globule composed of fats mixed with cholesterol and coated with proteins.

**chyme** (kim) The mixture of partially digested food and digestive juices formed in the stomach.

**ciliate** (sil'-ē-it) A type of protist that moves by means of cilia.

**cilium** (sil'-ē-um) (plural, **cilia**) A short appendage containing microtubules in eukaryotic cells. A motile cilium is specialized for locomotion or moving fluid past the cell; it is formed from a core of nine outer doublet microtubules and two inner single microtubules (the " $9 + 2$ " arrangement) ensheathed in an extension of the plasma membrane. A primary cilium is usually nonmotile and plays a sensory and signaling role; it lacks the two inner microtubules (the " $9 + 0$ " arrangement).

**circadian rhythm** (ser-kā'-dē-un) A physiological cycle of about 24 hours that persists even in the absence of external cues.

**citric acid cycle** A chemical cycle involving eight steps that completes the metabolic breakdown of glucose molecules begun in glycolysis by oxidizing acetyl CoA (derived from pyruvate) to carbon dioxide; occurs

- within the mitochondrion in eukaryotic cells and in the cytosol of prokaryotes; together with pyruvate oxidation, the second major stage in cellular respiration.
- clade** (klayd) A group of species that includes an ancestral species and all of its descendants.
- cladistics** (kluh-dis'-tiks) An approach to systematics in which organisms are placed into groups called clades based primarily on common descent.
- class** In Linnaean classification, the taxonomic category above the level of order.
- cleavage** (1) The process of cytokinesis in animal cells, characterized by pinching of the plasma membrane. (2) The succession of rapid cell divisions without significant growth during early embryonic development that converts the zygote to a ball of cells.
- cleavage furrow** The first sign of cleavage in an animal cell; a shallow groove around the cell in the cell surface near the old metaphase plate.
- climate** The long-term prevailing weather conditions at a given place.
- climograph** A plot of the temperature and precipitation in a particular region.
- clitoris** (klit'-uh-ris) An organ at the upper intersection of the labia minora that engorges with blood and becomes erect during sexual arousal.
- cloaca** (klō-ā'-kuh) A common opening for the digestive, urinary, and reproductive tracts found in many nonmammalian vertebrates but in few mammals.
- clonal selection** The process by which an antigen selectively binds to and activates only those lymphocytes bearing receptors specific for the antigen. The selected lymphocytes proliferate and differentiate into a clone of effector cells and a clone of memory cells specific for the stimulating antigen.
- clone** (1) A lineage of genetically identical individuals or cells. (2) In popular usage, an individual that is genetically identical to another individual. (3) As a verb, to make one or more genetic replicas of an individual or cell. *See also* gene cloning.
- cloning vector** In genetic engineering, a DNA molecule that can carry foreign DNA into a host cell and replicate there. Cloning vectors include plasmids.
- closed circulatory system** A circulatory system in which blood is confined to vessels and is kept separate from the interstitial fluid.
- cochlea** (kok'-lē-uh) The complex, coiled organ of hearing that contains the organ of Corti.
- codominance** The situation in which the phenotypes of both alleles are exhibited in the heterozygote because both alleles affect the phenotype in separate, distinguishable ways.
- codon** (kō'-don) A three-nucleotide sequence of DNA or mRNA that specifies a particular amino acid or termination signal; the basic unit of the genetic code.
- coefficient of relatedness** The fraction of genes that, on average, are shared by two individuals.
- coenzyme** (kō-en'-zim) An organic molecule serving as a cofactor. Most vitamins function as coenzymes in metabolic reactions.
- cofactor** Any nonprotein molecule or ion that is required for the proper functioning of an enzyme. Cofactors can be permanently bound to the active site or may bind loosely and reversibly, along with the substrate, during catalysis.
- cognition** The process of knowing that may include awareness, reasoning, recollection, and judgment.
- cognitive map** A neural representation of the abstract spatial relationships between objects in an animal's surroundings.
- cohesion** The linking together of like molecules, often by hydrogen bonds.
- cohesion-tension hypothesis** The leading explanation for the ascent of xylem sap. It states that transpiration exerts pull on xylem sap, putting the sap under negative pressure or tension, and that the cohesion of water molecules transmits this pull along the entire length of the xylem from shoots to roots.
- cohort** A group of individuals of the same age in a population.
- coleoptile** (kō'-lē-op'-tul) The covering of the young shoot of the embryo of a grass seed.
- coleorhiza** (kō'-lē-uh-rī'-zuh) The covering of the young root of the embryo of a grass seed.
- collagen** A glycoprotein in the extracellular matrix of animal cells that forms strong fibers, found extensively in connective tissue and bone; the most abundant protein in the animal kingdom.
- collecting duct** The location in the kidney where processed filtrate, called urine, is collected from the renal tubules.
- collenchyma cell** (kō-len'-kim-uh) A flexible plant cell type that occurs in strands or cylinders that support young parts of the plant without restraining growth.
- colon** (kō'-len) The largest section of the vertebrate large intestine; functions in water absorption and formation of feces.
- commensalism** (kuh-men'-suh-lizm) A symbiotic relationship in which one organism benefits but the other is neither helped nor harmed.
- communication** In animal behavior, a process involving transmission of, reception of, and response to signals. The term is also used in connection with other organisms, as well as individual cells of multicellular organisms.
- community** All the organisms that inhabit a particular area; an assemblage of populations of different species living close enough together for potential interaction.
- community ecology** The study of how interactions between species affect community structure and organization.
- companion cell** A type of plant cell that is connected to a sieve-tube element by many plasmodesmata and whose nucleus and ribosomes may serve one or more adjacent sieve-tube elements.
- competitive exclusion** The concept that when populations of two similar species compete for the same limited resources, one population will use the resources more efficiently and have a reproductive advantage that will eventually lead to the elimination of the other population.
- competitive inhibitor** A substance that reduces the activity of an enzyme by entering the active site in place of the substrate, whose structure it mimics.
- complement system** A group of about 30 blood proteins that may amplify the inflammatory response, enhance phagocytosis, or directly lyse extracellular pathogens.
- complementary DNA (cDNA)** A double-stranded DNA molecule made *in vitro* using mRNA as a template and the enzymes reverse transcriptase and DNA polymerase. A cDNA molecule corresponds to the exons of a gene.
- complete dominance** The situation in which the phenotypes of the heterozygote and dominant homozygote are indistinguishable.
- complete flower** A flower that has all four basic floral organs: sepals, petals, stamens, and carpels.
- compound** A substance consisting of two or more different elements combined in a fixed ratio.
- compound eye** A type of multifaceted eye in insects and crustaceans consisting of up to several thousand light-detecting, focusing ommatidia.
- concentration gradient** A region along which the density of a chemical substance increases or decreases.
- conception** The fertilization of an egg by a sperm in humans.
- cone** A cone-shaped cell in the retina of the vertebrate eye, sensitive to color.
- conformer** An animal for which an internal condition conforms to (changes in accordance with) changes in an environmental variable.
- conifer** Member of the largest gymnosperm phylum. Most conifers are cone-bearing trees, such as pines and firs.
- conjugation** (kon'-jū-gā'-shun) (1) In prokaryotes, the direct transfer of DNA between two cells that are temporarily joined. When the two cells are members of different species, conjugation results in horizontal

- gene transfer. (2) In ciliates, a sexual process in which two cells exchange haploid micro-nuclei but do not reproduce.
- connective tissue** Animal tissue that functions mainly to bind and support other tissues, having a sparse population of cells scattered through an extracellular matrix.
- conservation biology** The integrated study of ecology, evolutionary biology, physiology, molecular biology, and genetics to sustain biological diversity at all levels.
- contraception** The deliberate prevention of pregnancy.
- contractile vacuole** A membranous sac that helps move excess water out of certain freshwater protists.
- control element** A segment of noncoding DNA that helps regulate transcription of a gene by serving as a binding site for a transcription factor. Multiple control elements are present in a eukaryotic gene's enhancer.
- control group** In a controlled experiment, a set of subjects that lacks (or does not receive) the specific factor being tested. Ideally, the control group should be identical to the experimental group in other respects.
- controlled experiment** An experiment in which an experimental group is compared with a control group that varies only in the factor being tested.
- convergent evolution** The evolution of similar features in independent evolutionary lineages.
- cooperativity** A kind of allosteric regulation whereby a shape change in one subunit of a protein caused by substrate binding is transmitted to all the other subunits, facilitating binding of additional substrate molecules to those subunits.
- coral reef** Typically a warm-water, tropical ecosystem dominated by the hard skeletal structures secreted primarily by corals. Some coral reefs also exist in cold, deep waters.
- corepressor** A small molecule that binds to a bacterial repressor protein and changes the protein's shape, allowing it to bind to the operator and switch an operon off.
- cork cambium** (kam'-bē-um) A cylinder of meristematic tissue in woody plants that replaces the epidermis with thicker, tougher cork cells.
- corpus callosum** (kor'-pus kuh-lō'-sum) The thick band of nerve fibers that connects the right and left cerebral hemispheres in mammals, enabling the hemispheres to process information together.
- corpus luteum** (kor'-pus lū'-tē-um) A secreting tissue in the ovary that forms from the collapsed follicle after ovulation and produces progesterone.
- cortex** (1) The outer region of cytoplasm in a eukaryotic cell, lying just under the plasma membrane, that has a more gel-like consistency than the inner regions due to the presence of multiple microfilaments. (2) In plants, ground tissue that is between the vascular tissue and dermal tissue in a root or eudicot stem.
- cortical nephron** In mammals and birds, a nephron with a loop of Henle located almost entirely in the renal cortex.
- cotransport** The coupling of the "downhill" diffusion of one substance to the "uphill" transport of another against its own concentration gradient.
- countercurrent exchange** The exchange of a substance or heat between two fluids flowing in opposite directions. For example, blood in a fish gill flows in the opposite direction of water passing over the gill, maximizing diffusion of oxygen into and carbon dioxide out of the blood.
- countercurrent multiplier system** A countercurrent system in which energy is expended in active transport to facilitate exchange of materials and generate concentration gradients.
- covalent bond** (kō-vā'-lent) A type of strong chemical bond in which two atoms share one or more pairs of valence electrons.
- crassulacean acid metabolism (CAM)** An adaptation for photosynthesis in arid conditions, first discovered in the family Crassulaceae. In this process, a plant takes up CO<sub>2</sub> at night when stomata are open and incorporates it into a variety of organic acids; during the day, when stomata are closed, CO<sub>2</sub> is released from the organic acids for use in the Calvin cycle.
- crista** (plural, **cristae**) (kris'-tuh, kris'-tē) An infolding of the inner membrane of a mitochondrion. The inner membrane houses electron transport chains and molecules of the enzyme catalyzing the synthesis of ATP (ATP synthase).
- critical load** The amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity.
- cross-fostering study** A behavioral study in which the young of one species are placed in the care of adults from another species.
- crossing over** The reciprocal exchange of genetic material between nonsister chromatids during prophase I of meiosis.
- cryptic coloration** Camouflage that makes a potential prey difficult to spot against its background.
- culture** A system of information transfer through social learning or teaching that influences the behavior of individuals in a population.
- cuticle** (kyū'-tuh-kul) (1) A waxy covering on the surface of stems and leaves that prevents desiccation in terrestrial plants. (2) The exoskeleton of an arthropod, consisting of layers of protein and chitin that are variously modified for different functions. (3) A tough coat that covers the body of a nematode.
- cyclic AMP (cAMP)** Cyclic adenosine monophosphate, a ring-shaped molecule made from ATP that is a common intracellular signaling molecule (second messenger) in eukaryotic cells. It is also a regulator of some bacterial operons.
- cystic fibrosis** (sis'-tik fi-brō'-sis) A human genetic disorder caused by a recessive allele for a chloride channel protein; characterized by an excessive secretion of mucus and consequent vulnerability to infection; fatal if untreated.
- cytochrome** (si'-tō-krōm) An iron-containing protein that is a component of electron transport chains in the mitochondria and chloroplasts of eukaryotic cells and the plasma membranes of prokaryotic cells.
- cytogenetic map** A map of a chromosome that locates genes with respect to chromosomal features distinguishable in a microscope.
- cytokine** (si'-tō-kin') Any of a group of small proteins secreted by a number of cell types, including macrophages and helper T cells, that regulate the function of other cells.
- cytokinesis** (si'-tō-kuh-nē'-sis) The division of the cytoplasm to form two separate daughter cells immediately after mitosis, meiosis I, or meiosis II.
- cytokinin** (si'-tō-ki'-nin) Any of a class of related plant hormones that retard aging and act in concert with auxin to stimulate cell division, influence the pathway of differentiation, and control apical dominance.
- cytoplasm** (si'-tō-plaz'-um) The contents of the cell enclosed by the plasma membrane; in eukaryotes, the portion exclusive of the nucleus.
- cytoplasmic determinant** A maternal substance, such as a protein or RNA, that when placed into an egg influences the course of early development by regulating the expression of genes that affect the developmental fate of cells.
- cytoskeleton** A network of microtubules, microfilaments, and intermediate filaments that extends throughout the cytoplasm and serves a variety of mechanical, transport, and signaling functions.
- cytosol** (si'-tō-sol) The semifluid portion of the cytoplasm.
- cytotoxic T cell** A type of lymphocyte that, when activated, kills infected cells as well as certain cancer cells and transplanted cells.
- dalton** A measure of mass for atoms and subatomic particles; the same as the atomic mass unit, or amu.
- data** Recorded observations.
- day-neutral plant** A plant in which flower formation is not controlled by photoperiod or day length.
- decomposer** An organism that absorbs nutrients from nonliving organic material such as corpses, fallen plant material, and the wastes

- of living organisms and converts them to inorganic forms; a detritivore.
- deductive reasoning** A type of logic in which specific results are predicted from a general premise.
- deep-sea hydrothermal vent** A dark, hot, oxygen-deficient environment associated with volcanic activity on or near the seafloor. The producers in a vent community are chemoautotrophic prokaryotes.
- de-etiolation** The changes a plant shoot undergoes in response to sunlight; also known informally as greening.
- dehydration reaction** A chemical reaction in which two molecules become covalently bonded to each other with the removal of a water molecule.
- deletion** (1) A deficiency in a chromosome resulting from the loss of a fragment through breakage. (2) A mutational loss of one or more nucleotide pairs from a gene.
- demography** The study of changes over time in the vital statistics of populations, especially birth rates and death rates.
- denaturation** (dē-nā'-chur-ā'-shun) In proteins, a process in which a protein loses its native shape due to the disruption of weak chemical bonds and interactions, thereby becoming biologically inactive; in DNA, the separation of the two strands of the double helix. Denaturation occurs under extreme (noncellular) conditions of pH, salt concentration, or temperature.
- dendrite** (den'-drīt) One of usually numerous, short, highly branched extensions of a neuron that receive signals from other neurons.
- density** The number of individuals per unit area or volume.
- density dependent** Referring to any characteristic that varies with population density.
- density independent** Referring to any characteristic that is not affected by population density.
- density-dependent inhibition** The phenomenon observed in normal animal cells that causes them to stop dividing when they come into contact with one another.
- deoxyribonucleic acid (DNA)** (dē-ok'-sē-rī'-bō-nū-klā'-ik) A nucleic acid molecule, usually a double-stranded helix, in which each polynucleotide strand consists of nucleotide monomers with a deoxyribose sugar and the nitrogenous bases adenine (A), cytosine (C), guanine (G), and thymine (T); capable of being replicated and determining the inherited structure of a cell's proteins.
- deoxyribose** (dē-ok'-si-rī'-bōs) The sugar component of DNA nucleotides, having one fewer hydroxyl group than ribose, the sugar component of RNA nucleotides.
- dependent variable** In an experiment, a variable whose value is influenced by changes in another variable (the independent variable).
- depolarization** A change in a cell's membrane potential such that the inside of the membrane is made less negative relative to the outside. For example, a neuron membrane is depolarized if a stimulus decreases its voltage from the resting potential of  $-70$  mV in the direction of zero voltage.
- dermal tissue system** The outer protective covering of plants.
- desert** A terrestrial biome characterized by very low precipitation.
- desmosome** A type of intercellular junction in animal cells that functions as a rivet, fastening cells together.
- determinate growth** A type of growth characteristic of most animals and some plant organs, in which growth stops after a certain size is reached.
- determination** The progressive restriction of developmental potential whereby the possible fate of each cell becomes more limited as an embryo develops. At the end of determination, a cell is committed to its fate.
- detritivore** (deh-trī'-tuh-vōr) A consumer that derives its energy and nutrients from nonliving organic material such as corpses, fallen plant material, and the wastes of living organisms; a decomposer.
- detritus** (di-trī'-tus) Dead organic matter.
- diabetes mellitus** (dī'-uh-bē'-tis mel'-uh-tus) An endocrine disorder marked by an inability to maintain glucose homeostasis. The type 1 form results from autoimmune destruction of insulin-secreting cells; treatment usually requires daily insulin injections. The type 2 form most commonly results from reduced responsiveness of target cells to insulin; obesity and lack of exercise are risk factors.
- diaphragm** (dī'-uh-fram') (1) A sheet of muscle that forms the bottom wall of the thoracic cavity in mammals. Contraction of the diaphragm pulls air into the lungs. (2) A dome-shaped rubber cup fitted into the upper portion of the vagina before sexual intercourse. It serves as a physical barrier to the passage of sperm into the uterus.
- diastole** (dī-as'-tō-lē) The stage of the cardiac cycle in which a heart chamber is relaxed and fills with blood.
- diatom** A photosynthetic protist in the stramenopile clade; diatoms have a unique glass-like wall made of silicon dioxide embedded in an organic matrix.
- differential gene expression** The expression of different sets of genes by cells with the same genome.
- differentiation** The process by which a cell or group of cells becomes specialized in structure and function.
- diffusion** The random thermal motion of particles of liquids, gases, or solids. In the presence of a concentration or electrochemical gradient, diffusion results in the net movement of a substance from a region where it is more concentrated to a region where it is less concentrated.
- digestion** The second stage of food processing in animals: the breaking down of food into molecules small enough for the body to absorb.
- dihybrid** (dī'-hī'-brid) An organism that is heterozygous with respect to two genes of interest. All the offspring from a cross between parents doubly homozygous for different alleles are dihybrids. For example, parents of genotypes *AABB* and *aabb* produce a dihybrid of genotype *AaBb*.
- dihybrid cross** A cross between two organisms that are each heterozygous for both of the characters being followed (or the self-pollination of a plant that is heterozygous for both characters).
- dinoflagellate** (dī'-nō-flaj'-uh-let) Member of a group of mostly unicellular photosynthetic algae with two flagella situated in perpendicular grooves in cellulose plates covering the cell.
- dioecious** (dī-ē'-shus) In plant biology, having the male and female reproductive parts on different individuals of the same species.
- diploid cell** (dip'-loyd) A cell containing two sets of chromosomes ( $2n$ ), one set inherited from each parent.
- diplomonad** A protist that has modified mitochondria and multiple flagella.
- directional selection** Natural selection in which individuals at one end of the phenotypic range survive or reproduce more successfully than do other individuals.
- disaccharide** (di-sak'-uh-rid) A double sugar, consisting of two monosaccharides joined by a glycosidic linkage formed by a dehydration reaction.
- dispersal** The movement of individuals or gametes away from their parent location. This movement sometimes expands the geographic range of a population or species.
- dispersion** The pattern of spacing among individuals within the boundaries of a population.
- disruptive selection** Natural selection in which individuals on both extremes of a phenotypic range survive or reproduce more successfully than do individuals with intermediate phenotypes.
- distal tubule** In the vertebrate kidney, the portion of a nephron that helps refine filtrate and empties it into a collecting duct.
- disturbance** A natural or human-caused event that changes a biological community and usually removes organisms from it. Disturbances, such as fires and storms, play a pivotal role in structuring many communities.
- disulfide bridge** A strong covalent bond formed when the sulfur of one cysteine monomer bonds to the sulfur of another cysteine monomer.

**DNA (deoxyribonucleic acid)** (dē-ok'-sē-ri'-bō-nū-klā'-ik) A nucleic acid molecule, usually a double-stranded helix, in which each polynucleotide strand consists of nucleotide monomers with a deoxyribose sugar and the nitrogenous bases adenine (A), cytosine (C), guanine (G), and thymine (T); capable of being replicated and determining the inherited structure of a cell's proteins.

**DNA ligase** (lī'-gās) A linking enzyme essential for DNA replication; catalyzes the covalent bonding of the 3' end of one DNA fragment (such as an Okazaki fragment) to the 5' end of another DNA fragment (such as a growing DNA chain).

**DNA methylation** The presence of methyl groups on the DNA bases (usually cytosine) of plants, animals, and fungi. (The term also refers to the process of adding methyl groups to DNA bases.)

**DNA microarray assay** A method to detect and measure the expression of thousands of genes at one time. Tiny amounts of a large number of single-stranded DNA fragments representing different genes are fixed to a glass slide and tested for hybridization with samples of labeled cDNA.

**DNA polymerase** (puh-līm'-er-ās) An enzyme that catalyzes the elongation of new DNA (for example, at a replication fork) by the addition of nucleotides to the 3' end of an existing chain. There are several different DNA polymerases; DNA polymerase III and DNA polymerase I play major roles in DNA replication in *E. coli*.

**DNA replication** The process by which a DNA molecule is copied; also called DNA synthesis.

**DNA sequencing** Determining the order of nucleotide bases in a gene or DNA fragment.

**domain** (1) A taxonomic category above the kingdom level. The three domains are Archaea, Bacteria, and Eukarya. (2) A discrete structural and functional region of a protein.

**dominant allele** An allele that is fully expressed in the phenotype of a heterozygote.

**dominant species** A species with substantially higher abundance or biomass than other species in a community. Dominant species exert a powerful control over the occurrence and distribution of other species.

**dopamine** A neurotransmitter that is a catecholamine, like epinephrine and norepinephrine.

**dormancy** A condition typified by extremely low metabolic rate and a suspension of growth and development.

**dorsal** Pertaining to the top of an animal with radial or bilateral symmetry.

**double bond** A double covalent bond; the sharing of two pairs of valence electrons by two atoms.

**double circulation** A circulatory system consisting of separate pulmonary and systemic circuits, in which blood passes through the heart after completing each circuit.

**double fertilization** A mechanism of fertilization in angiosperms in which two sperm cells unite with two cells in the female gametophyte (embryo sac) to form the zygote and endosperm.

**double helix** The form of native DNA, referring to its two adjacent antiparallel polynucleotide strands wound around an imaginary axis into a spiral shape.

**Down syndrome** A human genetic disease usually caused by the presence of an extra chromosome 21; characterized by developmental delays and heart and other defects that are generally treatable or non-life-threatening.

**Duchenne muscular dystrophy** (duh-shen') A human genetic disease caused by a sex-linked recessive allele; characterized by progressive weakening and a loss of muscle tissue.

**duodenum** (dū'-uh-dēn'-um) The first section of the small intestine, where chyme from the stomach mixes with digestive juices from the pancreas, liver, and gallbladder as well as from gland cells of the intestinal wall.

**duplication** An aberration in chromosome structure due to fusion with a fragment from a homologous chromosome, such that a portion of a chromosome is duplicated.

**dynein** (dī'-nē-un) In cilia and flagella, a large motor protein extending from one microtubule doublet to the adjacent doublet. ATP hydrolysis drives changes in dynein shape that lead to bending of cilia and flagella.

**E site** One of a ribosome's three binding sites for tRNA during translation. The E site is the place where discharged tRNAs leave the ribosome. (E stands for exit.)

**ecological footprint** The aggregate land and water area required by a person, city, or nation to produce all of the resources it consumes and to absorb all of the wastes it generates.

**ecological niche** (nich) The sum of a species' use of the biotic and abiotic resources in its environment.

**ecological species concept** Definition of a species in terms of ecological niche, the sum of how members of the species interact with the nonliving and living parts of their environment.

**ecological succession** Transition in the species composition of a community following a disturbance; establishment of a community in an area virtually barren of life.

**ecology** The study of how organisms interact with each other and their environment.

**ecosystem** All the organisms in a given area as well as the abiotic factors with which they

interact; one or more communities and the physical environment around them.

**ecosystem ecology** The study of energy flow and the cycling of chemicals among the various biotic and abiotic components in an ecosystem.

**ecosystem engineer** An organism that influences community structure by causing physical changes in the environment.

**ecosystem service** A function performed by an ecosystem that directly or indirectly benefits humans.

**ecotone** The transition from one type of habitat or ecosystem to another, such as the transition from a forest to a grassland.

**ectoderm** (ek'-tō-durm) The outermost of the three primary germ layers in animal embryos; gives rise to the outer covering and, in some phyla, the nervous system, inner ear, and lens of the eye.

**ectomycorrhizae** (ek'-tō-mī'-kō-rī'-zē) Associations of a fungus with a plant root system in which the fungus surrounds the roots but does not cause invagination of the host (plant) cell's plasma membrane.

**ectomycorrhizal fungus** A symbiotic fungus that forms sheaths of hyphae over the surface of plant roots and also grows into extracellular spaces of the root cortex.

**ectoparasite** A parasite that feeds on the external surface of a host.

**ectothermic** Referring to organisms for which external sources provide most of the heat for temperature regulation.

**Ediacaran biota** (ē'-dē-uh-keh'-run bī-ō'-tuh) An early group of macroscopic, soft-bodied, multicellular eukaryotes known from fossils that range in age from 635 million to 535 million years old.

**effective population size** An estimate of the size of a population based on the numbers of females and males that successfully breed; generally smaller than the total population.

**effector cell** (1) A muscle cell or gland cell that performs the body's response to stimuli as directed by signals from the brain or other processing center of the nervous system. (2) A lymphocyte that has undergone clonal selection and is capable of mediating an adaptive immune response.

**egg** The female gamete.

**egg-polarity gene** A gene that helps control the orientation (polarity) of the egg; also called a maternal effect gene.

**ejaculation** The propulsion of sperm from the epididymis through the muscular vas deferens, ejaculatory duct, and urethra.

**ejaculatory duct** In mammals, the short section of the ejaculatory route formed by the convergence of the vas deferens and a duct from the seminal vesicle. The ejaculatory duct transports sperm from the vas deferens to the urethra.

**electrocardiogram (ECG or EKG)** A record of the electrical impulses that travel

through heart muscle during the cardiac cycle.

**electrochemical gradient** The diffusion gradient of an ion, which is affected by both the concentration difference of an ion across a membrane (a chemical force) and the ion's tendency to move relative to the membrane potential (an electrical force).

**electrogenic pump** An active transport protein that generates voltage across a membrane while pumping ions.

**electromagnetic receptor** A receptor of electromagnetic energy, such as visible light, electricity, or magnetism.

**electromagnetic spectrum** The entire spectrum of electromagnetic radiation, ranging in wavelength from less than a nanometer to more than a kilometer.

**electron** A subatomic particle with a single negative electrical charge and a mass about 1/2,000 that of a neutron or proton. One or more electrons move around the nucleus of an atom.

**electron microscope (EM)** A microscope that uses magnets to focus an electron beam on or through a specimen, resulting in a practical resolution a hundredfold greater than that of a light microscope using standard techniques. A transmission electron microscope (TEM) is used to study the internal structure of thin sections of cells. A scanning electron microscope (SEM) is used to study the fine details of cell surfaces.

**electron shell** An energy level of electrons at a characteristic average distance from the nucleus of an atom.

**electron transport chain** A sequence of electron carrier molecules (membrane proteins) that shuttle electrons down a series of redox reactions that release energy used to make ATP.

**electronegativity** The attraction of a given atom for the electrons of a covalent bond.

**element** Any substance that cannot be broken down to any other substance by chemical reactions.

**elimination** The fourth and final stage of food processing in animals: the passing of undigested material out of the body.

**embryo sac** (em'-brē-ō) The female gametophyte of angiosperms, formed from the growth and division of the megaspore into a multicellular structure that typically has eight haploid nuclei.

**embryonic lethal** A mutation with a phenotype leading to death of an embryo or larva.

**embryophyte** Alternate name for land plants that refers to their shared derived trait of multicellular, dependent embryos.

**emergent properties** New properties that arise with each step upward in the hierarchy of life, owing to the arrangement and interactions of parts as complexity increases.

**emigration** The movement of individuals out of a population.

**endangered species** A species that is in danger of extinction throughout all or a significant portion of its range.

**endemic** (en-dem'-ik) Referring to a species that is confined to a specific geographic area.

**endergonic reaction** (en'-der-gon'-ik) A nonspontaneous chemical reaction, in which free energy is absorbed from the surroundings.

**endocrine gland** (en'-dō-krin) A gland that secretes hormones directly into the interstitial fluid, from which they diffuse into the bloodstream.

**endocrine system** The internal system of communication involving hormones, the ductless glands that secrete hormones, and the molecular receptors on or in target cells that respond to hormones; functions in concert with the nervous system to effect internal regulation and maintain homeostasis.

**endocytosis** (en'-dō-sī-tō'-sis) Cellular uptake of biological molecules and particulate matter via formation of vesicles from the plasma membrane.

**endoderm** (en'-dō-durm) The innermost of the three primary germ layers in animal embryos; lines the archenteron and gives rise to the liver, pancreas, lungs, and the lining of the digestive tract in species that have these structures.

**endodermis** In plant roots, the innermost layer of the cortex that surrounds the vascular cylinder.

**endomembrane system** The collection of membranes inside and surrounding a eukaryotic cell, related either through direct physical contact or by the transfer of membranous vesicles; includes the plasma membrane, the nuclear envelope, the smooth and rough endoplasmic reticulum, the Golgi apparatus, lysosomes, vesicles, and vacuoles.

**endometrium** (en'-dō-mē'-trē-um) The inner lining of the uterus, which is richly supplied with blood vessels.

**endoparasite** A parasite that lives within a host.

**endophyte** A fungus that lives inside a leaf or other plant part without causing harm to the plant.

**endoplasmic reticulum (ER)** (en'-dō-plaz'-mik ruh-tik'-yū-lum) An extensive membranous network in eukaryotic cells, continuous with the outer nuclear membrane and composed of ribosome-studded (rough) and ribosome-free (smooth) regions.

**endorphin** (en-dōr'-fin) Any of several hormones produced in the brain and anterior pituitary that inhibit pain perception.

**endoskeleton** A hard skeleton buried within the soft tissues of an animal.

**endosperm** In angiosperms, a nutrient-rich tissue formed by the union of a sperm with two polar nuclei during double fertilization.

The endosperm provides nourishment to the developing embryo in angiosperm seeds.

**endospore** A thick-coated, resistant cell produced by some bacterial cells when they are exposed to harsh conditions.

**endosymbiont theory** The theory that mitochondria and plastids, including chloroplasts, originated as prokaryotic cells engulfed by host cells. The engulfed cell and its host cell then evolved into a single organism. *See also* endosymbiosis.

**endosymbiosis** A mutually beneficial relationship between two species in which one organism lives inside the cell or cells of another organism.

**endothelium** (en'-dō-thē'-lē-um) The simple squamous layer of cells lining the lumen of blood vessels.

**endothermic** Referring to organisms that are warmed by heat generated by their own metabolism. This heat usually maintains a relatively stable body temperature higher than that of the external environment.

**endotoxin** A toxic component of the outer membrane of certain gram-negative bacteria that is released only when the bacteria die.

**energy** The capacity to cause change, especially to do work (to move matter against an opposing force).

**energy coupling** In cellular metabolism, the use of energy released from an exergonic reaction to drive an endergonic reaction.

**enhancer** A segment of eukaryotic DNA containing multiple control elements, usually located far from the gene whose transcription it regulates.

**enteric division** One of three divisions of the autonomic nervous system; consists of networks of neurons in the digestive tract, pancreas, and gallbladder; normally regulated by the sympathetic and parasympathetic divisions of the autonomic nervous system.

**entropy** A measure of disorder, or randomness.

**enzyme** (en'-zīm) A macromolecule serving as a catalyst, a chemical agent that increases the rate of a reaction without being consumed by the reaction. Most enzymes are proteins.

**enzyme-substrate complex** A temporary complex formed when an enzyme binds to its substrate molecule(s).

**epicotyl** (ep'-uh-kot'-ul) In an angiosperm embryo, the embryonic axis above the point of attachment of the cotyledon(s) and below the first pair of miniature leaves.

**epidemic** A general outbreak of a disease.

**epidermis** (1) The dermal tissue system of nonwoody plants, usually consisting of a single layer of tightly packed cells. (2) The outermost layer of cells in an animal.

**epididymis** (ep'-uh-did'-uh-mus) A coiled tubule located adjacent to the mammalian testis where sperm are stored.

- epigenetic inheritance** Inheritance of traits transmitted by mechanisms not directly involving the nucleotide sequence of a genome.
- epinephrine** (ep'-i-nef'-rin) A catecholamine that, when secreted as a hormone by the adrenal medulla, mediates “fight-or-flight” responses to short-term stresses; also released by some neurons as a neurotransmitter; also known as adrenaline.
- epiphyte** (ep'-uh-fit) A plant that nourishes itself but grows on the surface of another plant for support, usually on the branches or trunks of trees.
- epistasis** (ep'-i-stā'-sis) A type of gene interaction in which the phenotypic expression of one gene alters that of another independently inherited gene.
- epithelial tissue** (ep'-uh-thē'-lē-ul) Sheets of tightly packed cells that line organs and body cavities as well as external surfaces; also called epithelium.
- epithelium** An epithelial tissue.
- epitope** A small, accessible region of an antigen to which an antigen receptor or antibody binds; also called an antigenic determinant.
- equilibrium potential ( $E_{ion}$ )** The magnitude of a cell's membrane voltage at equilibrium, calculated using the Nernst equation.
- erythrocyte** (eh-rith'-ruh-sīt) A blood cell that contains hemoglobin, which transports oxygen; also called a red blood cell.
- esophagus** (eh-sof'-uh-gus) A muscular tube that conducts food, by peristalsis, from the pharynx to the stomach.
- essential amino acid** An amino acid that an animal cannot synthesize itself and must be obtained from food in prefabricated form.
- essential element** A chemical element required for an organism to survive, grow, and reproduce.
- essential fatty acid** An unsaturated fatty acid that an animal needs but cannot make.
- essential nutrient** A substance that an organism cannot synthesize from any other material and therefore must absorb in preassembled form.
- estradiol** (es'-truh-dī'-ol) A steroid hormone that stimulates the development and maintenance of the female reproductive system and secondary sex characteristics; the major estrogen in mammals.
- estrogen** (es'-trō-jen) Any steroid hormone, such as estradiol, that stimulates the development and maintenance of the female reproductive system and secondary sex characteristics.
- estrous cycle** (es'-trus) A reproductive cycle characteristic of female mammals except humans and certain other primates, in which the nonpregnant endometrium is reabsorbed rather than shed, and sexual response occurs only during mid-cycle at estrus.
- estuary** The area where a freshwater stream or river merges with the ocean.
- ethylene** (eth'-uh-lēn) A gaseous plant hormone involved in responses to mechanical stress, programmed cell death, leaf abscission, and fruit ripening.
- etiolation** Plant morphological adaptations for growing in darkness.
- euchromatin** (yū-krō'-muh-tin) The less condensed form of eukaryotic chromatin that is available for transcription.
- euglenozoan** Member of a diverse clade of flagellated protists that includes predatory heterotrophs, photosynthetic autotrophs, and pathogenic parasites.
- Eukarya** (yū-kar'-ē-uh) The domain that includes all eukaryotic organisms.
- eukaryotic cell** (yū'-ker-ē-ot'-ik) A type of cell with a membrane-enclosed nucleus and membrane-enclosed organelles. Organisms with eukaryotic cells (protists, plants, fungi, and animals) are called eukaryotes.
- eumetazoan** (yū'-met-uh-zō'-un) Member of a clade of animals with true tissues. All animals except sponges and a few other groups are eumetazoans.
- Eustachian tube** (yū-stā'-shun) The tube that connects the middle ear to the pharynx.
- eutherian** (yū-thēr'-ē-un) Placental mammal; mammal whose young complete their embryonic development within the uterus, joined to the mother by the placenta.
- eutrophic lake** (yū-trōf'-ik) A lake that has a high rate of biological productivity supported by a high rate of nutrient cycling.
- eutrophication** A process by which nutrients, particularly phosphorus and nitrogen, become highly concentrated in a body of water, leading to increased growth of organisms such as algae or cyanobacteria.
- evaporative cooling** The process in which the surface of an object becomes cooler during evaporation, a result of the molecules with the greatest kinetic energy changing from the liquid to the gaseous state.
- evapotranspiration** The total evaporation of water from an ecosystem, including water transpired by plants and evaporated from a landscape, usually measured in millimeters and estimated for a year.
- evo-devo** Evolutionary developmental biology; a field of biology that compares developmental processes of different multicellular organisms to understand how these processes have evolved and how changes can modify existing organismal features or lead to new ones.
- evolution** Descent with modification; the idea that living species are descendants of ancestral species that were different from the present-day ones; also defined more narrowly as the change in the genetic composition of a population from generation to generation.
- Excavata** One of four supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. Excavates have unique cytoskeletal features, and some species have an “excavated” feeding groove on one side of the cell body. *See also* “SAR” clade, Archaeplastida, and Unikonta.
- excitatory postsynaptic potential (EPSP)** An electrical change (depolarization) in the membrane of a postsynaptic cell caused by the binding of an excitatory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more likely for a postsynaptic cell to generate an action potential.
- excretion** The disposal of nitrogen-containing metabolites and other waste products.
- exergonic reaction** (ek'-ser-gon'-ik) A spontaneous chemical reaction, in which there is a net release of free energy.
- exocrine gland** (ek'-sō-krin) A gland that secretes substances through a duct onto a body surface or into a body cavity.
- exocytosis** (ek'-sō-sī-tō'-sis) The cellular secretion of biological molecules by the fusion of vesicles containing them with the plasma membrane.
- exon** A sequence within a primary transcript that remains in the RNA after RNA processing; also refers to the region of DNA from which this sequence was transcribed.
- exoskeleton** A hard encasement on the surface of an animal, such as the shell of a mollusc or the cuticle of an arthropod, that provides protection and points of attachment for muscles.
- exotoxin** (ek'-sō-tok'-sin) A toxic protein that is secreted by a prokaryote or other pathogen and that produces specific symptoms, even if the pathogen is no longer present.
- expansin** Plant enzyme that breaks the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric.
- experimental group** A set of subjects that has (or receives) the specific factor being tested in a controlled experiment.
- exponential population growth** Growth of a population in an ideal, unlimited environment, represented by a J-shaped curve when population size is plotted over time.
- external fertilization** The fusion of gametes that parents have discharged into the environment.
- extinction vortex** A downward population spiral in which inbreeding and genetic drift combine to cause a small population to shrink and, unless the spiral is reversed, become extinct.
- extracellular matrix (ECM)** The meshwork surrounding animal cells, consisting of glycoproteins, polysaccharides, and proteoglycans synthesized and secreted by the cells.
- extreme halophile** An organism that lives in a highly saline environment, such as the Great Salt Lake or the Dead Sea.
- extreme thermophile** An organism that thrives in hot environments (often 60–80°C or hotter).
- extremophile** An organism that lives in environmental conditions so extreme that few

- other species can survive there. Extremophiles include extreme halophiles (“salt lovers”) and extreme thermophiles (“heat lovers”).
- F factor** In bacteria, the DNA segment that confers the ability to form pili for conjugation and associated functions required for the transfer of DNA from donor to recipient. The F factor may exist as a plasmid or be integrated into the bacterial chromosome.
- F plasmid** The plasmid form of the F factor.
- F<sub>1</sub> generation** The first filial, hybrid (heterozygous) offspring arising from a parental (P generation) cross.
- F<sub>2</sub> generation** The offspring resulting from interbreeding (or self-pollination) of the hybrid F<sub>1</sub> generation.
- facilitated diffusion** The passage of molecules or ions down their electrochemical gradient across a biological membrane with the assistance of specific transmembrane transport proteins, requiring no energy expenditure.
- facilitation** An interaction in which one species has a positive effect on the survival and reproduction of another species without the intimate association of a symbiosis.
- facultative anaerobe** (fak’-ul-tā’-tiv an’-uh-rōb) An organism that makes ATP by aerobic respiration if oxygen is present but that switches to anaerobic respiration or fermentation if oxygen is not present.
- family** In Linnaean classification, the taxonomic category above genus.
- fast-twitch fiber** A muscle fiber used for rapid, powerful contractions.
- fat** A lipid consisting of three fatty acids linked to one glycerol molecule; also called a triacylglycerol or triglyceride.
- fatty acid** A carboxylic acid with a long carbon chain. Fatty acids vary in length and in the number and location of double bonds; three fatty acids linked to a glycerol molecule form a fat molecule, also known as a triacylglycerol or triglyceride.
- feces** (fē’-sēz) The wastes of the digestive tract.
- feedback inhibition** A method of metabolic control in which the end product of a metabolic pathway acts as an inhibitor of an enzyme within that pathway.
- fermentation** A catabolic process that makes a limited amount of ATP from glucose (or other organic molecules) without an electron transport chain and that produces a characteristic end product, such as ethyl alcohol or lactic acid.
- fertilization** (1) The union of haploid gametes to produce a diploid zygote. (2) The addition of mineral nutrients to the soil.
- fetus** (fē’-tus) A developing mammal that has all the major structures of an adult. In humans, the fetal stage lasts from the 9th week of gestation until birth.
- fiber** A lignified cell type that reinforces the xylem of angiosperms and functions in mechanical support; a slender, tapered sclerenchyma cell that usually occurs in bundles.
- fibronectin** An extracellular glycoprotein secreted by animal cells that helps them attach to the extracellular matrix.
- filtrate** Cell-free fluid extracted from the body fluid by the excretory system.
- filtration** In excretory systems, the extraction of water and small solutes, including metabolic wastes, from the body fluid.
- fimbria** (plural, **fimbriae**) A short, hairlike appendage of a prokaryotic cell that helps it adhere to the substrate or to other cells.
- first law of thermodynamics** The principle of conservation of energy: Energy can be transferred and transformed, but it cannot be created or destroyed.
- fixed action pattern** In animal behavior, a sequence of unlearned acts that is essentially unchangeable and, once initiated, usually carried to completion.
- flaccid** (flas’-id) Limp. Lacking turgor (stiffness or firmness), as in a plant cell in surroundings where there is a tendency for water to leave the cell. (A walled cell becomes flaccid if it has a higher water potential than its surroundings, resulting in the loss of water.)
- flagellum** (fluh-jel’-um) (plural, **flagella**) A long cellular appendage specialized for locomotion. Like motile cilia, eukaryotic flagella have a core with nine outer doublet microtubules and two inner single microtubules (the “9 + 2” arrangement) ensheathed in an extension of the plasma membrane. Prokaryotic flagella have a different structure.
- florigen** A flowering signal, probably a protein, that is made in leaves under certain conditions and that travels to the shoot apical meristems, inducing them to switch from vegetative to reproductive growth.
- flower** In an angiosperm, a specialized shoot with up to four sets of modified leaves, bearing structures that function in sexual reproduction.
- fluid feeder** An animal that lives by sucking nutrient-rich fluids from another living organism.
- fluid mosaic model** The currently accepted model of cell membrane structure, which envisions the membrane as a mosaic of protein molecules drifting laterally in a fluid bilayer of phospholipids.
- follicle** (fol’-uh-kul) A microscopic structure in the ovary that contains the developing oocyte and secretes estrogens.
- follicle-stimulating hormone (FSH)** A tropic hormone that is produced and secreted by the anterior pituitary and that stimulates the production of eggs by the ovaries and sperm by the testes.
- follicular phase** That part of the ovarian cycle during which follicles are growing and oocytes maturing.
- food chain** The pathway along which food energy is transferred from trophic level to trophic level, beginning with producers.
- food vacuole** A membranous sac formed by phagocytosis of microorganisms or particles to be used as food by the cell.
- food web** The interconnected feeding relationships in an ecosystem.
- foraging** The seeking and obtaining of food.
- foram (foraminiferan)** An aquatic protist that secretes a hardened shell containing calcium carbonate and extends pseudopodia through pores in the shell.
- forebrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into the thalamus, hypothalamus, and cerebrum.
- fossil** A preserved remnant or impression of an organism that lived in the past.
- founder effect** Genetic drift that occurs when a few individuals become isolated from a larger population and form a new population whose gene pool composition is not reflective of that of the original population.
- fovea** (fō’-vê-uh) The place on the retina at the eye’s center of focus, where cones are highly concentrated.
- fragmentation** A means of asexual reproduction whereby a single parent breaks into parts that regenerate into whole new individuals.
- frameshift mutation** A mutation occurring when nucleotides are inserted in or deleted from a gene and the number inserted or deleted is not a multiple of three, resulting in the improper grouping of the subsequent nucleotides into codons.
- free energy** The portion of a biological system’s energy that can perform work when temperature and pressure are uniform throughout the system. The change in free energy of a system ( $\Delta G$ ) is  $G_{\text{final state}} - G_{\text{initial state}}$ . It can be calculated by the equation  $\Delta G = \Delta H - T\Delta S$ , where  $\Delta H$  is the change in enthalpy (in biological systems, equivalent to total energy),  $T$  is the absolute temperature, and  $\Delta S$  is the change in entropy.
- frequency-dependent selection** Selection in which the fitness of a phenotype depends on how common the phenotype is in a population.
- fruit** A mature ovary of a flower. The fruit protects dormant seeds and often aids in their dispersal.
- functional group** A specific configuration of atoms commonly attached to the carbon skeletons of organic molecules and involved in chemical reactions.
- G protein** A GTP-binding protein that relays signals from a plasma membrane signal receptor, known as a G protein-coupled receptor, to other signal transduction proteins inside the cell.

- G protein-coupled receptor (GPCR)** A signal receptor protein in the plasma membrane that responds to the binding of a signaling molecule by activating a G protein. Also called a G protein-linked receptor.
- G<sub>0</sub> phase** A nondividing state occupied by cells that have left the cell cycle, sometimes reversibly.
- G<sub>1</sub> phase** The first gap, or growth phase, of the cell cycle, consisting of the portion of interphase before DNA synthesis begins.
- G<sub>2</sub> phase** The second gap, or growth phase, of the cell cycle, consisting of the portion of interphase after DNA synthesis occurs.
- gallbladder** An organ that stores bile and releases it as needed into the small intestine.
- gamete** (gam'-ēt) A haploid reproductive cell, such as an egg or sperm. Gametes unite during sexual reproduction to produce a diploid zygote.
- gametogenesis** The process by which gametes are produced.
- gametophyte** (guh-mē'-tō-fit) In organisms (plants and some algae) that have alternation of generations, the multicellular haploid form that produces haploid gametes by mitosis. The haploid gametes unite and develop into sporophytes.
- gamma-aminobutyric acid (GABA)** An amino acid that functions as a neurotransmitter in the central nervous system of vertebrates.
- ganglion** (gang'-glē-uhn) (plural, **ganglia**) A cluster (functional group) of nerve cell bodies.
- gap junction** A type of intercellular junction in animal cells, consisting of proteins surrounding a pore that allows the passage of materials between cells.
- gas exchange** The uptake of molecular oxygen from the environment and the discharge of carbon dioxide to the environment.
- gas exchange circuit** The branch of the circulatory system that supplies the organs where gases are exchanged with the environment; in many amphibians, it supplies the lungs and skin and is called a *pulmocutaneous circuit*, whereas in birds and mammals, it supplies only the lungs and is called a *pulmonary circuit*.
- gastric juice** A digestive fluid secreted by the stomach.
- gastrovascular cavity** A central cavity with a single opening in the body of certain animals, including cnidarians and flatworms, that functions in both the digestion and distribution of nutrients.
- gastrula** (gas'-trū-luh) An embryonic stage in animal development encompassing the formation of three layers: ectoderm, mesoderm, and endoderm.
- gastrulation** (gas'-trū-lā'-shun) In animal development, a series of cell and tissue movements in which the blastula-stage embryo folds inward, producing a three-layered embryo, the gastrula.
- gated channel** A transmembrane protein channel that opens or closes in response to a particular stimulus.
- gated ion channel** A gated channel for a specific ion. The opening or closing of such channels may alter a cell's membrane potential.
- gel electrophoresis** (ē-lek'-trō-fōr-ē'-sis) A technique for separating nucleic acids or proteins on the basis of their size and electrical charge, both of which affect their rate of movement through an electric field in a gel made of agarose or another polymer.
- gene** A discrete unit of hereditary information consisting of a specific nucleotide sequence in DNA (or RNA, in some viruses).
- gene cloning** The production of multiple copies of a gene.
- gene expression** The process by which information encoded in DNA directs the synthesis of proteins or, in some cases, RNAs that are not translated into proteins and instead function as RNAs.
- gene flow** The transfer of alleles from one population to another, resulting from the movement of fertile individuals or their gametes.
- gene pool** The aggregate of all copies of every type of allele at all loci in every individual in a population. The term is also used in a more restricted sense as the aggregate of alleles for just one or a few loci in a population.
- gene-for-gene recognition** A widespread form of plant disease resistance involving recognition of pathogen-derived molecules by the protein products of specific plant disease resistance genes.
- genetic drift** A process in which chance events cause unpredictable fluctuations in allele frequencies from one generation to the next. Effects of genetic drift are most pronounced in small populations.
- genetic engineering** The direct manipulation of genes for practical purposes.
- genetic map** An ordered list of genetic loci (genes or other genetic markers) along a chromosome.
- genetic profile** An individual's unique set of genetic markers, detected most often today by PCR.
- genetic recombination** General term for the production of offspring with combinations of traits that differ from those found in either parent.
- genetic variation** Differences among individuals in the composition of their genes or other DNA segments.
- genetics** The scientific study of heredity and hereditary variation.
- genome** (jē'-nōm) The genetic material of an organism or virus; the complete complement of an organism's or virus's genes along with its noncoding nucleic acid sequences.
- genomics** (juh-nō'-miks) The study of whole sets of genes and their interactions within a species, as well as genome comparisons between species.
- genotype** (jē'-nō-tip) The genetic makeup, or set of alleles, of an organism.
- genus** (jē'-nus) (plural, **genera**) A taxonomic category above the species level, designated by the first word of a species' two-part scientific name.
- geologic record** A standard time scale dividing Earth's history into time periods grouped into four eons—Hadean, Archean, Proterozoic, and Phanerozoic—and further subdivided into eras, periods, and epochs.
- gestation** (jes-tā'-shun) Pregnancy; the state of carrying developing young within the female reproductive tract.
- gibberellin** (jib'-uh-rel'-in) Any of a class of related plant hormones that stimulate growth in the stem and leaves, trigger the germination of seeds and breaking of bud dormancy, and (with auxin) stimulate fruit development.
- glans** The rounded structure at the tip of the clitoris or penis that is involved in sexual arousal.
- glia (glial cells)** Cells of the nervous system that support, regulate, and augment the functions of neurons.
- global ecology** The study of the functioning and distribution of organisms across the biosphere and how the regional exchange of energy and materials affects them.
- glomerulus** (glō-mār'-yū-lus) A ball of capillaries surrounded by Bowman's capsule in the nephron and serving as the site of filtration in the vertebrate kidney.
- glucagon** (glū'-kuh-gon) A hormone secreted by pancreatic alpha cells that raises blood glucose levels. It promotes glycogen breakdown and release of glucose by the liver.
- glutamate** An amino acid that functions as a neurotransmitter in the central nervous system.
- glyceraldehyde 3-phosphate (G3P)** (glis'-er-al'-de-hid) A three-carbon carbohydrate that is the direct product of the Calvin cycle; it is also an intermediate in glycolysis.
- glycogen** (gli'-kō-jen) An extensively branched glucose storage polysaccharide found in the liver and muscle of animals; the animal equivalent of starch.
- glycolipid** A lipid with one or more covalently attached carbohydrates.
- glycolysis** (gli-kol'-uh-sis) A series of reactions that ultimately splits glucose into pyruvate. Glycolysis occurs in almost all living cells, serving as the starting point for fermentation or cellular respiration.
- glycoprotein** A protein with one or more covalently attached carbohydrates.
- glycosidic linkage** A covalent bond formed between two monosaccharides by a dehydration reaction.
- gnathostome** (na'-thu-stōm) Member of the vertebrate subgroup possessing jaws.
- Golgi apparatus** (gol'-jē) An organelle in eukaryotic cells consisting of stacks of flat

- membranous sacs that modify, store, and route products of the endoplasmic reticulum and synthesize some products, notably noncellulose carbohydrates.
- gonad** (gō'-nad) A male or female gamete-producing organ.
- graded potential** In a neuron, a shift in the membrane potential that has an amplitude proportional to signal strength and that decays as it spreads.
- gram-negative** Describing the group of bacteria that have a cell wall that is structurally more complex and contains less peptidoglycan than the cell wall of gram-positive bacteria. Gram-negative bacteria are often more toxic than gram-positive bacteria.
- gram-positive** Describing the group of bacteria that have a cell wall that is structurally less complex and contains more peptidoglycan than the cell wall of gram-negative bacteria. Gram-positive bacteria are usually less toxic than gram-negative bacteria.
- granum** (gran'-um) (plural, **grana**) A stack of membrane-bounded thylakoids in the chloroplast. Grana function in the light reactions of photosynthesis.
- gravitropism** (grav'-uh-trō'-pizm) A response of a plant or animal to gravity.
- gray matter** Regions of dendrites and clustered neuron cell bodies within the CNS.
- green alga** A photosynthetic protist, named for green chloroplasts that are similar in structure and pigment composition to the chloroplasts of land plants. Green algae are a paraphyletic group; some members are more closely related to land plants than they are to other green algae.
- greenhouse effect** The warming of Earth due to the atmospheric accumulation of carbon dioxide and certain other gases, which absorb reflected infrared radiation and reradiate some of it back toward Earth.
- gross primary production (GPP)** The total primary production of an ecosystem.
- ground tissue system** Plant tissues that are neither vascular nor dermal, fulfilling a variety of functions, such as storage, photosynthesis, and support.
- growth factor** (1) A protein that must be present in the extracellular environment (culture medium or animal body) for the growth and normal development of certain types of cells. (2) A local regulator that acts on nearby cells to stimulate cell proliferation and differentiation.
- guard cells** The two cells that flank the stomatal pore and regulate the opening and closing of the pore.
- gustation** The sense of taste.
- gymnosperm** (jim'-nō-sperm) A vascular plant that bears naked seeds—seeds not enclosed in protective chambers.
- hair cell** A mechanosensory cell that alters output to the nervous system when hairlike projections on the cell surface are displaced.
- half-life** The amount of time it takes for 50% of a sample of a radioactive isotope to decay.
- Hamilton's rule** The principle that for natural selection to favor an altruistic act, the benefit to the recipient, devalued by the coefficient of relatedness, must exceed the cost to the altruist.
- haploid cell** (hap'-loyd) A cell containing only one set of chromosomes (*n*).
- Hardy-Weinberg principle** The principle that frequencies of alleles and genotypes in a population remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work.
- haustorium** (plural, **haustoria**) (ho-stōr'-ē-um, ho-stōr'-ē-uh) In certain symbiotic fungi, a specialized hypha that can penetrate the tissues of host organisms.
- heart** A muscular pump that uses metabolic energy to elevate the hydrostatic pressure of the circulatory fluid (blood or hemolymph). The fluid then flows down a pressure gradient through the body and eventually returns to the heart.
- heart attack** The damage or death of cardiac muscle tissue resulting from prolonged blockage of one or more coronary arteries.
- heart murmur** A hissing sound that most often results from blood squirting backward through a leaky valve in the heart.
- heat** Thermal energy in transfer from one body of matter to another.
- heat of vaporization** The quantity of heat a liquid must absorb for 1 g of it to be converted from the liquid to the gaseous state.
- heat-shock protein** A protein that helps protect other proteins during heat stress. Heat-shock proteins are found in plants, animals, and microorganisms.
- heavy chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigen-binding site, and a constant region.
- helicase** An enzyme that untwists the double helix of DNA at replication forks, separating the two strands and making them available as template strands.
- helper T cell** A type of T cell that, when activated, secretes cytokines that promote the response of B cells (humoral response) and cytotoxic T cells (cell-mediated response) to antigens.
- hemoglobin** (hē'-mō-glō'-bin) An iron-containing protein in red blood cells that reversibly binds oxygen.
- hemolymph** (hē'-mō-limf') In invertebrates with an open circulatory system, the body fluid that bathes tissues.
- hemophilia** (hē'-muh-fil'-ē-uh) A human genetic disease caused by a sex-linked recessive allele, resulting in the absence of one or more blood-clotting proteins; characterized by excessive bleeding following injury.
- hepatic portal vein** A large vessel that conveys nutrient-laden blood from the small intestine to the liver, which regulates the blood's nutrient content.
- herbivore** (hur'-bi-vōr') An animal that mainly eats plants or algae.
- herbivory** An interaction in which an organism eats parts of a plant or alga.
- heredity** The transmission of traits from one generation to the next.
- hermaphroditism** (hur-maf'-rō-dī-tizm) A condition in which an individual has both female and male gonads and functions as both a male and female in sexual reproduction by producing both sperm and eggs.
- heterochromatin** (het'-er-ō-krō'-muh-tin) Eukaryotic chromatin that remains highly compacted during interphase and is generally not transcribed.
- heterochrony** (het'-uh-rok'-ruh-nē) Evolutionary change in the timing or rate of an organism's development.
- heterocyst** (het'-er-ō-sist) A specialized cell that engages in nitrogen fixation in some filamentous cyanobacteria; also called a heterocyte.
- heterotroph** (het'-er-ō-trōf) An organism that obtains organic food molecules by eating other organisms or substances derived from them.
- heterozygote advantage** Greater reproductive success of heterozygous individuals compared with homozygotes; tends to preserve variation in a gene pool.
- heterozygous** (het'-er-ō-zī'-gus) Having two different alleles for a given gene.
- high-density lipoprotein (HDL)** A particle in the blood made up of thousands of cholesterol molecules and other lipids bound to a protein. HDL scavenges excess cholesterol.
- hindbrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into the medulla oblongata, pons, and cerebellum.
- histamine** (his'-tuh-mēn) A substance released by mast cells that causes blood vessels to dilate and become more permeable in inflammatory and allergic responses.
- histogram** A variant of a bar graph in which a numerical independent variable is divided into equal intervals (or groups called "bins"). The height (or length) of each bar represents the value of the dependent variable for a particular interval.
- histone** (his'-tōn) A small protein with a high proportion of positively charged amino acids that binds to the negatively charged DNA and plays a key role in chromatin structure.
- histone acetylation** The attachment of acetyl groups to certain amino acids of histone proteins.
- HIV (human immunodeficiency virus)** The infectious agent that causes AIDS. HIV is a retrovirus.

**holdfast** A rootlike structure that anchors a seaweed.

**homeobox** (hō'-mē-ō-boks') A 180-nucleotide sequence within homeotic genes and some other developmental genes that is widely conserved in animals. Related sequences occur in plants and yeasts.

**homeostasis** (hō'-mē-ō-stā'-sis) The steady-state physiological condition of the body.

**homeotic gene** (hō-mē-o'-tik) Any of the master regulatory genes that control placement and spatial organization of body parts in animals, plants, and fungi by controlling the developmental fate of groups of cells.

**homologous chromosomes** (hō-mol'-uh-gus) A pair of chromosomes of the same length, centromere position, and staining pattern that possess genes for the same characters at corresponding loci. One homologous chromosome is inherited from the organism's father, the other from the mother. Also called homologs, or a homologous pair.

**homologous structures** Structures in different species that are similar because of common ancestry.

**homology** (hō-mol'-ō-jē) Similarity in characteristics resulting from a shared ancestry.

**homoplasy** (hō'-muh-play'-zē) A similar (analogous) structure or molecular sequence that has evolved independently in two species.

**homozygous** (hō'-mō-zī'-gus) Having two identical alleles for a given gene.

**horizontal gene transfer** The transfer of genes from one genome to another through mechanisms such as transposable elements, plasmid exchange, viral activity, and perhaps fusions of different organisms.

**hormone** In multicellular organisms, one of many types of secreted chemicals that are formed in specialized cells, travel in body fluids, and act on specific target cells in other parts of the body, changing the target cells' functioning. Hormones are thus important in long-distance signaling.

**host** The larger participant in a symbiotic relationship, often providing a home and food source for the smaller symbiont.

**host range** The limited number of species whose cells can be infected by a particular virus.

**Human Genome Project** An international collaborative effort to map and sequence the DNA of the entire human genome.

**human immunodeficiency virus (HIV)** The pathogen that causes AIDS (acquired immune deficiency syndrome).

**humoral immune response** (hyū'-mer-ul) The branch of adaptive immunity that involves the activation of B cells and that leads to the production of antibodies, which defend against bacteria and viruses in body fluids.

**humus** (hyū'-mus) Decomposing organic material that is a component of topsoil.

**Huntington's disease** A human genetic disease caused by a dominant allele; characterized by uncontrollable body movements and degeneration of the nervous system; usually fatal 10 to 20 years after the onset of symptoms.

**hybrid** Offspring that results from the mating of individuals from two different species or from two true-breeding varieties of the same species.

**hybrid zone** A geographic region in which members of different species meet and mate, producing at least some offspring of mixed ancestry.

**hybridization** In genetics, the mating, or crossing, of two true-breeding varieties.

**hydration shell** The sphere of water molecules around a dissolved ion.

**hydrocarbon** An organic molecule consisting of only carbon and hydrogen.

**hydrogen bond** A type of weak chemical bond that is formed when the slightly positive hydrogen atom of a polar covalent bond in one molecule is attracted to the slightly negative atom of a polar covalent bond in another molecule or in another region of the same molecule.

**hydrogen ion** A single proton with a charge of 1+. The dissociation of a water molecule (H<sub>2</sub>O) leads to the generation of a hydroxide ion (OH<sup>-</sup>) and a hydrogen ion (H<sup>+</sup>); in water, H<sup>+</sup> is not found alone but associates with a water molecule to form a hydronium ion.

**hydrolysis** (hī-drol'-uh-sis) A chemical reaction that breaks bonds between two molecules by the addition of water; functions in disassembly of polymers to monomers.

**hydronium ion** A water molecule that has an extra proton bound to it; H<sub>3</sub>O<sup>+</sup>, commonly represented as H<sup>+</sup>.

**hydrophilic** (hī'-drō-fil'-ik) Having an affinity for water.

**hydrophobic** (hī'-drō-fō'-bik) Having no affinity for water; tending to coalesce and form droplets in water.

**hydrophobic interaction** A type of weak chemical interaction caused when molecules that do not mix with water coalesce to exclude water.

**hydroponic culture** A method in which plants are grown in mineral solutions rather than in soil.

**hydrostatic skeleton** A skeletal system composed of fluid held under pressure in a closed body compartment; the main skeleton of most cnidarians, flatworms, nematodes, and annelids.

**hydroxide ion** A water molecule that has lost a proton; OH<sup>-</sup>.

**hydroxyl group** (hī-drok'-sil) A chemical group consisting of an oxygen atom joined to a hydrogen atom. Molecules possessing

this group are soluble in water and are called alcohols.

**hymen** A thin membrane that partly covers the vaginal opening in the human female. The hymen is ruptured by sexual intercourse or other vigorous activity.

**hyperpolarization** A change in a cell's membrane potential such that the inside of the membrane becomes more negative relative to the outside. Hyperpolarization reduces the chance that a neuron will transmit a nerve impulse.

**hypersensitive response** A plant's localized defense response to a pathogen, involving the death of cells around the site of infection.

**hypertension** A disorder in which blood pressure remains abnormally high.

**hypertonic** Referring to a solution that, when surrounding a cell, will cause the cell to lose water.

**hypha** (plural, **hyphae**) (hī'-fuh, hī'-fē) One of many connected filaments that collectively make up the mycelium of a fungus.

**hypocotyl** (hī'-puh-cot'-ul) In an angiosperm embryo, the embryonic axis below the point of attachment of the cotyledon(s) and above the radicle.

**hypothalamus** (hī'-pō-thal'-uh-mus) The ventral part of the vertebrate forebrain; functions in maintaining homeostasis, especially in coordinating the endocrine and nervous systems; secretes hormones of the posterior pituitary and releasing factors that regulate the anterior pituitary.

**hypothesis** (hī-poth'-uh-sis) A testable explanation for a set of observations based on the available data and guided by inductive reasoning. A hypothesis is narrower in scope than a theory.

**hypotonic** Referring to a solution that, when surrounding a cell, will cause the cell to take up water.

**imbibition** The physical adsorption of water onto the internal surfaces of structures.

**immigration** The influx of new individuals into a population from other areas.

**immune system** An animal body's system of defenses against agents that cause disease.

**immunization** The process of generating a state of immunity by artificial means. In active immunization, also called vaccination, an inactive or weakened form of a pathogen is administered, inducing B and T cell responses and immunological memory. In passive immunization, antibodies specific for a particular microbe are administered, conferring immediate but temporary protection.

**immunoglobulin (Ig)** (im'-yū-nō-glob'-yū-lin) See antibody.

**imprinting** In animal behavior, the formation at a specific stage in life of a long-lasting behavioral response to a specific individual or object.

**in situ hybridization** A technique using nucleic acid hybridization with a labeled probe to detect the location of a specific mRNA in an intact organism.

**in vitro fertilization (IVF)** (vē'-trō) Fertilization of oocytes in laboratory containers followed by artificial implantation of the early embryo in the mother's uterus.

**inclusive fitness** The total effect an individual has on proliferating its genes by producing its own offspring and by providing aid that enables other close relatives to increase production of their offspring.

**incomplete dominance** The situation in which the phenotype of heterozygotes is intermediate between the phenotypes of individuals homozygous for either allele.

**incomplete flower** A flower in which one or more of the four basic floral organs (sepals, petals, stamens, or carpels) are either absent or nonfunctional.

**independent variable** A variable whose value is manipulated or changed during an experiment to reveal possible effects on another variable (the dependent variable).

**indeterminate growth** A type of growth characteristic of plants, in which the organism continues to grow as long as it lives.

**induced fit** Caused by entry of the substrate, the change in shape of the active site of an enzyme so that it binds more snugly to the substrate.

**inducer** A specific small molecule that binds to a bacterial repressor protein and changes the repressor's shape so that it cannot bind to an operator, thus switching an operon on.

**induction** The process in which one group of embryonic cells influences the development of another, usually by causing changes in gene expression.

**inductive reasoning** A type of logic in which generalizations are based on a large number of specific observations.

**inflammatory response** An innate immune defense triggered by physical injury or infection of tissue involving the release of substances that promote swelling, enhance the infiltration of white blood cells, and aid in tissue repair and destruction of invading pathogens.

**inflorescence** A group of flowers tightly clustered together.

**ingestion** The first stage of food processing in animals: the act of eating.

**ingroup** A species or group of species whose evolutionary relationships are being examined in a given analysis.

**inhibitory postsynaptic potential (IPSP)** An electrical change (usually hyperpolarization) in the membrane of a postsynaptic neuron caused by the binding of an inhibitory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more difficult for a postsynaptic neuron to generate an action potential.

**innate behavior** Animal behavior that is developmentally fixed and under strong

genetic control. Innate behavior is exhibited in virtually the same form by all individuals in a population despite internal and external environmental differences during development and throughout their lifetimes.

**innate immunity** A form of defense common to all animals that is active immediately upon exposure to pathogens and that is the same whether or not the pathogen has been encountered previously.

**inner ear** One of three main regions of the vertebrate ear; includes the cochlea (which in turn contains the organ of Corti) and the semicircular canals.

**inquiry** The search for information and explanation, often focusing on specific questions.

**insertion** A mutation involving the addition of one or more nucleotide pairs to a gene.

**insulin** (in'-suh-lin) A hormone secreted by pancreatic beta cells that lowers blood glucose levels. It promotes the uptake of glucose by most body cells and the synthesis and storage of glycogen in the liver.

**integral protein** A transmembrane protein with hydrophobic regions that extend into and often completely span the hydrophobic interior of the membrane and with hydrophilic regions in contact with the aqueous solution on one or both sides of the membrane (or lining the channel in the case of a channel protein).

**integrin** In animal cells, a transmembrane receptor protein with two subunits that interconnects the extracellular matrix and the cytoskeleton.

**integument** (in-teg'-yū-ment) Layer of sporophyte tissue that contributes to the structure of an ovule of a seed plant.

**intercalated disk** (in-ter'-kuh-lā'-ted) A specialized junction between cardiac muscle cells that provides direct electrical coupling between the cells.

**interferon** (in'-ter-fēr'-on) A protein that has antiviral or immune regulatory functions. Interferon- $\alpha$  and interferon- $\beta$ , secreted by virus-infected cells, help nearby cells resist viral infection; interferon- $\gamma$ , secreted by T cells, helps activate macrophages.

**intermediate disturbance hypothesis** The concept that moderate levels of disturbance can foster greater species diversity than low or high levels of disturbance.

**intermediate filament** A component of the cytoskeleton that includes filaments intermediate in size between microtubules and microfilaments.

**internal fertilization** The fusion of eggs and sperm within the female reproductive tract. The sperm are typically deposited in or near the tract.

**interneuron** An association neuron; a nerve cell within the central nervous system that forms synapses with sensory and/or motor neurons and integrates sensory input and motor output.

**internode** A segment of a plant stem between the points where leaves are attached.

**interphase** The period in the cell cycle when the cell is not dividing. During interphase, cellular metabolic activity is high, chromosomes and organelles are duplicated, and cell size may increase. Interphase often accounts for about 90% of the cell cycle.

**interspecific competition** Competition for resources between individuals of two or more species when resources are in short supply.

**interspecific interaction** A relationship between individuals of two or more species in a community.

**interstitial fluid** The fluid filling the spaces between cells in most animals.

**intertidal zone** The shallow zone of the ocean adjacent to land and between the high- and low-tide lines.

**introduced species** A species moved by humans, either intentionally or accidentally, from its native location to a new geographic region; also called a non-native or exotic species.

**intron** (in'-tron) A noncoding, intervening sequence within a primary transcript that is removed from the transcript during RNA processing; also refers to the region of DNA from which this sequence was transcribed.

**invasive species** A species, often introduced by humans, that takes hold outside its native range.

**inversion** An aberration in chromosome structure resulting from reattachment of a chromosomal fragment in a reverse orientation to the chromosome from which it originated.

**invertebrate** An animal without a backbone. Invertebrates make up 95% of animal species.

**ion** (i'-on) An atom or group of atoms that has gained or lost one or more electrons, thus acquiring a charge.

**ion channel** A transmembrane protein channel that allows a specific ion to diffuse across the membrane down its concentration or electrochemical gradient.

**ionic bond** (i-on'-ik) A chemical bond resulting from the attraction between oppositely charged ions.

**ionic compound** A compound resulting from the formation of an ionic bond; also called a salt.

**iris** The colored part of the vertebrate eye, formed by the anterior portion of the choroid.

**isotonic** (i'-sō-ton'-ik) Referring to a solution that, when surrounding a cell, causes no net movement of water into or out of the cell.

**isotope** (i'-sō-tōp') One of several atomic forms of an element, each with the same number of protons but a different number of neutrons, thus differing in atomic mass.

**iteroparity** Reproduction in which adults produce offspring over many years; also known as repeated reproduction.

**joule (J)** A unit of energy:  $1 \text{ J} = 0.239 \text{ cal}$ ;  $1 \text{ cal} = 4.184 \text{ J}$ .

**juxtaglomerular apparatus (JGA)** (juks'-tuh-gluh-mâr'-yû-ler) A specialized tissue in nephrons that releases the enzyme renin in response to a drop in blood pressure or volume.

**juxtamedullary nephron** In mammals and birds, a nephron with a loop of Henle that extends far into the renal medulla.

**karyogamy** (kâr'-ê-og'-uh-mê) In fungi, the fusion of haploid nuclei contributed by the two parents; occurs as one stage of sexual reproduction, preceded by plasmogamy.

**karyotype** (kâr'-ê-ô-tip) A display of the chromosome pairs of a cell arranged by size and shape.

**keystone species** A species that is not necessarily abundant in a community yet exerts strong control on community structure by the nature of its ecological role or niche.

**kidney** In vertebrates, one of a pair of excretory organs where blood filtrate is formed and processed into urine.

**kilocalorie (kcal)** A thousand calories; the amount of heat energy required to raise the temperature of 1 kg of water by  $1^\circ\text{C}$ .

**kin selection** Natural selection that favors altruistic behavior by enhancing the reproductive success of relatives.

**kinetic energy** (kuh-net'-ik) The energy associated with the relative motion of objects. Moving matter can perform work by imparting motion to other matter.

**kinetochore** (kuh-net'-uh-kôr) A structure of proteins attached to the centromere that links each sister chromatid to the mitotic spindle.

**kingdom** A taxonomic category, the second broadest after domain.

**K-selection** Selection for life history traits that are sensitive to population density; also called density-dependent selection.

**labia majora** A pair of thick, fatty ridges that encloses and protects the rest of the vulva.

**labia minora** A pair of slender skin folds that surrounds the openings of the vagina and urethra.

**lacteal** (lak'-tê-ul) A tiny lymph vessel extending into the core of an intestinal villus and serving as the destination for absorbed chylomicrons.

**lactic acid fermentation** Glycolysis followed by the reduction of pyruvate to lactate, regenerating  $\text{NAD}^+$  with no release of carbon dioxide.

**lagging strand** A discontinuously synthesized DNA strand that elongates by means of Okazaki fragments, each synthesized in a  $5' \rightarrow 3'$  direction away from the replication fork.

**landscape** An area containing several different ecosystems linked by exchanges of energy, materials, and organisms.

**landscape ecology** The study of how the spatial arrangement of habitat types affects the distribution and abundance of organisms and ecosystem processes.

**large intestine** The portion of the vertebrate alimentary canal between the small intestine and the anus; functions mainly in water absorption and the formation of feces.

**larynx** (lâr'-inks) The portion of the respiratory tract containing the vocal cords; also called the voice box.

**lateral meristem** (mâr'-uh-stem) A meristem that thickens the roots and shoots of woody plants. The vascular cambium and cork cambium are lateral meristems.

**lateral root** A root that arises from the pericycle of an established root.

**lateralization** Segregation of functions in the cortex of the left and right cerebral hemispheres.

**law of conservation of mass** A physical law stating that matter can change form but cannot be created or destroyed. In a closed system, the mass of the system is constant.

**law of independent assortment** Mendel's second law, stating that each pair of alleles segregates, or assort, independently of each other pair during gamete formation; applies when genes for two characters are located on different pairs of homologous chromosomes or when they are far enough apart on the same chromosome to behave as though they are on different chromosomes.

**law of segregation** Mendel's first law, stating that the two alleles in a pair segregate (separate from each other) into different gametes during gamete formation.

**leading strand** The new complementary DNA strand synthesized continuously along the template strand toward the replication fork in the mandatory  $5' \rightarrow 3'$  direction.

**leaf** The main photosynthetic organ of vascular plants.

**leaf primordium** A finger-like projection along the flank of a shoot apical meristem, from which a leaf arises.

**learning** The modification of behavior based on specific experiences.

**lens** The structure in an eye that focuses light rays onto the photoreceptors.

**lenticel** (len'-ti-sel) A small raised area in the bark of stems and roots that enables gas exchange between living cells and the outside air.

**leukocyte** (lû'-kô-sit') A blood cell that functions in fighting infections; also called a white blood cell.

**Leydig cell** (li'-dig) A cell that produces testosterone and other androgens and is located between the seminiferous tubules of the testes.

**lichen** A mutualistic association between a fungus and a photosynthetic alga or cyanobacterium.

**life cycle** The generation-to-generation sequence of stages in the reproductive history of an organism.

**life history** The traits that affect an organism's schedule of reproduction and survival.

**life table** An age-specific summary of the survival pattern of a population.

**ligand** (lig'-und) A molecule that binds specifically to another molecule, usually a larger one.

**ligand-gated ion channel** A transmembrane protein containing a pore that opens or closes as it changes shape in response to a signaling molecule (ligand), allowing or blocking the flow of specific ions; also called an ionotropic receptor.

**light chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigen-binding site, and a constant region.

**light microscope (LM)** An optical instrument with lenses that refract (bend) visible light to magnify images of specimens.

**light reactions** The first of two major stages in photosynthesis (preceding the Calvin cycle). These reactions, which occur on the thylakoid membranes of the chloroplast or on membranes of certain prokaryotes, convert solar energy to the chemical energy of ATP and NADPH, releasing oxygen in the process.

**light-harvesting complex** A complex of proteins associated with pigment molecules (including chlorophyll *a*, chlorophyll *b*, and carotenoids) that captures light energy and transfers it to reaction-center pigments in a photosystem.

**lignin** (lig'-nin) A strong polymer embedded in the cellulose matrix of the secondary cell walls of vascular plants that provides structural support in terrestrial species.

**limiting nutrient** An element that must be added for production to increase in a particular area.

**limnetic zone** In a lake, the well-lit, open surface waters far from shore.

**linear electron flow** A route of electron flow during the light reactions of photosynthesis that involves both photosystems (I and II) and produces ATP, NADPH, and  $\text{O}_2$ . The net electron flow is from  $\text{H}_2\text{O}$  to  $\text{NADP}^+$ .

**line graph** A two-dimensional graph in which each data point is connected to the next point in the data set with a straight line.

**linkage map** A genetic map based on the frequencies of recombination between markers during crossing over of homologous chromosomes.

**linked genes** Genes located close enough together on a chromosome that they tend to be inherited together.

**lipid** (lip'-id) Any of a group of large biological molecules, including fats, phospholipids, and steroids, that mix poorly, if at all, with water.

**littoral zone** In a lake, the shallow, well-lit waters close to shore.

**liver** A large internal organ in vertebrates that performs diverse functions, such as producing bile, maintaining blood glucose level, and detoxifying poisonous chemicals in the blood.

**loam** The most fertile soil type, made up of roughly equal amounts of sand, silt, and clay.

**lobe-fin** Member of a clade of osteichthyans having rod-shaped muscular fins. The group includes coelacanths, lungfishes, and tetrapods.

**local regulator** A secreted molecule that influences cells near where it is secreted.

**locomotion** Active motion from place to place.

**locus** (plural, **loci**) (lō'-kus, lō'-sī) A specific place along the length of a chromosome where a given gene is located.

**logistic population growth** Population growth that levels off as population size approaches carrying capacity.

**long-day plant** A plant that flowers (usually in late spring or early summer) only when the light period is longer than a critical length.

**long-term memory** The ability to hold, associate, and recall information over one's lifetime.

**loop of Henle** The hairpin turn, with a descending and ascending limb, between the proximal and distal tubules of the vertebrate kidney; functions in water and salt reabsorption.

**low-density lipoprotein (LDL)** A particle in the blood made up of thousands of cholesterol molecules and other lipids bound to a protein. LDL transports cholesterol from the liver for incorporation into cell membranes.

**lung** An infolded respiratory surface of a terrestrial vertebrate, land snail, or spider that connects to the atmosphere by narrow tubes.

**luteinizing hormone (LH)** (lū'-tē-uh-nī'-zing) A tropic hormone that is produced and secreted by the anterior pituitary and that stimulates ovulation in females and androgen production in males.

**lycophyte** (li'-kuh-fit) An informal name for a member of the phylum Lycophyta, a group of seedless vascular plants that includes club mosses and their relatives.

**lymph** The colorless fluid, derived from interstitial fluid, in the lymphatic system of vertebrates

**lymph node** An organ located along a lymph vessel. Lymph nodes filter lymph and contain cells that attack viruses and bacteria.

**lymphatic system** A system of vessels and nodes, separate from the circulatory system, that returns fluid, proteins, and cells to the blood.

**lymphocyte** A type of white blood cell that mediates immune responses. The two main classes are B cells and T cells.

**lysogenic cycle** (li'-sō-jen'-ik) A type of phage replicative cycle in which the viral genome becomes incorporated into the bacterial host chromosome as a prophage, is replicated along with the chromosome, and does not kill the host.

**lysosome** (li'-suh-sōm) A membrane-enclosed sac of hydrolytic enzymes found in the cytoplasm of animal cells and some protists.

**lysozyme** (li'-sō-zīm) An enzyme that destroys bacterial cell walls; in mammals, found in sweat, tears, and saliva.

**lytic cycle** (li'-ik) A type of phage replicative cycle resulting in the release of new phages by lysis (and death) of the host cell.

**macroclimate** Large-scale patterns in climate; the climate of an entire region.

**macroevolution** Evolutionary change above the species level. Examples of macroevolutionary change include the origin of a new group of organisms through a series of speciation events and the impact of mass extinctions on the diversity of life and its subsequent recovery.

**macromolecule** A giant molecule formed by the joining of smaller molecules, usually by a dehydration reaction. Polysaccharides, proteins, and nucleic acids are macromolecules.

**macronutrient** An essential element that an organism must obtain in relatively large amounts. *See also* micronutrient.

**macrophage** (mak'-rō-fā) A phagocytic cell present in many tissues that functions in innate immunity by destroying microbes and in acquired immunity as an antigen-presenting cell.

**major histocompatibility complex (MHC) molecule** A host protein that functions in antigen presentation. Foreign MHC molecules on transplanted tissue can trigger T cell responses that may lead to rejection of the transplant.

**malignant tumor** A cancerous tumor containing cells that have significant genetic and cellular changes and are capable of invading and surviving in new sites. Malignant tumors can impair the functions of one or more organs.

**mammal** Member of the class Mammalia, amniotes that have hair and mammary glands (glands that produce milk).

**mammary gland** An exocrine gland that secretes milk to nourish the young. Mammary glands are characteristic of mammals.

**map unit** A unit of measurement of the distance between genes. One map unit is equivalent to a 1% recombination frequency.

**marine benthic zone** The ocean floor.

**marsupial** (mar-sū'-pē-ul) A mammal, such as a koala, kangaroo, or opossum,

whose young complete their embryonic development inside a maternal pouch.

**mass extinction** The elimination of a large number of species throughout Earth, the result of global environmental changes.

**mass number** The sum of the number of protons and neutrons in an atom's nucleus.

**mast cell** A vertebrate body cell that produces histamine and other molecules that trigger inflammation in response to infection and in allergic reactions.

**maternal effect gene** A gene that, when mutant in the mother, results in a mutant phenotype in the offspring, regardless of the offspring's genotype. Maternal effect genes, also called egg-polarity genes, were first identified in *Drosophila melanogaster*.

**matter** Anything that takes up space and has mass.

**maximum parsimony** A principle that states that when considering multiple explanations for an observation, one should first investigate the simplest explanation that is consistent with the facts.

**mechanoreceptor** A sensory receptor that detects physical deformation in the body's environment associated with pressure, touch, stretch, motion, or sound.

**medulla oblongata** (meh-dul'-uh ōb'-long-go'-tuh) The lowest part of the vertebrate brain, commonly called the medulla; a swelling of the hindbrain anterior to the spinal cord that controls autonomic, homeostatic functions, including breathing, heart and blood vessel activity, swallowing, digestion, and vomiting.

**megapascal (MPa)** (meg'-uh-pas-kal') A unit of pressure equivalent to about 10 atmospheres of pressure.

**megaspore** A spore from a heterosporous plant species that develops into a female gametophyte.

**meiosis** (mī-ō'-sis) A modified type of cell division in sexually reproducing organisms consisting of two rounds of cell division but only one round of DNA replication. It results in cells with half the number of chromosome sets as the original cell.

**meiosis I** The first division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the number of chromosome sets as the original cell.

**meiosis II** The second division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the number of chromosome sets as the original cell.

**membrane potential** The difference in electrical charge (voltage) across a cell's plasma membrane due to the differential distribution of ions. Membrane potential affects the activity of excitable cells and the transmembrane movement of all charged substances.

**memory cell** One of a clone of long-lived lymphocytes, formed during the primary immune response, that remains in a lymphoid organ until activated by exposure to the same antigen that triggered its formation. Activated memory cells mount the secondary immune response.

**menopause** The cessation of ovulation and menstruation, marking the end of a human female's reproductive years.

**menstrual cycle** (men'-strū-ul) In humans and certain other primates, a type of reproductive cycle in which the nonpregnant endometrium is shed through the cervix into the vagina; also called the uterine cycle.

**menstruation** The shedding of portions of the endometrium during a uterine (menstrual) cycle.

**meristem** (mār'-uh-stem) Plant tissue that remains embryonic as long as the plant lives, allowing for indeterminate growth.

**mesoderm** (mez'-ō-derm) The middle primary germ layer in a triploblastic animal embryo; develops into the notochord, the lining of the coelom, muscles, skeleton, gonads, kidneys, and most of the circulatory system in species that have these structures.

**mesophyll** (mez'-ō-fil) Leaf cells specialized for photosynthesis. In  $C_3$  and CAM plants, mesophyll cells are located between the upper and lower epidermis; in  $C_4$  plants, they are located between the bundle-sheath cells and the epidermis.

**messenger RNA (mRNA)** A type of RNA, synthesized using a DNA template, that attaches to ribosomes in the cytoplasm and specifies the primary structure of a protein. (In eukaryotes, the primary RNA transcript must undergo RNA processing to become mRNA.)

**metabolic pathway** A series of chemical reactions that either builds a complex molecule (anabolic pathway) or breaks down a complex molecule to simpler molecules (catabolic pathway).

**metabolic rate** The total amount of energy an animal uses in a unit of time.

**metabolism** (muh-tab'-uh-lizm) The totality of an organism's chemical reactions, consisting of catabolic and anabolic pathways, which manage the material and energy resources of the organism.

**metagenomics** The collection and sequencing of DNA from a group of species, usually an environmental sample of microorganisms. Computer software sorts partial sequences and assembles them into genome sequences of individual species making up the sample.

**metaphase** The third stage of mitosis, in which the spindle is complete and the chromosomes, attached to microtubules at their kinetochores, are all aligned at the metaphase plate.

**metaphase plate** An imaginary structure located at a plane midway between the two poles of a cell in metaphase on which the centromeres of all the duplicated chromosomes are located.

**metapopulation** A group of spatially separated populations of one species that interact through immigration and emigration.

**metastasis** (muh-tas'-tuh-sis) The spread of cancer cells to locations distant from their original site.

**methanogen** (meth-an'-ō-jen) An organism that produces methane as a waste product of the way it obtains energy. All known methanogens are in domain Archaea.

**methyl group** A chemical group consisting of a carbon bonded to three hydrogen atoms. The methyl group may be attached to a carbon or to a different atom.

**microevolution** Evolutionary change below the species level; change in the allele frequencies in a population over generations.

**microfilament** A cable composed of actin proteins in the cytoplasm of almost every eukaryotic cell, making up part of the cytoskeleton and acting alone or with myosin to cause cell contraction; also known as an actin filament.

**micronutrient** An essential element that an organism needs in very small amounts. *See also* macronutrient.

**microRNA (miRNA)** A small, single-stranded RNA molecule, generated from a hairpin structure on a precursor RNA transcribed from a particular gene. The miRNA associates with one or more proteins in a complex that can degrade or prevent translation of an mRNA with a complementary sequence.

**microspore** A spore from a heterosporous plant species that develops into a male gametophyte.

**microtubule** A hollow rod composed of tubulin proteins that makes up part of the cytoskeleton in all eukaryotic cells and is found in cilia and flagella.

**microvillus** (plural, **microvilli**) One of many fine, finger-like projections of the epithelial cells in the lumen of the small intestine that increase its surface area.

**midbrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into sensory integrating and relay centers that send sensory information to the cerebrum.

**middle ear** One of three main regions of the vertebrate ear; in mammals, a chamber containing three small bones (the malleus, incus, and stapes) that convey vibrations from the eardrum to the oval window.

**middle lamella** (luh-mel'-uh) In plants, a thin layer of adhesive extracellular material, primarily pectins, found between the primary walls of adjacent young cells.

**migration** A regular, long-distance change in location.

**mineral** In nutrition, a simple nutrient that is inorganic and therefore cannot be synthesized in the body.

**minimum viable population (MVP)** The smallest population size at which a species is able to sustain its numbers and survive.

**mismatch repair** The cellular process that uses specific enzymes to remove and replace incorrectly paired nucleotides.

**missense mutation** A nucleotide-pair substitution that results in a codon that codes for a different amino acid.

**mitochondrial matrix** The compartment of the mitochondrion enclosed by the inner membrane and containing enzymes and substrates for the citric acid cycle, as well as ribosomes and DNA.

**mitochondrion** (mī'-tō-kon'-drē-un) (plural, **mitochondria**) An organelle in eukaryotic cells that serves as the site of cellular respiration; uses oxygen to break down organic molecules and synthesize ATP.

**mitosis** (mī-tō'-sis) A process of nuclear division in eukaryotic cells conventionally divided into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. Mitosis conserves chromosome number by allocating replicated chromosomes equally to each of the daughter nuclei.

**mitotic (M) phase** The phase of the cell cycle that includes mitosis and cytokinesis.

**mitotic spindle** An assemblage of microtubules and associated proteins that is involved in the movement of chromosomes during mitosis.

**mixotroph** An organism that is capable of both photosynthesis and heterotrophy.

**model** A physical or conceptual representation of a natural phenomenon.

**model organism** A particular species chosen for research into broad biological principles because it is representative of a larger group and usually easy to grow in a lab.

**molarity** A common measure of solute concentration, referring to the number of moles of solute per liter of solution.

**mole (mol)** The number of grams of a substance that equals its molecular weight in daltons and contains Avogadro's number of molecules.

**molecular clock** A method for estimating the time required for a given amount of evolutionary change, based on the observation that some regions of genomes evolve at constant rates.

**molecular mass** The sum of the masses of all the atoms in a molecule; sometimes called molecular weight.

**molecule** Two or more atoms held together by covalent bonds.

**monilophyte** An informal name for a member of the phylum Monilophyta, a group of

seedless vascular plants that includes ferns and their relatives.

**monoclonal antibody** (mon'-ō-klōn'-ul) Any of a preparation of antibodies that have been produced by a single clone of cultured cells and thus are all specific for the same epitope.

**monogamous** (muh-nog'-uh-mus) Referring to a type of relationship in which one male mates with just one female.

**monohybrid** An organism that is heterozygous with respect to a single gene of interest. All the offspring from a cross between parents homozygous for different alleles are monohybrids. For example, parents of genotypes *AA* and *aa* produce a monohybrid of genotype *Aa*.

**monohybrid cross** A cross between two organisms that are heterozygous for the character being followed (or the self-pollination of a heterozygous plant).

**monomer** (mon'-uh-mer) The subunit that serves as the building block of a polymer.

**monophyletic** (mon'-ō-fi-let'-ik) Pertaining to a group of taxa that consists of a common ancestor and all of its descendants. A monophyletic taxon is equivalent to a clade.

**monosaccharide** (mon'-ō-sak'-uh-rīd) The simplest carbohydrate, active alone or serving as a monomer for disaccharides and polysaccharides. Also known as simple sugars, monosaccharides have molecular formulas that are generally some multiple of  $\text{CH}_2\text{O}$ .

**monosomic** Referring to a diploid cell that has only one copy of a particular chromosome instead of the normal two.

**monotreme** An egg-laying mammal, such as a platypus or echidna. Like all mammals, monotremes have hair and produce milk, but they lack nipples.

**morphogen** A substance, such as Bicoid protein in *Drosophila*, that provides positional information in the form of a concentration gradient along an embryonic axis.

**morphogenesis** (mōr'-fō-jen'-uh-sis) The development of the form of an organism and its structures.

**morphological species concept** Definition of a species in terms of measurable anatomical criteria.

**motor neuron** A nerve cell that transmits signals from the brain or spinal cord to muscles or glands.

**motor protein** A protein that interacts with cytoskeletal elements and other cell components, producing movement of the whole cell or parts of the cell.

**motor system** An efferent branch of the vertebrate peripheral nervous system composed of motor neurons that carry signals to skeletal muscles in response to external stimuli.

**motor unit** A single motor neuron and all the muscle fibers it controls.

**movement corridor** A series of small clumps or a narrow strip of quality habitat (usable by organisms) that connects otherwise isolated patches of quality habitat.

**mucus** A viscous and slippery mixture of glycoproteins, cells, salts, and water that moistens and protects the membranes lining body cavities that open to the exterior.

**Müllerian mimicry** (myū-lār'-ē-un) Reciprocal mimicry by two unpalatable species.

**multifactorial** Referring to a phenotypic character that is influenced by multiple genes and environmental factors.

**multigene family** A collection of genes with similar or identical sequences, presumably of common origin.

**multiple fruit** A fruit derived from an entire inflorescence.

**multiplication rule** A rule of probability stating that the probability of two or more independent events occurring together can be determined by multiplying their individual probabilities.

**muscle tissue** Tissue consisting of long muscle cells that can contract, either on its own or when stimulated by nerve impulses.

**mutagen** (myū'-tuh-jen) A chemical or physical agent that interacts with DNA and can cause a mutation.

**mutation** (myū-tā'-shun) A change in the nucleotide sequence of an organism's DNA or in the DNA or RNA of a virus.

**mutualism** (myū'-chū-ul-izm) A symbiotic relationship in which both participants benefit.

**mycelium** (mī-sē'-lē-um) The densely branched network of hyphae in a fungus.

**mycorrhiza** (plural, **mycorrhizae**) (mī'-kō-rī'-zuh, mī'-kō-rī'-zē) A mutualistic association of plant roots and fungus.

**myelin sheath** (mī'-uh-lin) Wrapped around the axon of a neuron, an insulating coat of cell membranes from Schwann cells or oligodendrocytes. It is interrupted by nodes of Ranvier, where action potentials are generated.

**myofibril** (mī'-ō-fi'-bril) A longitudinal bundle in a muscle cell (fiber) that contains thin filaments of actin and regulatory proteins and thick filaments of myosin.

**myoglobin** (mī'-uh-glō'-bin) An oxygen-storing, pigmented protein in muscle cells.

**myosin** (mī'-uh-sin) A type of motor protein that associates into filaments that interact with actin filaments, causing cell contraction.

**NAD<sup>+</sup>** Nicotinamide adenine dinucleotide, a coenzyme that cycles easily between oxidized ( $\text{NAD}^+$ ) and reduced ( $\text{NADH}$ ) states, thus acting as an electron carrier.

**NADP<sup>+</sup>** Nicotinamide adenine dinucleotide phosphate, an electron acceptor that, as  $\text{NADPH}$ , temporarily stores energized electrons produced during the light reactions.

**natural killer cell** A type of white blood cell that can kill tumor cells and virus-infected cells as part of innate immunity.

**natural selection** A process in which individuals that have certain inherited traits tend to survive and reproduce at higher rates than other individuals *because of* those traits.

**negative feedback** A form of regulation in which accumulation of an end product of a process slows the process; in physiology, a primary mechanism of homeostasis, whereby a change in a variable triggers a response that counteracts the initial change.

**negative pressure breathing** A breathing system in which air is pulled into the lungs.

**nephron** (nef'-ron) The tubular excretory unit of the vertebrate kidney.

**nerve** A fiber composed primarily of the bundled axons of neurons.

**nerve net** A weblike system of neurons, characteristic of radially symmetric animals, such as hydras.

**nervous system** The fast-acting internal system of communication involving sensory receptors, networks of nerve cells, and connections to muscles and glands that respond to nerve signals; functions in concert with the endocrine system to effect internal regulation and maintain homeostasis.

**nervous tissue** Tissue made up of neurons and supportive cells.

**net ecosystem production (NEP)** The gross primary production of an ecosystem minus the energy used by all autotrophs and heterotrophs for respiration.

**net primary production (NPP)** The gross primary production of an ecosystem minus the energy used by the producers for respiration.

**neural plasticity** The capacity of a nervous system to change with experience.

**neuron** (nyūr'-on) A nerve cell; the fundamental unit of the nervous system, having structure and properties that allow it to conduct signals by taking advantage of the electrical charge across its plasma membrane.

**neuropeptide** A relatively short chain of amino acids that serves as a neurotransmitter.

**neurotransmitter** A molecule that is released from the synaptic terminal of a neuron at a chemical synapse, diffuses across the synaptic cleft, and binds to the postsynaptic cell, triggering a response.

**neutral variation** Genetic variation that does not provide a selective advantage or disadvantage.

**neutron** A subatomic particle having no electrical charge (electrically neutral), with a mass of about  $1.7 \times 10^{-24}$  g, found in the nucleus of an atom.

**neutrophil** The most abundant type of white blood cell. Neutrophils are phagocytic and tend to self-destruct as they destroy foreign

invaders, limiting their life span to a few days.

**nitrogen cycle** The natural process by which nitrogen, either from the atmosphere or from decomposed organic material, is converted by soil bacteria to compounds assimilated by plants. This incorporated nitrogen is then taken in by other organisms and subsequently released, acted on by bacteria, and made available again to the nonliving environment.

**nitrogen fixation** The conversion of atmospheric nitrogen ( $N_2$ ) to ammonia ( $NH_3$ ). Biological nitrogen fixation is carried out by certain prokaryotes, some of which have mutualistic relationships with plants.

**nociceptor** (nô'-si-sep'-tur) A sensory receptor that responds to noxious or painful stimuli; also called a pain receptor.

**node** A point along the stem of a plant at which leaves are attached.

**node of Ranvier** (ron'-vê-ã') Gap in the myelin sheath of certain axons where an action potential may be generated. In saltatory conduction, an action potential is regenerated at each node, appearing to "jump" along the axon from node to node.

**nodule** A swelling on the root of a legume. Nodules are composed of plant cells that contain nitrogen-fixing bacteria of the genus *Rhizobium*.

**noncompetitive inhibitor** A substance that reduces the activity of an enzyme by binding to a location remote from the active site, changing the enzyme's shape so that the active site no longer effectively catalyzes the conversion of substrate to product.

**nondisjunction** An error in meiosis or mitosis in which members of a pair of homologous chromosomes or sister chromatids fail to separate properly from each other.

**nonequilibrium model** A model that maintains that communities change constantly after being buffeted by disturbances.

**nonpolar covalent bond** A type of covalent bond in which electrons are shared equally between two atoms of similar electronegativity.

**nonsense mutation** A mutation that changes an amino acid codon to one of the three stop codons, resulting in a shorter and usually nonfunctional protein.

**norepinephrine** A catecholamine that is chemically and functionally similar to epinephrine and that acts as a hormone or neurotransmitter; also known as noradrenaline.

**northern coniferous forest** A terrestrial biome characterized by long, cold winters and dominated by cone-bearing trees.

**notochord** (nô'-tuh-kord') A longitudinal, flexible rod that runs along the anterior-posterior axis of a chordate in the dorsal part of the body.

**nuclear envelope** In a eukaryotic cell, the double membrane that surrounds the

nucleus, perforated with pores that regulate traffic with the cytoplasm. The outer membrane is continuous with the endoplasmic reticulum.

**nuclear lamina** A netlike array of protein filaments that lines the inner surface of the nuclear envelope and helps maintain the shape of the nucleus.

**nuclearioid** Member of a group of unicellular, amoeboid protists that are more closely related to fungi than they are to other protists.

**nuclease** An enzyme that cuts DNA or RNA, either removing one or a few bases or hydrolyzing the DNA or RNA completely into its component nucleotides.

**nucleic acid** (nū-klā'-ik) A polymer (polynucleotide) consisting of many nucleotide monomers; serves as a blueprint for proteins and, through the actions of proteins, for all cellular activities. The two types are DNA and RNA.

**nucleic acid hybridization** The process of base pairing between a gene and a complementary sequence on another nucleic acid molecule.

**nucleic acid probe** In DNA technology, a labeled single-stranded nucleic acid molecule used to locate a specific nucleotide sequence in a nucleic acid sample. Molecules of the probe hydrogen-bond to the complementary sequence wherever it occurs; radioactive, fluorescent, or other labeling of the probe allows its location to be detected.

**nucleoid** (nū'-klē-oyd) A non-membrane-enclosed region in a prokaryotic cell where its chromosome is located.

**nucleolus** (nū-klē'-ō-lus) (plural, **nucleoli**) A specialized structure in the nucleus consisting of chromosomal regions containing ribosomal RNA (rRNA) genes along with ribosomal proteins imported from the cytoplasm; site of rRNA synthesis and ribosomal subunit assembly. *See also* ribosome.

**nucleosome** (nū'-klē-ō-sōm') The basic, bead-like unit of DNA packing in eukaryotes, consisting of a segment of DNA wound around a protein core composed of two copies of each of four types of histone.

**nucleotide** (nū'-klē-ō-tid') The building block of a nucleic acid, consisting of a five-carbon sugar covalently bonded to a nitrogenous base and one or more phosphate groups.

**nucleotide excision repair** A repair system that removes and then correctly replaces a damaged segment of DNA using the undamaged strand as a guide.

**nucleotide-pair substitution** A type of point mutation in which one nucleotide in a DNA strand and its partner in the complementary strand are replaced by another pair of nucleotides.

**nucleus** (1) An atom's central core, containing protons and neutrons. (2) The organelle of a eukaryotic cell that contains the genetic ma-

terial in the form of chromosomes, made up of chromatin. (3) A cluster of neurons.

**nutrition** The process by which an organism takes in and makes use of food substances.

**obligate anaerobe** (ob'-lig-et an'-uh-rōb) An organism that only carries out fermentation or anaerobic respiration. Such organisms cannot use oxygen and in fact may be poisoned by it.

**oceanic pelagic zone** Most of the ocean's waters far from shore, constantly mixed by ocean currents.

**odorant** A molecule that can be detected by sensory receptors of the olfactory system.

**Okazaki fragment** (ō'-kah-zah'-kē) A short segment of DNA synthesized away from the replication fork on a template strand during DNA replication. Many such segments are joined together to make up the lagging strand of newly synthesized DNA.

**olfaction** The sense of smell.

**oligodendrocyte** A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the central nervous system.

**oligotrophic lake** A nutrient-poor, clear lake with few phytoplankton.

**ommatidium** (ōm'-uh-tid'-ē-um) (plural, **ommatidia**) One of the facets of the compound eye of arthropods and some polychaete worms.

**omnivore** An animal that regularly eats animals as well as plants or algae.

**oncogene** (on'-kō-jēn) A gene found in viral or cellular genomes that is involved in triggering molecular events that can lead to cancer.

**oocyte** A cell in the female reproductive system that differentiates to form an egg.

**oogenesis** (ō'-uh-jen'-uh-sis) The process in the ovary that results in the production of female gametes.

**oogonium** (ō'-uh-gō'-nē-em) (plural, **oogonia**) A cell that divides mitotically to form oocytes.

**open circulatory system** A circulatory system in which fluid called hemolymph bathes the tissues and organs directly and there is no distinction between the circulating fluid and the interstitial fluid.

**operator** In bacterial and phage DNA, a sequence of nucleotides near the start of an operon to which an active repressor can attach. The binding of the repressor prevents RNA polymerase from attaching to the promoter and transcribing the genes of the operon.

**operon** (op'-er-on) A unit of genetic function found in bacteria and phages, consisting of a promoter, an operator, and a coordinately regulated cluster of genes whose products function in a common pathway.

**opisthokont** (uh-pis'-thuh-kont') Member of an extremely diverse clade of eukaryotes

that includes fungi, animals, and several closely-related groups of protists.

**opsin** A membrane protein bound to a light-absorbing pigment molecule.

**oral cavity** The mouth of an animal.

**order** In Linnaean classification, the taxonomic category above the level of family.

**organ** A specialized center of body function composed of several different types of tissues.

**organ of Corti** The actual hearing organ of the vertebrate ear, located in the floor of the cochlear duct in the inner ear; contains the receptor cells (hair cells) of the ear.

**organ system** A group of organs that work together in performing vital body functions.

**organelle** (ôr-guh-nel') Any of several kinds of membrane-enclosed structures with specialized functions, suspended in the cytosol of eukaryotic cells.

**organic compound** A chemical compound containing carbon.

**organismal ecology** The branch of ecology concerned with the morphological, physiological, and behavioral ways in which individual organisms meet the challenges posed by their biotic and abiotic environments.

**organogenesis** (ôr-gan'-ô-jen'-uh-sis) The process in which organ rudiments develop from the three germ layers after gastrulation.

**origin of replication** Site where the replication of a DNA molecule begins, consisting of a specific sequence of nucleotides.

**osmoconformer** An animal that is isoosmotic with its environment.

**osmolarity** (oz'-mô-lâr'-uh-tê) Solute concentration expressed as molarity.

**osmoregulation** Regulation of solute concentrations and water balance by a cell or organism.

**osmoregulator** An animal that controls its internal osmolarity independent of the external environment.

**osmosis** (oz-mô'-sis) The diffusion of free water molecules across a selectively permeable membrane.

**osteichthyan** (os'-tê-ik'-thê-an) Member of a vertebrate clade with jaws and mostly bony skeletons.

**outer ear** One of three main regions of the ear in reptiles (including birds) and mammals; made up of the auditory canal and, in many birds and mammals, the pinna.

**outgroup** A species or group of species from an evolutionary lineage that is known to have diverged before the lineage that contains the group of species being studied. An outgroup is selected so that its members are closely related to the group of species being studied, but not as closely related as any study-group members are to each other.

**oval window** In the vertebrate ear, a membrane-covered gap in the skull bone,

through which sound waves pass from the middle ear to the inner ear.

**ovarian cycle** (ô-vâr'-ê-un) The cyclic recurrence of the follicular phase, ovulation, and the luteal phase in the mammalian ovary, regulated by hormones.

**ovary** (ô'-vuh-rê) (1) In flowers, the portion of a carpel in which the egg-containing ovules develop. (2) In animals, the structure that produces female gametes and reproductive hormones.

**oviduct** (ô'-vuh-duct) A tube passing from the ovary to the vagina in invertebrates or to the uterus in vertebrates, where it is also known as a fallopian tube.

**ovulation** The release of an egg from an ovary. In humans, an ovarian follicle releases an egg during each uterine (menstrual) cycle.

**ovule** (ô'-vyûl) A structure that develops within the ovary of a seed plant and contains the female gametophyte.

**oxidation** The complete or partial loss of electrons from a substance involved in a redox reaction.

**oxidative phosphorylation** (fos'-fôr-uh-lâ'-shun) The production of ATP using energy derived from the redox reactions of an electron transport chain; the third major stage of cellular respiration.

**oxidizing agent** The electron acceptor in a redox reaction.

**oxytocin** (ok'-si-tô'-sen) A hormone produced by the hypothalamus and released from the posterior pituitary. It induces contractions of the uterine muscles during labor and causes the mammary glands to eject milk during nursing.

**P generation** The true-breeding (homozygous) parent individuals from which F<sub>1</sub> hybrid offspring are derived in studies of inheritance; P stands for "parental."

**P site** One of a ribosome's three binding sites for tRNA during translation. The P site holds the tRNA carrying the growing polypeptide chain. (P stands for peptidyl tRNA.)

**p53 gene** A tumor-suppressor gene that codes for a specific transcription factor that promotes the synthesis of proteins that inhibit the cell cycle.

**paedomorphosis** (pê'-duh-môr'-fuh-sis) The retention in an adult organism of the juvenile features of its evolutionary ancestors.

**pain receptor** A sensory receptor that responds to noxious or painful stimuli; also called a nociceptor.

**paleontology** (pâ'-lê-un-tol'-ô-jê) The scientific study of fossils.

**pancreas** (pan'-krê-us) A gland with exocrine and endocrine tissues. The exocrine portion functions in digestion, secreting enzymes and an alkaline solution into the small intestine via a duct; the ductless endocrine portion functions in homeostasis, secreting the hormones insulin and glucagon into the blood.

**pandemic** A global epidemic.

**Pangaea** (pan-jê'-uh) The supercontinent that formed near the end of the Paleozoic era, when plate movements brought all the landmasses of Earth together.

**parabasalid** A protist, such as a trichomonad, with modified mitochondria.

**paraphyletic** (pâr'-uh-fi-lê'-ik) Pertaining to a group of taxa that consists of a common ancestor and some, but not all, of its descendants.

**parasite** (pâr'-uh-sit) An organism that feeds on the cell contents, tissues, or body fluids of another species (the host) while in or on the host organism. Parasites harm but usually do not kill their host.

**parasitism** (pâr'-uh-sit-izm) A symbiotic relationship in which one organism, the parasite, benefits at the expense of another, the host, by living either within or on the host.

**parasympathetic division** One of three divisions of the autonomic nervous system; generally enhances body activities that gain and conserve energy, such as digestion and reduced heart rate.

**parenchyma cell** (puh-ren'-ki-muh) A relatively unspecialized plant cell type that carries out most of the metabolism, synthesizes and stores organic products, and develops into a more differentiated cell type.

**parental type** An offspring with a phenotype that matches one of the true-breeding parental (P generation) phenotypes; also refers to the phenotype itself.

**parthenogenesis** (par'-thuh-nô'-jen'-uh-sis) A form of asexual reproduction in which females produce offspring from unfertilized eggs.

**partial pressure** The pressure exerted by a particular gas in a mixture of gases (for instance, the pressure exerted by oxygen in air).

**passive immunity** Short-term immunity conferred by the transfer of antibodies, as occurs in the transfer of maternal antibodies to a fetus or nursing infant.

**passive transport** The diffusion of a substance across a biological membrane with no expenditure of energy.

**pathogen** An organism or virus that causes disease.

**pattern formation** The development of a multicellular organism's spatial organization, the arrangement of organs and tissues in their characteristic places in three-dimensional space.

**PCR** See polymerase chain reaction.

**pedigree** A diagram of a family tree with conventional symbols, showing the occurrence of heritable characters in parents and offspring over multiple generations.

**pelagic zone** The open-water component of aquatic biomes.

**penis** The copulatory structure of male mammals.

**pepsin** An enzyme present in gastric juice that begins the hydrolysis of proteins. Pepsin is synthesized as an inactive precursor form, pepsinogen.

**peptide bond** The covalent bond between the carboxyl group on one amino acid and the amino group on another, formed by a dehydration reaction.

**peptidoglycan** (pep'-tid-ō-gli'-kan) A type of polymer in bacterial cell walls consisting of modified sugars cross-linked by short polypeptides.

**perception** The interpretation of sensory system input by the brain.

**pericycle** The outermost layer in the vascular cylinder, from which lateral roots arise.

**periderm** (pār'-uh-derm') The protective coat that replaces the epidermis in woody plants during secondary growth, formed of the cork and cork cambium.

**peripheral nervous system (PNS)** The sensory and motor neurons that connect to the central nervous system.

**peripheral protein** A protein loosely bound to the surface of a membrane or to part of an integral protein and not embedded in the lipid bilayer.

**peristalsis** (pār'-uh-stal'-sis) (1) Alternating waves of contraction and relaxation in the smooth muscles lining the alimentary canal that push food along the canal. (2) A type of movement on land produced by rhythmic waves of muscle contractions passing from front to back, as in many annelids.

**peritubular capillary** One of the tiny blood vessels that form a network surrounding the proximal and distal tubules in the kidney.

**peroxisome** (puh-rok'-suh-sōm') An organelle containing enzymes that transfer hydrogen atoms from various substrates to oxygen (O<sub>2</sub>), producing and then degrading hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>).

**petal** A modified leaf of a flowering plant. Petals are the often colorful parts of a flower that advertise it to insects and other pollinators.

**petiole** (pet'-ē-ōl) The stalk of a leaf, which joins the leaf to a node of the stem.

**pH** A measure of hydrogen ion concentration equal to  $-\log [H^+]$  and ranging in value from 0 to 14.

**phage** (faj) A virus that infects bacteria; also called a bacteriophage.

**phagocytosis** (fag'-ō-si-tō'-sis) A type of endocytosis in which large particulate substances or small organisms are taken up by a cell. It is carried out by some protists and by certain immune cells of animals (in mammals, mainly macrophages, neutrophils, and dendritic cells).

**pharyngeal cleft** (fuh-rin'-jē-ul) In chordate embryos, one of the grooves that separate a series of pouches along the sides of the pharynx and may develop into a pharyngeal slit.

**pharyngeal slit** (fuh-rin'-jē-ul) In chordate embryos, one of the slits that form from the pharyngeal clefts and communicate to the outside, later developing into gill slits in many vertebrates.

**pharynx** (fār'-inks) (1) An area in the vertebrate throat where air and food passages cross. (2) In flatworms, the muscular tube that protrudes from the ventral side of the worm and ends in the mouth.

**phenotype** (fē'-nō-tip) The observable physical and physiological traits of an organism, which are determined by its genetic makeup.

**pheromone** (fār'-uh-mōn) In animals and fungi, a small molecule released into the environment that functions in communication between members of the same species. In animals, it acts much like a hormone in influencing physiology and behavior.

**phloem** (flō'-em) Vascular plant tissue consisting of living cells arranged into elongated tubes that transport sugar and other organic nutrients throughout the plant.

**phloem sap** The sugar-rich solution carried through a plant's sieve tubes.

**phosphate group** A chemical group consisting of a phosphorus atom bonded to four oxygen atoms; important in energy transfer.

**phospholipid** (fos'-fō-lip'-id) A lipid made up of glycerol joined to two fatty acids and a phosphate group. The hydrocarbon chains of the fatty acids act as nonpolar, hydrophobic tails, while the rest of the molecule acts as a polar, hydrophilic head. Phospholipids form bilayers that function as biological membranes.

**phosphorylated intermediate** A molecule (often a reactant) with a phosphate group covalently bound to it, making it more reactive (less stable) than the unphosphorylated molecule.

**photic zone** (fō'-tic) The narrow top layer of an ocean or lake, where light penetrates sufficiently for photosynthesis to occur.

**photomorphogenesis** Effects of light on plant morphology.

**photon** (fō'-ton) A quantum, or discrete quantity, of light energy that behaves as if it were a particle.

**photoperiodism** (fō'-tō-pēr'-ē-ō-dizm) A physiological response to photoperiod, the relative lengths of night and day. An example of photoperiodism is flowering.

**photophosphorylation** (fō'-tō-fos'-fōr-uh-lā'-shun) The process of generating ATP from ADP and phosphate by means of chemiosmosis, using a proton-motive force generated across the thylakoid membrane of the chloroplast or the membrane of certain prokaryotes during the light reactions of photosynthesis.

**photoreceptor** An electromagnetic receptor that detects the radiation known as visible light.

**photorespiration** A metabolic pathway that consumes oxygen and ATP, releases carbon dioxide, and decreases photosynthetic output. Photorespiration generally occurs on hot, dry, bright days, when stomata close and the O<sub>2</sub>/CO<sub>2</sub> ratio in the leaf increases, favoring the binding of O<sub>2</sub> rather than CO<sub>2</sub> by rubisco.

**photosynthesis** (fō'-tō-sin'-thi-sis) The conversion of light energy to chemical energy that is stored in sugars or other organic compounds; occurs in plants, algae, and certain prokaryotes.

**photosystem** A light-capturing unit located in the thylakoid membrane of the chloroplast or in the membrane of some prokaryotes, consisting of a reaction-center complex surrounded by numerous light-harvesting complexes. There are two types of photosystems, I and II; they absorb light best at different wavelengths.

**photosystem I (PS I)** One of two light-capturing units in a chloroplast's thylakoid membrane or in the membrane of some prokaryotes; it has two molecules of P700 chlorophyll *a* at its reaction center.

**photosystem II (PS II)** One of two light-capturing units in a chloroplast's thylakoid membrane or in the membrane of some prokaryotes; it has two molecules of P680 chlorophyll *a* at its reaction center.

**phototropism** (fō'-tō-trō'-pizm) Growth of a plant shoot toward or away from light.

**phyllotaxy** (fil'-uh-tak'-sē) The pattern of leaf attachment to the stem of a plant.

**phylogenetic species concept** Definition of a species as the smallest group of individuals that share a common ancestor, forming one branch on the tree of life.

**phylogenetic tree** A branching diagram that represents a hypothesis about the evolutionary history of a group of organisms.

**phylogeny** (fī-loj'-uh-nē) The evolutionary history of a species or group of related species.

**phylum** (fī'-lum) (plural, **phyla**) In Linnaean classification, the taxonomic category above class.

**physiology** The processes and functions of an organism.

**phytochrome** (fī'-tuh-krōm) A type of light receptor in plants that mostly absorbs red light and regulates many plant responses, such as seed germination and shade avoidance.

**pilus** (plural, **pili**) (pi'-lus, pi'-li) In bacteria, a structure that links one cell to another at the start of conjugation; also known as a sex pilus or conjugation pilus.

**pinocytosis** (pi'-nō-sī-tō'-sis) A type of endocytosis in which the cell ingests extracellular fluid and its dissolved solutes.

**pistil** A single carpel or a group of fused carpels.

**pith** Ground tissue that is internal to the vascular tissue in a stem; in many monocot

- roots, parenchyma cells that form the central core of the vascular cylinder.
- pituitary gland** (puh-tū'-uh-tār'-ē) An endocrine gland at the base of the hypothalamus; consists of a posterior lobe, which stores and releases two hormones produced by the hypothalamus, and an anterior lobe, which produces and secretes many hormones that regulate diverse body functions.
- placenta** (pluh-sen'-tuh) A structure in the pregnant uterus for nourishing a viviparous fetus with the mother's blood supply; formed from the uterine lining and embryonic membranes.
- plasma** (plaz'-muh) The liquid matrix of blood in which the blood cells are suspended.
- plasma cell** The antibody-secreting effector cell of humoral immunity. Plasma cells arise from antigen-stimulated B cells.
- plasma membrane** The membrane at the boundary of every cell that acts as a selective barrier, regulating the cell's chemical composition.
- plasmid** (plaz'-mid) A small, circular, double-stranded DNA molecule that carries accessory genes separate from those of a bacterial chromosome; in DNA cloning, can be used as a vector carrying up to about 10,000 base pairs (10 kb) of DNA.
- plasmodesma** (plaz'-mō-dez'-muh) (plural, **plasmodesmata**) An open channel through the cell wall that connects the cytoplasm of adjacent plant cells, allowing water, small solutes, and some larger molecules to pass between the cells.
- plasmogamy** (plaz-moh'-guh-mē) In fungi, the fusion of the cytoplasm of cells from two individuals; occurs as one stage of sexual reproduction, followed later by karyogamy.
- plasmolysis** (plaz-mol'-uh-sis) A phenomenon in walled cells in which the cytoplasm shrivels and the plasma membrane pulls away from the cell wall; occurs when the cell loses water to a hypertonic environment.
- plastid** One of a family of closely related organelles that includes chloroplasts, chromoplasts, and amyloplasts. Plastids are found in the cells of photosynthetic eukaryotes.
- plate tectonics** The theory that the continents are part of great plates of Earth's crust that float on the hot, underlying portion of the mantle. Movements in the mantle cause the continents to move slowly over time.
- platelet** A pinched-off cytoplasmic fragment of a specialized bone marrow cell. Platelets circulate in the blood and are important in blood clotting.
- pleiotropy** (pli'-o-truh-pē) The ability of a single gene to have multiple effects.
- pluripotent** Describing a cell that can give rise to many, but not all, parts of an organism.
- point mutation** A change in a single nucleotide pair of a gene.
- polar covalent bond** A covalent bond between atoms that differ in electronegativity. The shared electrons are pulled closer to the more electronegative atom, making it slightly negative and the other atom slightly positive.
- polar molecule** A molecule (such as water) with an uneven distribution of charges in different regions of the molecule.
- pollen grain** In seed plants, a structure consisting of the male gametophyte enclosed within a pollen wall.
- pollen tube** A tube that forms after germination of the pollen grain and that functions in the delivery of sperm to the ovule.
- pollination** (pol'-uh-nā'-shun) The transfer of pollen to the part of a seed plant containing the ovules, a process required for fertilization.
- poly-A tail** A sequence of 50–250 adenine nucleotides added onto the 3' end of a pre-mRNA molecule.
- polygamous** Referring to a type of relationship in which an individual of one sex mates with several of the other.
- polygenic inheritance** (pol'-ē-jen'-ik) An additive effect of two or more genes on a single phenotypic character.
- polymer** (pol'-uh-mer) A long molecule consisting of many similar or identical monomers linked together by covalent bonds.
- polymerase chain reaction (PCR)** (puh-lim'-uh-rās) A technique for amplifying DNA *in vitro* by incubating it with specific primers, a heat-resistant DNA polymerase, and nucleotides.
- polynucleotide** (pol'-ē-nū'-klē-ō-tīd) A polymer consisting of many nucleotide monomers in a chain. The nucleotides can be those of DNA or RNA.
- polypeptide** (pol'-ē-pep'-tīd) A polymer of many amino acids linked together by peptide bonds.
- polyphyletic** (pol'-ē-fī-let'-ik) Pertaining to a group of taxa derived from two or more different ancestors.
- polyploidy** (pol'-ē-ploy'-dē) A chromosomal alteration in which the organism possesses more than two complete chromosome sets. It is the result of an accident of cell division.
- polyribosome** (pol'-ē-rī'-buh-sōm') A group of several ribosomes attached to, and translating, the same messenger RNA molecule; also called a polysome.
- polysaccharide** (pol'-ē-sak'-uh-rīd) A polymer of many monosaccharides, formed by dehydration reactions.
- polyspermy** Fusion of the egg with more than one sperm.
- polytomy** (puh-lit'-uh-mē) In a phylogenetic tree, a branch point from which more than two descendant taxa emerge. A polytomy indicates that the evolutionary relationships between the descendant taxa are not yet clear.
- pons** A portion of the brain that participates in certain automatic, homeostatic functions, such as regulating the breathing centers in the medulla.
- population** A group of individuals of the same species that live in the same area and interbreed, producing fertile offspring.
- population dynamics** The study of how complex interactions between biotic and abiotic factors influence variations in population size.
- population ecology** The study of populations in relation to their environment, including environmental influences on population density and distribution, age structure, and variations in population size.
- positional information** Molecular cues that control pattern formation in an animal or plant embryonic structure by indicating a cell's location relative to the organism's body axes. These cues elicit a response by genes that regulate development.
- positive feedback** A form of regulation in which an end product of a process speeds up that process; in physiology, a control mechanism in which a change in a variable triggers a response that reinforces or amplifies the change.
- positive pressure breathing** A breathing system in which air is forced into the lungs.
- posterior** Pertaining to the rear, or tail end, of a bilaterally symmetric animal.
- posterior pituitary** An extension of the hypothalamus composed of nervous tissue that secretes oxytocin and antidiuretic hormone made in the hypothalamus; a temporary storage site for these hormones.
- postzygotic barrier** (pöst'-zī-got'-ik) A reproductive barrier that prevents hybrid zygotes produced by two different species from developing into viable, fertile adults.
- potential energy** The energy that matter possesses as a result of its location or spatial arrangement (structure).
- predation** An interaction between species in which one species, the predator, eats the other, the prey.
- prediction** In deductive reasoning, a forecast that follows logically from a hypothesis. By testing predictions, experiments may allow certain hypotheses to be rejected.
- prepuce** (prē'-pyūs) A fold of skin covering the head of the clitoris or penis.
- pressure potential ( $\Psi_p$ )** A component of water potential that consists of the physical pressure on a solution, which can be positive, zero, or negative.
- prezygotic barrier** (prē'-zī-got'-ik) A reproductive barrier that impedes mating between species or hinders fertilization if interspecific mating is attempted.
- primary cell wall** In plants, a relatively thin and flexible layer that surrounds the plasma membrane of a young cell.

**primary consumer** An herbivore; an organism that eats plants or other autotrophs.

**primary electron acceptor** In the thylakoid membrane of a chloroplast or in the membrane of some prokaryotes, a specialized molecule that shares the reaction-center complex with a pair of chlorophyll *a* molecules and that accepts an electron from them.

**primary growth** Growth produced by apical meristems, lengthening stems and roots.

**primary immune response** The initial adaptive immune response to an antigen, which appears after a lag of about 10–17 days.

**primary oocyte** (ō'-uh-sīt) An oocyte prior to completion of meiosis I.

**primary producer** An autotroph, usually a photosynthetic organism. Collectively, autotrophs make up the trophic level of an ecosystem that ultimately supports all other levels.

**primary production** The amount of light energy converted to chemical energy (organic compounds) by the autotrophs in an ecosystem during a given time period.

**primary structure** The level of protein structure referring to the specific linear sequence of amino acids.

**primary succession** A type of ecological succession that occurs in an area where there were originally no organisms present and where soil has not yet formed.

**primary transcript** An initial RNA transcript from any gene; also called pre-mRNA when transcribed from a protein-coding gene.

**primase** An enzyme that joins RNA nucleotides to make a primer during DNA replication, using the parental DNA strand as a template.

**primer** A short stretch of RNA with a free 3' end, bound by complementary base pairing to the template strand and elongated with DNA nucleotides during DNA replication.

**problem solving** The cognitive activity of devising a method to proceed from one state to another in the face of real or apparent obstacles.

**producer** An organism that produces organic compounds from CO<sub>2</sub> by harnessing light energy (in photosynthesis) or by oxidizing inorganic chemicals (in chemosynthetic reactions carried out by some prokaryotes).

**product** A material resulting from a chemical reaction.

**production efficiency** The percentage of energy stored in assimilated food that is not used for respiration or eliminated as waste.

**progesterone** A steroid hormone that prepares the uterus for pregnancy.

**prokaryote** An organism that has a prokaryotic cell; an informal term for an organism in either domain Bacteria or domain Archaea.

**prokaryotic cell** (prō'-kār'-ē-ot'-ik) A type of cell lacking a membrane-enclosed nucleus and membrane-enclosed organelles. Organisms with prokaryotic cells (bacteria and archaea) are called prokaryotes.

**prometaphase** The second stage of mitosis, in which the nuclear envelope fragments and the spindle microtubules attach to the kinetochores of the chromosomes.

**promoter** A specific nucleotide sequence in the DNA of a gene that binds RNA polymerase, positioning it to start transcribing RNA at the appropriate place.

**prophage** (prō'-fāj) A phage genome that has been inserted into a specific site on a bacterial chromosome.

**prophase** The first stage of mitosis, in which the chromatin condenses into discrete chromosomes visible with a light microscope, the mitotic spindle begins to form, and the nucleolus disappears but the nucleus remains intact.

**prostate gland** (pros'-tāt) A gland in human males that secretes an acid-neutralizing component of semen.

**protease** An enzyme that digests proteins by hydrolysis.

**protein** (prō'-tēn) A biologically functional molecule consisting of one or more polypeptides folded and coiled into a specific three-dimensional structure.

**protein kinase** An enzyme that transfers phosphate groups from ATP to a protein, thus phosphorylating the protein.

**protein phosphatase** An enzyme that removes phosphate groups from (dephosphorylates) proteins, often functioning to reverse the effect of a protein kinase.

**proteoglycan** (prō'-tē-ō-gli'-kan) A large molecule consisting of a small core protein with many carbohydrate chains attached, found in the extracellular matrix of animal cells. A proteoglycan may consist of up to 95% carbohydrate.

**proteomics** (prō'-tē-ō'-miks) The systematic study of the full protein sets (proteomes) encoded by genomes.

**protist** An informal term applied to any eukaryote that is not a plant, animal, or fungus. Most protists are unicellular, though some are colonial or multicellular.

**protocell** An abiotic precursor of a living cell that had a membrane-like structure and that maintained an internal chemistry different from that of its surroundings.

**proton** (prō'-ton) A subatomic particle with a single positive electrical charge, with a mass of about  $1.7 \times 10^{-24}$  g, found in the nucleus of an atom.

**proton pump** An active transport protein in a cell membrane that uses ATP to transport hydrogen ions out of a cell against their concentration gradient, generating a membrane potential in the process.

**proton-motive force** The potential energy stored in the form of a proton

electrochemical gradient, generated by the pumping of hydrogen ions (H<sup>+</sup>) across a biological membrane during chemiosmosis.

**proto-oncogene** (prō'-tō-on'-kō-jēn) A normal cellular gene that has the potential to become an oncogene.

**protoplast** The living part of a plant cell, which also includes the plasma membrane.

**provirus** A viral genome that is permanently inserted into a host genome.

**proximal tubule** In the vertebrate kidney, the portion of a nephron immediately downstream from Bowman's capsule that conveys and helps refine filtrate.

**pseudogene** (sū'-dō-jēn) A DNA segment that is very similar to a real gene but does not yield a functional product; a DNA segment that formerly functioned as a gene but has become inactivated in a particular species because of mutation.

**pseudopodium** (sū'-dō-pō'-dē-um) (plural, **pseudopodia**) A cellular extension of amoeboid cells used in moving and feeding.

**pulse** The rhythmic bulging of the artery walls with each heartbeat.

**punctuated equilibria** In the fossil record, long periods of apparent stasis, in which a species undergoes little or no morphological change, interrupted by relatively brief periods of sudden change.

**Punnett square** A diagram used in the study of inheritance to show the predicted genotypic results of random fertilization in genetic crosses between individuals of known genotype.

**pupil** The opening in the iris, which admits light into the interior of the vertebrate eye. Muscles in the iris regulate its size.

**purine** (pyū'-rēn) One of two types of nitrogenous bases found in nucleotides, characterized by a six-membered ring fused to a five-membered ring. Adenine (A) and guanine (G) are purines.

**pyrimidine** (puh-rim'-uh-dēn) One of two types of nitrogenous bases found in nucleotides, characterized by a six-membered ring. Cytosine (C), thymine (T), and uracil (U) are pyrimidines.

**quantitative character** A heritable feature that varies continuously over a range rather than in an either-or fashion.

**quaternary structure** (kwot'-er-nār'-ē) The particular shape of a complex, aggregate protein, defined by the characteristic three-dimensional arrangement of its constituent subunits, each a polypeptide.

**R plasmid** A bacterial plasmid carrying genes that confer resistance to certain antibiotics.

**radial symmetry** Symmetry in which the body is shaped like a pie or barrel (lacking a left side and a right side) and can be divided into mirror-imaged halves by any plane through its central axis.

**radicle** An embryonic root of a plant.

**radioactive isotope** An isotope (an atomic form of a chemical element) that is unstable;

- the nucleus decays spontaneously, giving off detectable particles and energy.
- radiometric dating** A method for determining the absolute age of rocks and fossils, based on the half-life of radioactive isotopes.
- ras gene** A gene that codes for Ras, a G protein that relays a growth signal from a growth factor receptor on the plasma membrane to a cascade of protein kinases, ultimately resulting in stimulation of the cell cycle.
- ray-finned fish** Member of the class Actinopterygii, aquatic osteichthyans with fins supported by long, flexible rays, including tuna, bass, and herring.
- reabsorption** In excretory systems, the recovery of solutes and water from filtrate.
- reactant** A starting material in a chemical reaction.
- reaction-center complex** A complex of proteins associated with a special pair of chlorophyll *a* molecules and a primary electron acceptor. Located centrally in a photosystem, this complex triggers the light reactions of photosynthesis. Excited by light energy, the pair of chlorophylls donates an electron to the primary electron acceptor, which passes an electron to an electron transport chain.
- reading frame** On an mRNA, the triplet grouping of ribonucleotides used by the translation machinery during polypeptide synthesis.
- receptacle** The base of a flower; the part of the stem that is the site of attachment of the floral organs.
- reception** The binding of a signaling molecule to a receptor protein, activating the receptor by causing it to change shape. *See also* sensory reception.
- receptor potential** An initial response of a receptor cell to a stimulus, consisting of a change in voltage across the receptor membrane proportional to the stimulus strength.
- receptor-mediated endocytosis** (en'-dō-sī-tō'-sis) The movement of specific molecules into a cell by the inward budding of vesicles containing proteins with receptor sites specific to the molecules being taken in; enables a cell to acquire bulk quantities of specific substances.
- recessive allele** An allele whose phenotypic effect is not observed in a heterozygote.
- recombinant chromosome** A chromosome created when crossing over combines DNA from two parents into a single chromosome.
- recombinant DNA** A DNA molecule made *in vitro* with segments from different sources.
- recombinant type (recombinant)** An offspring whose phenotype differs from that of the true-breeding P generation parents; also refers to the phenotype itself.
- rectum** The terminal portion of the large intestine, where the feces are stored prior to elimination.
- red alga** A photosynthetic protist, named for its color, which results from a red pigment that masks the green of chlorophyll. Most red algae are multicellular and marine.
- redox reaction** (rē'-doks) A chemical reaction involving the complete or partial transfer of one or more electrons from one reactant to another; short for **reduction-oxidation** reaction.
- reducing agent** The electron donor in a redox reaction.
- reduction** The complete or partial addition of electrons to a substance involved in a redox reaction.
- reflex** An automatic reaction to a stimulus, mediated by the spinal cord or lower brain.
- refractory period** (rē-frakt'-ōr-ē) The short time immediately after an action potential in which the neuron cannot respond to another stimulus, owing to the inactivation of voltage-gated sodium channels.
- regression line** A line drawn through a scatter plot that shows the general trend of the data. It represents an equation that is calculated mathematically to best fit the data and can be used to predict the value of the dependent variable for any value of the independent variable.
- regulator** An animal for which mechanisms of homeostasis moderate internal changes in a particular variable in the face of external fluctuation of that variable.
- regulatory gene** A gene that codes for a protein, such as a repressor, that controls the transcription of another gene or group of genes.
- reinforcement** In evolutionary biology, a process in which natural selection strengthens prezygotic barriers to reproduction, thus reducing the chances of hybrid formation. Such a process is likely to occur only if hybrid offspring are less fit than members of the parent species.
- relative abundance** The proportional abundance of different species in a community.
- relative fitness** The contribution an individual makes to the gene pool of the next generation, relative to the contributions of other individuals in the population.
- renal cortex** The outer portion of the vertebrate kidney.
- renal medulla** The inner portion of the vertebrate kidney, beneath the renal cortex.
- renal pelvis** The funnel-shaped chamber that receives processed filtrate from the vertebrate kidney's collecting ducts and is drained by the ureter.
- renin-angiotensin-aldosterone system (RAAS)** A hormone cascade pathway that helps regulate blood pressure and blood volume.
- repetitive DNA** Nucleotide sequences, usually noncoding, that are present in many copies in a eukaryotic genome. The repeated units may be short and arranged tandemly (in series) or long and dispersed in the genome.
- replication fork** A Y-shaped region on a replicating DNA molecule where the parental strands are being unwound and new strands are being synthesized.
- repressor** A protein that inhibits gene transcription. In prokaryotes, repressors bind to the DNA in or near the promoter. In eukaryotes, repressors may bind to control elements within enhancers, to activators, or to other proteins in a way that blocks activators from binding to DNA.
- reproductive isolation** The existence of biological factors (barriers) that impede members of two species from producing viable, fertile offspring.
- reproductive table** An age-specific summary of the reproductive rates in a population.
- reptile** Member of the clade of amniotes that includes tuataras, lizards, snakes, turtles, crocodilians, and birds.
- residual volume** The amount of air that remains in the lungs after forceful exhalation.
- resource partitioning** The division of environmental resources by coexisting species such that the niche of each species differs by one or more significant factors from the niches of all coexisting species.
- respiratory pigment** A protein that transports oxygen in blood or hemolymph.
- response** (1) In cellular communication, the change in a specific cellular activity brought about by a transduced signal from outside the cell. (2) In feedback regulation, a physiological activity triggered by a change in a variable.
- resting potential** The membrane potential characteristic of a nonconducting excitable cell, with the inside of the cell more negative than the outside.
- restriction enzyme** An endonuclease (type of enzyme) that recognizes and cuts DNA molecules foreign to a bacterium (such as phage genomes). The enzyme cuts at specific nucleotide sequences (restriction sites).
- restriction fragment** A DNA segment that results from the cutting of DNA by a restriction enzyme.
- restriction site** A specific sequence on a DNA strand that is recognized and cut by a restriction enzyme.
- retina** (ret'-i-nuh) The innermost layer of the vertebrate eye, containing photoreceptor cells (rods and cones) and neurons; transmits images formed by the lens to the brain via the optic nerve.
- retinal** The light-absorbing pigment in rods and cones of the vertebrate eye.
- retrotransposon** (re'-trō-trans-pō'-zon) A transposable element that moves within a genome by means of an RNA intermediate, a transcript of the retrotransposon DNA.
- retrovirus** (re'-trō-vī'-rus) An RNA virus that replicates by transcribing its RNA into

DNA and then inserting the DNA into a cellular chromosome; an important class of cancer-causing viruses.

**reverse transcriptase** (tran-skip'-tās) An enzyme encoded by certain viruses (retroviruses) that uses RNA as a template for DNA synthesis.

**reverse transcriptase–polymerase chain reaction (RT-PCR)** A technique for determining expression of a particular gene. It uses reverse transcriptase and DNA polymerase to synthesize cDNA from all the mRNA in a sample and then subjects the cDNA to PCR amplification using primers specific for the gene of interest.

**rhizarians** (rī-za'-rē-uhns) One of the three major subgroups for which the “SAR” eukaryotic supergroup is named. Many species in this clade are amoebas characterized by threadlike pseudopodia.

**rhizobacterium** A soil bacterium whose population size is much enhanced in the rhizosphere, the soil region close to a plant's roots.

**rhizoid** (rī'-zoyd) A long, tubular single cell or filament of cells that anchors bryophytes to the ground. Unlike roots, rhizoids are not composed of tissues, lack specialized conducting cells, and do not play a primary role in water and mineral absorption.

**rhizosphere** The soil region close to plant roots and characterized by a high level of microbiological activity.

**rhodopsin** (rō-dop'-sin) A visual pigment consisting of retinal and opsin. Upon absorbing light, the retinal changes shape and dissociates from the opsin.

**ribonucleic acid (RNA)** (rī'-bō-nū-klā'-ik) A type of nucleic acid consisting of a polynucleotide made up of nucleotide monomers with a ribose sugar and the nitrogenous bases adenine (A), cytosine (C), guanine (G), and uracil (U); usually single-stranded; functions in protein synthesis, gene regulation, and as the genome of some viruses.

**ribose** The sugar component of RNA nucleotides.

**ribosomal RNA (rRNA)** (rī'-buh-sō'-mul) RNA molecules that, together with proteins, make up ribosomes; the most abundant type of RNA.

**ribosome** (rī'-buh-sōm') A complex of rRNA and protein molecules that functions as a site of protein synthesis in the cytoplasm; consists of a large subunit and a small subunit. In eukaryotic cells, each subunit is assembled in the nucleolus. *See also* nucleolus.

**ribozyme** (rī'-buh-zīm) An RNA molecule that functions as an enzyme, such as an intron that catalyzes its own removal during RNA splicing.

**RNA interference (RNAi)** A technique used to silence the expression of selected genes. RNAi uses synthetic double-stranded

RNA molecules that match the sequence of a particular gene to trigger the breakdown of the gene's messenger RNA.

**RNA polymerase** An enzyme that links ribonucleotides into a growing RNA chain during transcription, based on complementary binding to nucleotides on a DNA template strand.

**RNA processing** Modification of RNA primary transcripts, including splicing out of introns, joining together of exons, and alteration of the 5' and 3' ends.

**RNA splicing** After synthesis of a eukaryotic primary RNA transcript, the removal of portions of the transcript (introns) that will not be included in the mRNA and the joining together of the remaining portions (exons).

**rod** A rodlike cell in the retina of the vertebrate eye, sensitive to low light intensity.

**root** An organ in vascular plants that anchors the plant and enables it to absorb water and minerals from the soil.

**root cap** A cone of cells at the tip of a plant root that protects the apical meristem.

**root hair** A tiny extension of a root epidermal cell, growing just behind the root tip and increasing surface area for absorption of water and minerals.

**root system** All of a plant's roots, which anchor it in the soil, absorb and transport minerals and water, and store food.

**rooted** Describing a phylogenetic tree that contains a branch point (often, the one farthest to the left) representing the most recent common ancestor of all taxa in the tree.

**rough ER** That portion of the endoplasmic reticulum with ribosomes attached.

**round window** In the mammalian ear, the point of contact where vibrations of the stapes create a traveling series of pressure waves in the fluid of the cochlea.

**r-selection** Selection for life history traits that maximize reproductive success in uncrowded environments; also called density-independent selection.

**rubisco** (rū-bis'-kō) Ribulose biphosphate (RuBP) carboxylase, the enzyme that catalyzes the first step of the Calvin cycle (the addition of CO<sub>2</sub> to RuBP).

**ruminant** (rū'-muh-nent) An animal, such as a cow or a sheep, with multiple stomach compartments specialized for an herbivorous diet.

**S phase** The synthesis phase of the cell cycle; the portion of interphase during which DNA is replicated.

**sacculle** In the vertebrate ear, a chamber in the vestibule behind the oval window that participates in the sense of balance.

**salicylic acid** (sal'-i-sil'-ik) A signaling molecule in plants that may be partially responsible for activating systemic acquired resistance to pathogens.

**salivary gland** A gland associated with the oral cavity that secretes substances that lubricate food and begin the process of chemical digestion.

**salt** A compound resulting from the formation of an ionic bond; also called an ionic compound.

**saltatory conduction** (sol'-tuh-tōr'-ē) Rapid transmission of a nerve impulse along an axon, resulting from the action potential jumping from one node of Ranvier to another, skipping the myelin-sheathed regions of membrane.

**“SAR” clade** One of four supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. This supergroup contains a large, extremely diverse collection of protists from three major subgroups: stramenopiles, alveolates, and rhizarians. *See also* Excavata, Archaeplastida, and Unikonta.

**sarcomere** (sar'-kō-mēr) The fundamental, repeating unit of striated muscle, delimited by the Z lines.

**sarcoplasmic reticulum (SR)** (sar'-kō-plaz'-mik ruh-tik'-yū-lum) A specialized endoplasmic reticulum that regulates the calcium concentration in the cytosol of muscle cells.

**saturated fatty acid** A fatty acid in which all carbons in the hydrocarbon tail are connected by single bonds, thus maximizing the number of hydrogen atoms attached to the carbon skeleton.

**savanna** A tropical grassland biome with scattered trees and large herbivores and maintained by occasional fires and drought.

**scanning electron microscope (SEM)** A microscope that uses an electron beam to scan the surface of a sample, coated with metal atoms, to study details of its topography.

**scatter plot** A graph in which each piece of data is represented by a point, but individual points are not connected by lines.

**Schwann cell** A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the peripheral nervous system.

**science** An approach to understanding the natural world.

**scion** (sī'-un) The twig grafted onto the stock when making a graft.

**sclereid** (sklār'-ē-id) A short, irregular sclerenchyma cell in nutshells and seed coats. Sclereids are scattered throughout the parenchyma of some plants.

**sclerenchyma cell** (skluh-ren'-kim-uh) A rigid, supportive plant cell type usually lacking a protoplast and possessing thick secondary walls strengthened by lignin at maturity.

**scrotum** A pouch of skin outside the abdomen that houses the testes; functions in maintaining the testes at the lower temperature required for spermatogenesis.

**second law of thermodynamics** The principle stating that every energy transfer or transformation increases the entropy of the universe. Usable forms of energy are at least partly converted to heat.

**second messenger** A small, nonprotein, water-soluble molecule or ion, such as a calcium ion ( $\text{Ca}^{2+}$ ) or cyclic AMP, that relays a signal to a cell's interior in response to a signaling molecule bound by a signal receptor protein.

**secondary cell wall** In plant cells, a strong and durable matrix that is often deposited in several laminated layers around the plasma membrane and that provides protection and support.

**secondary consumer** A carnivore that eats herbivores.

**secondary endosymbiosis** A process in eukaryotic evolution in which a heterotrophic eukaryotic cell engulfed a photosynthetic eukaryotic cell, which survived in a symbiotic relationship inside the heterotrophic cell.

**secondary growth** Growth produced by lateral meristems, thickening the roots and shoots of woody plants.

**secondary immune response** The adaptive immune response elicited on second or subsequent exposures to a particular antigen. The secondary immune response is more rapid, of greater magnitude, and of longer duration than the primary immune response.

**secondary oocyte** ( $\delta'$ -uh-sit) An oocyte that has completed the first of the two meiotic divisions.

**secondary production** The amount of chemical energy in consumers' food that is converted to their own new biomass during a given time period.

**secondary structure** Regions of repetitive coiling or folding of the polypeptide backbone of a protein due to hydrogen bonding between constituents of the backbone (not the side chains).

**secondary succession** A type of succession that occurs where an existing community has been cleared by some disturbance that leaves the soil or substrate intact.

**secretion** (1) The discharge of molecules synthesized by a cell. (2) The discharge of wastes from the body fluid into the filtrate.

**seed** An adaptation of some terrestrial plants consisting of an embryo packaged along with a store of food within a protective coat.

**seed coat** A tough outer covering of a seed, formed from the outer coat of an ovule. In a flowering plant, the seed coat encloses and protects the embryo and endosperm.

**seedless vascular plant** An informal name for a plant that has vascular tissue but lacks seeds. Seedless vascular plants form a paraphyletic group that includes the phyla

Lycophyta (club mosses and their relatives) and Monilophyta (ferns and their relatives).

**selective permeability** A property of biological membranes that allows them to regulate the passage of substances across them.

**self-incompatibility** The ability of a seed plant to reject its own pollen and sometimes the pollen of closely related individuals.

**semelparity** Reproduction in which an organism produces all of its offspring in a single event; also known as big-bang reproduction.

**semen** ( $\text{s}\bar{\text{e}}'$ -mun) The fluid that is ejaculated by the male during orgasm; contains sperm and secretions from several glands of the male reproductive tract.

**semicircular canals** A three-part chamber of the inner ear that functions in maintaining equilibrium.

**semiconservative model** Type of DNA replication in which the replicated double helix consists of one old strand, derived from the parental molecule, and one newly made strand.

**semilunar valve** A valve located at each exit of the heart, where the aorta leaves the left ventricle and the pulmonary artery leaves the right ventricle.

**seminal vesicle** ( $\text{sem}'$ -i-nul ves'-i-kul) A gland in males that secretes a fluid component of semen that lubricates and nourishes sperm.

**seminiferous tubule** ( $\text{sem}'$ -i-nif'-er-us) A highly coiled tube in the testis in which sperm are produced.

**senescence** ( $\text{se-n}\bar{\text{e}}\text{'}$ -ens) The growth phase in a plant or plant part (as a leaf) from full maturity to death.

**sensitive period** A limited phase in an animal's development when learning of particular behaviors can take place; also called a critical period.

**sensor** In homeostasis, a receptor that detects a stimulus.

**sensory adaptation** The tendency of sensory neurons to become less sensitive when they are stimulated repeatedly.

**sensory neuron** A nerve cell that receives information from the internal or external environment and transmits signals to the central nervous system.

**sensory reception** The detection of a stimulus by sensory cells.

**sensory receptor** An organ, cell, or structure within a cell that responds to specific stimuli from an organism's external or internal environment.

**sensory transduction** The conversion of stimulus energy to a change in the membrane potential of a sensory receptor cell.

**sepal** ( $\text{s}\bar{\text{e}}'$ -pul) A modified leaf in angiosperms that helps enclose and protect a flower bud before it opens.

**serial endosymbiosis** A hypothesis for the origin of eukaryotes consisting of a sequence

of endosymbiotic events in which mitochondria, chloroplasts, and perhaps other cellular structures were derived from small prokaryotes that had been engulfed by larger cells.

**serotonin** ( $\text{ser}'$ -uh-tō'-nin) A neurotransmitter, synthesized from the amino acid tryptophan, that functions in the central nervous system.

**Sertoli cell** A support cell of the seminiferous tubule that surrounds and nourishes developing sperm.

**set point** In homeostasis in animals, a value maintained for a particular variable, such as body temperature or solute concentration.

**sex chromosome** A chromosome responsible for determining the sex of an individual.

**sex-linked gene** A gene located on either sex chromosome. Most sex-linked genes are on the X chromosome and show distinctive patterns of inheritance; there are very few genes on the Y chromosome.

**sexual dimorphism** ( $\text{d}\bar{\text{i}}\text{-m}\bar{\text{o}}\text{'}$ -fizm) Differences between the secondary sex characteristics of males and females of the same species.

**sexual reproduction** A type of reproduction in which two parents give rise to offspring that have unique combinations of genes inherited from both parents via the gametes.

**sexual selection** A form of natural selection in which individuals with certain inherited characteristics are more likely than other individuals to obtain mates.

**Shannon diversity index** An index of community diversity symbolized by  $H$  and represented by the equation  $H = -(p_A \ln p_A + p_B \ln p_B + p_C \ln p_C + \dots)$ , where A, B, C . . . are species,  $p$  is the relative abundance of each species, and  $\ln$  is the natural logarithm.

**shared ancestral character** A character that is shared by members of a particular clade but that originated in an ancestor that is not a member of that clade.

**shared derived character** An evolutionary novelty that is unique to a particular clade.

**shoot system** The aerial portion of a plant body, consisting of stems, leaves, and (in angiosperms) flowers.

**short tandem repeat (STR)** Simple sequence DNA containing multiple tandemly repeated units of two to five nucleotides. Variations in STRs act as genetic markers in STR analysis, used to prepare genetic profiles.

**short-day plant** A plant that flowers (usually in late summer, fall, or winter) only when the light period is shorter than a critical length.

**short-term memory** The ability to hold information, anticipations, or goals for a time and then release them if they become irrelevant.

**sickle-cell disease** A recessively inherited human blood disorder in which a single

- nucleotide change in the  $\beta$ -globin gene causes hemoglobin to aggregate, changing red blood cell shape and causing multiple symptoms in afflicted individuals.
- sieve plate** An end wall in a sieve-tube element, which facilitates the flow of phloem sap in angiosperm sieve tubes.
- sieve-tube element** A living cell that conducts sugars and other organic nutrients in the phloem of angiosperms; also called a sieve-tube member. Connected end to end, they form sieve tubes.
- sign stimulus** An external sensory cue that triggers a fixed action pattern by an animal.
- signal** In animal behavior, transmission of a stimulus from one animal to another. The term is also used in the context of communication in other kinds of organisms and in cell-to-cell communication in all multicellular organisms.
- signal peptide** A sequence of about 20 amino acids at or near the leading (amino) end of a polypeptide that targets it to the endoplasmic reticulum or other organelles in a eukaryotic cell.
- signal transduction pathway** A series of steps linking a mechanical, chemical, or electrical stimulus to a specific cellular response.
- signal-recognition particle (SRP)** A protein-RNA complex that recognizes a signal peptide as it emerges from a ribosome and helps direct the ribosome to the endoplasmic reticulum (ER) by binding to a receptor protein on the ER.
- silent mutation** A nucleotide-pair substitution that has no observable effect on the phenotype; for example, within a gene, a mutation that results in a codon that codes for the same amino acid.
- simple fruit** A fruit derived from a single carpel or several fused carpels.
- simple sequence DNA** A DNA sequence that contains many copies of tandemly repeated short sequences.
- single bond** A single covalent bond; the sharing of a pair of valence electrons by two atoms.
- single circulation** A circulatory system consisting of a single pump and circuit, in which blood passes from the sites of gas exchange to the rest of the body before returning to the heart.
- single nucleotide polymorphism (SNP)** A single base-pair site in a genome where nucleotide variation is found in at least 1% of the population.
- single-lens eye** The camera-like eye found in some jellies, polychaete worms, spiders, and many molluscs.
- single-strand binding protein** A protein that binds to the unpaired DNA strands during DNA replication, stabilizing them and holding them apart while they serve as templates for the synthesis of complementary strands of DNA.
- sinoatrial (SA) node** A region in the right atrium of the heart that sets the rate and timing at which all cardiac muscle cells contract; the pacemaker.
- sister chromatids** Two copies of a duplicated chromosome attached to each other by proteins at the centromere and, sometimes, along the arms. While joined, two sister chromatids make up one chromosome. Chromatids are eventually separated during mitosis or meiosis II.
- sister taxa** Groups of organisms that share an immediate common ancestor and hence are each other's closest relatives.
- skeletal muscle** A type of striated muscle that is generally responsible for the voluntary movements of the body.
- sliding-filament model** The idea that muscle contraction is based on the movement of thin (actin) filaments along thick (myosin) filaments, shortening the sarcomere, the basic unit of muscle organization.
- slow-twitch fiber** A muscle fiber that can sustain long contractions.
- small interfering RNA (siRNA)** One of multiple small, single-stranded RNA molecules generated by cellular machinery from a long, linear, double-stranded RNA molecule. The siRNA associates with one or more proteins in a complex that can degrade or prevent translation of an mRNA with a complementary sequence. In some cases, siRNA can also block transcription by promoting chromatin modification.
- small intestine** The longest section of the alimentary canal, so named because of its small diameter compared with that of the large intestine; the principal site of the enzymatic hydrolysis of food macromolecules and the absorption of nutrients.
- smooth ER** That portion of the endoplasmic reticulum that is free of ribosomes.
- smooth muscle** A type of muscle lacking the striations of skeletal and cardiac muscle because of the uniform distribution of myosin filaments in the cells; responsible for involuntary body activities.
- social learning** Modification of behavior through the observation of other individuals.
- sodium-potassium pump** A transport protein in the plasma membrane of animal cells that actively transports sodium out of the cell and potassium into the cell.
- solute** (sol'-yüt) A substance that is dissolved in a solution.
- solute potential ( $\Psi_s$ )** A component of water potential that is proportional to the molarity of a solution and that measures the effect of solutes on the direction of water movement; also called osmotic potential, it can be either zero or negative.
- solution** A liquid that is a homogeneous mixture of two or more substances.
- solvent** The dissolving agent of a solution. Water is the most versatile solvent known.
- somatic cell** (sō-mat'-ik) Any cell in a multicellular organism except a sperm or egg or their precursors.
- spatial learning** The establishment of a memory that reflects the environment's spatial structure.
- spatial summation** A phenomenon of neural integration in which the membrane potential of the postsynaptic cell is determined by the combined effect of EPSPs or IPSPs produced nearly simultaneously by different synapses.
- speciation** (spē'-sē-ā'-shun) An evolutionary process in which one species splits into two or more species.
- species** (spē'-sēz) A population or group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but do not produce viable, fertile offspring with members of other such groups.
- species diversity** The number and relative abundance of species in a biological community.
- species richness** The number of species in a biological community.
- species-area curve** The biodiversity pattern that shows that the larger the geographic area of a community is, the more species it has.
- specific heat** The amount of heat that must be absorbed or lost for 1 g of a substance to change its temperature by 1°C.
- spectrophotometer** An instrument that measures the proportions of light of different wavelengths absorbed and transmitted by a pigment solution.
- sperm** The male gamete.
- spermatogenesis** The continuous and prolific production of mature sperm cells in the testis.
- spermatogonium** (plural, **spermatogonia**) A cell that divides mitotically to form spermatocytes.
- sphincter** (sfink'-ter) A ringlike band of muscle fibers that controls the size of an opening in the body, such as the passage between the esophagus and the stomach.
- spliceosome** (spli'-sō-sōm) A large complex made up of proteins and RNA molecules that splices RNA by interacting with the ends of an RNA intron, releasing the intron and joining the two adjacent exons.
- spontaneous process** A process that occurs without an overall input of energy; a process that is energetically favorable.
- sporangium** (spōr-an'-jē-um) (plural, **sporangia**) A multicellular organ in fungi and plants in which meiosis occurs and haploid cells develop.
- spore** (1) In the life cycle of a plant or alga undergoing alternation of generations, a haploid cell produced in the sporophyte by meiosis. A spore can divide by mitosis to develop into a multicellular haploid individual, the gametophyte, without fusing

- with another cell. (2) In fungi, a haploid cell, produced either sexually or asexually, that produces a mycelium after germination.
- sporophyte** (spō-ruh-fit') In organisms (plants and some algae) that have alternation of generations, the multicellular diploid form that results from the union of gametes. The sporophyte produces haploid spores by meiosis that develop into gametophytes.
- sporopollenin** (spōr-uh-pol'-eh-nin) A durable polymer that covers exposed zygotes of charophyte algae and forms the walls of plant spores, preventing them from drying out.
- stabilizing selection** Natural selection in which intermediate phenotypes survive or reproduce more successfully than do extreme phenotypes.
- stamen** (stā'-men) The pollen-producing reproductive organ of a flower, consisting of an anther and a filament.
- starch** A storage polysaccharide in plants, consisting entirely of glucose monomers joined by α glycosidic linkages.
- start point** In transcription, the nucleotide position on the promoter where RNA polymerase begins synthesis of RNA.
- statocyst** (stat'-uh-sist') A type of mechanoreceptor that functions in equilibrium in invertebrates by use of statoliths, which stimulate hair cells in relation to gravity.
- statolith** (stat'-uh-lith') (1) In plants, a specialized plastid that contains dense starch grains and may play a role in detecting gravity. (2) In invertebrates, a dense particle that settles in response to gravity and is found in sensory organs that function in equilibrium.
- stele** (stēl) The vascular tissue of a stem or root.
- stem** A vascular plant organ consisting of an alternating system of nodes and internodes that support the leaves and reproductive structures.
- stem cell** Any relatively unspecialized cell that can produce, during a single division, one identical daughter cell and one more specialized daughter cell that can undergo further differentiation.
- steroid** A type of lipid characterized by a carbon skeleton consisting of four fused rings with various chemical groups attached.
- sticky end** A single-stranded end of a double-stranded restriction fragment.
- stigma** (plural, **stigmata**) The sticky part of a flower's carpel, which receives pollen grains.
- stimulus** In feedback regulation, a fluctuation in a variable that triggers a response.
- stipe** A stemlike structure of a seaweed.
- stock** The plant that provides the root system when making a graft.
- stoma** (stō'-muh) (plural, **stomata**) A microscopic pore surrounded by guard cells in the epidermis of leaves and stems that allows gas exchange between the environment and the interior of the plant.
- stomach** An organ of the digestive system that stores food and performs preliminary steps of digestion.
- stramenopiles** One of the three major subgroups for which the "SAR" eukaryotic supergroup is named. This clade arose by secondary endosymbiosis and includes diatoms and brown algae.
- stratum** (strah'-tum) (plural, **strata**) A rock layer formed when new layers of sediment cover older ones and compress them.
- stroke** The death of nervous tissue in the brain, usually resulting from rupture or blockage of arteries in the head.
- stroma** (strō'-muh) The dense fluid within the chloroplast surrounding the thylakoid membrane and containing ribosomes and DNA; involved in the synthesis of organic molecules from carbon dioxide and water.
- stromatolite** Layered rock that results from the activities of prokaryotes that bind thin films of sediment together.
- style** The stalk of a flower's carpel, with the ovary at the base and the stigma at the top.
- substrate** The reactant on which an enzyme works.
- substrate feeder** An animal that lives in or on its food source, eating its way through the food.
- substrate-level phosphorylation** The enzyme-catalyzed formation of ATP by direct transfer of a phosphate group to ADP from an intermediate substrate in catabolism.
- sugar sink** A plant organ that is a net consumer or storer of sugar. Growing roots, shoot tips, stems, and fruits are examples of sugar sinks supplied by phloem.
- sugar source** A plant organ in which sugar is being produced by either photosynthesis or the breakdown of starch. Mature leaves are the primary sugar sources of plants.
- sulphydryl group** A chemical group consisting of a sulfur atom bonded to a hydrogen atom.
- suprachiasmatic nucleus (SCN)** A group of neurons in the hypothalamus of mammals that functions as a biological clock.
- surface tension** A measure of how difficult it is to stretch or break the surface of a liquid.
- surfactant** A substance secreted by alveoli that decreases surface tension in the fluid that coats the alveoli.
- survivorship curve** A plot of the number of members of a cohort that are still alive at each age; one way to represent age-specific mortality.
- suspension feeder** An animal that feeds by capturing small organisms or food particles suspended in the surrounding medium.
- sustainable development** Development that meets the needs of people today without limiting the ability of future generations to meet their needs.
- symbiont** (sim'-bē-ont) The smaller participant in a symbiotic relationship, living in or on the host.
- symbiosis** An ecological relationship between organisms of two different species that live together in direct and intimate contact.
- sympathetic division** One of three divisions of the autonomic nervous system; generally increases energy expenditure and prepares the body for action.
- sympatric speciation** (sim-pat'-rik) The formation of new species in populations that live in the same geographic area.
- symplast** In plants, the continuum of cytoplasm connected by plasmodesmata between cells.
- synapse** (sin'-aps) The junction where a neuron communicates with another cell across a narrow gap via a neurotransmitter or an electrical coupling.
- synapsid** Member of an amniote clade distinguished by a single hole on each side of the skull. Synapsids include the mammals.
- synapsis** (si-nap'-sis) The pairing and physical connection of duplicated homologous chromosomes during prophase I of meiosis.
- systematics** A scientific discipline focused on classifying organisms and determining their evolutionary relationships.
- systemic acquired resistance** A defensive response in infected plants that helps protect healthy tissue from pathogenic invasion.
- systemic circuit** The branch of the circulatory system that supplies oxygenated blood to and carries deoxygenated blood away from organs and tissues throughout the body.
- systems biology** An approach to studying biology that aims to model the dynamic behavior of whole biological systems based on a study of the interactions among the system's parts.
- systole** (sis'-tō-lē) The stage of the cardiac cycle in which a heart chamber contracts and pumps blood.
- T cells** The class of lymphocytes that mature in the thymus; they include both effector cells for the cell-mediated immune response and helper cells required for both branches of adaptive immunity.
- taproot** A main vertical root that develops from an embryonic root and gives rise to lateral (branch) roots.
- tastant** Any chemical that stimulates the sensory receptors in a taste bud.
- taste bud** A collection of modified epithelial cells on the tongue or in the mouth that are receptors for taste in mammals.
- TATA box** A DNA sequence in eukaryotic promoters crucial in forming the transcription initiation complex.
- taxis** (tak'-sis) An oriented movement toward or away from a stimulus.
- taxon** (plural, **taxa**) A named taxonomic unit at any given level of classification.
- taxonomy** (tak-son'-uh-mē) A scientific discipline concerned with naming and classifying the diverse forms of life.

**Tay-Sachs disease** A human genetic disease caused by a recessive allele for a dysfunctional enzyme, leading to accumulation of certain lipids in the brain. Seizures, blindness, and degeneration of motor and mental performance usually become manifest a few months after birth, followed by death within a few years.

**technology** The application of scientific knowledge for a specific purpose, often involving industry or commerce but also including uses in basic research.

**telophase** The fifth and final stage of mitosis, in which daughter nuclei are forming and cytokinesis has typically begun.

**temperate broadleaf forest** A biome located throughout midlatitude regions where there is sufficient moisture to support the growth of large, broadleaf deciduous trees.

**temperate grassland** A terrestrial biome that exists at midlatitude regions and is dominated by grasses and forbs.

**temperate phage** A phage that is capable of replicating by either a lytic or lysogenic cycle.

**temperature** A measure in degrees of the average kinetic energy (thermal energy) of the atoms and molecules in a body of matter.

**template strand** The DNA strand that provides the pattern, or template, for ordering, by complementary base pairing, the sequence of nucleotides in an RNA transcript.

**temporal summation** A phenomenon of neural integration in which the membrane potential of the postsynaptic cell in a chemical synapse is determined by the combined effect of EPSPs or IPSPs produced in rapid succession.

**terminator** In bacteria, a sequence of nucleotides in DNA that marks the end of a gene and signals RNA polymerase to release the newly made RNA molecule and detach from the DNA.

**territoriality** A behavior in which an animal defends a bounded physical space against encroachment by other individuals, usually of its own species.

**tertiary consumer** (ter'-shē-ār'-ē) A carnivore that eats other carnivores.

**tertiary structure** The overall shape of a protein molecule due to interactions of amino acid side chains, including hydrophobic interactions, ionic bonds, hydrogen bonds, and disulfide bridges.

**test** In foram protists, a porous shell that consists of a single piece of organic material hardened with calcium carbonate.

**testcross** Breeding an organism of unknown genotype with a homozygous recessive individual to determine the unknown genotype. The ratio of phenotypes in the offspring reveals the unknown genotype.

**testis** (plural, **testes**) The male reproductive organ, or gonad, in which sperm and reproductive hormones are produced.

**testosterone** A steroid hormone required for development of the male reproductive system, spermatogenesis, and male secondary sex characteristics; the major androgen in mammals.

**tetanus** (tet'-uh-nus) The maximal, sustained contraction of a skeletal muscle, caused by a very high frequency of action potentials elicited by continual stimulation.

**tetrapod** Member of a vertebrate clade characterized by limbs with digits. Tetrapods include mammals, amphibians, and birds and other reptiles.

**thalamus** (thal'-uh-mus) An integrating center of the vertebrate forebrain. Neurons with cell bodies in the thalamus relay neural input to specific areas in the cerebral cortex and regulate what information goes to the cerebral cortex.

**theory** An explanation that is broader in scope than a hypothesis, generates new hypotheses, and is supported by a large body of evidence.

**thermal energy** Kinetic energy due to the random motion of atoms and molecules; energy in its most random form. *See also* heat.

**thermocline** A narrow stratum of abrupt temperature change in the ocean and in many temperate-zone lakes.

**thermodynamics** (ther'-mō-di-nam'-iks) The study of energy transformations that occur in a collection of matter. *See* first law of thermodynamics; second law of thermodynamics.

**thermoreceptor** A receptor stimulated by either heat or cold.

**thermoregulation** The maintenance of internal body temperature within a tolerable range.

**thick filament** A filament composed of staggered arrays of myosin molecules; a component of myofibrils in muscle fibers.

**thigmomorphogenesis** A response in plants to chronic mechanical stimulation, resulting from increased ethylene production. An example is thickening stems in response to strong winds.

**thigmotropism** (thig-mo'-truh-pizm) A directional growth of a plant in response to touch.

**thin filament** A filament consisting of two strands of actin and two strands of regulatory protein coiled around one another; a component of myofibrils in muscle fibers.

**threatened species** A species that is considered likely to become endangered in the foreseeable future.

**threshold** The potential that an excitable cell membrane must reach for an action potential to be initiated.

**thrombus** A fibrin-containing clot that forms in a blood vessel and blocks the flow of blood.

**thylakoid** (thi'-luh-koyd) A flattened, membranous sac inside a chloroplast. Thylakoids

often exist in stacks called grana that are interconnected; their membranes contain molecular "machinery" used to convert light energy to chemical energy.

**thymus** (thi'-mus) A small organ in the thoracic cavity of vertebrates where maturation of T cells is completed.

**tidal volume** The volume of air a mammal inhales and exhales with each breath.

**tight junction** A type of intercellular junction between animal cells that prevents the leakage of material through the space between cells.

**tissue** An integrated group of cells with a common structure, function, or both.

**Toll-like receptor (TLR)** A membrane receptor on a phagocytic white blood cell that recognizes fragments of molecules common to a set of pathogens.

**tonicity** The ability of a solution surrounding a cell to cause that cell to gain or lose water.

**top-down model** A model of community organization in which predation influences community organization by controlling herbivore numbers, which in turn control plant or phytoplankton numbers, which in turn control nutrient levels; also called the trophic cascade model.

**topoisomerase** A protein that breaks, swivels, and rejoins DNA strands. During DNA replication, topoisomerase helps to relieve strain in the double helix ahead of the replication fork.

**totipotent** (tō'-tuh-pōt'-ent) Describing a cell that can give rise to all parts of the embryo and adult, as well as extraembryonic membranes in species that have them.

**trace element** An element indispensable for life but required in extremely minute amounts.

**trachea** (trā'-kē-uh) The portion of the respiratory tract that passes from the larynx to the bronchi; also called the windpipe.

**tracheal system** In insects, a system of branched, air-filled tubes that extends throughout the body and carries oxygen directly to cells.

**tracheid** (trā'-kē-id) A long, tapered water-conducting cell found in the xylem of nearly all vascular plants. Functioning tracheids are no longer living.

**trait** One of two or more detectable variants in a genetic character.

**transcription** The synthesis of RNA using a DNA template.

**transcription factor** A regulatory protein that binds to DNA and affects transcription of specific genes.

**transcription initiation complex** The completed assembly of transcription factors and RNA polymerase bound to a promoter.

**transcription unit** A region of DNA that is transcribed into an RNA molecule.

**transduction** (1) A process in which phages (viruses) carry bacterial DNA from one

bacterial cell to another. When these two cells are members of different species, transduction results in horizontal gene transfer. (2) In cellular communication, the conversion of a signal from outside the cell to a form that can bring about a specific cellular response; also called signal transduction.

**transfer RNA (tRNA)** An RNA molecule that functions as a translator between nucleic acid and protein languages by carrying specific amino acids to the ribosome, where they recognize the appropriate codons in the mRNA.

**transformation** (1) The conversion of a normal animal cell to a cancerous cell. (2) A change in genotype and phenotype due to the assimilation of external DNA by a cell. When the external DNA is from a member of a different species, transformation results in horizontal gene transfer.

**transgenic** Pertaining to an organism whose genome contains a gene introduced from another organism of the same or a different species.

**translation** The synthesis of a polypeptide using the genetic information encoded in an mRNA molecule. There is a change of “language” from nucleotides to amino acids.

**translocation** (1) An aberration in chromosome structure resulting from attachment of a chromosomal fragment to a nonhomologous chromosome. (2) During protein synthesis, the third stage in the elongation cycle, when the RNA carrying the growing polypeptide moves from the A site to the P site on the ribosome. (3) The transport of organic nutrients in the phloem of vascular plants.

**transmission electron microscope (TEM)** A microscope that passes an electron beam through very thin sections stained with metal atoms and is primarily used to study the internal ultrastructure of cells.

**transpiration** The evaporative loss of water from a plant.

**transport epithelium** One or more layers of specialized epithelial cells that carry out and regulate solute movement.

**transport protein** A transmembrane protein that helps a certain substance or class of closely related substances to cross the membrane.

**transport vesicle** A small membranous sac in a eukaryotic cell's cytoplasm carrying molecules produced by the cell.

**transposable element** A segment of DNA that can move within the genome of a cell by means of a DNA or RNA intermediate; also called a transposable genetic element.

**transposon** A transposable element that moves within a genome by means of a DNA intermediate.

**transverse (T) tubule** An infolding of the plasma membrane of skeletal muscle cells.

**triacylglycerol** (trī-as’-ul-glīs’-uh-rol) A lipid consisting of three fatty acids linked to one glycerol molecule; also called a fat or triglyceride.

**triple response** A plant growth maneuver in response to mechanical stress, involving slowing of stem elongation, thickening of the stem, and a curvature that causes the stem to start growing horizontally.

**triplet code** A genetic information system in which a set of three-nucleotide-long words specifies the amino acids for polypeptide chains.

**trisomic** Referring to a diploid cell that has three copies of a particular chromosome instead of the normal two.

**trophic efficiency** The percentage of production transferred from one trophic level to the next.

**trophic structure** The different feeding relationships in an ecosystem, which determine the route of energy flow and the pattern of chemical cycling.

**trophoblast** The outer epithelium of a mammalian blastocyst. It forms the fetal part of the placenta, supporting embryonic development but not forming part of the embryo proper.

**tropic hormone** A hormone that has an endocrine gland or endocrine cells as a target.

**tropical dry forest** A terrestrial biome characterized by relatively high temperatures and precipitation overall but with a pronounced dry season.

**tropical rain forest** A terrestrial biome characterized by relatively high precipitation and temperatures year-round.

**tropics** Latitudes between 23.5° north and south.

**tropism** A growth response that results in the curvature of whole plant organs toward or away from stimuli due to differential rates of cell elongation.

**tropomyosin** The regulatory protein that blocks the myosin-binding sites on actin molecules.

**tropoin complex** The regulatory proteins that control the position of tropomyosin on the thin filament.

**true-breeding** Referring to organisms that produce offspring of the same variety over many generations of self-pollination.

**tumor-suppressor gene** A gene whose protein product inhibits cell division, thereby preventing the uncontrolled cell growth that contributes to cancer.

**tundra** A terrestrial biome at the extreme limits of plant growth. At the northernmost limits, it is called arctic tundra, and at high altitudes, where plant forms are limited to low shrubby or matlike vegetation, it is called alpine tundra.

**turgid** (ter’-jid) Swollen or distended, as in plant cells. (A walled cell becomes turgid if

it has a lower water potential than its surroundings, resulting in entry of water.)

**turgor pressure** The force directed against a plant cell wall after the influx of water and swelling of the cell due to osmosis.

**turnover time** The time required to replace the standing crop of a population or group of populations (for example, of phytoplankton), calculated as the ratio of standing crop to production.

**twin study** A behavioral study in which researchers compare the behavior of identical twins raised apart with that of identical twins raised in the same household.

**tympanic membrane** Another name for the eardrum, the membrane between the outer and middle ear.

**Unikonta** (yū’-ni-kon’-tuh) One of four supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. This clade, which is supported by studies of myosin proteins and DNA, consists of amoebozoans and opisthokonts. *See also* Excavata, “SAR” clade, and Archaeplastida.

**unsaturated fatty acid** A fatty acid that has one or more double bonds between carbons in the hydrocarbon tail. Such bonding reduces the number of hydrogen atoms attached to the carbon skeleton.

**urea** A soluble nitrogenous waste produced in the liver by a metabolic cycle that combines ammonia with carbon dioxide.

**ureter** (yū-rē’-ter) A duct leading from the kidney to the urinary bladder.

**urethra** (yū-rē’-thruh) A tube that releases urine from the mammalian body near the vagina in females and through the penis in males; also serves in males as the exit tube for the reproductive system.

**uric acid** A product of protein and purine metabolism and the major nitrogenous waste product of insects, land snails, and many reptiles. Uric acid is relatively nontoxic and largely insoluble.

**urinary bladder** The pouch where urine is stored prior to elimination.

**uterine cycle** The changes that occur in the uterus during the reproductive cycle of the human female; also called the menstrual cycle.

**uterus** A female organ where eggs are fertilized and/or development of the young occurs.

**utricle** In the vertebrate ear, a chamber in the vestibule behind the oval window that opens into the three semicircular canals.

**vaccine** A harmless variant or derivative of a pathogen that stimulates a host's immune system to mount defenses against the pathogen.

**vacuole** (vak’-yū-ōl’) A membrane-bounded vesicle whose specialized function varies in different kinds of cells.

**vagina** Part of the female reproductive system between the uterus and the outside opening;

- the birth canal in mammals. During copulation, the vagina accommodates the male's penis and receives sperm.
- valence** The bonding capacity of a given atom; the number of covalent bonds an atom can form usually equals the number of unpaired electrons in its outermost (valence) shell.
- valence electron** An electron in the outermost electron shell.
- valence shell** The outermost energy shell of an atom, containing the valence electrons involved in the chemical reactions of that atom.
- van der Waals interactions** Weak attractions between molecules or parts of molecules that results from transient local partial charges.
- variation** Differences between members of the same species.
- vas deferens** In mammals, the tube in the male reproductive system in which sperm travel from the epididymis to the urethra.
- vasa recta** The capillary system in the kidney that serves the loop of Henle.
- vascular cambium** A cylinder of meristematic tissue in woody plants that adds layers of secondary vascular tissue called secondary xylem (wood) and secondary phloem.
- vascular plant** A plant with vascular tissue. Vascular plants include all living plant species except liverworts, mosses, and hornworts.
- vascular tissue** Plant tissue consisting of cells joined into tubes that transport water and nutrients throughout the plant body.
- vascular tissue system** A transport system formed by xylem and phloem throughout a vascular plant. Xylem transports water and minerals; phloem transports sugars, the products of photosynthesis.
- vasoconstriction** A decrease in the diameter of blood vessels caused by contraction of smooth muscles in the vessel walls.
- vasodilation** An increase in the diameter of blood vessels caused by relaxation of smooth muscles in the vessel walls.
- vasopressin** See antidiuretic hormone.
- vector** An organism that transmits pathogens from one host to another.
- vegetative propagation** Cloning of plants by humans.
- vegetative reproduction** Cloning of plants in nature.
- vein** (1) In animals, a vessel that carries blood toward the heart. (2) In plants, a vascular bundle in a leaf.
- ventilation** The flow of air or water over a respiratory surface.
- ventral** Pertaining to the underside, or bottom, of an animal with radial or bilateral symmetry.
- ventricle** (ven'-tri-kul) (1) A heart chamber that pumps blood out of the heart. (2) A space in the vertebrate brain, filled with cerebrospinal fluid.
- vernalization** The use of cold treatment to induce a plant to flower.
- vertebrate** A chordate animal with a backbone. Vertebrates include sharks and rays, ray-finned fishes, coelacanths, lungfishes, amphibians, reptiles, and mammals.
- vesicle** (ves'-i-kul) A membranous sac in the cytoplasm of a eukaryotic cell.
- vessel** A nonliving, water-conducting tube found in most angiosperms and a few nonflowering vascular plants that is formed by the end-to-end connection of vessel elements.
- vessel element** A short, wide, water-conducting cell found in the xylem of most angiosperms and a few nonflowering vascular plants. Dead at maturity, vessel elements are aligned end to end to form vessels.
- vestigial structure** A feature of an organism that is a historical remnant of a structure that served a function in the organism's ancestors.
- villus** (plural, villi) (1) A finger-like projection of the inner surface of the small intestine. (2) A finger-like projection of the chorion of the mammalian placenta. Large numbers of villi increase the surface areas of these organs.
- viral envelope** A membrane, derived from membranes of the host cell, that cloaks the capsid, which in turn encloses a viral genome.
- virulent** Describing a pathogen against which an organism has little specific defense.
- virulent phage** A phage that replicates only by a lytic cycle.
- virus** An infectious particle incapable of replicating outside of a cell, consisting of an RNA or DNA genome surrounded by a protein coat (capsid) and, for some viruses, a membranous envelope.
- visible light** That portion of the electromagnetic spectrum that can be detected as various colors by the human eye, ranging in wavelength from about 380 nm to about 750 nm.
- vital capacity** The maximum volume of air that a mammal can inhale and exhale with each breath.
- vitamin** An organic molecule required in the diet in very small amounts. Many vitamins serve as coenzymes or parts of coenzymes.
- voltage-gated ion channel** A specialized ion channel that opens or closes in response to changes in membrane potential.
- vulva** Collective term for the female external genitalia.
- water potential ( $\Psi$ )** The physical property predicting the direction in which water will flow, governed by solute concentration and applied pressure.
- wavelength** The distance between crests of waves, such as those of the electromagnetic spectrum.
- wetland** A habitat that is inundated by water at least some of the time and that supports plants adapted to water-saturated soil.
- white matter** Tracts of axons within the CNS.
- whole-genome shotgun approach** Procedure for genome sequencing in which the genome is randomly cut into many overlapping short segments that are sequenced; computer software then assembles the complete sequence.
- wild type** The phenotype most commonly observed in natural populations; also refers to the individual with that phenotype.
- wilting** The drooping of leaves and stems that occurs when plant cells become flaccid.
- wobble** Flexibility in the base-pairing rules in which the nucleotide at the 5' end of a tRNA anticodon can form hydrogen bonds with more than one kind of base in the third position (3' end) of a codon.
- xerophyte** A plant adapted to an arid climate.
- X-linked gene** A gene located on the X chromosome; such genes show a distinctive pattern of inheritance.
- X-ray crystallography** A technique used to study the three-dimensional structure of molecules. It depends on the diffraction of an X-ray beam by the individual atoms of a crystallized molecule.
- xylem** (zi'-lum) Vascular plant tissue consisting mainly of tubular dead cells that conduct most of the water and minerals upward from the roots to the rest of the plant.
- xylem sap** The dilute solution of water and dissolved minerals carried through vessels and tracheids.
- yeast** Single-celled fungus. Yeasts reproduce asexually by binary fission or by the pinching of small buds off a parent cell. Many fungal species can grow both as yeasts and as a network of filaments; relatively few species grow only as yeasts.
- zero population growth (ZPG)** A period of stability in population size, when additions to the population through births and immigration are balanced by subtractions through deaths and emigration.
- zoned reserve** An extensive region that includes areas relatively undisturbed by humans surrounded by areas that have been changed by human activity and are used for economic gain.
- zoonotic pathogen** A disease-causing agent that is transmitted to humans from other animals.
- zygote** (zi'-gōt) The diploid cell produced by the union of haploid gametes during fertilization; a fertilized egg.

**NOTE:** A page number in regular type indicates where a topic is discussed in the text (the topic may also be in a figure or table on that page); a **bold** page number indicates where a term is bold and defined; an *f* following a page number indicates a figure (the topic may also be discussed in the text on that page); a *t* following a page number indicates a table (the topic may also be discussed in the text on that page).

genetic variability as nucleotide variability in, 400–401*f*  
genetic variation due to mutations in, 401–402  
genomes as complete sequences of, 6 (*see also* Genome(s))  
homeoboxes in, 360–361  
homologies and, 385–387  
human gene microarray chips containing, 347  
inheritance of, in genes and chromosomes, 193  
interpreting data from, in phylogenetic trees, 394  
interpreting sequence logos for, 284  
introns and exons, 277  
as measure of evolution, 62–63  
methylation of, in eukaryotic gene regulation, 299  
in mitochondria and chloroplasts, 82  
as molecular homology, 376  
monitoring gene expression and, 307–309  
*p53* gene and repair of, 326  
packing of proteins and, into chromosomes, 259–261*f*  
phylogenies based on, 381*f*  
in plant cells, 73*f*  
prokaryotic, 464–465  
in prokaryotic and eukaryotic cells, 69–70  
prokaryotic genetic recombination of, 468–470  
recombinant (*see* Recombinant DNA)  
repetitive and noncoding, in genomes, 349–352  
replication of, 245, 251–259 (*see also* DNA replication)  
role of, in protein synthesis, 60  
species identity in mitochondrial, 384*f*  
structure and function of, 5–6  
structure of molecules of, 62  
template strands of, 272–273  
transcription by, 274–276  
viral (*see* DNA viruses)

   skeletal muscles of (*see* Skeletal muscles)  
   swimming, 802  
   terrestrial, 540*f*, 542–546  
   visual systems of, 787–789  
 Vertical layering, terrestrial biome, 824  
 Vertical transmission, viral, 341  
 Vesicles, **76**  
   abiotically produced, as protocells, 460  
   in bulk transport, 106–107*f*  
   in endomembrane system, 76–77, 81*f*  
   in lysosomal autophagy, 80*f*  
   in plant cytokinesis, 181*f*, 182  
   transport (*see* Transport vesicles)  
 Vessel elements, **559f**  
 Vessels, circulatory, 685–686. *See also* Blood vessels  
 Vessels, lymphatic, 694*f*  
 Vessels, xylem, **559f**  
 Vestibular canal, 783*f*, 784  
 Vestibular glands, 735  
 Vestigial structures, **375**–376  
 Viagra, 734–735, 765  
*Vibrio cholerae*, 472*f*, 476  
 Villi, 674*f*, **675**  
 Viral envelopes, **332**, 335–336  
 Viral integration, 328  
 Virchow, Rudolf, 174  
 Virulent pathogens, **636**  
 Virulent phages, **333**–334  
 Viruses, **246**, **330**–342  
   analyzing DNA sequence-based phylogenetic tree to understand evolution of influenza, 340  
   in cancer development, 328, 726–727  
   characteristics of life and, 330  
   community ecology and zoonotic, 853  
   evidence for viral DNA in bacteriophages, 246–248  
   evolution of, 336–337  
   importance of, for molecular biology, 337  
   interferons and, 714  
   latency of, 725  
   as pathogens, 338–341  
   rapid reproduction of, as source of genetic variation, 402  
   replicative cycles of, 332–336, 337*f*  
   RNAi pathways and, 306  
   structure of, 330–332  
 Visible light, **160**  
 Vision. *See* Visual systems  
 Visual association cortex, 776*f*  
 Visual communication, 806  
 Visual cortex, 776*f*  
 Visual fields, 788, 789  
 Visual pigments, 787*f*, 789  
 Visual systems, 785–789  
   color vision in, 789  
   compound eyes in, 786  
   evolution of, 785–787  
   light-detecting organs in, 785  
   sensory transduction in, 787–788  
   single-lens eyes in, 786–787  
   structure of human eyes in, 786*f*–787*f*  
   vertebrate, 787–789  
   visual fields in, 789  
   visual information processing in brain in, 788–789  
   visual information processing in retina in, 788  
 Vital capacity, **705**  
 Vitamin A, 612, 613*f*, 667  
 Vitamin B<sub>9</sub>, 668  
 Vitamin C, 666–667  
 Vitamin D, 667  
 Vitamins, **666**–668  
 Vitreous humor, 786*f*  
 Vocal cords and vocal folds, 702  
 Vocalization, *FOXP2* gene and, 359  
 Volcanic springs, 471  
 Volcanoes, 445, 459  
 Voles, 812  
 Voltage, membrane potential, 104–105  
 Voltage-gated ion channels, 756*f*, **757**–760, 761*f*  
 Volume, cell, 70–71*f*, 74  
 Volume, sound, 784  
 Voluntary nervous system, 771  
*Volvox*, 487–488, 491*f*, 496  
 von Frisch, Karl, 803, 805  
 von Humboldt, Alexander, 860  
 Vulva, **735**
- W**  
 Waggle dance, honeybee, 805*f*  
 Waists, chromatid, 176  
 Wakefulness, brain functions and, 774  
 Walking, 802  
 Wallace, Alfred Russel, 369, 859  
 Walnut trees, 839  
 Walrus, 645*f*  
 Warren, Robin, 673  
 Washington, stream biome in, 828*f*  
 Wasps, 541*f*, 636, 808  
*Watasenia scintillans*, 116  
 Water, 29–37  
   acids, bases, buffers, and pH of solutions of, 34–36  
   aqueous solutions and, as solvent of life, 33–34  
   biomanipulation and quality of, 855  
   bioremediation of polluted, 868–869, 878–879*f*  
   in blood plasma, 695  
   catabolic pathways and, 136  
   cell balance of (*see* Water balance)  
   cohesion and adhesion of, 30  
   as compound, 25  
   conduction of, in plant cells, 559*f*  
   covalent bonding of, 25*f*  
   effect of large bodies of, on climate, 31*f*  
   evapotranspiration of, 859  
   evolution of alternative plant mechanisms to reduce loss of, 169–171  
   floating of ice on liquid, 32–33  
   fruit and seed dispersal by, 607*f*  
   hydrogen bonds and properties of, 27, 29–30  
   kidney conservation of, 659–660  
   land plants and, 505, 507  
   moderation of temperature by, 30–32  
   molecular shape of, 27*f*  
   ocean acidification and, 36–37  
   pH of, 35*f*  
   in photosynthesis, 28–29*f*  
   plant responses to flooding, 633–634, 635*f*  
   regulation of plant transpiration and loss of, 590–593  
   root architecture and acquisition of, 573–574  
   seed germination and imbibition of, 605  
   species distributions and availability of, 831–832  
   splitting of, in photosynthesis, 158  
   temperature and uptake of, by seeds, 576  
   in thigmotropism, 633

- transpiration of, from roots to shoots via xylem, 587–590  
 transport of, in plants, 30  
 vascular plant transport of, across plasma membranes, 575–578
- Water balance  
   kidney processing and, 658–659  
   osmoregulation and, 653–655  
   osmosis and, 100–102
- Water bugs, 733*f*
- Water cycle, 874*f*
- Water fleas, 838*f*
- Water lilies, 520*f*–521
- Water potential, **575**  
   in plant transpiration, 588–589  
   in vascular plant water transport, 575–577
- Water-soluble vitamins, 666–667
- Watkinson, Andrew, 840
- Watson, James  
   discovery of DNA molecular structure by, 245, 249–251  
   model of DNA replication of, 252, 253*f*  
   reductionism of, 3
- Wavelengths, light, **160**–162

   ensuring survival of, 732–733  
   fertilization and, 742–744  
   human, 195–196, 746

# Brief Contents

- 1** Introduction: Evolution and the Foundations of Biology 1

## UNIT 1 Chemistry and Cells

- 2** The Chemical Context of Life 19  
**3** Carbon and the Molecular Diversity of Life 40  
**4** A Tour of the Cell 66  
**5** Membrane Transport and Cell Signaling 94  
**6** An Introduction to Metabolism 116  
**7** Cellular Respiration and Fermentation 135  
**8** Photosynthesis 155  
**9** The Cell Cycle 174

## UNIT 2 Genetics

- 10** Meiosis and Sexual Life Cycles 192  
**11** Mendel and the Gene Idea 206  
**12** The Chromosomal Basis of Inheritance 228  
**13** The Molecular Basis of Inheritance 245  
**14** Gene Expression: From Gene to Protein 268  
**15** Regulation of Gene Expression 293  
**16** Development, Stem Cells, and Cancer 311  
**17** Viruses 330  
**18** Genomes and Their Evolution 343

## UNIT 3 Evolution

- 19** Descent with Modification 365  
**20** Phylogeny 381  
**21** The Evolution of Populations 399  
**22** The Origin of Species 418  
**23** Broad Patterns of Evolution 436

## UNIT 4 The Evolutionary History of Life

- 24** Early Life and the Diversification of Prokaryotes 458  
**25** The Origin and Diversification of Eukaryotes 481  
**26** The Colonization of Land by Plants and Fungi 504  
**27** The Rise of Animal Diversity 528

## UNIT 5 Plant Form and Function

- 28** Plant Structure and Growth 553  
**29** Resource Acquisition, Nutrition, and Transport in Vascular Plants 571  
**30** Reproduction and Domestication of Flowering Plants 597  
**31** Plant Responses to Internal and External Signals 617

## UNIT 6 Animal Form and Function

- 32** Homeostasis and Endocrine Signaling 641  
**33** Animal Nutrition 665  
**34** Circulation and Gas Exchange 684  
**35** The Immune System 711  
**36** Reproduction and Development 729  
**37** Neurons, Synapses, and Signaling 751  
**38** Nervous and Sensory Systems 768  
**39** Motor Mechanisms and Behavior 792

## UNIT 7 Ecology

- 40** Population Ecology and the Distribution of Organisms 818  
**41** Species Interactions 845  
**42** Ecosystems and Energy 864  
**43** Global Ecology and Conservation Biology 882
