

A photograph of a person with blonde hair in a ponytail, wearing a blue and white plaid shirt, light-colored pants, and a black backpack, walking away from the camera on a dirt path through a lush green forest. A small brown dog is walking on a leash to the right of the person. The path is surrounded by tall grasses and dense foliage.

Myers' Psychology

Second Edition

for AP[®]

Timeline

The Story of Psychology: A Timeline

by Charles L. Brewer, Furman University

B.C.E.

387 — Plato, who believed in innate ideas, suggests that the brain is the seat of mental processes.

335 — Aristotle, who denied the existence of innate ideas, suggests that the heart is the seat of mental processes.

C.E.

1604 — Johannes Kepler describes inverted image on the retina.

1605 — Francis Bacon publishes *The Proficiency and Advancement of Learning*.

1636 — Harvard College is founded.

1637 — René Descartes, the French philosopher and mathematician who proposed mind-body interaction and the doctrine of innate ideas, publishes *A Discourse on Method*.

1690 — John Locke, the British philosopher who rejected Descartes' notion of innate ideas and insisted that the mind at birth is a "blank slate" (*tabula rasa*), publishes *An Essay Concerning Human Understanding*, which stresses empiricism over speculation.

1774 — Franz Mesmer, an Austrian physician, performs his first supposed cure using "animal magnetism" (later called Mesmerism and hypnosis). In **1777** he was expelled from the practice of medicine in Vienna.

1793 — Philippe Pinel releases the first mental patients from their chains at the Bicêtre Asylum in France and advocates more humane treatment of mental patients.

1802 — Thomas Young publishes *A Theory of Color Vision* in England. (His theory was later called the trichromatic theory.)

1808 — Franz Joseph Gall, a German physician, describes phrenology, the belief that the shape of a person's skull reveals mental faculties and character traits.

1834 — Ernst Heinrich Weber publishes *The Sense of Touch*, in which he discusses the just noticeable difference (*jnd*) and what we now call Weber's Law.

1848 — Phineas Gage suffers massive brain damage when a large iron rod accidentally pierces his brain, leaving his intellect and memory intact but altering his personality.

1859 — Charles Darwin publishes *On the Origin of Species by Means of Natural Selection*, synthesizing much previous work on the theory of evolution, including that of Herbert Spencer, who coined the phrase "survival of the fittest."

1861 — Paul Broca, a French physician, discovers an area in the left frontal lobe of the brain (now called Broca's area) that is critical for the production of spoken language.

1901 —

Ten founders establish the British Psychological Society.

1905 —

Mary Whiton Calkins becomes the first woman president of the APA.

—

Ivan Petrovich Pavlov begins publishing studies of conditioning in animals.

—

Alfred Binet and Théodore Simon produce the first intelligence test for assessing the abilities and academic progress of Parisian schoolchildren.

1913 —

John B. Watson outlines the tenets of behaviorism in a *Psychological Review* article, "Psychology as the Behaviorist Views It."

1914 —

During World War I, Robert Yerkes and his staff develop a group intelligence test for evaluating U.S. military personnel, which increases the U.S. public's acceptance of psychological testing.

1920 —

Leta Stetter Hollingworth publishes *The Psychology of Subnormal Children*, an early classic. In **1921** she is cited in *American Men of Science* for her research on the psychology of women.

—

Francis Cecil Summer receives a Ph.D. degree in psychology from Clark University, becoming the first African-American to earn a psychology doctorate.

—

John B. Watson and Rosalie Rayner report conditioning a fear reaction in a child called "Little Albert."

1921 —

Hermann Rorschach, a Swiss psychiatrist, introduces the Rorschach inkblot test.

1923 —

Developmental psychologist Jean Piaget publishes *The Language and Thought of the Child*.

1924 —

Mary Cover Jones reports reconditioning a fear reaction in a child (Peter), a forerunner of systematic desensitization developed by Joseph Wolpe.

1927 —

In *Introduction to the Technique of Child Analysis*, Anna Freud discusses psychoanalysis in the treatment of children.

1929 —

Wolfgang Köhler publishes *Gestalt Psychology*, which criticizes behaviorism and outlines essential elements of the Gestalt position and approach.

1931 —

Margaret Floy Washburn becomes the first female psychologist (and the second female scientist in any discipline) elected to the U.S. National Academy of Sciences.

1932 —

In *The Wisdom of the Body*, Walter B. Cannon coins the term *homeostasis*, discusses the fight-or-flight response, and identifies hormonal changes associated with stress.

Turn the page to continue

- 1869**— Francis Galton, Charles Darwin's cousin, publishes *Hereditary Genius*, in which he claims that intelligence is inherited. In **1876** he coins the expression “nature and nurture” to correspond with “heredity and environment.”
- 1874**— Carl Wernicke, a German neurologist and psychiatrist, shows that damage to a specific area in the left temporal lobe (now called Wernicke's area) disrupts ability to comprehend or produce spoken or written language.
- 1878**— G. Stanley Hall receives from Harvard University's Department of Philosophy the first U.S. Ph.D. degree based on psychological research.
- 1879**— Wilhelm Wundt establishes at the University of Leipzig, Germany, the first psychology laboratory, which becomes a Mecca for psychology students from all over the world.
- 1883**— G. Stanley Hall, student of Wilhelm Wundt, establishes the first formal U.S. psychology laboratory at Johns Hopkins University.
- 1885**— Hermann Ebbinghaus publishes *On Memory*, summarizing his extensive research on learning and memory, including the “forgetting curve.”
- 1886**— Joseph Jastrow receives from Johns Hopkins University the first Ph.D. degree in psychology awarded by a Department of Psychology in the United States.
- 1889**— Alfred Binet and Henri Beaunis establish the first psychology laboratory in France at the Sorbonne, and the first International Congress of Psychology meets in Paris.
- 1890**— William James, Harvard University philosopher and psychologist, publishes *The Principles of Psychology*, describing psychology as “the science of mental life.”
- 1891**— James Mark Baldwin establishes the first psychology laboratory in the British Commonwealth at the University of Toronto.
- 1892**— G. Stanley Hall spearheads the founding of the American Psychological Association (APA) and becomes its first president.
- 1893**— Mary Whiton Calkins and Christine Ladd-Franklin are the first women elected to membership in the APA.
- 1894**— Margaret Floy Washburn is the first woman to receive a Ph.D. degree in psychology (Cornell University).
- Harvard University denies Mary Whiton Calkins admission to doctoral candidacy because of her gender, despite Hugo Münsterberg's claim that she was the best student he had ever had there.
- 1896**— John Dewey publishes “The Reflex Arc Concept in Psychology,” helping to formalize the school of psychology called functionalism.
- 1898**— In “Animal Intelligence,” Edward L. Thorndike, Columbia University, describes his learning experiments with cats in “puzzle boxes.” In **1905**, he proposes the “law of effect.”
- 1900**— Sigmund Freud publishes *The Interpretation of Dreams*, his major theoretical work on psychoanalysis.
- 1933**— Inez Beverly Prosser becomes the first African-American woman to receive a doctoral degree in psychology from a U.S. institution (Ph.D., University of Cincinnati).
- 1935**— Christiana Morgan and Henry Murray introduce the Thematic Apperception Test to elicit fantasies from people undergoing psychoanalysis.
- 1936**— Egas Moniz, Portuguese physician, publishes work on the first frontal lobotomies performed on humans.
- 1938**— B. F. Skinner publishes *The Behavior of Organisms*, which describes operant conditioning of animals.
- In *Primary Mental Abilities*, Louis L. Thurstone proposes seven such abilities.
- Ugo Cerletti and Lucino Bini use electroshock treatment with a human patient.
- 1939**— David Wechsler publishes the Wechsler-Bellevue intelligence test, forerunner of the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Adult Intelligence Scale (WAIS).
- Mamie Phipps Clark receives a master's degree from Howard University. In collaboration with Kenneth B. Clark, she later extends her thesis, “The Development of Consciousness of Self in Negro Preschool Children,” providing joint research cited in the U.S. Supreme Court's **1954** decision to end racial segregation in public schools.
- Edward Alexander Bott helps found the Canadian Psychological Association. He becomes its first president in **1940**.
- World War II provides many opportunities for psychologists to enhance the popularity and influence of psychology, especially in applied areas.
- 1943**— Psychologist Starke Hathaway and physician J. Charnley McKinley publish the Minnesota Multiphasic Personality Inventory (MMPI).
- 1945**— Karen Horney, who criticized Freud's theory of female sexual development, publishes *Our Inner Conflicts*.
- 1946**— Benjamin Spock's first edition of *The Commonsense Book of Baby and Child Care* appears; the book will influence child rearing in North America for several decades.
- 1948**— Alfred Kinsey and his colleagues publish *Sexual Behavior in the Human Male*, and they publish *Sexual Behavior in the Human Female* in **1953**.
- B. F. Skinner's novel, *Walden Two*, describes a Utopian community based on positive reinforcement, which becomes a clarion call for applying psychological principles in everyday living, especially communal living.
- Ernest R. Hilgard publishes *Theories of Learning*, which was required reading for several generations of psychology students in North America.
- 1949**— Raymond B. Cattell publishes the Sixteen Personality Factor Questionnaire (16PF).

About the Author

Hope College Public Relations

DAVID MYERS received his psychology Ph.D. from the University of Iowa. He has spent his career at Hope College in Michigan, where he has taught dozens of introductory psychology sections. Hope College students have invited him to be their commencement speaker and voted him “outstanding professor.”

His research and writings have been recognized by the Gordon Allport Intergroup Relations Prize, by a 2010 Honored Scientist award from the Federation of Associations in Behavioral & Brain Sciences, by a 2010 Award for Service on Behalf of Personality and Social Psychology, by a 2013 Presidential Citation from the American Psychological Association (APA) Division 2, and by three honorary doctorates.

Myers’ scientific articles have, with support from National Science Foundation grants, appeared in three dozen scientific periodicals, including *Science*, *American Scientist*, *Psychological Science*, and *American Psychologist*. In addition to his scholarly writing and his textbooks for introductory and social psychology, he also digests psychological science for the general public. His writings have appeared in four dozen magazines, from *Today’s Education* to *Scientific American*. He also has authored five general audience books, including *The Pursuit of Happiness* and *Intuition: Its Powers and Perils*.

David Myers has chaired his city’s Human Relations Commission, helped found a thriving assistance center for families in poverty, and spoken to hundreds of college, community, and high school groups (including AP® Psychology conferences, an AP® Psychology Reading, Teachers of Psychology in Secondary Schools, and the National Council for Social Studies Psychology Community). He also served on the APA’s working group that created the 2010 revision of the *National Standards for High School Psychology Curricula*.

Drawing on his experience, Myers has written dozens of articles and a book (*A Quiet World*) about hearing loss, and he is advocating a transformation in American assistive listening technology (see www.hearingloop.org). For his leadership, he received an American Academy of Audiology Presidential Award in 2011, the Hearing Loss Association of America Walter T. Ridder Award in 2012, and Oticon’s Focus on People Award in 2013.

He bikes to work year-round and plays regular pickup basketball. David and Carol Myers have raised two sons and a daughter, and have one granddaughter.

Content Advisory Board

TINA ATHANASOPOULOS

John Hershey High School, IL

Strive for a 5: Preparing for the AP® Psychology Examination

Tina Athanasopoulos has taught AP® Psychology since 1997 and implemented the AP® Psychology program for District 214 in Illinois. She was on the Test Development Committee for the AP® Psychology exam from 2005 through 2009. She has been involved with the AP® Psychology Reading since 2000 as a Reader, Table Leader, and Exam Leader. She currently serves as the Assistant Chief Reader. Tina has also been a College Board® consultant since 2001 and has presented at College Board® workshops across the country. Currently, Tina is also a professor for North Park University's Education Department.

CHARLES BLAIR-BROEKER

Cedar Falls High School, IA

Charlie Blair-Broeker has taught psychology to over 1500 students since 1978 and is one of only two people who has been at every annual AP® Psychology Reading since the AP® exam was first administered in 1992. He has been a Question Leader, Rubric Writer, Table Leader, and Reader for the AP® Psychology exam, completed a three-year term on the AP® Psychology Test Development Committee, and led many conferences on AP® Psychology. Among Charlie's teaching awards are the Grinnell College Outstanding Iowa Teacher Award, the University of Iowa Distinguished Teacher Award, and the APA Division 2 Teaching Excellence Award.

LAURA BRANDT

Adlai E. Stevenson High School, IL

Strive for a 5: Preparing for the AP® Psychology Examination

Laura Brandt has taught AP® Psychology since 1997 and has been involved with the AP® Psychology Reading since 1999, serving as a Reader, Table Leader, and Question Leader. She also works for the College Board® to facilitate sessions for AP® Psychology instructors. Currently, Laura also teaches AP® Psychology online through the Center for Talent Development at Northwestern University.

JAMES COSTELLO

Alvirne High School, NH

Dr. Jim Costello is a psychology, history, and government teacher in Hudson, NH. Holding a *Juris Doctor* from the University of Notre Dame, he had extensive civil trial experience prior to beginning his teaching career. He has taught psychol-

ogy and numerous other AP® courses in the ten years since transitioning from the courtroom to the classroom.

RANDAL ERNST

Lincoln Public Schools, NE

Randy Ernst was a member of the initial AP® Psychology Test Development Committee and has served as a Table Leader, Question Leader, and Exam Leader at the annual AP® Psychology Reading. Randy authored the second edition of the College Board's® *Teacher's Guide for Advanced Placement® Psychology*. Randy has taught introductory psychology at both the high school and college level, and has run dozens of psychology-related workshops all over the world. He co-authored the *National Standards for High School Psychology Curricula*. He was part of the APA committee that founded the Teachers of Psychology in Secondary Schools (TOPSS), and was elected TOPSS Chair in 1995. Randy is also an adjunct professor at the University of Nebraska-Lincoln.

NANCY FENTON

Adlai E. Stevenson High School, IL

Nancy Fenton has taught high school psychology since 2004 and has served as an AP® Psychology Reader since 2008. She is currently serving on a panel of teachers reviewing submissions of performance indicators designed to accompany the *National Standards for High School Psychology Curricula*, and as the TOPSS liaison to the APA committee on psychology in schools and education. Nancy is also co-author of the review book *AP® Psychology: All Access*.

JOE GEIGER

Carl Sandburg High School, IL

Joe Geiger has been teaching high school psychology since 1995, and he entered the world of AP® Psychology in 2002. He has been a regular presenter at the National Council for the Social Studies conference for the past eight years. Currently, Joe serves as a vice chair for the National Council for the Social Studies Psychology Community. He also sits as a member of the House of Delegates for the National Council for the Social Studies.

ADAM GOODIE

University of Georgia, GA

Dr. Adam Goodie is a professor of psychology at the University of Georgia, where he teaches the introductory course and

serves as the undergraduate coordinator. As director of the Georgia Decision Lab, he has published over 50 journal articles, books, chapters, and proceedings, and his research has been funded by the National Institute of Mental Health, the National Center for Responsible Gaming, and other agencies. His teaching has been recognized by being awarded the Russell Hall Last Lecture, and he serves as a Reader for the AP® Psychology exam.

KENT KOREK

Germantown High School, WI

Key Contributors Appendix, Lecture PowerPoint® Presentations

Kent Korek has taught psychology since 1978 and AP® Psychology since its inception in 1992. He was first invited to the AP® Psychology Reading in 2005 and was promoted to Table Leader three years later. Kent was endorsed as a College Board® consultant in 2004 and since then has conducted numerous one-day workshops and week-long AP® summer institutes in the United States and Canada. He may be best known as a moderator for the award-winning blog *Teaching High School Psychology* (teachinghighschoolpsychology.blogspot.com).

NATHANIEL NAUGHTON

Arlington Catholic High School, MA

Strive for a 5: Preparing for the AP® Psychology Examination

Nate Naughton is the Social Studies Chairperson at Arlington Catholic High School. He has taught regular psychology since 1995 and AP® Psychology since 2001 when he began his school's AP® Psychology program. Nate has served as an AP® Reader since 2008. He is also an adjunct faculty member at Park University, teaching psychology and liberal education courses.

DEBRA PARK

Rutgers University–Camden, NJ

For 33 years, Debra Park taught psychology at West Deptford High School, and her teaching awards include Gloucester County Teacher of the Year, Rutgers University Public School Educator of the Year, APA Award for Excellence in Teaching Psychology, and the Moffett Memorial Teaching Excellence

Award. Debra has served as a Reader for the AP® Psychology Reading. In 2011 she received an APA Presidential Citation for her outstanding contributions to the organization, and currently she serves as the Membership Committee Chair for STP, Division 2 (Teaching of Psychology) of the APA. Debra has taught various psychology and behavior management courses for Rutgers University–Camden for the last 13 years.

KIMBERLY PATTERSON

Cypress Bay High School, FL

Kimberly Patterson teaches in a high school that has been recognized by the College Board® for an exemplary AP® program at a public school. She has been teaching AP® Psychology for over 10 years, has been an AP® Psychology Reader for six years, and has been an AP® Psychology exam question writer for four years. She has spoken at the AP® Annual Conference twice on staying positive about teaching biological bases of the behavior. She has also taught at Palm Beach State University and with North Carolina Virtual Public Schools.

HILARY ROSENTHAL

Glenbrook South High School, IL

Hilary Rosenthal has been teaching AP® Psychology since 1995 in the Glenview, Illinois, area and was named Distinguished Teacher by Glenbrook South High School. She has been part of the annual AP® Psychology Reading as both Reader and Table Leader since 1997. She is currently a part of APA's working group to revise the *National Standards for High School Psychology Curricula*.

KRISTIN WHITLOCK

Viewmont High School, UT

Kristin Whitlock has taught AP® Psychology since 1992 and currently serves as a College Board® Advisor. She serves as part of the administrative team at the annual AP® Psychology Reading, and she authored the College Board's® *AP® Psychology Teacher's Guide*. Kristin has presented at numerous conferences and was awarded a Presidential citation from the APA and the 2005 Moffett Memorial Teaching Excellence Award.

Supplement Authors

AMY FINEBURG

A+ College Ready, AL

Annotated Teacher's Edition, Teacher's Resource Materials

An award-winning teacher, Dr. Amy Fineburg chaired the TOPSS executive board, served as a Reader then Table Leader at the AP[®] Psychology Reading, and chaired the APA working group that created the 2010 *National Standards for High School Psychology Curricula*. She also wrote the 2003 edition of the *Teacher's Guide for AP[®] Psychology*. She has contributed numerous articles to AP[®] Central and is a frequent workshop presenter and consultant for AP[®] Coordinators for the College Board[®]. She is an adjunct instructor in psychology at Samford University and is the chief academic officer for A+ College Ready, which works in Alabama to establish and build AP[®] programs in public schools.

ALLISON HERZIG

Langley High School, VA

Strive for a 5: Preparing for the AP[®] Psychology Examination

Allison Herzig has been teaching AP[®] Psychology for 15 years. She has been a Reader and Table Leader at the AP[®] Psychology Reading since 2002 and has been a workshop consultant for the College Board[®] for over a decade, running various workshops nationwide for AP[®] Psychology instructors. Allison has served on the test development committee for the Psychology Praxis, published a sample syllabus in the College Board's[®] *Teacher Resource Manual*, and authored a curriculum module on intelligence for the College Board[®]. Allison also currently teaches Methods and Instructional Strategies at American University.

STEVE JONES

Durham Public Schools, NC

Test Bank, Teacher's Resource Materials

Steve Jones is a National Board Certified Teacher who has taught AP[®] Psychology for 11 years. He has served as chair and as a member at large for the TOPSS committee and established North Carolina Teachers of Psychology. He is a former contributing editor of the *Psychology Teacher Network* quarterly newsletter, published by the APA. He is also a co-founder of the award-winning blog *Teaching High School Psychology* (teachinghighschoolpsychology.blogspot.com).

ROBERT McENTARFFER

Lincoln Public Schools, NE

Test Bank

Dr. Robert McEntarffer is an award-winning psychology teacher who has taught at both the high school and college level. Rob became an AP[®] Psychology Reader in 1995, was promoted to Table Leader, and served as a Question Leader from 2004 to 2010. He chaired the Assessment Committee at the Psychology Partnerships Project (James Madison University), co-authored *How to Prepare for the Advanced Placement[®] Psychology Exam*, and won the 2004 Moffett Memorial Teaching Excellence Award. Rob currently works as an assessment specialist for the Lincoln Public School district.

In Appreciation

Reviewers

My gratitude extends to the colleagues who contributed criticism, corrections, and creative ideas related to the content, pedagogy, and format of the tenth edition of *Psychology*. For their expertise and encouragement, and the gifts of their time to the teaching of psychology, I thank the reviewers and consultants listed below.

Brief Contents

Preface / xxiii

Unit I Psychology's History and Approaches / 1

- Module 1 Psychology's History / 1
- Module 2 Psychology's Big Issues and Approaches / 9
- Module 3 Careers in Psychology / 20

Unit II Research Methods: Thinking Critically With Psychological Science / 29

- Module 4 The Need for Psychological Science / 30
- Module 5 The Scientific Method and Description / 38
- Module 6 Correlation and Experimentation / 46
- Module 7 Statistical Reasoning in Everyday Life / 56
- Module 8 Frequently Asked Questions About Psychology / 64

Unit III Biological Bases of Behavior / 75

- Module 9 Biological Psychology and Neurotransmission / 76
- Module 10 The Nervous and Endocrine Systems / 86
- Module 11 Studying the Brain, and Older Brain Structures / 94
- Module 12 The Cerebral Cortex / 104
- Module 13 Brain Hemisphere Organization and the Biology of Consciousness / 114
- Module 14 Behavior Genetics: Predicting Individual Differences / 123
- Module 15 Evolutionary Psychology: Understanding Human Nature / 135

Unit IV Sensation and Perception / 150

- Module 16 Basic Principles of Sensation and Perception / 151
- Module 17 Influences on Perception / 163
- Module 18 Vision / 171
- Module 19 Visual Organization and Interpretation / 182
- Module 20 Hearing / 194
- Module 21 The Other Senses / 202

Unit V States of Consciousness / 217

- Module 22 Understanding Consciousness and Hypnosis / 218
- Module 23 Sleep Patterns and Sleep Theories / 225
- Module 24 Sleep Deprivation, Sleep Disorders, and Dreams / 234
- Module 25 Psychoactive Drugs / 246

Unit VI Learning / 262

- Module 26 How We Learn and Classical Conditioning / 263
- Module 27 Operant Conditioning / 275
- Module 28 Operant Conditioning's Applications, and Comparison to Classical Conditioning / 286
- Module 29 Biology, Cognition, and Learning / 292
- Module 30 Learning by Observation / 304

Unit VII Cognition / 316

- Module 31 Studying and Building Memories / 317
- Module 32 Memory Storage and Retrieval / 329

- Module 33 Forgetting, Memory Construction, and Memory Improvement / 341
- Module 34 Thinking, Concepts, and Creativity / 356
- Module 35 Solving Problems and Making Decisions / 361
- Module 36 Thinking and Language / 372

Unit VIII Motivation, Emotion, and Stress / 389

- Module 37 Motivational Concepts / 390
- Module 38 Hunger Motivation / 396
- Module 39 Sexual Motivation / 406
- Module 40 Social Motivation: Affiliation Needs / 412
- Module 41 Theories and Physiology of Emotion / 420
- Module 42 Expressed Emotion / 432
- Module 43 Stress and Health / 441
- Module 44 Stress and Illness / 448

Unit IX Developmental Psychology / 460

- Module 45 Developmental Issues, Prenatal Development, and the Newborn / 462
- Module 46 Infancy and Childhood: Physical Development / 471
- Module 47 Infancy and Childhood: Cognitive Development / 476
- Module 48 Infancy and Childhood: Social Development / 488
- Module 49 Gender Development / 500
- Module 50 Parents, Peers, and Early Experiences / 508
- Module 51 Adolescence: Physical and Cognitive Development / 513
- Module 52 Adolescence: Social Development and Emerging Adulthood / 519

- Module 53 Sexual Development / 526
- Module 54 Adulthood: Physical, Cognitive, and Social Development / 539

Unit X Personality / 554

- Module 55 Freud's Psychoanalytic Perspective: Exploring the Unconscious / 556
- Module 56 Psychodynamic Theories and Modern Views of the Unconscious / 565
- Module 57 Humanistic Theories / 571
- Module 58 Trait Theories / 576
- Module 59 Social-Cognitive Theories and Exploring the Self / 587

Unit XI Testing and Individual Differences / 606

- Module 60 Introduction to Intelligence / 607
- Module 61 Assessing Intelligence / 617
- Module 62 The Dynamics of Intelligence / 625
- Module 63 Studying Genetic and Environmental Influences on Intelligence / 632
- Module 64 Group Differences and the Question of Bias / 638

Unit XII Abnormal Behavior / 649

- Module 65 Introduction to Psychological Disorders / 650
- Module 66 Anxiety Disorders, Obsessive-Compulsive Disorder, and Posttraumatic Stress Disorder / 661
- Module 67 Mood Disorders / 671

- Module 68 Schizophrenia / 684
Module 69 Other Disorders / 693

Unit XIII Treatment of Abnormal Behavior / 707

- Module 70 Introduction to Therapy, and Psychodynamic and Humanistic Therapies / 708
Module 71 Behavior, Cognitive, and Group Therapies / 716
Module 72 Evaluating Psychotherapies and Prevention Strategies / 728
Module 73 The Biomedical Therapies / 740

Unit XIV Social Psychology / 753

- Module 74 Attribution, Attitudes, and Actions / 754
Module 75 Conformity and Obedience / 762
Module 76 Group Behavior / 771
Module 77 Prejudice and Discrimination / 780
Module 78 Aggression / 789
Module 79 Attraction / 798
Module 80 Altruism, Conflict, and Peacemaking / 807

Enrichment Modules / 821

- Module 81 Influences on Drug Use / 822
Module 82 Psychology at Work / 827

- Module 83 Experienced Emotion: Anger and Happiness / 844
Module 84 Human Flourishing / 856
Module 85 Animal Thinking and Language / 867

Contents

Preface / xxiii

Unit I

Psychology's History and Approaches / 1

Module 1 Psychology's History / 1

Psychology's Roots 2
Psychological Science Develops 5

Module 2 Psychology's Big Issues and Approaches / 9

Psychology's Biggest Question 9
Psychology's Three Main Levels of Analysis 11
Psychology's Subfields 13

■ **Close-up:** Improve Your Retention—
and Your Grades! 16

Module 3 Careers in Psychology / 20

Basic Research Subfields 20
Applied Research Subfields 22
The Helping Professions 23

Unit II

Research Methods: Thinking Critically With Psychological Science / 29

Module 4 The Need for Psychological Science / 30

Did We Know It All Along? Hindsight Bias 31
Overconfidence 32
Perceiving Order in Random Events 33
The Scientific Attitude: Curious, Skeptical, and Humble 34
Critical Thinking 35

Module 5 The Scientific Method and Description / 38

The Scientific Method 38
Description 40

Module 6 Correlation and Experimentation / 46

Correlation 46
Experimentation 50

Module 7 Statistical Reasoning in Everyday Life / 56

The Need for Statistics 56
Descriptive Statistics 57
Inferential Statistics 60

Module 8 Frequently Asked Questions About Psychology / 64

Psychology Applied 64
Ethics in Research 66

Unit III

Biological Bases of Behavior / 75

Module 9 Biological Psychology and Neurotransmission / 76

Biology, Behavior, and Mind 76
Neural Communication 78

Module 10 The Nervous and Endocrine Systems / 86

The Nervous System 86
The Endocrine System 90

Module 11 Studying the Brain, and Older Brain Structures / 94

The Tools of Discovery: Having Our Head Examined 94
Older Brain Structures 96

Module 12 The Cerebral Cortex / 104

Structure of the Cortex 104
Functions of the Cortex 105
The Brain's Plasticity 110

Module 13 Brain Hemisphere Organization and the Biology of Consciousness / 114

Our Divided Brain 114
Right-Left Differences in the Intact Brain 117

■ **Close-up:** Handedness 118

The Biology of Consciousness 118

Module 14 Behavior Genetics: Predicting Individual Differences / 123

Genes: Our Codes for Life 124
Twin and Adoption Studies 125
The New Frontier: Molecular Genetics 129
Heritability 129
Gene-Environment Interaction 130

Module 15 Evolutionary Psychology: Understanding Human Nature / 135

Natural Selection and Adaptation 135
Evolutionary Success Helps Explain Similarities 136
An Evolutionary Explanation of Human Sexuality 137

■ **Thinking Critically About:** The Evolutionary Perspective on Human Sexuality 139

Reflections on Nature and Nurture 140

Unit IV

Sensation and Perception / 150

Module 16 Basic Principles of Sensation and Perception / 151

Selective Attention 152
Transduction 155
Thresholds 156

■ **Thinking Critically About:** Can Subliminal Messages Control Our Behavior? 158

Sensory Adaptation 159

Module 17 Influences on Perception / 163

Perceptual Set 163
Context Effects 164
Emotion and Motivation 166

■ **Thinking Critically About:** ESP—Perception Without Sensation? 167

Module 18 Vision / 171

The Stimulus Input: Light Energy 171
The Eye 172
Visual Information Processing 174
Color Vision 178

Module 19 Visual Organization and Interpretation / 182

Visual Organization 182
Visual Interpretation 190

Module 20 Hearing / 194

The Stimulus Input: Sound Waves 195
The Ear 195

Module 21 The Other Senses / 202

Touch 202

Pain 203

Taste 207

Smell 207

Body Position and Movement 209

Sensory Interaction 210

Unit V

States of Consciousness / 217

Module 22 Understanding Consciousness and Hypnosis / 218

Defining Consciousness 218
Hypnosis 219

Module 23 Sleep Patterns and Sleep Theories / 225

Biological Rhythms and Sleep 225
Sleep Theories 230

■ **Close-up:** Sleep and Athletic Performance 231

Module 24 Sleep Deprivation, Sleep Disorders, and Dreams / 234

Sleep Deprivation and Sleep Disorders 234
Dreams 240

Module 25 Psychoactive Drugs / 246

Tolerance and Addiction 246

■ **Thinking Critically About:** Addiction 248

Types of Psychoactive Drugs 248

Unit VI

Learning / 262

Module 26 How We Learn and Classical Conditioning / 263

How Do We Learn? 263
Classical Conditioning 266

Module 27 Operant Conditioning / 275

Operant Conditioning 275
Skinner's Experiments 275
Skinner's Legacy 282

Module 28 Operant Conditioning's Applications, and Comparison to Classical Conditioning / 286

Applications of Operant Conditioning 286

■ **Close-up:** Training Our Partners 288

■ **Close-up:** Biofeedback 289

Contrasting Classical and Operant Conditioning 289

Module 29 Biology, Cognition, and Learning / 292

Biological Constraints on Conditioning 292
Cognition's Influence on Conditioning 296
Learning and Personal Control 298

Module 30 Learning by Observation / 304

Mirrors and Imitation in the Brain 305
Applications of Observational Learning 307

■ **Thinking Critically About:** Does Viewing Media Violence Trigger Violent Behavior? 309

Unit VII

Cognition / 316

Module 31 Studying and Building Memories / 317

Studying Memory 318
Building Memories: Encoding 320

Module 32 Memory Storage and Retrieval / 329

Memory Storage 329
Retrieval: Getting Information Out 334

Module 33 Forgetting, Memory Construction, and Memory Improvement / 341

Forgetting 341
Memory Construction Errors 347
Improving Memory 352

Module 34 Thinking, Concepts, and Creativity / 356

Thinking and Concepts 356
Creativity 357

Module 35 Solving Problems and Making Decisions / 361

Problem Solving: Strategies and Obstacles 361
Forming Good and Bad Decisions and Judgments 363

■ **Thinking Critically About:** The Fear Factor—Why We Fear the Wrong Things 366

Module 36 Thinking and Language / 372

Language Structure 373
Language Development 373
The Brain and Language 377
Language and Thought 379

Unit VIII

Motivation, Emotion, and Stress / 389

Module 37 Motivational Concepts / 390

Instincts and Evolutionary Psychology 391
Drives and Incentives 391
Optimum Arousal 392
A Hierarchy of Motives 393

Module 38 Hunger Motivation / 396

The Physiology of Hunger 397
The Psychology of Hunger 399
Obesity and Weight Control 401

■ **Close-up:** Waist Management 403

Module 39 Sexual Motivation / 406

The Physiology of Sex 406
The Psychology of Sex 409

Module 40 Social Motivation: Affiliation Needs / 412

The Benefits of Belonging 412
The Pain of Being Shut Out 414
Connecting and Social Networking 415

■ **Close-up:** Managing Your Social Networking 417

Module 41 Theories and Physiology of Emotion / 420

Cognition and Emotion 421
Embodied Emotion 425

■ **Thinking Critically About:** Lie Detection 428

Module 42 Expressed Emotion / 432

Detecting Emotion in Others 432
Gender, Emotion, and Nonverbal Behavior 434
Culture and Emotional Expression 435
The Effects of Facial Expressions 437

Module 43 Stress and Health / 441

Stress: Some Basic Concepts 442

Module 44 Stress and Illness / 448

Stress and Susceptibility to Disease 450

Unit IX

Developmental Psychology / 460

Module 45 Developmental Issues, Prenatal Development, and the Newborn / 462

Developmental Psychology's Major Issues 462
Prenatal Development and the Newborn 465

Module 46 Infancy and Childhood: Physical Development / 471

Brain Development 471
Motor Development 472
Brain Maturation and Infant Memory 473

Module 47 Infancy and Childhood: Cognitive Development / 476

Piaget's Theory and Current Thinking 477

- Close-up: Autism Spectrum Disorder and "Mind-Blindness" 481
- An Alternative Viewpoint: Lev Vygotsky's Scaffolding 484
- Reflecting on Piaget's Theory 484

Module 48 Infancy and Childhood: Social Development / 488

Origins of Attachment 488
Attachment Differences: Temperament and Parenting 490
Deprivation of Attachment 492
Day Care 494
Self-Concept 495
Parenting Styles 496
Culture and Child Raising 497

Module 49 Gender Development / 500

How Are We Alike? How Do We Differ? 500
The Nurture of Gender: Our Culture 503

Module 50 Parents, Peers, and Early Experiences / 508

Experience and Brain Development 508
How Much Credit or Blame Do Parents Deserve? 510
Peer Influence 510

Module 51 Adolescence: Physical and Cognitive Development / 513

Cognitive Development 514

Module 52 Adolescence: Social Development and Emerging Adulthood / 519

Forming an Identity 519
Parent and Peer Relationships 521
Emerging Adulthood 522

Module 53 Sexual Development / 526

- Close-up: The Sexualization of Girls 531
- Sexual Orientation 531

Module 54 Adulthood: Physical, Cognitive, and Social Development / 539

Physical Development 539
Cognitive Development 542
Social Development 543

Unit X

Personality / 554

Module 55 Freud's Psychoanalytic Perspective: Exploring the Unconscious / 556

Psychoanalytic Theory's Core Ideas 556
Evaluating Freud's Psychoanalytic Perspective 561

Module 56 Psychodynamic Theories and Modern Views of the Unconscious / 565

The Neo-Freudian and Psychodynamic Theorists 565

Assessing Unconscious Processes 566
The Modern Unconscious Mind 568

Module 57 Humanistic Theories / 571

Abraham Maslow's Self-Actualizing Person 571
Carl Rogers' Person-Centered Perspective 572
Assessing the Self 573
Evaluating Humanistic Theories 573

Module 58 Trait Theories / 576

Exploring Traits 577

Assessing Traits 578

■ **Thinking Critically About:** How to Be a “Successful” Astrologer or Palm-Reader 579

The Big Five Factors 580

Evaluating Trait Theories 582

Module 59 Social-Cognitive Theories and Exploring the Self / 587

Social-Cognitive Theories 587

■ **Close-up:** Toward a More Positive Psychology 590

Exploring the Self 594

Unit XI

Testing and Individual Differences / 606

Module 60 Introduction to Intelligence / 607

Is Intelligence One General Ability or Several Specific Abilities? 608

Emotional Intelligence 612

Is Intelligence Neurologically Measurable? 613

Module 61 Assessing Intelligence / 617

The Origins of Intelligence Testing 617

Modern Tests of Mental Abilities 619

Principles of Test Construction 620

Module 62 The Dynamics of Intelligence / 625

Stability or Change? 625

Extremes of Intelligence 629

Module 63 Studying Genetic and Environmental Influences on Intelligence / 632

Twin and Adoption Studies 632

Environmental Influences 634

Module 64 Group Differences and the Question of Bias / 638

Group Differences in Intelligence Test Scores 638

The Question of Bias 641

Unit XII

Abnormal Behavior / 649

Module 65 Introduction to Psychological Disorders / 650

Defining Psychological Disorders 651

Understanding Psychological Disorders 651

■ **Thinking Critically About:** ADHD—Normal High Energy or Disordered Behavior? 652

Classifying Psychological Disorders 654

Labeling Psychological Disorders 655

■ **Thinking Critically About:** Insanity and Responsibility 656

Rates of Psychological Disorders 657

Module 66 Anxiety Disorders, Obsessive-Compulsive Disorder, and Posttraumatic Stress Disorder / 661

Generalized Anxiety Disorder 662

Panic Disorder 662

Phobias 662

Obsessive-Compulsive Disorder 663

Posttraumatic Stress Disorder 664

Understanding Anxiety Disorders, OCD, and PTSD 666

Module 67 Mood Disorders / 671

Major Depressive Disorder 671

Bipolar Disorder 673

Understanding Mood Disorders 674

■ **Close-up:** Suicide and Self-Injury 676

Module 68 Schizophrenia / 684

Symptoms of Schizophrenia 684

Onset and Development of Schizophrenia 685

Understanding Schizophrenia 686

- Module 69 Other Disorders / 693**
Somatic Symptom and Related Disorders 693

- Dissociative Disorders 694
Eating Disorders 697
Personality Disorders 698

Unit XIII

Treatment of Abnormal Behavior / 707

- Module 70 Introduction to Therapy, and Psychodynamic and Humanistic Therapies / 708**
Introduction to Therapy 709
Psychoanalysis and Psychodynamic Therapy 709
Humanistic Therapies 711
- Module 71 Behavior, Cognitive, and Group Therapies / 716**
Behavior Therapies 716
Cognitive Therapies 720
Group and Family Therapies 723

- Module 72 Evaluating Psychotherapies and Prevention Strategies / 728**
Evaluating Psychotherapies 728
- **Thinking Critically About:** “Regressing” from Unusual to Usual 730
 - **Close-up:** A Consumer’s Guide to Psychotherapists 736
- Preventing Psychological Disorders 737

- Module 73 The Biomedical Therapies / 740**
Drug Therapies 740
Brain Stimulation 743
Psychosurgery 746
Therapeutic Lifestyle Change 746

Unit XIV

Social Psychology / 753

- Module 74 Attribution, Attitudes, and Actions / 754**
The Fundamental Attribution Error 754
Attitudes and Actions 756
- Module 75 Conformity and Obedience / 762**
Conformity: Complying With Social Pressures 762
Obedience: Following Orders 765
- Module 76 Group Behavior / 771**
Social Facilitation 771
Social Loafing 772
Deindividuation 773
Group Polarization 773
Groupthink 775
The Power of Individuals 775
Cultural Influences 776

- Module 77 Prejudice and Discrimination / 780**
Prejudice 780
- **Close-up:** Automatic Prejudice 782

- Module 78 Aggression / 789**
The Biology of Aggression 789
Psychological and Social-Cultural Factors in Aggression 791

- Module 79 Attraction / 798**
The Psychology of Attraction 798
- **Close-up:** Online Matchmaking and Speed Dating 799
- Romantic Love 803

- Module 80 Altruism, Conflict, and Peacemaking / 807**
Altruism 807
Conflict and Peacemaking 810

Enrichment Modules / 821

- Module 81** Influences on Drug Use / 822
- Module 82** Psychology at Work / 827
- Module 83** Experienced Emotion: Anger and Happiness / 844
- Module 84** Human Flourishing / 856
- Module 85** Animal Thinking and Language / 837

How to Get the Most From Your AP® Psychology Resources

The Advanced Placement® (AP®) Psychology course represents a wonderful opportunity for high school students to be challenged by the rigor of a college-level course, while learning life-relevant, mind-expanding concepts from the humanly significant discipline of psychology.

My unwavering vision for *Psychology for AP®* has been to *merge rigorous science with a broad human perspective that engages both mind and heart*. I aim to offer a state-of-the-art introduction to psychological science that speaks to your needs and interests. I aspire to help you understand and appreciate the wonders of your everyday life. And I seek to convey the inquisitive spirit with which psychologists *do* psychology.

HIGH SCHOOL INSIGHT

Creating this book is a team sport. Like so many human achievements, it is the product of a collective intelligence. Woodrow Wilson spoke for me: “I not only use all the brains I have, but all I can borrow.”

For this edition, I was fortunate to collaborate closely with an expert Content Advisory Board throughout the development process. The Content Advisory Board understands the needs of the AP® Psychology teacher and student, and provided crucial direction on how to make the content relevant, engaging, and appropriate for a high school classroom. In addition, the Board members provided sage guidance on key content, organizational, and pedagogical issues and ensured that the end-of-module and end-of-unit assessments provide the practice you will need for the questions you will encounter on the AP® exam. More detailed information about our extensive teacher/student support package can be found in the *Annotated Teacher’s Edition* and on our catalog page: <http://highschool.bfwpub.com/MyersAP2e>.

I extend gratitude and admiration to each of our Board members for their enduring contributions to the teaching of psychology. See pages vii through ix for more information about each of these talented educators and assessment writers.

WHAT’S NEW?

The organization of this book is inspired by my goal of providing the ultimate teaching and learning tool for AP® Psychology teachers and students. With this in mind, the second edition has been carefully restructured and extensively updated, while keeping true to the most recently revised College Board® Course Description. It features improvements to the organization and presentation, as well as to our system of supporting student learning and remembering. For a visual walk-through of the features of the book, see pages xxxi through xxxiv.

Key Content Changes

New Research Throughout

My ongoing scrutiny of dozens of scientific periodicals and science news sources, in addition to regular correspondence with researchers, was enhanced by commissioned reviews and countless e-mails from teachers and students. All this supports my integrating the field's most important, thought-provoking, and student-relevant new discoveries. See the table below for details about new coverage.

Key Content Changes in *Myers' Psychology for AP[®], 2nd Edition*

Unit I: Psychology's History and Approaches

- Updated coverage of women in psychology and cross-cultural psychology.
- Introduction of *positive psychology* and *community psychology*, both new key terms.
- Increased coverage of psychology's subfields.

Unit II: Research Methods: Thinking Critically With Psychological Science

- Scientific method is now illustrated with theory about sleep's value for effective learning.
- Includes new survey data examples; *sampling bias* is a new key term.
- Improved clarification of random sampling and random assignment.
- New research demonstrating the dangers of statistical illiteracy, and expanded discussion of descriptive and inferential statistics.

Unit III: Biological Bases of Behavior

- Author's personal MRI experience demonstrates autonomic nervous system in action.
- Includes new coverage of cognitive neural prosthetics.
- New photo shows Phineas Gage as he looked *after* his famous accident.
- Now includes new research on blindsight.
- Several new key terms, including *refractory period*, *all-or-none response*, *agonist*, *antagonist*, and *epigenetics*.

Unit IV: Sensation and Perception

- Both topics covered in clearer and more efficient fashion.
- Expanded discussion and new research examples of selective attention.
- New section covers *embodied cognition*, the blending of tactile and social judgments.
- Includes new coverage of taste-touch sensory interaction, and new cognitive neuroscience research helps explain smell-cognition connection.

Unit V: States of Consciousness

- Expanded coverage and research examples of conscious awareness.
- Adopts the new American Academy of Sleep Medicine classification of sleep stages (REM, NREM-1, NREM-2, and NREM-3).
- Includes new research linking sleep loss and depression in adolescents, and new research support for sleep deprivation lowering immune system functioning.
- New illustration of physiological effects of sleep deprivation.
- Drugs discussion fully updated for DSM-5 (*substance use disorder* and *alcohol use disorder* are new key terms); new table outlines when drug use is a disorder.

Unit VI: Learning

- New biology, cognition, and learning section that more fully explores the biological and cognitive constraints on classical, operant, and observational learning.

- New learning and personal control section.
- New key terms include *cognitive learning*, *respondent behavior*, and *operant behavior*.
- New research examples of how children will over-imitate adult actions.
- Updated research examples of media violence viewing/violent behavior.

Unit VII: Cognition

- David Myers worked closely with Janie Wilson (professor of psychology at Georgia Southern University and vice president for programming of the Society for the Teaching of Psychology) for this unit's thorough revision.
- Atkinson-Shiffrin's three-stage model de-emphasized in favor of more current theories; coverage of working memory updated and expanded.
- New discussion of the testing effect and other study tips, including best times to study and effects of spacing on memory over time.
- New research on inaccurate autobiographical memories, memory reconsolidation, the misinformation effect, insight, confirmation bias, framing, and why we tend to fear the wrong things.
- New research updates the discussion of babies' productive language development and the nature–nurture debate over language development.
- Neuroscience research updates discussion of language development; coverage of aphasia, Broca's area, and Wernicke's area now appears here.

Unit VIII: Motivation, Emotion, and Stress

- Biochemistry of hunger and the biological and cultural influences on hunger updated.
- New research fully updated for DSM-5 enhances discussion of hormones and sexual behavior.
- New discussion of social networking.
- Theories of emotion coverage reorganized and improved.
- New research tracks positive vs. negative social media posts across days of the week.
- New research supports men's tendency to socially withdraw under stress and women's tendency to *tend and befriend*.
- New research shows health-depleting effects of depression, anxiety, and stress, including the links to genes controlling inflammation.

Unit IX: Developmental Psychology

- Discussion of teratogens expanded to include epigenetics.
- Autism spectrum disorder discussion extensively updated.
- Gender development section expanded and improved with new research.
- New research expands discussion of adolescent identity development to include effects on alcohol abuse and effects of romantic relationships; new social networking research updates peer relationship discussion.
- Sexual development now covered here.

Unit X: Personality

- Modern-day psychodynamic approaches now more clearly distinguished from historical Freudian roots.
- New research expands discussion of modern unconscious mind.
- New research supports value of humanistic psychology's positive regard as well as Big Five personality traits; new social networking research connects texting behavior with Big Five traits.

(continued on the next page)

- New cross-cultural research expands understanding of extraversion and well-being, and new research updates discussion of positive psychology.
- *Self-efficacy* and *narcissism* are new key terms.

Unit XI: Testing and Individual Differences

- New research updates discussion of *g* factor and cognitive abilities predicting later accomplishments.
- New research links emotional intelligence to unconscious processing and updates discussion of neurological measurements of intelligence.
- Research updates clarify discussion of twin studies and heritability and the variability of intelligence in gender, racial, ethnic, and socioeconomic groups.
- New research offers ideas for culturally less-biased intelligence tests and new examples support the effect of expectations on test performance.

Unit XII: Abnormal Behavior

- Fully updated to reflect DSM-5 changes.
- Updated PTSD coverage and related discussion of resilience and posttraumatic growth.
- New research on depression (including high school student population statistics); suicide box expanded to include nonsuicidal self-injury.
- New neuroscience research updates schizophrenia section; includes new risk factors and more research support for risk of maternal virus during midpregnancy.
- New cross-cultural research and art updates eating disorders coverage; antisocial personality disorder coverage updated.

Unit XIII: Treatment of Abnormal Behavior

- Fully updated to reflect DSM-5 changes.
- New case study demonstrates transference in therapy; now covers Ellis' *rational-emotive behavior therapy (REBT)*, with new key term and case study.
- Cognitive-behavioral therapy discussion expanded.
- Discussion of aims and benefits of group and family therapy clarified.
- Includes new research on certain psychotherapies working best on specific disorders, with *therapeutic alliance* a new key term.
- Improved antidepressants coverage for anxiety and other disorders.
- New research explores placebo effect in ECT treatment and alternative stimulation procedures.

Unit XIV: Social Psychology

- New research on persuasion uses climate change as central example; Milgram discussion includes cross-cultural, modern-day research replications.
- New coverage of online group polarization.
- New figure tracks prejudice over time in various age groups.
- Updated ingroup and outgroup discussion; new research on categorizing mixed-race people by their minority identity.
- New research on contributors to aggression; new research on prosocial effects of playing positive video games and on violent video games increasing aggression and decreasing compassion and altruism.

Enrichment Modules

- Engaging bonus material that teachers may choose to assign after the AP[®] exam: influences on drug use, psychology at work, experienced emotions, human flourishing, and animal thinking and language.

New Features

A Flexible Modular Approach

The second edition has been restructured with a modular approach. As in the first edition, the units still correspond to the College Board® AP® Topic Outline. For the second edition, the units have been divided into 3 to 10 modules each. Each module breaks the course material into a pedagogically appropriate “chunk” that is designed to be presented in one or two class periods, with additional class periods for activities, demonstrations, and reinforcement, as needed. The modular approach also makes it easier for you to remember what to study and read for homework.

In addition, the **Numbered Learning Objectives** have been improved and are now used more effectively to promote retention. They appear in statement form at the beginning of each module to help orient you to the material you are about to read. These clear and measurable Learning Objectives provide you with a snapshot preview of the section material, while allowing you to “check off” each objective as you master it. The objectives are repeated in an engaging question form in context within the module, and then used at the end of each module for review.

More AP®-Focused Elements and Study Aids

- **AP® Exam Tips**, found in the margin throughout the text, provide invaluable advice on where to focus and how to avoid pitfalls so that you may be successful in the course and on the exam. These tips also appear compiled in an appendix at the end of the book.
- More **AP® exam practice** is provided in the numerous, high-quality multiple-choice and free-response questions (FRQs) found at the end of each module and unit. These assessments not only test the material learned, but they also mimic AP® questions to train you for what you will see on the exam. The open-ended, conceptual FRQs familiarize you with the kind of synthesis skills you’ll need to master the exam.
- A **full-length AP®-style practice exam** is included at the end of the text to ensure you have nailed down the content and are ready to tackle the real test in May.
- A **Key Contributors list** appears at the end of each unit to highlight the most important people you should know in psychology. You can access the **Key Contributors Appendix** at the end of the text, and the *Key Contributors Study Guide* on the Book Companion Site (BCS) to be sure you are familiar with these core contributions to psychology. Access the BCS at www.worthpublishers.com/MyersAP2e.

What Continues?

Alignment With the College Board® Topic Outline

With help from my sharp-eyed editors and Content Advisory Board, I have worked to create an organization that matches up with the College Board’s® 2013 topic outline, so that teachers can be sure they are providing their students with the best possible preparation for the AP® exam. This means my text offers the same 14 units, in order, and the same distribution of content coverage among those 14 units. Where the outline has recommended coverage within specific units, you can be sure that you will find that coverage (sometimes with references to more, related coverage elsewhere).

Although the College Board® topic outline is not intended to be an exhaustive list of topics, it represents an excellent starting point—to which I have added coverage based on my own knowledge of what is needed to succeed in other college courses, what’s new and important in the world of psychology research, and perhaps most important, what an educated person needs to know. See the opening book pages for a table aligning each College Board® course description topic to the corresponding coverage in this text.

Thoughtful Study Aids

- **Numbered Learning Objective Questions**, as noted earlier, establish reading objectives for each significant section of text and direct your learning.

- **Before You Move On** features, found at the end of major sections of text, include **Ask Yourself questions**, which encourage you to apply new concepts to your own experiences, and **Test Yourself questions** (with answers in Appendix E) that assess mastery and encourage big-picture thinking.
- **Module Review Sections** repeat the numbered objective questions and address them with a bulleted summary. **Unit Review Sections** include page-referenced Terms and Concepts to Remember as well as a list of Key Contributors discussed in the unit.

Cultural and Gender Diversity Coverage

This text presents a thoroughly cross-cultural perspective on psychology (Table 1)—reflected in research findings, and text and photo examples. Coverage of the psychology of women and men is also thoroughly integrated (Table 2). Discussion of the relevance of cultural and gender diversity begins on the first page of the first unit and continues throughout the text.

Strong Critical Thinking Coverage and Research Emphasis

I aim to introduce you to critical thinking throughout the book. The text includes the following opportunities for you to learn or practice critical thinking skills and to work toward a better understanding of research design principles—both of which are essential to success on the AP[®] exam.

- Unit II, Research Methods: Thinking Critically With Psychological Science, introduces you to psychology's **research methods**, emphasizing the fallacies of our everyday intuition and common sense and, thus, the need for psychological science. Critical thinking is introduced as a key term in this unit (page 35). The Statistical Reasoning discussion encourages you to focus on thinking smarter by applying simple statistical principles to everyday reasoning.
- Throughout the text, additional opportunities may be found for you to test your understanding of **research design**, with narrative and marginal self-test review questions (with answers following in the narrative, or upside down in a nearby margin).
- **Critical examinations of key issues in psychology** appear throughout the narrative to spark interest and provide important lessons in thinking critically about everyday topics and pop psychology. (Consider, for example, the critical analysis of ESP on page 238.) See Table 3 for a summary of this text's coverage of critical thinking and research-related topics, and for a list of the Thinking Critically About boxes.

Table 1 Culture and Multicultural Experience

In Units I–XIV and the Enrichment Modules, coverage of culture and multicultural experience can be found on the following pages:

Aggression, p. 791	Behavioral effects of culture, p. 130	definition, pp. 776–777 and the self, pp. 598–600	use of, p. 824
AIDS, p. 450	Body ideal, pp. 697–698	shock, pp. 44, 777	Eating disorders: Western culture and, p. 698
Anger, p. 846	Categorization, pp. 256–257	Deaf culture, pp. 869, 117, 111, 374, 376, 377	Emotion:
Animal research ethics, pp. 66–67	Complementary/alternative medicine, p. 863	Development:	emotion-detecting ability, p. 432
Attraction:	Conformity, p. 765	attachment, pp. 492, 495	experiencing, p. 846
love and marriage, p. 803	Corporal punishment practices, pp. 281–282	child-rearing, p. 497	expressing, pp. 435–437, 435–437
speed-dating, p. 799	Cultural norms, pp. 140, 777, 503–504	cognitive development, p. 484	Enemy perceptions, p. 812
Attractiveness, pp. 138, 798–799, 801	Culture:	social development, p. 492	Fear, p. 367
Attribution, social and economic effects of, p. 755	context effects, p. 165	Drugs:	Flow, pp. 827–828
		psychological effects of, p. 247	Flynn effect, pp. 621–622

Fundamental attribution error, p. 755	Leaving the nest, p. 523	Participative management, p. 839	suicide, pp. 676–677
Gender:	Life satisfaction, p. 394	Peacemaking:	<i>susto</i> , p. 653
roles, pp. 503–504	Loop systems, p. 841	conciliation, p. 815	<i>taijin-kyofusho</i> , p. 653
social power, pp. 501–502	Management styles, p. 839	contact, pp. 812–813	Psychotherapy:
Grief, expressing, pp. 547–548	Marriage, pp. 544–545	cooperation, p. 814	culture and values in, p. 735
Happiness, pp. 851–852	Mating preferences, p. 138	Peer influence, p. 510	EMDR training, p. 733
Hindsight bias, p. 31	Meditation, p. 862	Personality, p. 588	Puberty and adult independence, p. 523
History of psychology, pp. 2–7	Memory encoding, p. 323	Prejudice, pp. 69, 52–53, 780–787	Self-esteem, p. 394
Human diversity/kinship, pp. 66, 776–777	Menopause, p. 540	Prejudice prototypes, pp. 356–357	Self-serving bias, pp. 596, 597
Identity, forming a social, p. 519	Mental illness rate, pp. 657–658	Psychological disorders:	Sex drive, p. 138
Individualism/collectivism, pp. 598–600	Molecular genetics: “missing women,” p. 129	antisocial personality disorder, pp. 700–701	Similarities, pp. 136–137
Intelligence, pp. 607, 617, 619, 614, 621–622	Motivation: hierarchy of needs, p. 394	cultural norms, p. 651	Social loafing, p. 773
bias, pp. 642–643	Need to belong, pp. 599–600	depression, pp. 671, 674, 675, 680	Social-cultural perspective, p. 11
nutrition and, pp. 640–641	Neurotransmitters: curare, p. 83	dissociative identity disorder, p. 695	Spirituality: Israeli kibbutz communities, p. 862
Language, pp. 376, 372–375, 377, 379–380, 776	Obesity, pp. 401, 402–403	eating disorders, pp. 698, 697–698	Stress:
monolingual/bilingual, p. 380	Observational learning: television and aggression, p. 309	rates of, pp. 657, 650	racism and, p. 444
	Optimism and health, p. 857	schizophrenia, pp. 653, 687–688	adjusting to a new culture, p. 443
	Organ donation, p. 368	somatoform, p. 693	Taste preferences, p. 400
	Pace of life, pp. 41, 777		Testing bias, pp. 642–643

Tools for Learning . . . Getting the Most From This Book

Each unit and its modules are structured with a common set of features designed to help students learn while remaining engaged.

Unit 1

Psychology's History and Approaches

Modules

- 1 Psychology's History
- 2 Psychology's Big Issues and Approaches
- 3 Careers in Psychology

For people whose exposure to psychology comes from news stories and TV, psychologists seem to analyze personality, offer counseling, dispense child-raising advice, examine crime scenes, and testify in court. Do they? Yes, and much more. Consider some of psychology's research questions, which you will be learning more about in this text.

- Have you ever found yourself reacting to something as one of your biological parents would—perhaps in a way you vowed you never would—and then wondered how much of your personality you inherited? *To what extent do genes predispose our person-to-person differences in personality? To what extent do home and community environments shape us?*
- Have you ever worried about how to act among people of a different culture, race, gender, or sexual orientation? *How do you think you would act in a different human family? How do you think you would act in a different human family?*
- Have you ever awakened wondering why you had a certain reaction? *What do you think you would do if you were in that situation?*
- Have you ever played a game so intently that you momentarily move behind the lines of reality? *What do you think you would do if you were in that situation?*

Each unit is designed with a different color so that you may easily distinguish which AP® exam topic you are studying.

Each unit is broken into easy-to-read **modules**, outlined at the beginning of every unit.

The **Unit Introduction** illustrates important psychological concepts with real-life examples that extend through that unit's modules.

Review the **Numbered Learning Objectives** at the beginning of each module for an overview of the critical concepts you will be tackling. These Learning Objectives are referenced throughout the module to keep you on track as you study each concept.

56 Unit II Research Methods: Thinking Critically With Psychological Science

Module 7

Statistical Reasoning in Everyday Life

Module Learning Objectives

- 7-1** Describe the three measures of central tendency, and discuss the relative usefulness of the two measures of variation.
- 7-2** Explain how we know whether an observed difference can be generalized to other populations.

The Scientific Method and Description **Module 5** 43

RANDOM SAMPLING

In everyday thinking, we tend to generalize from samples we observe, especially vivid cases. Given (a) a statistical summary of auto owners' evaluations of their car make and (b) the vivid comments of a biased sample—two frustrated owners—our impression may be influenced as much by the two unhappy owners as by the many more evaluations in the statistical summary. The temptation to ignore the **sampling bias** and to generalize from a few vivid but unrepresentative cases is nearly irresistible.

The point to remember: The best basis for generalizing is from a **representative sample**.

But it's not always possible to survey everyone in a group. So how do you obtain a representative sample—say, of the students at your high school? How could you choose a group that would represent the total student **population**, the whole group you want to study and describe? Typically, you would seek a **random sample**, in which every person in the entire group has an equal chance of participating. You might number the names in the general student listing and then use a random number generator to pick your survey participants. (Sending each student a questionnaire wouldn't work because the conscientious people who returned it would not be a random sample.) Large representative samples are better than small ones, but a small representative sample of 100 is better than an unrepresentative sample of 500.

Political pollsters sample voters in national election surveys just this way. Using only 1500 randomly sampled people, drawn from all areas of a country, they can provide a remarkably accurate snapshot of the nation's opinions. Without random sampling (also called **random selection**), large samples—including call-in phone samples and TV or website polls (think of *American Idol* fans voting)—often merely give misleading results.

The point to remember: Before accepting survey findings, think critically: Consider the sample. You cannot compensate for an unrepresentative sample by simply adding more people.

Before You Move On

▶ **ASK YOURSELF**
Can you recall examples of misleading surveys you have experienced or read about? What survey principles did they violate?

▶ **TEST YOURSELF**
What are some strengths and weaknesses of the three different methods psychologists use to describe behavior—case studies, naturalistic observation, and surveys?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

FY
With an estimated 586,742 people in the English and Spanish Glossary of the *Moby*, 586,742 of two of the of Mar News, 1997).

In descriptive, correlational, and experimental research, statistics are tools that help us see and interpret what the unaided eye might miss. Sometimes the unaided eye misses badly. Researchers invited 5522 Americans to estimate the percentage of wealth possessed by the richest 20 percent in their country (Norton & Ariely, 2011). Their average person's guess—58 percent—"dramatically underestimated" the actual wealth inequality. (The wealthiest 20 percent possess 84 percent of the wealth.)

The Need for Statistics

Accurate statistical understanding benefits everyone. To be an educated person today is to be able to apply simple statistical principles to everyday reasoning. One needn't memorize complicated formulas to think more clearly and critically about data.

Off-the-top-of-the-head estimates often misread reality and then mislead the public. Someone throws out a big, round number. Others echo it, and before long the big, round

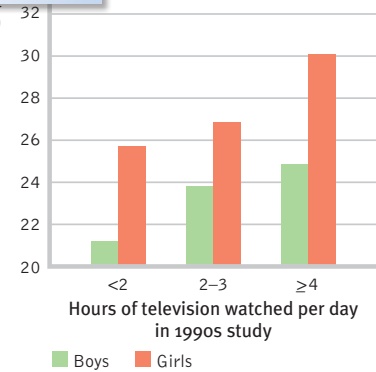

Watch for the beige **Key Term** boxes that highlight the vocabulary you'll need to master to realize success on the AP® exam. A list of each unit's key terms is available at the end of the unit. These words are also defined in the English and Spanish Glossary/Glosario at the end of the book.

Check your understanding with **Before You Move On** boxes at the end of main sections. **Ask Yourself** questions help you reflect on and make connections with the material, while **Test Yourself** questions assess your mastery of the content you've just read.

Study the **figures** and **graphs**, and read the captions carefully. Illustrations help clarify and support key concepts from the narrative, and understanding how to read and interpret graphs is a major component of this course.

Standard Unit
measure (mm)

Features

AP[®] Exam Tip

Be prepared for at least a multiple-choice question that tests your ability to tell the difference between the James-Lange theory and the Cannon-Bard theory.

Pay attention to the **AP[®] Exam Tip** boxes, written by longtime AP[®] teacher Charlie Blair-Broeker. They provide helpful advice on what to pay close attention to and what common pitfalls to avoid so you can succeed on the AP[®] exam.

FYI

The people who first dissected and labeled the brain used the language of scholars—Latin and Greek. Their words are actually attempts at graphic description: For example, *cortex* means “bark,” *cerebellum* is “little brain,” and *thalamus* is “inner chamber.”

FYI boxes are interesting tidbits of information that help connect the content you’re reading with real-life examples and research studies.

Try This

Most of us would be unable to name the order of the songs on our favorite album or playlist. Yet, hearing the end of one piece cues (by association) an anticipation of the next. Likewise, when singing your national anthem, you associate the end of each line with the beginning of the next. (Pick a line out of the middle and notice how much harder it is to recall the *previous* line.)

Connect more deeply with the concepts you’re learning by putting them into real-life practice with **Try This** boxes.

Improve Your Retention—and Your Grades!

2-4

How can psychological principles help you learn and remember, and do better on the AP[®] exam?

Do you, like most students, assume that the way to cement your new learning is to reread? What helps even more—and what this book therefore encourages—is repeated self-testing and rehearsal of previously studied material. Memory researchers Henry Roediger and Jeffrey Karpicke (2006) call this phenomenon the **testing effect**. They note that “testing is a powerful means of improving learning, not just assessing it.” In one of their studies, students recalled the meaning of 40

in the *Before You Move On* sections. After answering *Yourself* questions there, you can check your answers in appendix E at the end of this text and reread as needed.

Finally, *review*: Read over any notes you have taken with an eye on the module’s organization, and quickly review the whole module. Write or say what a concept is to check your understanding.

Survey, question, read, retrieve, review. I have organized this book’s modules to facilitate your use of the SQ3R study system. Each module begins with a list of objectives that aid your *survey*. Headings and the numbered Learning Objective Questions at the beginning of main sections suggest issues

Apply psychological findings to your life with **Close-up** boxes. This feature encourages application of new concepts by providing high-interest, real-life examples.

Thinking Critically About

Does Viewing Media Violence Trigger Violent Behavior?

Was the judge who, in 1993, tried two British 10-year-olds for the murder of a 2-year-old right to suspect that the pair had been influenced by “violent video films”? Were the American media right to wonder if Adam Lanza, the 2012 mass killer of 26 children and their teachers at Connecticut’s Sandy Hook school, was influenced by his playing of the video games found stockpiled in his home? To understand how violence viewing leads to violent behavior, researchers have done some 600 correlational and experimental studies (Gentile, 2008; Comstock, 2008; Murray, 2008). Correlational studies do support this link:

In the United States and Canada, homicide rates doubled between 1957 and 1974, just when TV was introduced and spreading. Moreover, census regions with later dates

people, when irritated, to react more cruelly? To some extent, it does. This is especially so when an attractive person commits seemingly justified, realistic violence that goes unpunished and causes no visible pain or harm (Donnerstein, 1998, 2011).

The violence-viewing effect seems to stem from at least two factors. One is *imitation* (Geen & Thomas, 1986). Children as young as 14 months will imitate acts they observe on TV (Meltzoff & Moore, 1989, 1997). As they watch, their brains simulate the behavior, and after this inner rehearsal they become more likely to act it out. Thus, in one experiment, violent play increased sevenfold immediately after children viewed *Power Rangers* episodes (Boyatzis et al., 1995). As happened in the Bobo doll experiment, children often precisely imitated the models’ violent acts—in this case, flying karate kicks.

Prolonged exposure to violence also *desensitizes* viewers.

Exercise your brain with the **Thinking Critically About** boxes. These boxes sharpen your analytical skills by modeling a critical thinking approach to key issues in psychology, and encourage you to apply psychological research to current topics. Before you know it, you’ll be thinking like a psychological scientist!

Each module concludes with a unique review.

Test yourself using the **Module Review**, organized by that module’s learning objectives, so you can be sure you’ve mastered all of the key concepts.

Module 9 Review

9-1 Why are psychologists concerned with human biology?

- Psychologists working from a *biological* perspective study the links between biology and behavior.
- We are biopsychosocial systems, in which biological, psychological, and social-cultural factors interact to influence behavior.

9-2 What are neurons and the neural system?

- *Neurons* are the basic units of the nervous system, the body’s communication system.
- A neuron receives information and sends signals to other neurons.
- Some axons are myelinated, which allows for faster transmission of signals.

9-3 How do nerve cells communicate with other nerve cells?

- When action potentials reach the end of an axon (the axon terminals), they stimulate the release of *neurotransmitters*.
- These chemical messengers carry a message from the sending neuron across a *synapse* to receptor sites on a receiving neuron.

Multiple-Choice Questions

- Multiple sclerosis is a result of degeneration in the
 - dendrite.
 - axon.
 - myelin sheath.
 - terminal button.
 - neuron.
- Junita does not feel like getting out of bed, has lost her appetite, and feels tired for most of the day. Which of the following neurotransmitters likely is in short supply for Junita?
 - Dopamine
 - Acetylcholine
 - GABA
 - Serotonin
- Which neurotransmitter inhibits CNS activity in order to calm a person down during stressful situations?
 - GABA
 - Norepinephrine
 - Acetylcholine
 - Dopamine
 - Serotonin
- Phrenology has been discredited, but which of the following ideas has its origins in phrenology?
 - Brain lateralization
 - Brain cavities contributing to sense of humor
 - Bumps in the left hemisphere leading to emotional responses
 - Brain lateralization

Practice FRQs

- While hiking, Ken stumbled and fell down a 10-foot drop-off. Upon landing, he sprained his ankle badly. Ken was surprised that he felt very little pain for the first half hour. Explain how the following helped Ken feel little pain in the moments after the injury.
 - Endorphins
 - The synapse
- Explain the role each of the following plays in sending a message through a neuron.
 - Dendrites
 - Axon
 - Myelin sheath

(3 points)

Improve your retention by testing yourself at the end of each module with **Multiple-Choice Questions** and skill-building **Practice FRQs**.

Answer

1 point: Endorphins are natural, opiate-like neurotransmitters linked to controlling pain.

Key Contributors to Remember

Wilhelm Wundt, p. 3	Sigmund Freud, p. 5	Jean Piaget, p. 9
G. Stanley Hall, p. 3	John B. Watson, p. 6	Charles Darwin, p. 10
William James, p. 4	B. F. Skinner, p. 6	Dorothea Dix, p. 14
Mary Whiton Calkins, p. 4	Carl Rogers, p. 6	

At the end of each unit, make sure you know all the **Key Terms and Concepts** and can explain the importance of each **Key Contributor** before moving on to the **AP[®] Exam Practice Questions**.

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Which perspective would be most useful when explaining how people from different countries express anger?
 - Social-cultural
 - Psychodynamic
 - Behavioral
- Which of the following professionals is required to have a medical degree?

Free-Response Questions

- Sam Greene noticed an ad for an Internet dating service that claimed more people who used its service are in long-term relationships than people who didn't. Sam, a good critical thinker, knows this isn't enough to claim that the service causes people to find long-term love and wants to create an experiment to investigate. Use the following terms to describe an experiment that would support or dispute the ad's claim.
 - Hypothesis
 - Random sample

1 point: Sam would need to operationally define what is meant by use of the Internet service, possibly including a precise number of visits to the website or time spent on the website. The phrase *long-term relationship* would also need an operational definition, possibly by the number of months together or a formal commitment (like engagement or marriage). [↪ Page 39](#)

1 point: In Sam's study, the use of the online dating service is the independent variable. [↪ Page 52](#)

1 point: The number of long-term relationships is the dependent variable. [↪ Page 52](#)

1 point: Sam will need to calculate statistical significance for the experimental findings. In order to claim support for the hypothesis, the results need to show that there is no more than a 5 percent chance the findings are due to chance. [↪ Page 60](#)

The **AP[®]-Style Multiple Choice Questions** and **Free-Response Questions** cover material from the unit to help you check your mastery of everything you've just learned. Once you get everything right, you're ready to move to the next unit!

Rubric for Free-Response Question 1

1 point: The hypothesis in this context is that the Internet dating service causes (or leads to) long-term relationships. [↪ Page 38](#)

1 point: Since the population of interest for this study should be people who are looking for long-term relationships, selecting a random sample of adults seeking relationships would help assure that the conclusions could be fairly generalized to the dating public. [↪ Page 43](#)

1 point: In this case, participants should be randomly assigned to use of the Internet service (the experimental group) or not (the control group). [↪ Page 51](#)

The end-of-book **Practice AP[®]-Style Exam** covers material learned through the entire course, simulating the real exam. This comprehensive test ensures that you get enough practice so you can strive for a 5 on the day of the exam.

Enrichment Modules

Learning about psychology doesn't stop after you take the exam in May. Continue your exploration with Enrichment Modules 81–85, to help round out your course and prepare you for further psychology study in college and beyond.

Innovative Multimedia Supplements Package

For Students

MYERS' PSYCHOLOGY FOR AP[®], SECOND EDITION E-BOOK

Our interactive e-Book fully integrates the text with student media. The e-Book also offers a range of customization features including bookmarking, highlighting, note-taking, note-sharing, and flashcards.

FLIP IT VIDEOS

If your teacher has flipped the classroom, you can watch the assigned lecture videos from links on the Book Companion Site at www.worthpublishers.com/MyersAP2e. You may also watch the videos as a refresher while studying, so that you can reflect on what you've learned and formulate meaningful questions to discuss with the teacher or your classmates.

STRIVE FOR A 5: PREPARING FOR THE AP[®] PSYCHOLOGY EXAMINATION

Prepared by longtime AP[®] teachers Allison Herzig, Nathaniel Naughton, Laura Brandt, and Tina Athanasopoulos, this supplement serves as a complete study guide and as the optimal preparation resource for the AP[®] exam. The unit-by-unit study guide reinforces the topics and key concepts covered in the text and on the AP[®] exam, and the two AP[®]-style practice tests at the end provide you with the opportunity to tackle the most important piece of the course.

Strive for a 5 begins with a context-setting, big-picture overview of each unit, along with a practical study tip. Next, there is a detailed, module-by-module review, which is organized as follows:

Before You Read

- Module summary, list of key terms and names in the module

While You Read

- Essential questions to answer for each module, organized by the numbered learning objectives

After You Read

- Application and vocabulary questions for you to practice what you've learned without looking at the book

Check Yourself

- High-level, open-ended questions that require you to synthesize what you've learned throughout the unit

The test preparation section of *Strive for a 5* is a comprehensive test review resource. To help you focus your efforts, the guide offers detailed test preparation tips, suggestions for setting a test preparation schedule, and advice on how to study effectively and efficiently. The guide includes two sample practice tests simulating the AP[®] exam, with solutions and sample grading rubrics found on the teacher's website and on the Teacher's Resource CD. Information about purchasing the *Strive for a 5* guide may be found on the catalog page (<http://highschool.bfwpub.com/MyersAP2e>).

BOOK COMPANION SITE

www.worthpublishers.com/MyersAP2e

The companion website offers valuable tools for both teachers and students. Students can access the following, free of charge:

- Quizzes
- Key Contributors Study Guide
- Flip It videos
- Podcast correlation
- Interactive flashcards that tutor students on all the key terms in the text

For Teachers

What an amazing success story AP® Psychology has become since 1992, when 3916 students took the first exam. As of 2013, 1.8 million students had sat for AP® Psychology exams, and more than 2 million had taken the course. For me, it has been an honor to support the teaching of our humanly significant discipline to so many of those students, and a great pleasure to have met or corresponded with so many AP® teachers and their students. It is also a keenly felt responsibility. So please do feel free to be in touch with your feedback and suggestions.

With every good wish,

A handwritten signature in black ink that reads "David Myers". The signature is fluid and cursive, with the first letters of "David" and "Myers" being capitalized and prominent.

Myers' Psychology for AP[®]

Unit 1

Psychology's History and Approaches

Modules

- 1 Psychology's History
- 2 Psychology's Big Issues and Approaches
- 3 Careers in Psychology

For people whose exposure to psychology comes from news stories and TV, psychologists seem to analyze personality, offer counseling, dispense child-raising advice, examine crime scenes, and testify in court. Do they? *Yes*, and much more. Consider some of psychology's research questions, which you will be learning more about in this text.

- Have you ever found yourself reacting to something as one of your biological parents would—perhaps in a way you vowed you never would—and then wondered how much of your personality you inherited? *To what extent do genes predispose our person-to-person differences in personality? To what extent do home and community environments shape us?*
- Have you ever worried about how to act among people of a different culture, race, gender, or sexual orientation? *In what ways are we alike as members of the human family? How do we differ?*
- Have you ever awakened from a nightmare and, with a wave of relief, wondered why you had such a crazy dream? *How often, and why, do we dream?*
- Have you ever played peekaboo with a 6-month-old and wondered why the baby finds the game so delightful? The infant reacts as though, when you momentarily move behind a door, you actually disappear—only to reappear out of thin air. *What do babies actually perceive and think?*

- Have you ever wondered what fosters school and work success? *Are some people just born smarter? And does sheer intelligence explain why some people get richer, think more creatively, or relate more sensitively?*
- Have you ever become depressed or anxious and wondered whether you'll ever feel "normal"? *What triggers our bad moods—and our good ones? Where is the line between a normal mood swing and a psychological disorder for which someone should seek help?*
- Have you ever wondered how the Internet, video games, and electronic social networks affect people? *How do today's electronic media influence how we think and how we relate?*

Psychology is a science that seeks to answer such questions about us all—how and why we think, feel, and act as we do.

Photos.com

Ariadne Van Zandt/Alamy

Jim Craigmyler/Corbis

A smile is a smile the world around Throughout this book, you will see examples not only of our cultural and gender diversity but also of the similarities that define our shared human nature. People in different cultures vary in when and how often they smile, but a naturally happy smile *means* the same thing anywhere in the world.

Module 1

Psychology's History

Module Learning Objectives

1-1

Describe how psychology developed from its prescientific roots in early understandings of mind and body to the beginnings of modern science.

1-2

Describe some important milestones in psychology's early development.

1-3

Describe how psychology continued to develop from the 1920s through today.

Pixland/Thinkstock/Getty Images

Psychology's Roots

Once upon a time, on a planet in this neighborhood of the universe, there came to be people. Soon thereafter, these creatures became intensely interested in themselves and in one another: *“Who are we? What produces our thoughts? Our feelings? Our actions? And how are we to understand and manage those around us?”*

AP® Exam Tip

To assist your active learning of psychology, Learning Objectives are grouped together at the start of each module, and then framed as questions that appear at the beginning of major sections.

Prescientific Psychology

1-1

How did psychology develop from its prescientific roots in early understandings of mind and body to the beginnings of modern science?

We can trace many of psychology's current questions back through human history. These early thinkers wondered: How does our mind work? How does our body relate to our mind? How much of what we know comes built in? How much is acquired through experience? In India, Buddha pondered how sensations and perceptions combine to form ideas. In China, Confucius stressed the power of ideas and of an educated mind. In ancient Israel, Hebrew scholars anticipated today's psychology by linking mind and emotion to the body; people were said to think with their heart and feel with their bowels.

In ancient Greece, the philosopher-teacher Socrates (469–399 B.C.E.) and his student Plato (428–348 B.C.E.) concluded that mind is separable from body and continues after the body dies, and that knowledge is innate—born within us. Unlike Socrates and Plato, who derived principles by logic, Plato's student Aristotle (384–322 B.C.E.) had a love of data. An intellectual ancestor of today's scientists, Aristotle derived principles from careful observations. Moreover, he said knowledge is *not* preexisting (sorry, Socrates and Plato); instead it grows from the experiences stored in our memories.

The next 2000 years brought few enduring new insights into human nature, but that changed in the 1600s, when modern science began to flourish. With it came new theories of human behavior, and new versions of the ancient debates. A frail but brilliant Frenchman named René Descartes (1595–1650) agreed with Socrates and Plato about the existence of innate ideas and mind's being “entirely distinct from body” and able to survive its death. Descartes' concept of mind forced him to conjecture, as people have ever since, how the immaterial mind and physical body communicate. A scientist as well as a philosopher, Descartes dissected animals and concluded that the fluid in the brain's cavities contained “animal spirits.” These spirits, he surmised, flowed from the brain through what we call the nerves (which he thought were hollow) to the muscles, provoking movement. Memories formed as experiences opened pores in the brain into which the animal spirits also flowed.

Descartes was right that nerve paths are important and that they enable reflexes. Yet, genius though he was, and standing upon the knowledge accumulated from 99+ percent of our human history, he hardly had a clue of what today's average 12-year-old knows. Indeed, most of the scientific story of our self-exploration—the story told in this book—has been written in but the last historical eye-blink of human time.

Meanwhile, across the English Channel in Britain, science was taking a more down-to-earth form, centered on experiment, experience, and common-sense judgment. Francis Bacon (1561–1626) became one of the founders of modern science, and his influence lingers in the experiments of today's psychological science. Bacon also was fascinated by the human mind and its failings. Anticipating what we have come to appreciate about our mind's hunger to perceive patterns even in random events, he wrote that “the human

understanding, from its peculiar nature, easily supposes a greater degree of order and equality in things than it really finds" (*Novum Organum*, 1620). He also foresaw research findings on our noticing and remembering events that confirm our beliefs: "All superstition is much the same whether it be that of astrology, dreams, omens . . . in all of which the deluded believers observe events which are fulfilled, but neglect and pass over their failure, though it be much more common."

Some 50 years after Bacon's death, John Locke (1632–1704), a British political philosopher, sat down to write a one-page essay on "our own abilities" for an upcoming discussion with friends. After 20 years and hundreds of pages, Locke had completed one of history's greatest late papers (*An Essay Concerning Human Understanding*), in which he famously argued that the mind at birth is a *tabula rasa*—a "blank slate"—on which experience writes. This idea, adding to Bacon's ideas, helped form modern **empiricism**, the idea that what we know comes from experience, and that observation and experimentation enable scientific knowledge.

empiricism the view that knowledge originates in experience and that science should, therefore, rely on observation and experimentation.

Psychological Science Is Born

1-2

What are some important milestones in psychology's early development?

Philosophers' thinking about thinking continued until the birth of psychology as we know it, on a December day in 1879, in a small, third-floor room at Germany's University of Leipzig. There, two young men were helping an austere, middle-aged professor, Wilhelm Wundt, create an experimental apparatus. Their machine measured the time lag between people's hearing a ball hit a platform and their pressing a telegraph key (Hunt, 1993). Curiously, people responded in about one-tenth of a second when asked to press the key as soon as the sound occurred—and in about two-tenths of a second when asked to press the key as soon as they were consciously aware of perceiving the sound. (To be aware of one's awareness takes a little longer.) Wundt was seeking to measure "atoms of the mind"—the fastest and simplest mental processes. So began the first psychological laboratory, staffed by Wundt and by psychology's first graduate students. (In 1883, Wundt's American student G. Stanley Hall went on to establish the first formal U.S. psychology laboratory, at Johns Hopkins University.)

Before long, this new science of psychology became organized into different branches, or schools of thought, each promoted by pioneering thinkers. These early schools included *structuralism*, *functionalism*, and *behaviorism*, described here (with more on behaviorism in Modules 26–30), and two schools described in later modules: Gestalt psychology (Module 19) and psychoanalysis (Module 55).

Wilhelm Wundt Wundt established the first psychology laboratory at the University of Leipzig, Germany.

FYI

Information sources are cited in parentheses, with name and date. Every citation can be found in the end-of-book References, with complete documentation that follows American Psychological Association (APA) style.

AP® Exam Tip

Every question on the AP® Psychology exam will reflect the fact that psychology is a science built on the tradition of Wundt and his laboratory. Correct answers on the test are based on what research has revealed; not on "common sense"!

Edward Bradford Titchener

Titchener used introspection to search for the mind's structural elements.

Thinking About the Mind's Structure

Soon after receiving his Ph.D. in 1892, Wundt's student Edward Bradford Titchener joined the Cornell University faculty and introduced **structuralism**. As physicists and chemists discerned the structure of matter, so Titchener aimed to discover the structural elements of mind. His method was to engage people in self-reflective *introspection* (looking inward), training them to report elements of their experience as they looked at a rose, listened to a metronome, smelled a scent, or tasted a substance. What were their immediate sensations, their images, their feelings? And how did these relate to one another? Titchener shared with the English essayist C. S. Lewis the view that "there is one thing, and only one in the whole universe which

we know more about than we could learn from external observation." That one thing, Lewis said, is ourselves. "We have, so to speak, inside information" (1960, pp. 18–19).

Alas, introspection required smart, verbal people. It also proved somewhat unreliable, its results varying from person to person and experience to experience. Moreover, we often just don't know why we feel what we feel and do what we do. Recent studies indicate that people's recollections frequently err. So do their self-reports about what, for example, has caused them to help or hurt another (Myers, 2002). As introspection waned, so did structuralism.

"You don't know your own mind." -JONATHAN SWIFT, *POLITE CONVERSATION*, 1738

Thinking About the Mind's Functions

Hoping to assemble the mind's structure from simple elements was rather like trying to understand a car by examining its disconnected parts. Philosopher-psychologist William James thought it would be more fruitful to consider the evolved functions of our thoughts and feelings. Smelling is what the nose does; thinking is what the brain does. But *why* do the nose and brain do these things? Under the influence of evolutionary theorist Charles Darwin, James assumed that thinking, like smelling, developed because it was *adaptive*—it contributed to our ancestors' survival. Consciousness serves a function. It enables us to consider our past, adjust to our present, and plan our future. As a **functionalist**, James encouraged explorations of down-to-earth emotions, memories, willpower, habits, and moment-to-moment streams of consciousness.

James' greatest legacy, however, came less from his laboratory than from his Harvard teaching and his writing. When not plagued by ill health and depression, James was an impish, outgoing, and joyous man, who once recalled that "the first lecture on psychology I ever heard was the first I ever gave." During one of his wise-cracking lectures, a student interrupted and asked him to get serious (Hunt, 1993). He loved his students, his family, and the world of ideas, but he tired of painstaking chores such as proofreading. "Send me no proofs!" he once told an editor. "I will return them unopened and never speak to you again" (Hunt, 1993, p. 145).

James displayed the same spunk in 1890, when—over the objections of Harvard's president—he admitted Mary Whiton Calkins into his graduate seminar (Scarborough & Furumoto, 1987). (In those years women lacked even the right to vote.) When Calkins joined, the other students (all men) dropped out. So James tutored her alone. Later, she finished all the requirements for a Harvard Ph.D., outscoring all the male students on the qualifying exams. Alas, Harvard denied her the degree she had earned, offering her instead a degree from Radcliffe College, its undergraduate sister school for women. Calkins resisted the unequal treatment and refused the degree. (More than a century

structuralism early school of thought promoted by Wundt and Titchener; used introspection to reveal the structure of the human mind.

functionalism early school of thought promoted by James and influenced by Darwin; explored how mental and behavioral processes function—how they enable the organism to adapt, survive, and flourish.

William James and Mary Whiton Calkins James was a legendary teacher-writer who authored an important 1890 psychology text. He mentored Calkins, who became a pioneering memory researcher and the first woman to be president of the American Psychological Association (APA).

Margaret Floy Washburn The first woman to receive a psychology Ph.D., Washburn synthesized animal behavior research in *The Animal Mind*.

later, psychologists and psychology students were lobbying Harvard to posthumously award Calkins the Ph.D. she earned [*Feminist Psychologist*, 2002].) Calkins nevertheless went on to become a distinguished memory researcher and the APA's first female president in 1905.

When Harvard denied Calkins the claim to being psychology's first female psychology Ph.D., that honor fell to Margaret Floy Washburn, who later wrote an influential book, *The Animal Mind*, and became the second female APA president in 1921. Although Washburn's thesis was the first foreign study Wundt published in his journal, her gender meant she was barred from joining the organization of **experimental psychologists** (who explore behavior and thinking with experiments), despite its being founded by Titchener, her own graduate adviser (Johnson, 1997). What a different world from the recent past—1996 to 2013—when women claimed two-thirds or more of new U.S. psychology Ph.D.s and were 9 of the 18 elected presidents of the science-oriented Association for Psychological Science. In Canada and Europe, too, most recent psychology doctorates have been earned by women.

James' influence reached even further through his dozens of well-received articles, which moved the publisher Henry Holt to offer a contract for a textbook of the new science of psychology. James agreed and began work in 1878, with an apology for requesting two years to finish his writing. The text proved an unexpected chore and actually took him 12 years. (Why am I not surprised?) More than a century later, people still read the resulting *Principles of Psychology* and marvel at the brilliance and elegance with which James introduced psychology to the educated public.

Psychological Science Develops

1-3

How did psychology continue to develop from the 1920s through today?

In psychology's early days, Wundt and Titchener focused on inner sensations, images, and feelings. James, too, engaged in introspective examination of the stream of consciousness and of emotion. Sigmund Freud emphasized the ways emotional responses to childhood experiences and our unconscious thought processes affect our behavior. Thus, until the 1920s, *psychology* was defined as "the science of mental life."

experimental psychology the study of behavior and thinking using the experimental method.

AP® Exam Tip

There are lots of important people in psychology. As you study, focus on the significance of their accomplishments. You are more likely to be tested on what a finding means than who discovered it.

John B. Watson and Rosalie Rayner

Working with Rayner, Watson championed psychology as the science of behavior and demonstrated conditioned responses on a baby who became famous as “Little Albert.” (More about Watson’s controversial study in Module 26.)

behaviorism the view that psychology (1) should be an objective science that (2) studies behavior without reference to mental processes. Most research psychologists today agree with (1) but not with (2).

humanistic psychology a historically significant perspective that emphasized the growth potential of healthy people.

And so it continued until the 1920s, when the first of two larger-than-life American psychologists appeared on the scene. Flamboyant and provocative John B. Watson, and later the equally provocative B. F. Skinner, dismissed introspection and redefined *psychology* as “the scientific study of observable behavior.” After all, they said, science is rooted in observation. You cannot observe a sensation, a feeling, or a thought, but you *can* observe and record people’s *behavior* as they respond to different situations. They further suggested that our behavior is influenced by learned associations, through a process called *conditioning*. Many agreed, and the **behaviorists** were one of two major forces in psychology well into the 1960s. (More on these psychologists in Modules 26–30.)

The other major force was *Freudian psychology*, which emphasized the ways our unconscious thought processes and our emotional responses to childhood experiences affect our behavior. (In modules to come, we’ll look more closely at Sigmund Freud’s teachings, including his theory of personality and his views on unconscious sexual conflicts and the mind’s defenses against its own wishes and impulses. We will also study the *psychodynamic approach*, which is the updated, modern-day version of Freud’s ideas.)

As the behaviorists had done in the early 1900s, two other groups rejected the definition of psychology that was current in the 1960s. The first, the **humanistic psychologists**, led by Carl Rogers and Abraham Maslow, found both Freudian psychology and behaviorism too limiting. Rather than focusing on the meaning of early childhood memories or the learning of conditioned responses, the humanistic psychologists drew attention to ways that current environmental influences can nurture or limit our growth potential, and to the importance of having our needs for love and acceptance satisfied. (More on this in Module 57.)

B. F. Skinner A leading behaviorist, Skinner rejected introspection and studied how consequences shape behavior.

Sigmund Freud The controversial ideas of this famed personality theorist and therapist have influenced humanity’s self-understanding.

The rebellion of a second group of psychologists during the 1960s is now known as the *cognitive revolution*, and it led the field back to its early interest in mental processes, such as the importance of how our mind processes and retains information. Cognitive psychology scientifically explores the ways we perceive, process, and remember information. **Cognitive neuroscience**, an interdisciplinary study, has enriched our understanding of the brain activity underlying mental activity. The cognitive approach has given us new ways to understand ourselves and to treat disorders such as depression, as we shall see in Module 71.

To encompass psychology's concern with observable behavior *and* with inner thoughts and feelings, today we define **psychology** as the *science of behavior and mental processes*. Let's unpack this definition. *Behavior* is anything an organism *does*—any action we can observe and record. Yelling, smiling, blinking, sweating, talking, and questionnaire marking are all observable behaviors. *Mental processes* are the internal, subjective experiences we infer from behavior—sensations, perceptions, dreams, thoughts, beliefs, and feelings.

The key word in psychology's definition is *science*. Psychology, as I will emphasize throughout this book, is less a set of findings than a way of asking and answering questions. My aim, then, is not merely to report results but also to show you how psychologists play their game. You will see how researchers evaluate conflicting opinions and ideas. And you will learn how all of us, whether scientists or simply curious people, can think smarter when describing and explaining the events of our lives.

cognitive neuroscience the interdisciplinary study of the brain activity linked with cognition (including perception, thinking, memory, and language).

psychology the science of behavior and mental processes.

AP® Exam Tip

Memory research reveals a *testing effect*: We retain information much better if we actively retrieve it by self-testing and rehearsing. (More on this in the Close-up box at the end of Module 2.) To bolster your learning and memory, take advantage of all the self-testing opportunities you'll find throughout this text. These "Before You Move On" sections will appear at the end of each main section of text. The *Ask Yourself* questions will help you make the material more meaningful to your own life (and therefore more memorable). You can check your answers to the *Test Yourself* review questions in Appendix E at the end of the book.

Before You Move On

▶ ASK YOURSELF

How do you think psychology might change as more and more women contribute their ideas to the field?

▶ TEST YOURSELF

What event defined the founding of modern scientific psychology?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 1 Review

1-1

How did psychology develop from its prescientific roots in early understandings of mind and body to the beginnings of modern science?

- Psychology traces its roots back through recorded history to India, China, the Middle East, and Europe. Buddha and Confucius focused on the power and origin of ideas. The ancient Hebrews, Socrates, Plato, and Aristotle pondered whether mind and body are connected or distinct, and whether human ideas are innate or result from experience.
- Descartes and Locke reengaged those ancient debates, with Locke offering his famous description of the mind as a "blank slate" on which experience writes. The ideas of Bacon and Locke contributed to the development of modern *empiricism*.

1-2

What are some important milestones in psychology's early development?

- Wilhelm Wundt established the first psychological laboratory in 1879 in Germany.
- Two early schools of psychology were *structuralism* and *functionalism*.
- Structuralism, promoted by Wundt and Titchener, used self-reflection to learn about the mind's structure. Functionalism, promoted by James, explored how behavior and thinking function.

1-3

How did psychology continue to develop from the 1920s through today?

- Early researchers defined *psychology* as a "science of mental life."

- In the 1920s, under the influence of John B. Watson and the *behaviorists*, the field's focus changed to the "scientific study of observable behavior."
- In the 1960s, the *humanistic psychologists* and the *cognitive psychologists* revived interest in the study of mental processes.
- Psychology is now defined as the science of behavior and mental processes.

Multiple-Choice Questions*

- By seeking to measure "atoms of the mind," who established the first psychology laboratory?
 - Sigmund Freud
 - John B. Watson
 - Wilhelm Wundt
 - G. Stanley Hall
 - William James
- Which philosopher proposed that nerve pathways allowed for reflexes?
 - Socrates
 - René Descartes
 - John Locke
 - Aristotle
 - Plato
- Who coined the term "tabula rasa" (blank slate) to help explain the impact experience has on shaping an individual?
 - Francis Bacon
 - René Descartes
 - John B. Watson
 - Sigmund Freud
 - John Locke
- Which of the following best describes research typical of Wilhelm Wundt's first psychology laboratory?
 - Examining the unconscious to determine behavior motivation
 - Using a brain-scanning device to determine the impact events have on brain function
 - Measuring the reaction time between hearing a sound and pressing a button
 - Studying helping behavior, based on the premise that people are good
 - Examining how collective life experiences combine to create individuality
- With which of the following statements would John B. Watson most likely agree?
 - Psychology should study the growth potential in all people.
 - Psychology should study the unconscious.
 - Psychology should focus on observable behavior.
 - Psychology should study mental thought processes.
 - Psychology should study how culture and beliefs impact an individual.

Practice FRQs**

- The definition of psychology changed as the field evolved during the early years. Why did John B. Watson object to the definition preferred by Wundt, Titchener, and James? What group of psychologists did Watson's ideas influence? How did Watson redefine psychology?

Answer

1 point: Watson objected to the "science of mental life" because he felt it was impossible to be scientific without observation.

1 point: Watson's ideas influenced the behaviorists.

1 point: Watson preferred limiting psychology to behavior, because behavior could be observed and scientifically analyzed.

- Identify the founder of structuralism, and explain structuralism's four foundational concepts.

(6 points)

*Note: If you are a student using these Multiple-Choice Questions for self-testing, please consult with your teacher to check your answers.

** "FRQ" stands for "Free-Response Question." The AP® exam contains two of these essay-style questions, which count for one-third of your final score. The actual FRQs will be complex, requiring you to integrate knowledge from across multiple modules, like the practice questions you will find at the end of each *unit* in this text. These simpler "Practice FRQs" that appear at the end of each *module*, along with a sample grading rubric, will help you get started practicing this skill.

Module 2

Psychology's Big Issues and Approaches

Module Learning Objectives

- 2-1** Summarize the nature–nurture debate in psychology.
- 2-2** Describe psychology's three main levels of analysis and related perspectives.
- 2-3** Identify psychology's main subfields.
- 2-4** Explain how psychological principles can help you learn and remember, and do better on the AP[®] exam.

The young science of psychology developed from the more established fields of philosophy and biology. Wundt was both a philosopher and a physiologist. James was an American philosopher. Freud was an Austrian physician. Ivan Pavlov, who pioneered the study of learning (Module 26), was a Russian physiologist. Jean Piaget, the last century's most influential observer of children (Module 47), was a Swiss biologist. These “Magellans of the mind,” as Morton Hunt (1993) has called them, illustrate psychology's origins in many disciplines and many countries.

Like those early pioneers, today's psychologists are citizens of many lands. The International Union of Psychological Science has 71 member nations, from Albania to Zimbabwe. In China, the first university psychology department began in 1978; by 2008 there were nearly 200 (Han, 2008; Tversky, 2008). Moreover, thanks to international publications, joint meetings, and the Internet, collaboration and communication now cross borders. Psychology is *growing* and it is *globalizing*. The story of psychology—the subject of this book—continues to develop in many places, at many levels, with interests ranging from the study of nerve cell activity to the study of international conflicts.

Across the world, psychologists are debating enduring issues, viewing behavior from the differing perspectives offered by the subfields in which they teach, work, and do research.

Psychology's Biggest Question

- 2-1** What is psychology's historic big issue?

Are our human traits present at birth, or do they develop through experience? This has been psychology's biggest and most persistent issue. As we have seen, the debate over the **nature–nurture issue** is ancient. The ancient Greeks debated this, with Plato assuming that we

AP[®] Exam Tip

Pay close attention to what David Myers, your author, is emphasizing as he tells the story of psychology. When he says the nature–nurture issue is the *biggest* question in psychology, that's a sign. It's a safe bet that this concept will be covered on the AP[®] exam.

nature–nurture issue the longstanding controversy over the relative contributions that genes and experience make to the development of psychological traits and behaviors. Today's science sees traits and behaviors arising from the interaction of nature and nurture.

Charles Darwin Darwin argued that natural selection shapes behaviors as well as bodies.

natural selection the principle that, among the range of inherited trait variations, those contributing to reproduction and survival will most likely be passed on to succeeding generations.

A nature-made nature–nurture experiment Because identical twins have the same genes, they are ideal participants in studies designed to shed light on hereditary and environmental influences on intelligence, personality, and other traits. Studies of identical and fraternal twins provide a rich array of findings—described in later modules—that underscore the importance of both nature and nurture.

Rubberball / Getty Images

Tony Freeman/Photo Edit

inherit character and intelligence and that certain ideas are also inborn, and Aristotle countering that there is nothing in the mind that does not first come in from the external world through the senses.

In the 1600s, philosophers rekindled the debate. Locke rejected the notion of inborn ideas, suggesting that the mind is a blank slate on which experience writes. Descartes disagreed, believing that some ideas are innate. Descartes' views gained support from a curious naturalist two centuries later. In 1831, an indifferent student but ardent collector of beetles, mollusks, and shells set sail on a historic round-the-world journey. The 22-year-old voyager, Charles Darwin, pondered the incredible species variation he encountered, including tortoises on one island that differed from those on nearby islands. Darwin's 1859 *On the Origin of Species* explained this diversity by proposing the evolutionary process of **natural selection**: From among chance variations, nature selects traits that best enable an organism to survive and reproduce in a particular environment. Darwin's principle of natural selection—what philosopher Daniel Dennett (1996) has called “the single best idea anyone has ever had”—is still with us 150+ years later as biology's organizing principle. Evolution also has become an important principle for twenty-first-century psychology. This would surely have pleased Darwin, for he believed his theory explained not only animal structures (such as a polar bear's white coat) but also animal behaviors (such as the emotional expressions associated with human lust and rage).

The nature–nurture issue recurs throughout this text as today's psychologists explore the relative contributions of biology and experience, asking, for example, how we humans are alike (because of our common biology and evolutionary history) and diverse (because of our differing environments). Are gender differences biologically predisposed or socially constructed? Is children's grammar mostly innate or formed by experience? How are intelligence and personality differences influenced by heredity and by environment? Are sexual behaviors more “pushed” by inner biology or “pulled” by external incentives? Should we treat psychological disorders—depression, for example—as disorders of the brain, disorders of thought, or both?

Such debates continue. Yet over and over again we will see that in contemporary science the nature–nurture tension dissolves: *Nurture works on what nature endows*. Our species is biologically endowed with an enormous capacity to learn and adapt. Moreover, every psychological event (every thought, every emotion) is simultaneously a biological event. Thus, depression can be both a brain disorder and a thought disorder.

Psychology's Three Main Levels of Analysis

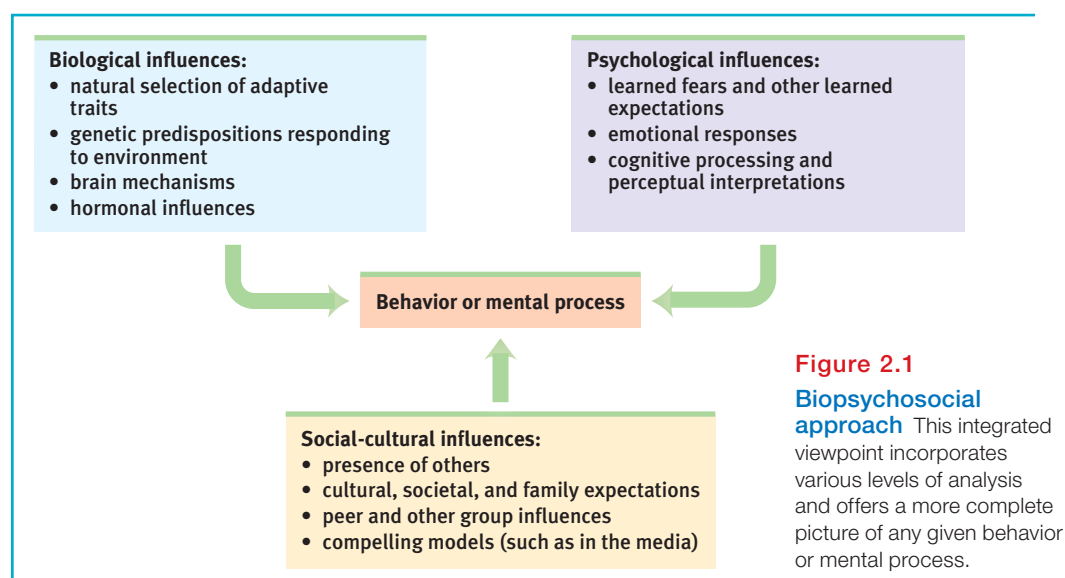

2-2 What are psychology's levels of analysis and related perspectives?

Each of us is a complex system that is part of a larger social system. But each of us is also composed of smaller systems, such as our nervous system and body organs, which are composed of still smaller systems—cells, molecules, and atoms.

These tiered systems suggest different **levels of analysis**, which offer complementary outlooks. It's like explaining why horrific school shootings have occurred. Is it because the shooters have brain disorders or genetic tendencies that cause them to be violent? Because they have been rewarded for violent behavior? Because we, in the United States, live in a gun-promoting society that accepts violence? Such perspectives are complementary because "everything is related to everything else" (Brewer, 1996). Together, different levels of analysis form an integrated **biopsychosocial approach**, which considers the influences of biological, psychological, and social-cultural factors (**FIGURE 2.1**).

levels of analysis the differing complementary views, from biological to psychological to social-cultural, for analyzing any given phenomenon.

biopsychosocial approach an integrated approach that incorporates biological, psychological, and social-cultural levels of analysis.

AP® Exam Tip

You will see versions of Figure 2.1 throughout the text. Spend some time right now familiarizing yourself with how the figure's three corners might contribute to behavior or mental processes, the very stuff of psychology.

Figure 2.1
Biopsychosocial approach This integrated viewpoint incorporates various levels of analysis and offers a more complete picture of any given behavior or mental process.

Each level provides a valuable vantage point for looking at a behavior or mental process, yet each by itself is incomplete. Like different academic disciplines, psychology's varied approaches, or perspectives, ask different questions and have their own limits. One perspective may stress the biological, psychological, or social-cultural level more than another, but the different perspectives described in **TABLE 2.1** on the next page complement one another. Consider, for example, how they shed light on anger.

© Paeilius Images/Alamy

Views of anger How would each of psychology's levels of analysis explain what's going on here?

Table 2.1 Psychology's Approaches

Perspective	Focus	Sample Questions
<i>Behavioral</i>	How we learn observable responses	How do we learn to fear particular objects or situations? What is the most effective way to alter our behavior, say, to lose weight?
<i>Biological</i>	How the body and brain enable emotions, memories, and sensory experiences; how genes combine with environment to influence individual differences	How do pain messages travel from the hand to the brain? How is blood chemistry linked with moods and motives? To what extent are traits such as intelligence, personality, sexual orientation, and depression attributable to our genes? To our environment?
<i>Cognitive</i>	How we encode, process, store, and retrieve information	How do we use information in remembering? Reasoning? Solving problems?
<i>Evolutionary</i>	How the natural selection of traits has promoted the survival of genes	How does evolution influence behavior tendencies?
<i>Humanistic</i>	How we meet our needs for love and acceptance and achieve self-fulfillment	How can we work toward fulfilling our potential? How can we overcome barriers to our personal growth?
<i>Psychodynamic</i>	How behavior springs from unconscious drives and conflicts	How can someone's personality traits and disorders be explained by unfulfilled wishes and childhood traumas?
<i>Social-cultural</i>	How behavior and thinking vary across situations and cultures	How are we alike as members of one human family? How do we differ as products of our environment?

AP® Exam Tip

These perspectives will come up again and again throughout your AP® Psychology course, and they *will* be on the exam. You need to become very comfortable with the meaning of terms like cognitive, behavioral, and psychodynamic. Ask your teacher for clarification if you are the least bit unclear about what the perspectives mean.

- Someone working from the **behavioral** perspective might attempt to determine which external stimuli trigger angry responses or aggressive acts.
- Someone working from a **biological** perspective might study brain circuits that cause us to be “red in the face” and “hot under the collar,” or how heredity and experience influence our individual differences in temperament.
- Someone working from the **cognitive** perspective might study how our interpretation of a situation affects our anger and how our anger affects our thinking.
- Someone working from the **evolutionary** perspective might analyze how anger facilitated the survival of our ancestors' genes.
- Someone working from the *humanistic* perspective (a historically important approach) might have been interested in understanding how angry feelings affect a person's potential for growth. As we will see, modern-day *positive psychology* incorporates humanistic psychology's emphasis on human flourishing.
- Someone working from the **psychodynamic** perspective (which evolved from Freud's psychoanalysis) might view an outburst as an outlet for unconscious hostility.
- Someone working from the **social-cultural** perspective might explore how expressions of anger vary across cultural contexts.

The point to remember: Like two-dimensional views of a three-dimensional object, each of psychology's perspectives is helpful. But each by itself fails to reveal the whole picture.

behavioral psychology the scientific study of observable behavior, and its explanation by principles of learning.

biological psychology the scientific study of the links between biological (genetic, neural, hormonal) and psychological processes. (Some biological psychologists call themselves *behavioral neuroscientists*, *neuropsychologists*, *behavior geneticists*, *physiological psychologists*, or *biopsychologists*.)

Psychology's Subfields

2-3

What are psychology's main subfields?

Picturing a chemist at work, you probably envision a white-coated scientist surrounded by glassware and high-tech equipment. Picture a psychologist at work and you would be right to envision

- a white-coated scientist probing a rat's brain.
- an intelligence researcher measuring how quickly an infant shows boredom by looking away from a familiar picture.
- an executive evaluating a new "healthy lifestyles" training program for employees.
- someone at a computer analyzing data on whether adopted teens' temperaments more closely resemble those of their adoptive parents or their biological parents.
- a therapist listening carefully to a client's depressed thoughts.
- a researcher visiting another culture and collecting data on variations in human values and behaviors.
- a teacher or writer sharing the joy of psychology with others.

The cluster of subfields we call psychology is a meeting ground for different disciplines. "Psychology is a hub scientific discipline," said Association for Psychological Science president John Cacioppo (2007). Thus, it's a perfect home for those with wide-ranging interests. In its diverse activities, from biological experimentation to cultural comparisons, the tribe of psychology is united by a common quest: *describing and explaining behavior and the mind underlying it*. There is even a branch of psychology devoted to studying the measurement of our abilities, attitudes, and traits: **psychometrics**.

© The New Yorker Collection, 1986. J.B. Handelsman from cartoonbank.com. All Rights Reserved.

"I'm a social scientist, Michael. That means I can't explain electricity or anything like that, but if you ever want to know about people I'm your man."

cognitive psychology the scientific study of all the mental activities associated with thinking, knowing, remembering, and communicating.

evolutionary psychology the study of the evolution of behavior and mind, using principles of natural selection.

psychodynamic psychology a branch of psychology that studies how unconscious drives and conflicts influence behavior, and uses that information to treat people with psychological disorders.

social-cultural psychology the study of how situations and cultures affect our behavior and thinking.

psychometrics the scientific study of the measurement of human abilities, attitudes, and traits.

Laura Dwight

I see you! A biological psychologist might view this child's delighted response as evidence of brain maturation. A cognitive psychologist might see it as a demonstration of the baby's growing knowledge of his surroundings. For a social-cultural psychologist, the role of grandparents in different societies might be the issue of interest. As you will see throughout this book, these and other perspectives offer complementary views of behavior.

Mary Kate Denny/Photo Edit

Psychology: A science and a profession

Psychologists experiment with, observe, test, and treat behavior. Here we see psychologists testing a child, measuring emotion-related physiology, and doing group therapy.

basic research pure science that aims to increase the scientific knowledge base.

developmental psychology a branch of psychology that studies physical, cognitive, and social change throughout the life span.

educational psychology the study of how psychological processes affect and can enhance teaching and learning.

personality psychology the study of an individual's characteristic pattern of thinking, feeling, and acting.

social psychology the scientific study of how we think about, influence, and relate to one another.

AP® Exam Tip

Take careful note of the fact that psychiatry is a medical specialty and not a part of psychology. Can you summarize the similarities and differences among counseling psychologists, clinical psychologists, and psychiatrists?

Some psychologists conduct **basic research** that builds psychology's knowledge base. In the pages that follow we will meet a wide variety of such researchers, including

- **biological psychologists** exploring the links between brain and mind.
- **developmental psychologists** studying our changing abilities from womb to tomb.
- **cognitive psychologists** experimenting with how we perceive, think, and solve problems.
- **educational psychologists** studying influences on teaching and learning.
- **personality psychologists** investigating our persistent traits.
- **social psychologists** exploring how we view and affect one another.

(Read on to the next module for a more complete list of what psychologists in various professions do and where they work.)

These and other psychologists also may conduct **applied research**, tackling practical problems. **Industrial-organizational (I/O) psychologists**, for example, use psychology's concepts and methods in the workplace to help organizations and companies select and train employees, boost morale and productivity, design products, and implement systems. Within that domain, **human factors psychologists** focus on the interaction of people, machines, and physical environments. (More on this subject in Enrichment Module 82.)

Although most psychology textbooks focus on psychological science, psychology is also a helping profession devoted to such practical issues as how to have a happy marriage, how to overcome anxiety or depression, and how to raise thriving children. As a science, psychology at its best bases such interventions on *evidence of effectiveness*. **Counseling psychologists** help people to cope with challenges and crises (including academic, vocational, and marital issues) and to improve their personal and social functioning. **Clinical psychologists** assess and treat mental, emotional, and behavior disorders. Both counseling and clinical psychologists administer and interpret tests, provide counseling and therapy, and sometimes conduct basic and applied research. By contrast, **psychiatrists**, who also may provide psychotherapy, are medical doctors licensed to prescribe drugs and otherwise treat physical causes of psychological disorders.

We will study the history of therapy, including the role of pioneering Dorothea Dix, in the Therapy unit. Reformers such as Dix and Philippe Pinel led the way to humane treatment of those with psychological disorders.

To balance historic psychology's focus on human problems, Martin Seligman and others (2002, 2005, 2011) have called for more research on human strengths and human flourishing.

Their **positive psychology** scientifically explores “positive emotions, positive character traits, and enabling institutions.” What, they ask, can psychology contribute to a “good life” that engages one’s skills, and a “meaningful life” that points beyond oneself?

Rather than seeking to change people to fit their environment, **community psychologists** work to create social and physical environments that are healthy for all (Bradshaw et al., 2009; Trickett, 2009). For example, if school bullying is a problem, some psychologists will seek to change the bullies. Knowing that many students struggle with the transition from elementary to middle school, they might train individual kids how to cope. Community psychologists instead seek ways to adapt the school experience to early adolescent needs. To prevent bullying, they might study how the school and neighborhood foster bullying.

With perspectives ranging from the biological to the social, and with settings from the laboratory to the clinic, psychology relates to many fields. As we will see in Module 3, psychologists teach in medical schools, law schools, and high schools, and they work in hospitals, factories, and corporate offices. They engage in interdisciplinary studies, such as psychohistory (the psychological analysis of historical characters), psycholinguistics (the study of language and thinking), and psychoceramics (the study of crackpots).¹

Psychology also influences modern culture. Knowledge transforms us. Learning about the solar system and the germ theory of disease alters the way people think and act. Learning about psychology’s findings also changes people: They less often judge psychological disorders as moral failings, treatable by punishment and ostracism. They less often regard and treat women as men’s mental inferiors. They less often view and rear children as ignorant, willful beasts in need of taming. “In each case,” noted Morton Hunt (1990, p. 206), “knowledge has modified attitudes, and, through them, behavior.” Once aware of psychology’s well-researched ideas—about how body and mind connect, how a child’s mind grows, how we construct our perceptions, how we remember (and misremember) our experiences, how people across the world differ (and are alike)—your mind may never again be quite the same.

But bear in mind psychology’s limits. Don’t expect it to answer the ultimate questions, such as those posed by Russian novelist Leo Tolstoy (1904): “Why should I live? Why should I do anything? Is there in life any purpose which the inevitable death that awaits me does not undo and destroy?”

Although many of life’s significant questions are beyond psychology, some very important ones are illuminated by even a first psychology course. Through painstaking research, psychologists have gained insights into brain and mind, dreams and memories, depression and joy. Even the unanswered questions can renew our sense of mystery about “things too wonderful” for us yet to understand. And, as you will see in Modules 4–8, your study of psychology can help teach you how to ask and answer important questions—how to think critically as you evaluate competing ideas and claims.

Psychology deepens our appreciation for how we humans perceive, think, feel, and act. By so doing, it can indeed enrich our lives and enlarge our vision. Throughout this book I hope to help guide you toward that end. As educator Charles Eliot said a century ago: “Books are the quietest and most constant of friends, and the most patient of teachers.”

Dorothea Dix (1802–1887)

“I . . . call your attention to the state of the Insane Persons confined within this Commonwealth, in cages.”

applied research scientific study that aims to solve practical problems.

industrial-organizational (I/O) psychology the application of psychological concepts and methods to optimizing human behavior in workplaces.

human factors psychology an I/O psychology subfield that explores how people and machines interact and how machines and physical environments can be made safe and easy to use.

counseling psychology a branch of psychology that assists people with problems in living (often related to school, work, or marriage) and in achieving greater well-being.

clinical psychology a branch of psychology that studies, assesses, and treats people with psychological disorders.

psychiatry a branch of medicine dealing with psychological disorders; practiced by physicians who sometimes provide medical (for example, drug) treatments as well as psychological therapy.

positive psychology the scientific study of human functioning, with the goals of discovering and promoting strengths and virtues that help individuals and communities to thrive.

community psychology a branch of psychology that studies how people interact with their social environments and how social institutions affect individuals and groups.

“Once expanded to the dimensions of a larger idea, [the mind] never returns to its original size.” -OLIVER WENDELL HOLMES, 1809–1894

¹Confession: I wrote the last part of this sentence on April Fools’ Day.

Close-up

Improve Your Retention—and Your Grades!

2-4

How can psychological principles help you learn and remember, and do better on the AP® exam?

Do you, like most students, assume that the way to cement your new learning is to reread? What helps even more—and what this book therefore encourages—is repeated self-testing and rehearsal of previously studied material. Memory researchers Henry Roediger and Jeffrey Karpicke (2006) call this phenomenon the **testing effect**. They note that “testing is a powerful means of improving learning, not just assessing it.” In one of their studies, students recalled the meaning of 40 previously learned Swahili words much better if tested repeatedly than if they spent the same time restudying the words (Karpicke & Roediger, 2008).

As you will see in Modules 31–33, to master information you must *actively process it*. Your mind is not like your stomach, something to be filled passively; it is more like a muscle that grows stronger with exercise. Countless experiments reveal that people learn and remember best when they put material in their own words, rehearse it, and then retrieve and review it again.

The **SQ3R** study method incorporates these principles (McDaniel et al., 2009; Robinson, 1970). SQ3R is an acronym for its five steps: Survey, Question, Read, Retrieve,² Review.

To study a module, first *survey*, taking a bird’s-eye view. Scan the headings, and notice how the module is organized.

Before you read each main section, try to answer its numbered Learning Objective Question (for this box: “How can psychological principles help you learn and remember, and do better on the AP® exam?”). Roediger and Bridgid Finn (2010) have found that “trying and failing to retrieve the answer is actually helpful to learning.” Those who test their understanding before reading, and discover what they don’t yet know, will learn and remember better.

Then *read*, actively searching for the answer to the question. At each sitting, read only as much of the module (usually a single main section) as you can absorb without tiring. Read actively and critically. Ask questions. Take notes. Make the ideas your own: How does what you’ve read relate to your own life? Does it support or challenge your assumptions? How convincing is the evidence?

Having read a section, *retrieve* its main ideas. *Test yourself*. This will not only help you figure out what you know; the testing itself will help you learn and retain the information more effectively. Even better, test yourself repeatedly. To facilitate this, I offer self-testing opportunities in each module—for example,

in the *Before You Move On* sections. After answering the *Test Yourself* questions there, you can check your answers in Appendix E at the end of this text and reread as needed.

Finally, *review*: Read over any notes you have taken, again with an eye on the module’s organization, and quickly review the whole module. Write or say what a concept is before re-reading to check your understanding.

Survey, question, read, retrieve, review. I have organized this book’s modules to facilitate your use of the SQ3R study system. Each module begins with a list of objectives that aid your *survey*. Headings and the numbered Learning Objective Questions at the beginning of main sections suggest issues and concepts you should consider as you *read*. The material is organized into sections of readable length. At the end of main sections is a “Before You Move On” box with Ask Yourself and Test Yourself questions that help you *retrieve* what you know. The Module *Review* provides answers to the learning objective questions along with helpful review questions. The Unit Review offers a list of Key Terms and Key Contributors, along with AP® Exam Practice Questions. Appendix C, Psychological Science’s Key Contributors, at the end of the text will also be an important review tool—especially in preparing for the AP® exam. In addition to learning psychology’s key concepts and key people, you will also need to learn the style of writing that is required for success on the exam. The sample grading rubrics provided for some of the *Free-Response Questions* (essay-style questions) in the Module and Unit Reviews will help get you started.

Five additional study tips may further boost your learning:

Distribute your study time. One of psychology’s oldest findings is that *spaced practice* promotes better retention than *massed practice*. You’ll remember material better if you space your time over several study periods—perhaps one hour a day, six days a week—rather than cram it into one long study blitz. For example, rather than trying to read an entire module in a single sitting, read just one main section and then turn to something else. *Interleaving* your study of psychology with your study of other subjects boosts long-term retention and protects against overconfidence (Kornell & Bjork, 2008; Taylor & Rohrer, 2010).

Spacing your study sessions requires a disciplined approach to managing your time. (Richard O. Straub explains time management in a helpful preface at the beginning of this text.)

testing effect enhanced memory after retrieving, rather than simply rereading, information. Also sometimes referred to as a *retrieval practice effect* or *test-enhanced learning*.

SQ3R a study method incorporating five steps: Survey, Question, Read, Retrieve, Review.

² Also sometimes called “Recite.”

Close-up *(continued)*

Learn to think critically. Whether you are reading or in class, note people's assumptions and values. What perspective or bias underlies an argument? Evaluate evidence. Is it anecdotal? Or is it based on informative experiments? (More on this in Module 6.) Assess conclusions. Are there alternative explanations?

Process class information actively. Listen for the main ideas and sub-ideas of a lesson. *Write them down.* Ask questions during and after class. In class, as with your homework, process the information actively and you will understand and retain it better. As psychologist William James urged a century ago, "*No reception without reaction, no impression without . . . expression.*" Make the information your own. Take notes in your own words. Relate what you read to what you already know. Tell someone else about it. (As any teacher will confirm, to teach is to remember.)

Overlearn. Psychology tells us that overlearning improves retention. We are prone to overestimating how much we know. You may understand a module as you read it, but that feeling of familiarity can be deceptively comforting. By devoting extra study time to testing yourself, you may retain your new knowledge much more effectively.

Be a smart test-taker. If a test contains both multiple-choice questions and an essay question, turn first to the essay. Read the question carefully, noting exactly what the teacher is asking. On the back of a page, pencil in a list of points you'd like to make and then organize them. Before writing, put aside the essay and work through the multiple-choice questions. (As you do so, your mind may continue to mull over the essay question. Sometimes the multiple-choice questions will bring pertinent thoughts to mind.) Then reread the essay question, rethink your answer, and start writing. When you finish, proof-read your answer to eliminate spelling and grammatical errors that make you look less competent than you are.

When reading multiple-choice questions, don't confuse yourself by trying to imagine how each choice might be the right one. Instead, try to answer each question as if it were a fill-in-the-blank question. First cover the answers and form a sentence in your mind, recalling what you know to complete the sentence. Then read the answers on the test and find the alternative that best matches your own answer.

Memory experts Elizabeth Bjork and Robert Bjork (2011, p. 63) offer the bottom line for how to improve your retention and your grades:

Spend less time on the input side and more time on the output side, such as summarizing what you have read from memory or getting together with friends and asking each other questions. Any activities that involve testing yourself—that is, activities that require you to retrieve or generate information, rather than just representing information to yourself—will make your learning both more durable and flexible.

**Before You Move On****▶ ASK YOURSELF**

When you signed up for this course, what did you think psychology would be all about?

▶ TEST YOURSELF

What are psychology's major levels of analysis?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 2 Review

2-1 What is psychology's historic big issue?

- Psychology's biggest and most enduring issue has been the *nature–nurture issue*, which focuses on the relative contributions of genes and experience.
- Charles Darwin's view that *natural selection* shapes behaviors as well as bodies is an important principle in contemporary psychology.
- Today's science emphasizes the interaction of genes and experiences in specific environments.

2-2 What are psychology's levels of analysis and related perspectives?

- The *biopsychosocial approach* integrates information from three differing but complementary levels of analysis: the biological, psychological, and social-cultural.
- This approach offers a more complete understanding than could usually be reached by relying on only one of psychology's current perspectives (*biological, evolutionary, psychodynamic, behavioral, cognitive, and social-cultural*) or historically influential perspectives (such as the *humanistic approach*).

2-3 What are psychology's main subfields?

- Within the science of psychology, researchers may conduct *basic research* to increase the field's knowledge base (often in biological, *developmental, cognitive, educational, personality, and social psychology*) or *applied research* to

solve practical problems (in *industrial-organizational and human factors psychology*).

- *Psychometric* psychologists study measurement methods.
- Those who engage in psychology as a helping profession may assist people as *counseling psychologists* (helping people with problems in living or achieving greater well-being) or as *clinical psychologists*, studying and assessing people with psychological disorders and treating them with psychotherapy. (*Psychiatrists* also study, assess, and treat people with disorders, but as medical doctors, they may prescribe drugs in addition to psychotherapy.)
- *Positive psychology* attempts to discover and promote traits that help people to thrive.
- *Community psychologists* work to create healthy social and physical environments.

2-4 How can psychological principles help you learn and remember, and do better on the AP® exam?

- The *testing effect* shows that learning and memory are enhanced by actively retrieving, rather than simply rereading, previously studied material.
- The SQ3R study method—survey, question, read, retrieve, and review—applies the principles derived from memory research.
- Five additional tips are (1) distribute your study time; (2) learn to think critically; (3) process class information actively; (4) overlearn; (5) be a smart test-taker.

Multiple-Choice Questions

1. Which of the following perspectives is most likely to address how the encoding, storing, and retrieval of information might alter our thoughts?
 - a. Behavioral
 - b. Psychodynamic
 - c. Humanistic
 - d. Cognitive
 - e. Biological
2. Who among the following would most likely study the interaction of people, machines, and physical environments?
 - a. Human factors psychologist
 - b. Personality psychologist
 - c. Industrial-organizational psychologist
 - d. Counseling psychologist
 - e. Experimental psychologist

3. Psychiatrists differ from psychologists in that they
 - a. help people cope with challenges and crises.
 - b. conduct research.
 - c. explore how we view and affect one another.
 - d. experiment with how people perceive, think, and solve problems.
 - e. are medical doctors licensed to prescribe medication.
4. A humanistic psychologist working with some poets might ask which of the following questions?
 - a. How can we get them to reach their highest potential?
 - b. How did their childhood experiences impact their current behavior?
 - c. How have rewards and punishments shaped their behavior?
 - d. How do society's attitudes affect their writing topics?
 - e. How do their brains differ from those of other successful people?
5. Betsy works in a human resources department. She plans training sessions, recruits people to work for the company, and implements techniques to boost morale around the office. Of the following, Betsy is most likely a(n)
 - a. developmental psychologist.
 - b. personality psychologist.
 - c. counseling psychologist.
 - d. educational psychologist.
 - e. industrial-organizational psychologist.

Practice FRQs

1. George is said to have an “easy-going” personality. How might the biopsychosocial approach be used to explain an easy-going personality?

Answer

1 point: Biological factors would include George's genetic, physiological, and chemical makeup. For instance, George's easy-going manner may be the result of brain chemistry.

1 point: Psychological factors would include a discussion of how George learned that an easy-going personality makes people want to spend time with him. In response, he keeps anxiety and negative feelings to himself. He has the perception that others do not want to deal with his stress and anxiety.

1 point: Social-cultural factors would include George's family or cultural upbringing and expectations. If those who surround George expect him to be relaxed and laid-back, and this is what is supported in his community, George will be likely to act accordingly.

2. Six months ago, Carlos emigrated from Spain to the United States. Although fluent in English and an honor student in Spain, Carlos has had difficulty completing his assignments since moving to the United States. His parents don't understand why he is not succeeding like he did in his last school. Carlos has quit participating in family traditions.

Explain how each of the following psychological perspectives might explain Carlos' behavior:

- Psychodynamic
- Cognitive

(2 points)

Module 3

Careers in Psychology

Module Learning Objective

3-1

Describe what psychologists in various professions do and where they work.

This module was written by Jennifer Zwolinski, Associate Professor of Psychology at the University of San Diego.

3-1

What do psychologists in various professions do, and where do they work?

What can you do with a college degree in psychology? Lots!

If you major in psychology, you will graduate with a scientific mind-set and an awareness of basic principles of human behavior (biological mechanisms, development, cognition, psychological disorders, social interaction). This background will prepare you for success in many areas, including business, the helping professions, health services, marketing, law, sales, and teaching. You may even go on to graduate school for specialized training to become a psychology professional. This module describes psychology's specialized subfields. Appendix D, Preparing for Further Psychology Studies, provides tips for preparing to earn a bachelor's, master's, or doctoral degree in psychology, with information about the career options that become available at those varying levels of education.

If you are like most students, you may be unaware of the wide variety of specialties and work settings available in psychology (Terre & Stoddart, 2000). To date, the American Psychological Association (APA) has formed 56 divisions. Let's look at some of the basic research, applied research, and helping profession careers (arranged alphabetically) in the main specialty areas of psychology, most of which require a graduate degree in psychology.

AP® Exam Tip

You are about to read about a lot of career possibilities in psychology. Note the division between basic subfields and applied subfields. The work of some of these specialties is pretty obvious (it's not that hard to figure out in general what an educational psychologist or a health psychologist might do). Devote extra attention to those specialties that may be unfamiliar to you.

Karen Moskowitz/Getty Images

Consulting psychologist Cognitive psychologists may advise businesses on how to operate more effectively by understanding the human factors involved.

Basic Research Subfields

COGNITIVE PSYCHOLOGISTS study thought processes and focus on such topics as perception, language, attention, problem solving, memory, judgment and decision making, forgetting, and intelligence. Research interests include designing computer-based models of thought processes and identifying biological correlates of cognition. As a cognitive psychologist, you might work as a professor, industrial consultant, or human factors specialist in an educational or business setting.

DEVELOPMENTAL PSYCHOLOGISTS conduct research on age-related behavioral changes and apply their scientific knowledge to educational, child-care, policy, and related settings. As a developmental psychologist, you would investigate change across a broad range of topics, including the biological, psychological, cognitive, and social aspects of development. Developmental psychology informs a number of applied fields, including educational psychology, school psychology, child psychopathology, and gerontology. The field also informs public policy in areas such as education and child-care reform, maternal and child health, and attachment and adoption. You would probably specialize in a specific stage of the life span, such as infancy, childhood, adolescence, or middle or late adulthood. Your work setting could be an educational institution, day-care center, youth group program, or senior center.

EDUCATIONAL PSYCHOLOGISTS are interested in the psychological processes involved in learning. They study the relationship between learning and physical and social environments, and they develop strategies for enhancing the learning process. As an educational psychologist, working in a university psychology department or school of education, you might conduct basic research on topics related to learning or develop innovative methods of teaching to enhance the learning process. You might design effective tests, including measures of aptitude and achievement. You might be employed by a school or government agency or charged with designing and implementing effective employee-training programs in a business setting.

EXPERIMENTAL PSYCHOLOGISTS are a diverse group of scientists who investigate a variety of basic behavioral processes in humans and other animals. Prominent areas of experimental research include comparative methods of science, motivation, learning, thought, attention, memory, perception, and language. Most experimental psychologists identify with a particular subfield, such as cognitive psychology, depending on their interests and training. It is important to note that experimental research methods are not limited to the field of experimental psychology; many other subfields rely on experimental methodology to conduct studies. As an experimental psychologist, you would most likely work in an academic setting, teaching courses and supervising students' research in addition to conducting your own research. Or you might be employed by a research institution, zoo, business, or government agency.

PSYCHOMETRIC AND QUANTITATIVE PSYCHOLOGISTS study the methods and techniques used to acquire psychological knowledge. A psychometrician may update existing neurocognitive or personality tests or devise new tests for use in clinical and school settings or in business and industry. These psychologists also administer, score, and interpret such tests. Quantitative psychologists collaborate with researchers to design, analyze, and interpret the results of research programs. As a psychometric or quantitative psychologist, you will need to be well trained in research methods, statistics, and computer technology. You will most likely be employed by a university or college, testing company, private research firm, or government agency.

SOCIAL PSYCHOLOGISTS are interested in our interactions with others. Social psychologists study how our beliefs, feelings, and behaviors are affected by and influence other people. They study topics such as attitudes, aggression, prejudice, interpersonal attraction, group behavior, and leadership. As a social psychologist, you would probably be a college or university faculty member. You might also work in organizational consultation, market research, or other applied psychology fields, including social neuroscience. Some social psychologists work for hospitals, federal agencies, or businesses performing applied research.

AP[®] Exam Tip

Educational psychologists apply psychology's findings in an effort to improve learning, and *school psychologists* assess and assist individual schoolchildren.

Psychology in court Forensic psychologists apply psychology's principles and methods in the criminal justice system. They may assess witness credibility or testify in court on a defendant's state of mind and future risk.

Applied Research Subfields

FORENSIC PSYCHOLOGISTS apply psychological principles to legal issues. They conduct research on the interface of law and psychology, help to create public policies related to mental health, help law-enforcement agencies in criminal investigations, or consult on jury selection and deliberation processes. They also provide assessment to assist the legal community. Although most forensic psychologists are clinical psychologists, they might have expertise in other areas of psychology, such as social or cognitive psychology. Some also hold law degrees. As a forensic psychologist, you might work in a university psychology department, law school, research organization, community mental health agency, law-enforcement agency, court, or correctional setting.

HEALTH PSYCHOLOGISTS are researchers and practitioners concerned with psychology's contribution to promoting health and preventing disease. As applied psychologists or clinicians, they may help individuals lead healthier lives by designing, conducting, and evaluating programs to stop smoking, lose weight, improve sleep, manage pain, prevent the spread of sexually transmitted infections, or treat psychosocial problems associated with chronic and terminal illnesses. As researchers and clinicians, they identify conditions and practices associated with health and illness to help create effective interventions. In public service, health psychologists study and work to improve government policies and health care systems. As a health psychologist, you could be employed in a hospital, medical school, rehabilitation center, public health agency, college or university, or, if you are also a clinical psychologist, in private practice.

INDUSTRIAL-ORGANIZATIONAL (I/O) PSYCHOLOGISTS study the relationship between people and their working environments. They may develop new ways to increase productivity, improve personnel selection, or promote job satisfaction in an organizational setting. Their interests include organizational structure and change, consumer behavior, and personnel selection and training. As an I/O psychologist, you might conduct workplace training or provide organizational analysis and development. You may find yourself working in business, industry, the government, or a college or university. Or you may be self-employed as a consultant or work for a management consulting firm.

NEUROPSYCHOLOGISTS investigate the relationship between neurological processes (structure and function of the nervous system) and behavior. As a neuropsychologist you might assess, diagnose, or treat central nervous system disorders, such as Alzheimer's disease or stroke. You might also evaluate individuals for evidence of head injuries; learning and developmental disabilities, such as autism spectrum disorder; and other psychiatric disorders, such as attention-deficit/hyperactivity disorder (ADHD). If you are a *clinical neuropsychologist*, you might work in a hospital's neurology, neurosurgery, or psychiatric unit. Neuropsychologists also work in academic settings, where they conduct research and teach.

REHABILITATION PSYCHOLOGISTS are researchers and practitioners who work with people who have lost optimal functioning after an accident, illness, or other event. As a rehabilitation psychologist, you would probably work in a medical rehabilitation institution or hospital. You might also work in a medical school, university, state or federal vocational rehabilitation agency, or in private practice serving people with physical disabilities.

SCHOOL PSYCHOLOGISTS are involved in the assessment of and intervention for children in educational settings. They diagnose and treat cognitive, social, and emotional problems that may negatively influence children's learning or overall functioning at school. As a school psychologist, you would collaborate with teachers, parents, and administrators, making recommendations to improve student learning. You could work in an academic setting, a federal or state government agency, a child guidance center, or a behavioral research laboratory.

Spencer Grant/Photo Edit

Class counselor School psychologists, who have their master's degree in psychology, may find themselves working with students individually or in groups, as well as in a consultative role for their school's administrators.

SPORT PSYCHOLOGISTS study the psychological factors that influence, and are influenced by, participation in sports and other physical activities. Their professional activities include coach education and athlete preparation, as well as research and teaching. Sport psychologists who also have a clinical or counseling degree can apply those skills to working with individuals with psychological problems, such as anxiety or substance abuse, that might interfere with optimal performance. As a sport psychologist, if you were not working in an academic or research setting, you would most likely work as part of a team or organization, or in a private capacity.

Phil Walter/Getty Images

Athlete assistance

Sport psychologists often work directly with athletes to help them improve their performance.

The Helping Professions

CLINICAL PSYCHOLOGISTS promote psychological health in individuals, groups, and organizations. Some clinical psychologists specialize in specific psychological disorders. Others treat a range of disorders, from adjustment difficulties to severe psychopathology. Clinical psychologists might engage in research, teaching, assessment, and consultation. Some hold workshops and lectures on psychological issues for other professionals or for the public. Clinical psychologists work in a variety of settings, including private practice, mental health service organizations, schools, universities, industries, legal systems, medical systems, counseling centers, government agencies, and military services.

To become a clinical psychologist, you will need to earn a doctorate from a clinical psychology program. The APA sets the standards for clinical psychology graduate programs, offering accreditation (official recognition) to those who meet their standards. In all U.S. states, clinical psychologists working in independent practice must obtain a license to offer services such as therapy and testing.

COMMUNITY PSYCHOLOGISTS move beyond focusing on specific individuals or families and deal with broad problems of mental health in community settings. These psychologists believe that human behavior is powerfully influenced by the interaction between people and their physical, social, political, and economic environments. They seek to promote psychological health by enhancing environmental settings, focusing on preventive measures and crisis intervention, with special attention to the problems of underserved groups and ethnic minorities. Given the shared emphasis on prevention, some community psychologists collaborate with

Coping with disaster After Haiti's disastrous 2010 earthquake, this community psychologist helped survivors cope with the loss of their homes and, for many, the death of family members and friends.

professionals in other areas, such as public health. As a community psychologist, your work settings could include federal, state, and local departments of mental health, corrections, and welfare. You might conduct research or help evaluate research in health service settings, serve as an independent consultant for a private or government agency, or teach and consult as a college or university faculty member.

COUNSELING PSYCHOLOGISTS help people adjust to life transitions or make lifestyle changes. Although similar to clinical psychologists, counseling psychologists typically help people with adjustment problems rather than severe psychopathology. Like clinical psychologists, counseling psychologists conduct therapy and provide assessments to individuals and groups. As a counseling psychologist, you would emphasize your clients' strengths, helping them to use their own skills, interests, and abilities to cope during transitions. You might find yourself working in an academic setting as a faculty member or administrator or in a university counseling center, community mental health center, business, or private practice. As with clinical psychology, if you plan to work in independent practice you will need to obtain a state license to provide counseling services to the public.

* * *

So, the next time someone asks you what you could do with a psychology degree, tell them you will have a lot of options. You might use your acquired skills and understanding to get a job and succeed in any number of fields, or you might pursue graduate school and then career opportunities in associated professions. In any case, what you have learned about behavior and mental processes will surely enrich your life (Hammer, 2003).

Before You Move On

▶ ASK YOURSELF

Which of psychology's specialties were you aware of before taking this course? Which seem most interesting to you?

▶ TEST YOURSELF

Name the subfields that focus on a) people and their work environments, b) how people change over the life span, c) the human thinking involved in perceiving, remembering, speaking, and decision making, and d) diagnosing and treating psychological disorders.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 3 Review

3-1

What do psychologists in various professions do, and where do they work?

- The APA has formed 56 divisions.
- Psychology's specialties include the basic research subfields (cognitive, developmental, educational, experimental, psychometric and quantitative, and social psychology); the applied research subfields (forensic, health, industrial-organizational, neuropsychology, rehabilitation, school, and sport psychology); and the helping professions (clinical, community, and counseling).
- Work settings for psychologists include a wide range of government agencies, industrial and business settings, clinics and counseling centers, health care institutions, schools, universities, and research organizations.

Multiple-Choice Questions

- Which of the following psychologists most strongly emphasize that human behavior is powerfully influenced by the interaction between people and their physical, social, political, and economic environments?
 - Community
 - Clinical
 - Counseling
 - Industrial-organizational
 - Rehabilitation
- Which of the following psychologists would be most likely to investigate biological, psychological, cognitive, and social changes over time?
 - Educational
 - Experimental
 - Social
 - Cognitive
 - Developmental
- A psychologist investigates the methods teachers use to enhance student learning. With which of the following subfields is the psychologist most likely aligned?
 - Educational psychology
 - Experimental psychology
 - School psychology
 - Social psychology
 - Forensic psychology
- A psychologist works with children whose parents are divorcing. She helps them develop skills they need to cope with the situation. Of the following, what kind of psychologist is most likely helping these children?
 - Industrial-organizational
 - Social
 - Research
 - Counseling
 - Community
- Dwayne is interested in helping people make good decisions regarding their physical well-being. Dwayne should consider a career as a
 - community psychologist.
 - social psychologist.
 - forensic psychologist.
 - industrial-organizational psychologist.
 - health psychologist.

Practice FRQs

- Anisha, a high school junior, has been struggling recently in many areas of her life. She is overweight and spends several hours a day watching television. She is having trouble keeping up in her classes and says she cannot seem to keep her focus. She also is having trouble making friends and “fitting in” at school.

Explain how the following applied psychologists might attempt to help Anisha’s current situation.

- Health psychologists
- Social psychologists
- Counseling psychologists

Answer

1 point: A health psychologist might attempt to find ways to encourage Anisha to lead a more active lifestyle and focus on improving her diet and creating an exercise program. This should help her to lose some weight and become healthier in her daily habits.

1 point: A school psychologist might work with Anisha’s parents, teachers, and counselors to determine why she is struggling in her classes and make recommendations for improving her classroom performance.

1 point: A counseling psychologist might work with Anisha to find out why she has recently found numerous aspects of her life more challenging and might work on strategies for helping Anisha cope with challenging situations, such as how to make friends.

- Hurricane Katrina hit New Orleans in 2005, causing a staggering loss of life and cultural heritage and billions of dollars in damage. How might each of the following have contributed to making life better in New Orleans following the hurricane?

- Clinical psychologists
- Social psychologists

(2 points)

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Which perspective would be most useful when explaining how people from different countries express anger?
 - Social-cultural
 - Psychodynamic
 - Behavioral
 - Functionalist
 - Biological
- The debate about the relative contributions of biology and experience to human development is most often referred to as what?
 - Evolutionary analysis
 - Behaviorism
 - The cognitive revolution
 - The nature–nurture issue
 - Natural selection
- Which of the following professionals is required to have a medical degree?
 - Psychiatrist
 - Psychologist
 - Clinician
 - Counselor
 - Psychotherapist
- Which psychological principle best explains why studying an hour a day for a week is more effective than one 7-hour study session?
 - Testing effect
 - Distributed practice
 - SQ3R
 - Retrieval practice effect
 - Psychometrics

- 5.** Which of the following kinds of psychologists would most likely explore how we process and remember information?
- Developmental
 - Biological
 - Social
 - Cognitive
 - Personality
- 6.** According to the behaviorist perspective, psychological science should be rooted in what?
- Introspection
 - Observation
 - Cultural influences
 - Growth potential
 - Basic needs
- 7.** Which of the following psychologists would most likely conduct psychotherapy?
- Biological
 - Clinical
 - Industrial-organizational
 - Cognitive
 - Evolutionary
- 8.** Which field of psychology is most interested in studying the link between mental activity and brain activity?
- Humanistic psychology
 - Gestalt psychology
 - Cognitive neuroscience
 - Psychodynamic perspective
 - Evolutionary perspective
- 9.** What was the main difference between the psychological thinking of Wilhelm Wundt and earlier philosophers who were also interested in thinking and behavior?
- Wundt was European, earlier philosophers were American.
 - Wundt was the first professor from a major university interested in psychology.
 - Wundt was the first scholar to call himself a psychologist.
 - Wundt used psychotherapy techniques established by Freud to examine the thinking and behavior of healthy individuals.
 - Wundt and his students gathered data about human thinking and behavior in a laboratory setting.
- 10.** Which school of psychology focused on the adaptive nature of thinking and how our consciousness evolves to meet our needs?
- Functionalist
 - Structuralist
 - Behavioral
 - Humanistic
 - Psychodynamic
- 11.** The study of the importance of satisfying love and acceptance needs best describes which school of psychology?
- Behavioral
 - Functionalist
 - Humanistic
 - Psychodynamic
 - Structuralist
- 12.** Which of the following statements is the best example of applied research?
- Investigating personality traits
 - Using psychological concepts to boost worker productivity
 - Experimenting with how people perceive different stimuli
 - Studying the changing abilities of children from ages 2 to 5
 - Exploring the neural changes that occur during adolescence
- 13.** Self-reflective introspection about the elements of experience best describes a technique used by which school of psychology?
- Darwinists
 - Empiricists
 - Structuralists
 - Behaviorists
 - Psychiatrists
- 14.** Which psychological perspective is most likely to focus on how our interpretation of a situation affects how we react to it?
- Psychodynamic
 - Biological
 - Social-cultural
 - Evolutionary
 - Cognitive
- 15.** The science of behavior and mental processes is the definition of which field of study?
- Philosophy
 - Cognitive neuroscience
 - Basic research
 - Psychology
 - Applied research

Free-Response Questions

1. Arianna is nervous around large crowds, and often leaves social situations like school dances and parties because she feels like she might have a panic attack. Her father died when she was a young girl, but she still often has nightmares about his death. Arianna enjoys school, and because she generally receives good grades, she appreciates the positive feedback from her teachers that encourages her to improve her academic skills.

Using the seven major modern approaches to psychology, explain how each approach might explain Arianna's behavior.

2. In thinking of the question of nature versus nurture, explain how each of the following schools of psychology would address this debate.

- Behaviorism
- Biological perspective
- Personality psychologists
- Developmental psychologists

(4 points)

Multiple-choice self-tests and more may be found at www.worthpublishers.com/MyersAP2e

Rubric for Free-Response Question 1

1 point: The *biological approach* would likely attribute Arianna's nervousness to brain chemistry, hormones, or genetic influences.  Page 12

1 point: The *evolutionary approach* would explore how avoiding social crowds might have been a survival advantage for early humans, such as by reducing exposure to germs and violence.  Page 12

1 point: The *psychodynamic approach* would examine Arianna's early life and how she dealt with losing her father, focusing on Arianna's childhood experiences and unconscious anxieties.  Page 12

1 point: The *behavioral approach* would look at how Arianna has learned in the past through rewards and punishments. She may have had a negative experience in a large group in the past and as a result has learned to avoid social gatherings.  Page 12

1 point: The *cognitive approach* would focus on examining how Arianna perceives situations. Her interpretation of social situations may impact the outcome.  Page 12

1 point: The *humanistic approach* would look at how Arianna's environment may have hindered her growth and self-fulfillment.  Page 12

1 point: The *social-cultural approach* would examine how interactions within the cultures Arianna belongs to influence her expectations about social situations. If her family or other cultural influences encourage her to attend social functions, that might influence her to continue to try attending those kinds of events.  Page 12

Unit II

Research Methods: Thinking Critically With Psychological Science

Modules

- 4 The Need for Psychological Science
- 5 The Scientific Method and Description
- 6 Correlation and Experimentation
- 7 Statistical Reasoning in Everyday Life
- 8 Frequently Asked Questions About Psychology

In a difficult moment—after an argument with a loved one, a social embarrassment, or a bad grade—to whom do you turn? For advice and comfort, we often turn to friends and family, or search online. Psychology can also shed insight. Psychologists start with the questions that intrigue all of us: How can we be happier, healthier, and more successful? What can we do to improve our relationships? Why do people act and think as they do? But psychological *science* takes it a step further and uses careful research to separate uninformed opinions from examined conclusions.

Module 4

The Need for Psychological Science

Module Learning Objectives

4-1 Describe how hindsight bias, overconfidence, and the tendency to perceive order in random events illustrate why science-based answers are more valid than those based on intuition and common sense.

4-2 Identify how the three main components of the scientific attitude relate to critical thinking.

4-1 How do hindsight bias, overconfidence, and the tendency to perceive order in random events illustrate why science-based answers are more valid than those based on intuition and common sense?

Some people suppose that psychology merely documents and dresses in jargon what people already know: “So what else is new—you get paid for using fancy methods to prove what everyone knows?” Others place their faith in human intuition: “Buried deep within each and every one of us, there is an instinctive, heart-felt awareness that provides—if we allow it to—the most reliable guide,” offered Prince Charles (2000).

Prince Charles has much company, judging from the long list of pop psychology books on “intuitive managing,” “intuitive trading,” and “intuitive healing.” Today’s psychological science does document a vast intuitive mind. As we will see, our thinking, memory, and attitudes operate on two levels—conscious and unconscious—with the larger part operating automatically, off-screen. Like jumbo jets, we fly mostly on autopilot.

So, are we smart to listen to the whispers of our inner wisdom, to simply trust “the force within”? Or should we more often be subjecting our intuitive hunches to skeptical scrutiny?

This much seems certain: We often underestimate intuition’s perils. My geographical intuition tells me that Reno is east of Los Angeles, that Rome is south of New York, that Atlanta is east of Detroit. But I am wrong, wrong, and wrong.

Modules to come will show that experiments have found people greatly overestimating their lie detection accuracy, their eyewitness recollections, their interviewee assessments, their risk predictions, and their stock-picking talents. As a Nobel Prize-winning physicist explained, “The first principle is that you must not fool yourself—and you are the easiest person to fool” (Feynman, 1997).

The limits of intuition Personnel interviewers tend to be overconfident of their gut feelings about job applicants. Their confidence stems partly from their recalling cases where their favorable impression proved right, and partly from their ignorance about rejected applicants who succeeded elsewhere.

Indeed, observed novelist Madeleine L'Engle, “The naked intellect is an extraordinarily inaccurate instrument” (1973). Three phenomena—*hindsight bias*, *judgmental overconfidence*, and *our tendency to perceive patterns in random events*—illustrate why we cannot rely solely on intuition and common sense.

Did We Know It All Along? Hindsight Bias

Consider how easy it is to draw the bull’s eye *after* the arrow strikes. After the stock market drops, people say it was “due for a correction.” After the football game, we credit the coach if a “gutsy play” wins the game, and fault the coach for the “stupid play” if it doesn’t. After a war or an election, its outcome usually seems obvious. Although history may therefore seem like a series of inevitable events, the actual future is seldom foreseen. No one’s diary recorded, “Today the Hundred Years War began.”

This **hindsight bias** (also known as the *I-knew-it-all-along phenomenon*) is easy to demonstrate: Give half the members of a group some purported psychological finding, and give the other half an opposite result. Tell the first group, “Psychologists have found that separation weakens romantic attraction. As the saying goes, ‘Out of sight, out of mind.’” Ask them to imagine why this might be true. Most people can, and nearly all will then view this true finding as unsurprising.

Tell the second group the opposite, “Psychologists have found that separation strengthens romantic attraction. As the saying goes, ‘Absence makes the heart grow fonder.’” People given this untrue result can also easily imagine it, and most will also see it as unsurprising. When two opposite findings both seem like common sense, there is a problem.

Such errors in our recollections and explanations show why we need psychological research. Just asking people how and why they felt or acted as they did can sometimes be misleading—not because common sense is usually wrong, but because common sense more easily describes what *has* happened than what *will* happen. As physicist Niels Bohr reportedly said, “Prediction is very difficult, especially about the future.”

Some 100 studies have observed hindsight bias in various countries and among both children and adults (Blank et al., 2007). Nevertheless, our intuition is often right. As Yogi Berra once said, “You can observe a lot by watching.” (We have Berra to thank for other gems, such as “Nobody ever comes here—it’s too crowded,” and “If the people don’t want to come out to the ballpark, nobody’s gonna stop ‘em.”) Because we’re all behavior watchers, it would be

“Those who trust in their own wits are fools.” -PROVERBS 28:26

“Life is lived forwards, but understood backwards.”
-PHILOSOPHER SØREN KIERKEGAARD,
1813–1855

hindsight bias the tendency to believe, after learning an outcome, that one would have foreseen it. (Also known as the *I-knew-it-all-along phenomenon*.)

“Anything seems commonplace, once explained.” -DR. WATSON TO SHERLOCK HOLMES

REUTERS/U.S. Coast Guard/Handout

Hindsight bias When drilling the Deepwater Horizon oil well in 2010, BP employees took some shortcuts and ignored some warning signs, without intending to harm the environment or their company’s reputation. *After* the resulting Gulf oil spill, with the benefit of 20/20 hindsight, the foolishness of those judgments became obvious.

AP® Exam Tip

It is quite common for multiple-choice questions on the AP® exam to test your knowledge of “media myths.” Pay particular attention when psychological findings run counter to “common sense.”

surprising if many of psychology’s findings had *not* been foreseen. Many people believe that love breeds happiness, and they are right (we have what Module 40 calls a deep “need to belong”). Indeed, note Daniel Gilbert, Brett Pelham, and Douglas Krull (2003), “good ideas in psychology usually have an oddly familiar quality, and the moment we encounter them we feel certain that we once came close to thinking the same thing ourselves and simply failed to write it down.” Good ideas are like good inventions; once created, they seem obvious. (Why did it take so long for someone to invent suitcases on wheels and Post-it Notes?)

But sometimes our intuition, informed by countless casual observations, has it wrong. In later modules we will see how research has overturned popular ideas—that familiarity breeds contempt, that dreams predict the future, and that most of us use only 10 percent of our brain. (See also **TABLE 4.1**.) We will also see how it has surprised us with discoveries about how the brain’s chemical messengers control our moods and memories, about other animals’ abilities, and about the effects of stress on our capacity to fight disease.

Table 4.1 True or False?

Psychological research discussed in modules to come will either confirm or refute each of these statements (adapted, in part, from Furnham et al., 2003). Can you predict which of these popular ideas have been confirmed and which refuted? (Check your answers at the bottom of this table.)

1. If you want to teach a habit that persists, reward the desired behavior every time, not just intermittently (see Module 27).
2. Patients whose brains are surgically split down the middle survive and function much as they did before the surgery (see Module 13).
3. Traumatic experiences, such as sexual abuse or surviving the Holocaust, are typically “repressed” from memory (see Module 33).
4. Most abused children do *not* become abusive adults (see Module 50).
5. Most infants recognize their own reflection in a mirror by the end of their first year (see Module 47).
6. Adopted siblings usually do not develop similar personalities, even though they are reared by the same parents (see Module 14).
7. Fears of harmless objects, such as flowers, are just as easy to acquire as fears of potentially dangerous objects, such as snakes (see Module 15).
8. Lie detection tests often lie (see Module 41).
9. The brain remains active during sleep (see Modules 22–23).

Answers: 1. F, 2. T, 3. F, 4. T, 5. F, 6. T, 7. F, 8. T, 9. T

Overconfidence

We humans tend to think we know more than we do. Asked how sure we are of our answers to factual questions (*Is Boston north or south of Paris?*), we tend to be more confident than correct.¹ Or consider these three anagrams, which Richard Goranson (1978) asked people to unscramble:

WREAT → WATER

ETRYN → ENTRY

GRABE → BARGE

About how many seconds do you think it would have taken you to unscramble each of these? Did hindsight influence you? Knowing the answers tends to make us overconfident—surely the solution would take only 10 seconds or so, when in reality the average problem solver spends 3 minutes, as you also might, given a similar anagram without the solution: OCHSA.²

Are we any better at predicting social behavior? University of Pennsylvania psychologist Philip Tetlock (1998, 2005) collected more than 27,000 expert predictions of world events, such as the future of South Africa or whether Quebec would separate from Canada. His repeated finding: These predictions, which experts made with 80 percent confidence on average, were right less than 40 percent of the time. Nevertheless, even those who erred maintained their confidence by noting they were “almost right.” “The Québécois separatists *almost* won the secessionist referendum.”

Perceiving Order in Random Events

In our natural eagerness to make sense of our world—what poet Wallace Stevens called our “rage for order”—we are prone to perceive patterns. People see a face on the moon, hear Satanic messages in music, perceive the Virgin Mary’s image on a grilled cheese sandwich. Even in random data we often find order, because—here’s a curious fact of life—*random sequences often don’t look random* (Falk et al., 2009; Nickerson, 2002, 2005). Consider a random coin flip: If someone flipped a coin six times, which of the following sequences of heads (H) and tails (T) would be most likely: HHHTTT or HTTHTH or HHHHHH?

Daniel Kahneman and Amos Tversky (1972) found that most people believe HTTHTH would be the most likely random sequence. Actually, all three are equally likely (or, you might say, equally unlikely). A poker hand of 10 through ace, all of hearts, would seem extraordinary; actually, it would be no more or less likely than any other specific hand of cards (**FIGURE 4.1**).

In actual random sequences, patterns and streaks (such as repeating digits) occur more often than people expect (Oskarsson et al., 2009). To demonstrate this phenomenon for myself, I flipped a coin 51 times, with these results:

1. H	10. T	19. H	28. T	37. T	46. H
2. T	11. T	20. H	29. H	38. T	47. H
3. T	12. H	21. T	30. T	39. H	48. T
4. T	13. H	22. T	31. T	40. T	49. T
5. H	14. T	23. H	32. T	41. H	50. T
6. H	15. T	24. T	33. T	42. H	51. T
7. H	16. H	25. T	34. T	43. H	
8. T	17. T	26. T	35. T	44. H	
9. T	18. T	27. H	36. H	45. T	

Looking over the sequence, patterns jump out: Tosses 10 to 22 provided an almost perfect pattern of pairs of tails followed by pairs of heads. On tosses 30 to 38 I had a “cold hand,” with only one head in nine tosses. But my fortunes immediately reversed with a “hot hand”—seven heads out of the next nine tosses. Similar streaks happen, about as often as one would expect in random sequences, in basketball shooting, baseball hitting, and mutual fund stock pickers’ selections (Gilovich et al., 1985; Malkiel, 2007; Myers, 2002). These sequences often don’t look random and so are overinterpreted. (“When you’re hot, you’re hot!”)

¹ Boston is south of Paris.

² The anagram solution: CHAOS.

Overconfidence in history:

“We don’t like their sound. Groups of guitars are on their way out.” -DECCA RECORDS, IN TURNING DOWN A RECORDING CONTRACT WITH THE BEATLES IN 1962

“Computers in the future may weigh no more than 1.5 tons.” -POPULAR MECHANICS, 1949

“They couldn’t hit an elephant at this distance.” -GENERAL JOHN SEDGWICK JUST BEFORE BEING KILLED DURING A U.S. CIVIL WAR BATTLE, 1864

“The telephone may be appropriate for our American cousins, but not here, because we have an adequate supply of messenger boys.” -BRITISH EXPERT GROUP EVALUATING THE INVENTION OF THE TELEPHONE

Figure 4.1

Two random sequences Your chances of being dealt either of these hands are precisely the same: 1 in 2,598,960.

What explains these streaky patterns? Was I exercising some sort of paranormal control over my coin? Did I snap out of my tails funk and get in a heads groove? No such explanations are needed, for these are the sorts of streaks found in any random data. Comparing each toss to the next, 23 of the 50 comparisons yielded a changed result—just the sort of near 50-50 result we expect from coin tossing. Despite seeming patterns, the outcome of one toss gives no clue to the outcome of the next.

However, some happenings seem so extraordinary that we struggle to conceive an ordinary, chance-related explanation (as applies to our coin tosses). In such cases, statisticians often are less mystified. When Evelyn Marie Adams won the New Jersey lottery *twice*, newspapers reported the odds of her feat as 1 in 17 trillion. Bizarre? Actually, 1 in 17 trillion are indeed the odds that a given person who buys a single ticket for two New Jersey lotteries will win both times. And given the millions of people who buy U.S. state lottery tickets, statisticians Stephen Samuels and George McCabe (1989) reported, it was “practically a sure thing” that someday, somewhere, someone would hit a state jackpot twice. Indeed, said fellow statisticians Persi Diaconis and Frederick Mosteller (1989), “with a large enough sample, any outrageous thing is likely to happen.” An event that happens to but 1 in 1 billion people every day occurs about 7 times a day, 2500 times a year.

The point to remember: Hindsight bias, overconfidence, and our tendency to perceive patterns in random events often lead us to overestimate our intuition. But scientific inquiry can help us sift reality from illusion.

“The really unusual day would be one where nothing unusual happens.” -STATISTICIAN PERSI DIACONIS (2002)

The Scientific Attitude: Curious, Skeptical, and Humble

4-2

How do the scientific attitude’s three main components relate to critical thinking?

Underlying all science is, first, a hard-headed *curiosity*, a passion to explore and understand without misleading or being misled. Some questions (*Is there life after death?*) are beyond science. Answering them in any way requires a leap of faith. With many other ideas (*Can some people demonstrate ESP?*), the proof is in the pudding. Let the facts speak for themselves.

Magician James Randi has used this *empirical approach* when testing those claiming to see auras around people’s bodies:

Randi: Do you see an aura around my head?

Aura-seer: Yes, indeed.

Randi: Can you still see the aura if I put this magazine in front of my face?

Aura-seer: Of course.

Randi: Then if I were to step behind a wall barely taller than I am, you could determine my location from the aura visible above my head, right?

Randi told me that no aura-seer has agreed to take this simple test.

No matter how sensible-seeming or wild an idea, the smart thinker asks: *Does it work?* When put to the test, can its predictions be confirmed? Subjected to such scrutiny, crazy-sounding ideas sometimes find support. During the 1700s, scientists scoffed at the notion that meteorites had extraterrestrial origins. When two Yale scientists challenged the conventional opinion, Thomas Jefferson jeered, “Gentlemen, I would rather believe that those two Yankee professors would lie than to believe that stones fell from Heaven.” Sometimes scientific inquiry turns jeers into cheers.

More often, science becomes society’s garbage disposal, sending crazy-sounding ideas to the waste heap, atop previous claims of perpetual motion machines, miracle cancer cures, and out-of-body travels into centuries past. To sift reality from fantasy, sense from nonsense, therefore requires a scientific attitude: being skeptical but not cynical, open but not gullible.

The Amazing Randi The magician James Randi exemplifies skepticism. He has tested and debunked supposed psychic phenomena.

AP Photo/Alan Diaz

“To believe with certainty,” says a Polish proverb, “we must begin by doubting.” As scientists, psychologists approach the world of behavior with a *curious skepticism*, persistently asking two questions: *What do you mean? How do you know?*

When ideas compete, skeptical testing can reveal which ones best match the facts. Do parental behaviors determine children’s sexual orientation? Can astrologers predict your future based on the position of the planets at your birth? Is electroconvulsive therapy (delivering an electric shock to the brain) an effective treatment for severe depression? As we will see, putting such claims to the test has led psychological scientists to answer *No* to the first two questions and *Yes* to the third.

Putting a scientific attitude into practice requires not only curiosity and skepticism but also *humility*—an awareness of our own vulnerability to error and an openness to surprises and new perspectives. In the last analysis, what matters is not my opinion or yours, but the truths nature reveals in response to our questioning. If people or other animals don’t behave as our ideas predict, then so much the worse for our ideas. This humble attitude was expressed in one of psychology’s early mottos: “The rat is always right.”

Historians of science tell us that these three attitudes—curiosity, skepticism, and humility—helped make modern science possible. Some deeply religious people today may view science, including psychological science, as a threat. Yet, many of the leaders of the scientific revolution, including Copernicus and Newton, were deeply religious people acting on the idea that “in order to love and honor God, it is necessary to fully appreciate the wonders of his handiwork” (Stark, 2003a,b).

Non Sequitur

Of course, scientists, like anyone else, can have big egos and may cling to their preconceptions. Nevertheless, the ideal of curious, skeptical, humble scrutiny of competing ideas unifies psychologists as a community as they check and recheck one another’s findings and conclusions.

Critical Thinking

The scientific attitude prepares us to think smarter. Smart thinking, called **critical thinking**, examines assumptions, assesses the source, discerns hidden values, confirms evidence, and assesses conclusions. Whether reading a news report or listening to a conversation, critical thinkers ask questions. Like scientists, they wonder: How do they know that? What is this person’s agenda? Is the conclusion based on anecdote and gut feelings, or on evidence? Does the evidence justify a cause-effect conclusion? What alternative explanations are possible?

Critical thinking, informed by science, helps clear the colored lenses of our biases. Consider: Does climate change threaten our future, and, if so, is it human-caused? In 2009, climate-action advocates interpreted an Australian heat wave and dust storms as evidence of climate change. In 2010, climate-change skeptics perceived North American bitter cold and East Coast blizzards as discounting global warming. Rather than having their understanding

“I’m a skeptic not because I do not want to believe but because I want to *know*. I believe that the truth is out there. But how can we tell the difference between what we would like to be true and what is actually true? The answer is science.” -MICHAEL SHERMER, “I WANT TO BELIEVE,” *SCIENTIFIC AMERICAN*, 2009

“My deeply held belief is that if a god anything like the traditional sort exists, our curiosity and intelligence are provided by such a god. We would be unappreciative of those gifts . . . if we suppressed our passion to explore the universe and ourselves.” -CARL SAGAN, *BROCA’S BRAIN*, 1979

critical thinking thinking that does not blindly accept arguments and conclusions. Rather, it examines assumptions, assesses the source, discerns hidden values, evaluates evidence, and assesses conclusions.

“The real purpose of the scientific method is to make sure Nature hasn’t misled you into thinking you know something you don’t actually know.” -ROBERT M. PIRSIG, *ZEN AND THE ART OF MOTORCYCLE MAINTENANCE*, 1974

of climate change swayed by today’s weather, or by their own political views, critical thinkers say, “Show me the evidence.” Over time, is the Earth actually warming? Are the polar ice caps melting? Are vegetation patterns changing? And is human activity spewing gases that would lead us to expect such changes? When contemplating such issues, critical thinkers will consider the credibility of sources. They will look at the evidence (“*Do the facts support them, or are they just makin’ stuff up?*”). They will recognize multiple perspectives. And they will expose themselves to news sources that challenge their preconceived ideas.

Has psychology’s critical inquiry been open to surprising findings? The answer, as ensuing modules illustrate, is plainly *Yes*. Believe it or not, massive losses of brain tissue early in life may have minimal long-term effects (see Module 12). Within days, newborns can recognize their mother’s odor and voice (see Module 45). After brain damage, a person may be able to learn new skills yet be unaware of such learning (see Modules 31–33). Diverse groups—men and women, old and young, rich and middle class, those with disabilities and without—report roughly comparable levels of personal happiness (see Module 83).

And has critical inquiry convincingly debunked popular presumptions? The answer, as ensuing modules also illustrate, is again *Yes*. The evidence indicates that sleepwalkers are *not* acting out their dreams (see Module 24). Our past experiences are *not* all recorded verbatim in our brains; with brain stimulation or hypnosis, one *cannot* simply “hit the replay button” and relive long-buried or repressed memories (see Module 33). Most people do *not* suffer from unrealistically low self-esteem, and high self-esteem is not all good (see Module 59). Opposites do *not* generally attract (see Module 79). In each of these instances and more, what has been learned is not what is widely believed.

Before You Move On

▶ ASK YOURSELF

How might critical thinking help us assess someone’s interpretations of people’s dreams or their claims to communicate with the dead?

▶ TEST YOURSELF

How does the scientific attitude contribute to critical thinking?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 4 Review

4-1

How do hindsight bias, overconfidence, and the tendency to perceive order in random events illustrate why science-based answers are more valid than those based on intuition and common sense?

- *Hindsight bias* (also called the “I-knew-it-all-along phenomenon”) is the tendency to believe, after learning an outcome, that we would have foreseen it.
- Overconfidence in our judgments results partly from our bias to seek information that confirms them.
- These tendencies, plus our eagerness to perceive patterns in random events, lead us to overestimate our intuition.

Although limited by the testable questions it can address, scientific inquiry can help us overcome our intuition’s biases and shortcomings.

4-2

How do the scientific attitude’s three main components relate to critical thinking?

- The scientific attitude equips us to be curious, skeptical, and humble in scrutinizing competing ideas or our own observations.
- This attitude carries into everyday life as *critical thinking*, which puts ideas to the test by examining assumptions, assessing the source, discerning hidden values, evaluating evidence, and assessing conclusions.

Multiple-Choice Questions

1. After the student council election, a friend tells you he has known for weeks who would be elected president. What does this seem to illustrate?
 - a. Skepticism
 - b. Critical thinking
 - c. Hindsight bias
 - d. Overconfidence
 - e. Perceiving order in random events
2. While taking a standardized test with randomly scrambled answers, you notice that your last four answers have been "c." Which of the following is true concerning the probability of the next answer being "c"?
 - a. It is higher. Once a streak begins, it is likely to last for a while.
 - b. It is lower. Since answers are distributed randomly, "c" answers become less common.
 - c. It is unaffected by previous answers. It is as likely to be "c" as any other answer.
 - d. You should check your previous answers. Four "c's" in a row is impossible.
 - e. It is higher. Test constructors trick students by keeping the same answer many times in a row.
3. What do we call the tendency to exaggerate the correctness or accuracy of our beliefs and predictions prior to testing?
 - a. Hindsight bias
 - b. Overconfidence
 - c. Critical thinking
 - d. Skepticism
 - e. Reliability
4. Which of the following is an example of hindsight bias?
 - a. Tom is certain that electric cars will represent 80 percent of vehicles in twenty years and only reads research studies that support his hypothesis.
 - b. Liza underestimates how much time it will take her to finish writing her college application essays and as a result fails to meet an important deadline.
 - c. Experts predicting world events with 80 percent confidence turned out to be correct less than 40 percent of the time.
 - d. Marcy cannot recognize a definition on a flashcard. After turning the card over and viewing the term, she tells herself she knew what the answer was all along.
 - e. Dr. Grace overestimates how effectively her new treatment method works because she fails to seek out any evidence refuting her theory.

Practice FRQs

1. Name the three components of the scientific attitude. Provide an example to show how each component contributes to the investigation of competing ideas in psychology.
2. Aziz has read that handwriting reveals important details about personality. Explain how each component of the scientific attitude can help Aziz investigate the accuracy of the information he has read about handwriting analysis.

Answer

1 point: Curiosity, or passion to explore, leads us to questions we want to investigate. Any examples of such questions will serve (For example, Does more money make us happier? Is schizophrenia inherited?).

1 point: Skepticism keeps us from accepting ideas without sound support. The work of The Amazing Randi would be a good example here.

1 point: Humility keeps us open to the possibility of changing our ideas when they are not supported by the data. For example, "the rat is always right."

(3 points)

Module 5

The Scientific Method and Description

Module Learning Objectives

- 5-1** Describe how theories advance psychological science.
- 5-2** Describe how psychologists use case studies, naturalistic observation, and surveys to observe and describe behavior, and explain the importance of random sampling.

AP® Exam Tip

As you read this module, keep in mind that the scientific method is a set of principles and procedures, not a list of facts. You will be expected to understand how the science of psychology is done, not just what it has discovered.

theory an explanation using an integrated set of principles that organizes observations and predicts behaviors or events.

hypothesis a testable prediction, often implied by a theory.

Psychologists arm their scientific attitude with the *scientific method*—a self-correcting process for evaluating ideas with observation and analysis. In its attempt to describe and explain human nature, psychological science welcomes hunches and plausible-sounding theories. And it puts them to the test. If a theory works—if the data support its predictions—so much the better for that theory. If the predictions fail, the theory will be revised or rejected.

The Scientific Method

- 5-1** How do theories advance psychological science?

Chatting with friends and family, we often use theory to mean “mere hunch.” In science, a **theory** *explains* behaviors or events by offering ideas that *organize* what we have observed. By organizing isolated facts, a theory simplifies. By linking facts with deeper principles, a theory offers a useful summary. As we connect the observed dots, a coherent picture emerges.

A theory about the effects of sleep on memory, for example, helps us organize countless sleep-related observations into a short list of principles. Imagine that we observe over and over that people with good sleep habits tend to answer questions correctly in class, and they do well at test time. We might therefore theorize that sleep improves memory. So far so good: Our principle neatly summarizes a list of facts about the effects of a good night’s sleep on memory.

Yet no matter how reasonable a theory may sound—and it does seem reasonable to suggest that sleep could improve memory—we must put it to the test. A good theory produces testable predictions, called **hypotheses**. Such predictions specify what results (what behaviors or events) would support the theory and what results would cast doubt on the theory. To test our theory about the effects of sleep on memory, our hypothesis might be that when sleep deprived, people will remember less from the day before. To test that hypothesis, we might assess how well people remember course materials they studied before a good night’s sleep, or before a shortened night’s sleep (**FIGURE 5.1**). The results will either confirm our theory or lead us to revise or reject it.

**Figure 5.1**

The scientific method A self-correcting process for asking questions and observing nature's answers.

Our theories can bias our observations. Having theorized that better memory springs from more sleep, we may see what we expect: We may perceive sleepy people's comments as less insightful. Perhaps you are aware of students who, because they have developed an excellent reputation, can now do no wrong in the eyes of teachers. If they're in the hall during class, nobody worries. Other students can do no good. Because they have behaved badly in the past, even their positive behaviors are viewed suspiciously.

As a check on their biases, psychologists use **operational definitions** when they report their studies. "Sleep deprived," for example, may be defined as "X hours less" than the person's natural sleep. Unlike dictionary definitions, operational definitions describe concepts with precise procedures or measures. These exact descriptions will allow anyone to **replicate** (repeat) the research. Other people can then re-create the study with different participants and in different situations. If they get similar results, we can be confident that the findings are reliable.

Let's summarize. A good theory:

- effectively *organizes* a range of self-reports and observations.
- leads to clear *hypotheses* (predictions) that anyone can use to check the theory.
- often stimulates research that leads to a revised theory which better organizes and predicts what we know. Or, our research may be replicated and supported by similar findings. (This has been the case for sleep and memory studies, as you will see in Module 24.)

We can test our hypotheses and refine our theories in several ways.

- *Descriptive* methods describe behaviors, often by using case studies, surveys, or naturalistic observations.
- *Correlational* methods associate different factors, or *variables*. (You'll see the word *variable* often in descriptions of research. It refers to anything that contributes to a result.)
- *Experimental* methods manipulate variables to discover their effects.

To think critically about popular psychology claims, we need to understand the strengths and weaknesses of these methods.

operational definition a carefully worded statement of the exact procedures (operations) used in a research study. For example, *human intelligence* may be operationally defined as what an intelligence test measures.

replication repeating the essence of a research study, usually with different participants in different situations, to see whether the basic finding extends to other participants and circumstances.

Description

5-2

How do psychologists use case studies, naturalistic observation, and surveys to observe and describe behavior, and why is random sampling important?

The starting point of any science is description. In everyday life, we all observe and describe people, often drawing conclusions about why they act as they do. Professional psychologists do much the same, though more objectively and systematically, through

- *case studies* (analyses of special individuals).
- *naturalistic observation* (watching and recording the natural behavior of many individuals).
- *surveys* and interviews (by asking people questions).

case study a descriptive technique in which one individual or group is studied in depth in the hope of revealing universal principles.

naturalistic observation

observing and recording behavior in naturally occurring situations without trying to manipulate and control the situation.

“Well my dear,’ said Miss Marple, ‘human nature is very much the same everywhere, and of course, one has opportunities of observing it at closer quarters in a village.’” -AGATHA CHRISTIE, *THE TUESDAY CLUB MURDERS*, 1933

The Case Study

Psychologists use the **case study**, which is among the oldest research methods, to examine one individual or group in depth in the hope of revealing things true of all of us. Some examples: Much of our early knowledge about the brain came from case studies of individuals who suffered a particular impairment after damage to a certain brain region. Jean Piaget taught us about children’s thinking through case studies in which he carefully observed and questioned individual children. Studies of only a few chimpanzees have revealed their capacity for understanding and language. Intensive case studies are sometimes very revealing. They show us what *can* happen, and they often suggest directions for further study.

But individual cases may mislead us if the individual is atypical. Unrepresentative information can lead to mistaken judgments and false conclusions. Indeed, anytime a researcher mentions a finding (“*Smokers die younger: ninety-five percent of men over 85 are nonsmokers*”) someone is sure to offer a contradictory anecdote (“*Well, I have an uncle who smoked two packs a day and lived to 89*”). Dramatic stories and personal experiences (even psychological case examples) command our attention and are easily remembered. Journalists

understand that, and so begin an article about bank foreclosures with the sad story of one family put out of their house, not with foreclosure statistics. Stories move us. But stories can mislead. Which of the following do you find more memorable? (1) “In one study of 1300 dream reports concerning a kidnapped child, only 5 percent correctly envisioned the child as dead” (Murray & Wheeler, 1937). (2) “I know a man who dreamed his sister was in a car accident, and two days later she died in a

head-on collision!” Numbers can be numbing, but the plural of *anecdote* is not *evidence*. As psychologist Gordon Allport (1954, p. 9) said, “Given a thimbleful of [dramatic] facts we rush to make generalizations as large as a tub.”

The point to remember: Individual cases can suggest fruitful ideas. What’s true of all of us can be glimpsed in any one of us. But to discern the general truths that cover individual cases, we must answer questions with other research methods.

Naturalistic Observation

A second descriptive method records behavior in natural environments. These **naturalistic observations** range from watching chimpanzee societies in the jungle, to unobtrusively videotaping (and later systematically analyzing) parent-child interactions in different cultures, to recording racial differences in students’ self-seating patterns in a school cafeteria.

Like the case study, naturalistic observation does not *explain* behavior. It *describes* it. Nevertheless, descriptions can be revealing. We once thought, for example, that only humans use tools. Then naturalistic observation revealed that chimpanzees sometimes insert a stick in a termite mound and withdraw it, eating the stick’s load of termites.

Juniors Bildarchiv/F355/Alamy

Freud and Little Hans Sigmund Freud’s case study of 5-year-old Hans’ extreme fear of horses led Freud to his theory of childhood sexuality. He conjectured that Hans felt unconscious desire for his mother, feared castration by his rival father, and then transferred this fear into his phobia about being bitten by a horse. As Module 56 will explain, today’s psychological science discounts Freud’s theory of childhood sexuality but acknowledges that much of the human mind operates outside our conscious awareness.

Such unobtrusive naturalistic observations paved the way for later studies of animal thinking, language, and emotion, which further expanded our understanding of our fellow animals. “Observations, made in the natural habitat, helped to show that the societies and behavior of animals are far more complex than previously supposed,” chimpanzee observer Jane Goodall noted (1998). Thanks to researchers’ observations, we know that chimpanzees and baboons use deception. Psychologists Andrew Whiten and Richard Byrne (1988) repeatedly saw one young baboon pretending to have been attacked by another as a tactic to get its mother to drive the other baboon away from its food. The more developed a primate species’ brain, the more likely it is that the animals will display deceptive behaviors (Byrne & Corp, 2004).

Naturalistic observations also illuminate human behavior. Here are four findings you might enjoy.

- *A funny finding.* We humans laugh 30 times more often in social situations than in solitary situations. (Have you noticed how seldom you laugh when alone?) As we laugh, 17 muscles contort our mouth and squeeze our eyes, and we emit a series of 75-millisecond vowel-like sounds, spaced about one-fifth of a second apart (Provine, 2001).
- *Sounding out students.* What, really, are college psychology students saying and doing during their everyday lives? To find out, researchers equipped 52 such students from the University of Texas with electronic recorders (Mehl & Pennebaker, 2003). For up to four days, the recorders captured 30 seconds of the students’ waking hours every 12.5 minutes, thus enabling the researchers to eavesdrop on more than 10,000 half-minute life slices by the end of the study. On what percentage of the slices do you suppose they found the students talking with someone? What percentage captured the students at a computer? The answers: 28 and 9 percent. (What percentage of *your* waking hours are spent in these activities?)
- *What’s on your mind?* To find out what was on the mind of their University of Nevada, Las Vegas, students, researchers gave them beepers (Heavey & Hurlburt, 2008). On a half-dozen occasions, a beep interrupted students’ daily activities, signaling them to pull out a notebook and record their inner experience at that moment. When the researchers later coded the reports in categories, they found five common forms of inner experience (**TABLE 5.1** on the next page).
- *Culture, climate, and the pace of life.* Naturalistic observation also enabled researchers to compare the pace of life in 31 countries (Levine & Norenzayan, 1999). (Their operational definition of *pace of life* included walking speed, the speed with which postal clerks completed a simple request, and the accuracy of public clocks.) Their conclusion: Life is fastest paced in Japan and Western Europe, and slower paced in economically less-developed countries. People in colder climates also tend to live at a faster pace (and are more prone to die from heart disease).

Martin Harvey/Getty Images

A natural observer Chimpanzee researcher Frans de Waal (2005) reported, “I am a born observer. . . . When picking a seat in a restaurant I want to face as many tables as possible. I enjoy following the social dynamics—love, tension, boredom, antipathy—around me based on body language, which I consider more informative than the spoken word. Since keeping track of others is something I do automatically, becoming a fly on the wall of an ape colony came naturally to me.”

Courtesy of Matthias Mehl

Naturalistic observation Researchers at the University of Texas used electronic recorders to sample naturally occurring slices of daily life.

Table 5.1 A Penny for Their Thoughts: The Inner Experience of University Students*

Inner Experience	Example	Frequency
Inner speech	Susan was saying to herself, “I’ve got to get to class.”	26%
Inner seeing	Paul was imagining the face of a best friend, including her neck and head.	34%
Unsymbolized thinking	Alphonse was wondering whether the workers would drop the bricks.	22%
Feeling	Courtney was experiencing anger and its physical symptoms.	26%
Sensory awareness	Fiona was feeling the cold breeze on her cheek and her hair moving.	22%

* More than one experience could occur at once.

Naturalistic observation offers interesting snapshots of everyday life, but it does so without controlling for all the variables that may influence behavior. It’s one thing to observe the pace of life in various places, but another to understand what makes some people walk faster than others.

The Survey

A **survey** looks at many cases in less depth. Researchers do surveys when wanting to estimate, from a representative sample of people, the attitudes or reported behaviors of a whole population. Questions about everything from cell-phone use to political opinions are put to the public. In recent surveys,

- half of all Americans reported experiencing more happiness and enjoyment than worry and stress on the previous day (Gallup, 2010).
- online Canadians reported using new forms of electronic communication and thus receiving 35 percent fewer e-mails in 2010 than 2008 (Ipsos, 2010a).
- 1 in 5 people across 22 countries reported believing that alien beings have come to Earth and now walk among us disguised as humans (Ipsos, 2010b).
- 68 percent of all humans—some 4.6 billion people—say that religion is important in their daily lives (Diener et al., 2011).

But asking questions is tricky, and the answers often depend on the ways questions are worded and respondents are chosen.

WORDING EFFECTS

As we will see in Module 35, even subtle changes in the order or wording of questions—the way we *frame* a question—can have major effects. People are much more approving of “aid to the needy” than of “welfare,” of “affirmative action” than of “preferential treatment,” of “not allowing” televised cigarette ads and pornography than of “censoring” them, and of “revenue enhancers” than of “taxes.” In 2009, three in four Americans in one national survey approved of giving people “a choice” of public, government-run, or private health insurance. Yet in another survey, most Americans were not in favor of “creating a public health care plan administered by the federal government that would compete directly with private health insurance companies” (Stein, 2009). Because wording is such a delicate matter, critical thinkers will reflect on how the phrasing of a question might affect people’s expressed opinions.

survey a technique for ascertaining the self-reported attitudes or behaviors of a particular group, usually by questioning a representative, random sample of the group.

RANDOM SAMPLING

In everyday thinking, we tend to generalize from samples we observe, especially vivid cases. Given (a) a statistical summary of auto owners' evaluations of their car make and (b) the vivid comments of a biased sample—two frustrated owners—our impression may be influenced as much by the two unhappy owners as by the many more evaluations in the statistical summary. The temptation to ignore the **sampling bias** and to generalize from a few vivid but unrepresentative cases is nearly irresistible.

The point to remember: The best basis for generalizing is from a *representative sample*.

But it's not always possible to survey everyone in a group. So how do you obtain a representative sample—say, of the students at your high school? How could you choose a group that would represent the total student **population**, the whole group you want to study and describe? Typically, you would seek a **random sample**, in which every person in the entire group has an equal chance of participating. You might number the names in the general student listing and then use a random number generator to pick your survey participants. (Sending each student a questionnaire wouldn't work because the conscientious people who returned it would not be a random sample.) Large representative samples are better than small ones, but a small representative sample of 100 is better than an unrepresentative sample of 500.

Political pollsters sample voters in national election surveys just this way. Using only 1500 randomly sampled people, drawn from all areas of a country, they can provide a remarkably accurate snapshot of the nation's opinions. Without random sampling (also called *random selection*), large samples—including call-in phone samples and TV or website polls (think of *American Idol* fans voting)—often merely give misleading results.

The point to remember: Before accepting survey findings, think critically: Consider the sample. You cannot compensate for an unrepresentative sample by simply adding more people.

Before You Move On**▶ ASK YOURSELF**

Can you recall examples of misleading surveys you have experienced or read about? What survey principles did they violate?

▶ TEST YOURSELF

What are some strengths and weaknesses of the three different methods psychologists use to describe behavior—case studies, naturalistic observation, and surveys?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

sampling bias a flawed sampling process that produces an unrepresentative sample.

population all those in a group being studied, from which samples may be drawn. (*Note:* Except for national studies, this does *not* refer to a country's whole population.)

random sample a sample that fairly represents a population because each member has an equal chance of inclusion.

FYI

With very large samples, estimates become quite reliable. *E* is estimated to represent 12.7 percent of the letters in written English. *E*, in fact, is 12.3 percent of the 925,141 letters in Melville's *Moby Dick*, 12.4 percent of the 586,747 letters in Dickens' *A Tale of Two Cities*, and 12.1 percent of the 3,901,021 letters in 12 of Mark Twain's works (*Chance News*, 1997).

Module 5 Review

5-1 How do theories advance psychological science?

- Psychological *theories* are explanations that apply an integrated set of principles to organize observations and generate *hypotheses*—predictions that can be used to check the theory or produce practical applications of it. By testing their hypotheses, researchers can confirm, reject, or revise their theories.
- To enable other researchers to *replicate* the studies, researchers report them using precise *operational definitions* of their procedures and concepts. If others achieve similar results, confidence in the conclusion will be greater.

5-2 How do psychologists use case studies, naturalistic observation, and surveys to observe and describe behavior, and why is random sampling important?

- Description methods, which include *case studies*, *naturalistic observations*, and *surveys*, show us what can happen, and they may offer ideas for further study.
- The best basis for generalizing about a *population* is a representative sample; in a *random sample*, every person in the entire population being studied has an equal chance of participating.
- Descriptive methods describe but do not *explain* behavior, because these methods do not control for the many variables that can affect behavior.

Multiple-Choice Questions

1. Why is an operational definition necessary when reporting research findings?
 - a. An operational definition allows others to replicate the procedure.
 - b. An operational definition provides more context and includes many examples of the concept described.
 - c. An operational definition is easier to translate into multiple languages than a dictionary definition.
 - d. An operational definition uses more scientific language than a dictionary definition.
 - e. An operational definition is not necessary since a dictionary definition will work as well for replication.
2. A researcher looking for gender differences in 3-year-olds observes a preschool class and records how many minutes children of each gender play with dolls. She then compares the two sets of numbers. What type of descriptive research is she conducting?
 - a. Case study
 - b. National study
 - c. Random sample method
 - d. Naturalistic observation
 - e. Survey
3. Which of the following questions is best investigated by means of a survey?
 - a. Is IQ related to grades?
 - b. Are violent criminals genetically different from nonviolent criminals?
 - c. Does extra sleep improve memory?
 - d. What is the best study technique for AP® tests?
 - e. Are students more likely to be politically liberal or conservative?
4. A testable prediction that drives research is known as a(n)
 - a. theory.
 - b. hypothesis.
 - c. operational definition.
 - d. guess.
 - e. random sample.
5. Researchers are interested in finding out if winning Congressional candidates display more positive facial expressions than losing candidates. The researchers attend political debates and record how frequently each candidate displays positive facial expressions. Which research method are the researchers using?
 - a. Random sample
 - b. Case study
 - c. Naturalistic observation
 - d. Survey
 - e. Interview

- 6.** An individual with an exceptional memory is identified. She is capable of recalling major events, the weather, and what she did on any given date. What research method is being used if a psychologist conducts an in-depth investigation of this individual including questionnaires, brain scans, and memory tests?
- Naturalistic observation
 - Survey
 - Interview
 - Case study
 - Correlational method
- 7.** Which of the following is most important when conducting survey research?
- Choosing a representative sample
 - Choosing a large sample
 - Choosing a biased sample
 - Choosing a sample that includes every member of the population
 - Choosing a sample whose answers will likely support your hypothesis

Practice FRQs

- 1.** A teacher wants to know if nightmares are more common than dreams. He asks volunteers from his second-period class to report how many dreams they had last week. He asks volunteers from his third-period class to report the number of nightmares they had last week. Describe two things wrong with the design of this study.
- 2.** Naturalistic observation is a research method used by psychologists to investigate human and animal behavior. Identify three weaknesses of naturalistic observation.

(3 points)

Answer (2 of the following)

1 point: There is no hypothesis stated.

1 point: In asking for volunteers, the teacher is taking a nonrandom sample that is probably not representative of the population of interest.

1 point: Neither dreams nor nightmares are operationally defined, so they might be interpreted differently by later researchers.

1 point: The research is not blind. The teacher could influence the results by the way he asked questions.

Module 6

Correlation and Experimentation

Module Learning Objectives

- 6-1** Describe positive and negative correlations, and explain how correlational measures can aid the process of prediction but not provide evidence of cause-effect relationships.
- 6-2** Explain illusory correlations.
- 6-3** Describe the characteristics of experimentation that make it possible to isolate cause and effect.

imagebroker/Alamy

“Study finds that increased parental support for college results in lower grades” (Jaschik, 2013). “People with mental illness more likely to be smokers” (Belluck, 2013). What should we make of such news headlines—telling us that students whose parents pay the college bill tend to underachieve, and that smoking is associated with mental illness? Do these correlations indicate that students would achieve more if their parents became less supportive and that stopping smoking could produce better mental health? *No*. Read on.

Correlation

- 6-1** What are positive and negative correlations, and why do they enable prediction but not cause-effect explanation?

Describing behavior is a first step toward predicting it. Naturalistic observations and surveys often show us that one trait or behavior is related to another. In such cases, we say the two **correlate**. A statistical measure (the **correlation coefficient**) helps us figure how closely two things vary together, and thus how well either one predicts the other. Knowing how much aptitude test scores correlate with school success tells us how well the scores predict school success.

Throughout this book we will often ask how strongly two things are related: For example, how closely related are the personality scores of identical twins? How well do intelligence test scores predict career achievement? How closely is stress related to disease? In such cases, **scatterplots** can be very revealing.

Each dot in a scatterplot represents the values of two variables. The three scatterplots in **FIGURE 6.1** illustrate the range of possible correlations from a perfect positive to a perfect negative. (Perfect correlations rarely occur in the “real world.”) A correlation is positive if two sets of scores, such as height and weight, tend to rise or fall together.

correlation a measure of the extent to which two variables change together, and thus of how well either variable predicts the other.

correlation coefficient a statistical index of the relationship between two variables (from -1.0 to $+1.0$).

scatterplot a graphed cluster of dots, each of which represents the values of two variables. The slope of the points suggests the direction of the relationship between the two variables. The amount of scatter suggests the strength of the correlation (little scatter indicates high correlation).

**Figure 6.1**

Scatterplots, showing patterns of correlation Correlations can range from +1.00 (scores on one measure increase in direct proportion to scores on another) to -1.00 (scores on one measure decrease precisely as scores rise on the other).

Saying that a correlation is “negative” says nothing about its strength or weakness. A correlation is negative if two sets of scores relate inversely, one set going up as the other goes down. The study of Nevada university students’ inner speech discussed in Module 5 also included a correlational component. Students’ reports of inner speech correlated negatively ($-.36$) with their scores on another measure: psychological distress. Those who reported more inner speech tended to report slightly *less* psychological distress.

Statistics can help us see what the naked eye sometimes misses. To demonstrate this for yourself, try an imaginary project. Wondering if tall men are more or less easygoing, you collect two sets of scores: men’s heights and men’s temperaments. You measure the heights of 20 men, and you have someone else independently assess their temperaments (from zero for extremely calm to 100 for highly reactive).

With all the relevant data right in front of you (**TABLE 6.1**), can you tell whether the correlation between height and reactive temperament is positive, negative, or close to zero?

Comparing the columns in Table 6.1, most people detect very little relationship between height and temperament. In fact, the correlation in this imaginary example is positive, $+0.63$, as we can see if we display the data as a scatterplot. In **FIGURE 6.2** on the next page, moving from left to right, the upward, oval-shaped slope of the cluster of points shows that our two imaginary sets of scores (height and temperament) tend to rise together.

If we fail to see a relationship when data are presented as systematically as in Table 6.1, how much less likely are we to notice them in everyday life? To see what is right in front of us, we sometimes need statistical illumination. We can easily see evidence of gender discrimination when given statistically summarized information about job level, seniority, performance,

Table 6.1 Height and Temperamental Reactivity of 20 Men

Person	Height in Inches	Temperament
1	80	75
2	63	66
3	61	60
4	79	90
5	74	60
6	69	42
7	62	42
8	75	60
9	77	81
10	60	39
11	64	48
12	76	69
13	71	72
14	66	57
15	73	63
16	70	75
17	63	30
18	71	57
19	68	84
20	70	39

AP® Exam Tip

This is the first of several times in your psychology course that you will see something labeled as being positive or negative. We often think that if something is positive it is good and if it’s negative it’s bad. That is rarely the case in this course. Here, positive and negative refer only to the direction of the correlation. They say nothing about whether the relationship is desirable or not.

Figure 6.2

Scatterplot for height and reactive temperament This display of data from 20 imagined people (each represented by a data point) reveals an upward slope, indicating a positive correlation. The considerable scatter of the data indicates the correlation is much lower than +1.0.

gender, and salary. But we often see no discrimination when the same information dribbles in, case by case (Twiss et al., 1989). See **TABLE 6.2** to test your understanding further.

The point to remember: A correlation coefficient, which can range from -1.0 to $+1.0$, reveals the extent to which two things relate. The closer the score gets to -1 or $+1$, the stronger the correlation.

Table 6.2

Test your understanding of correlation. Which of the following news reports are examples of a *positive* correlation, and which are examples of a *negative* correlation? (Check your answers below.)

1. The more children and youth used various media, the less happy they were with their lives (Kaiser, 2010). _____
2. The less sexual content teens saw on TV, the less likely they were to have sex (Collins et al., 2004). _____
3. The longer children were breast-fed, the greater their later academic achievement (Horwood & Ferguson, 1998). _____
4. The more income rose among a sample of poor families, the fewer psychiatric symptoms their children experienced (Costello et al., 2003). _____

ANSWERS: 1. negative, 2. positive, 3. positive, 4. negative

Correlation and Causation

Correlations help us predict. The *New York Times* reports that U.S. counties with high gun ownership rates tend to have high murder rates (Luo, 2011). Gun ownership predicts homicide. What might explain this guns-homicide correlation?

I can almost hear someone thinking, “Well, of course, guns kill people, often in moments of passion.” If so, that could be an example of A (guns) causes B (murder). But I can hear other readers saying, “Not so fast. Maybe people in dangerous places buy more guns for self-protection—maybe B causes A.” Or maybe some third variable C causes both A and B.

Another example: Self-esteem correlates negatively with (and therefore predicts) depression. (The lower people's self-esteem, the more they are at risk for depression.) So, does low self-esteem *cause* depression? If, based on the correlational evidence, you assume that it does, you have much company. A nearly irresistible thinking error is assuming that an association, sometimes presented as a correlation coefficient, proves causation. But no matter how strong the relationship, it does not.

© Nancy Brown/Getty Images

As options 2 and 3 in **FIGURE 6.3** show, we'd get the same negative correlation between self-esteem and depression if depression caused people to be down on themselves, or if some third variable—such as heredity or brain chemistry—caused both low self-esteem and depression.

This point is so important—so basic to thinking smarter with psychology—that it merits one more example. A survey of over 12,000 adolescents found that the more teens feel loved by their parents, the less likely they are to behave in unhealthy ways—having early sex, smoking, abusing alcohol and drugs, exhibiting violence (Resnick et al., 1997). “Adults have a powerful effect on their children’s behavior right through the high school years,” gushed an Associated Press (AP) story reporting the finding. But this correlation comes with no built-in cause-effect arrow. The AP could as well have reported, “Well-behaved teens feel their parents’ love and approval; out-of-bounds teens more often think their parents are disapproving jerks.”

The point to remember (turn the volume up here): *Association does not prove causation.*¹ Correlation indicates the *possibility* of a cause-effect relationship *but does not prove such*. Remember this principle and you will be wiser as you read and hear news of scientific studies.

¹Because many associations are stated as correlations, the famously worded principle is “Correlation does not prove causation.” That’s true, but it’s also true of associations verified by other nonexperimental statistics (Hatfield et al., 2006).

Correlation need not mean causation Length of marriage correlates with hair loss in men. Does this mean that marriage *causes* men to lose their hair (or that balding men make better husbands)? In this case, as in many others, a third variable probably explains the correlation: Golden anniversaries and baldness both accompany aging.

FYI

A *New York Times* writer reported a massive survey showing that “adolescents whose parents smoked were 50 percent more likely than children of nonsmokers to report having had sex.” He concluded (would you agree?) that the survey indicated a causal effect—that “to reduce the chances that their children will become sexually active at an early age” parents might “quit smoking” (O’Neil, 2002).

AP® Exam Tip

Take note of how much emphasis is put on this idea. Correlation and association do not prove a cause-effect relationship.

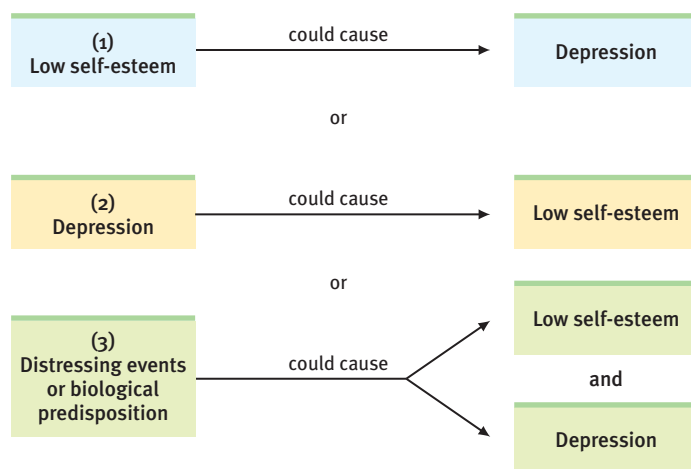

Figure 6.3

Three possible cause-effect relationships

People low in self-esteem are more likely to report depression than are those high in self-esteem. One possible explanation of this negative correlation is that a bad self-image causes depressed feelings. But, as the diagram indicates, other cause-effect relationships are possible.

Illusory Correlations

6-2 What are illusory correlations?

illusory correlation the perception of a relationship where none exists.

FYI

A study reported in the *British Medical Journal* found that youths who identify with the goth subculture attempt, more often than other young people, to harm or kill themselves (Young et al., 2006). Can you imagine multiple possible explanations for this association?

Correlation coefficients make visible the relationships we might otherwise miss. They also restrain our “seeing” relationships that actually do not exist. A perceived but nonexistent correlation is an **illusory correlation**. When we *believe* there is a relationship between two things, we are likely to *notice* and *recall* instances that confirm our belief (Trolier & Hamilton, 1986).

Because we are sensitive to dramatic or unusual events, we are especially likely to notice and remember the occurrence of two such events in sequence—say, a premonition of an unlikely phone call followed by the call. When the call does not follow the premonition, we are less likely to note and remember the nonevent. Illusory correlations help explain many superstitious beliefs, such as the presumption that infertile couples who adopt become more likely to conceive (Gilovich, 1991). Couples who conceive after adopting capture our attention. We’re less likely to notice those who adopt and never conceive, or those who conceive without adopting. In other words, illusory correlations occur when we over-rely on the top left cell of **FIGURE 6.4**, ignoring equally essential information in the other cells.

Such illusory thinking helps explain why for so many years people believed (and many still do) that sugar makes children hyperactive, that getting chilled and wet causes people to catch a cold, and that changes in the weather trigger arthritis pain. We are, it seems, prone to perceiving patterns, whether they’re there or not.

The point to remember: When we notice random coincidences, we may forget that they are random and instead see them as correlated. Thus, we can easily deceive ourselves by seeing what is not there.

Figure 6.4

Illusory correlation in everyday life

Many people believe infertile couples become more likely to conceive a child after adopting a baby. This belief arises from their attention being drawn to such cases. The many couples who adopt without conceiving or conceive without adopting grab less attention. To determine whether there actually is a correlation between adoption and conception, we need data from all four cells in this figure. (From Gilovich, 1991.)

	Conceive	Do not conceive
Adopt	confirming evidence	disconfirming evidence
Do not adopt	disconfirming evidence	confirming evidence

Michael Newman, Jr./PhotoEdit

Experimentation

6-3 What are the characteristics of experimentation that make it possible to isolate cause and effect?

Happy are they, remarked the Roman poet Virgil, “who have been able to perceive the causes of things.” How might psychologists perceive causes in correlational studies, such as the correlation between breast feeding and intelligence?

Researchers have found that the intelligence scores of children who were breast-fed as infants are somewhat higher than the scores of children who were bottle-fed (Angelsen et al., 2001; Mortensen et al., 2002; Quinn et al., 2001). In Britain, breast-fed babies have also been more likely than their bottle-fed counterparts to eventually move into a higher social class (Martin et al., 2007). The “breast is best” intelligence effect shrinks when researchers compare breast-fed and bottle-fed children from the same families (Der et al., 2006).

What do such findings mean? Do smarter mothers (who in modern countries more often breast feed) have smarter children? Or, as some researchers believe, do the nutrients of mother's milk contribute to brain development? To find answers to such questions—to isolate cause and effect—researchers can **experiment**. Experiments enable researchers to isolate the effects of one or more variables by (1) manipulating the variables of interest and (2) holding constant (“controlling”) other variables. To do so, they often create an **experimental group**, in which people receive the treatment, and a contrasting **control group** that does not receive the treatment.

Earlier we mentioned the place of *random sampling* in a well-done survey. Consider now the equally important place of *random assignment* in a well-done experiment. To minimize any preexisting differences between the two groups, researchers **randomly assign** people to the two conditions. Random assignment effectively equalizes the two groups. If one-third of the volunteers for an experiment can wiggle their ears, then about one-third of the people in each group will be ear wigglers. So, too, with ages, attitudes, and other characteristics, which will be similar in the experimental and control groups. Thus, if the groups differ at the experiment's end, we can surmise that the treatment had an effect.

To experiment with breast feeding, one research team randomly assigned some 17,000 Belarus newborns and their mothers either to a breast-feeding promotion group or to a normal pediatric care program (Kramer et al., 2008). At 3 months of age, 43 percent of the infants in the experimental group were being exclusively breast-fed, as were 6 percent in the control group. At age 6, when nearly 14,000 of the children were restudied, those who had been in the breast-feeding promotion group had intelligence test scores averaging six points higher than their control condition counterparts.

No single experiment is conclusive, of course. But randomly assigning participants to one feeding group or the other effectively eliminated all variables except nutrition. This supported the conclusion that breast is indeed best for developing intelligence: If a behavior (such as test performance) changes when we vary an experimental variable (such as infant nutrition), then we infer the variable is having an effect.

The point to remember: Unlike correlational studies, which uncover naturally occurring relationships, an experiment manipulates a variable to determine its effect.

Consider, then, how we might assess therapeutic interventions. Our tendency to seek new remedies when we are ill or emotionally down can produce misleading testimonies. If three days into a cold we start taking vitamin C tablets and find our cold symptoms lessening, we may credit the pills rather than the cold naturally subsiding. In the 1700s, blood-letting seemed effective. People sometimes improved after the treatment; when they didn't, the practitioner inferred the disease was too advanced to be reversed. So, whether or not a remedy is truly effective, enthusiastic users will probably endorse it. To determine its effect, we must control for other variables.

And that is precisely how investigators evaluate new drug treatments and new methods of psychological therapy (Modules 72–73). They randomly assign participants in these studies to research groups. One group receives a treatment (such as a medication). The other group receives a pseudotreatment—an inert placebo (perhaps a pill with no drug in it). The participants are often blind (uninformed) about what treatment, if any, they are receiving. If the study is using a **double-blind procedure**, neither the participants nor the research assistants who administer the drug and collect the data will know which group is receiving the treatment.

Lane Oatey/Getty Images

experiment a research method in which an investigator manipulates one or more factors (independent variables) to observe the effect on some behavior or mental process (the dependent variable). By *random assignment* of participants, the experimenter aims to control other relevant variables.

experimental group in an experiment, the group exposed to the treatment, that is, to one version of the independent variable.

control group in an experiment, the group *not* exposed to the treatment; contrasts with the experimental group and serves as a comparison for evaluating the effect of the treatment.

random assignment assigning participants to experimental and control groups by chance, thus minimizing preexisting differences between the different groups.

double-blind procedure an experimental procedure in which both the research participants and the research staff are ignorant (blind) about whether the research participants have received the treatment or a placebo. Commonly used in drug-evaluation studies.

DORA: removed acronyms from AP Exam Tip--per note from Christine. --JO'N

In such studies, researchers can check a treatment's actual effects apart from the participants' and the staff's belief in its healing powers. Just thinking you are getting a treatment can boost your spirits, relax your body, and relieve your symptoms. This **placebo effect** is well documented in reducing pain, depression, and anxiety (Kirsch, 2010). And the more expensive the placebo, the more "real" it seems to us—a fake pill that costs \$2.50 works better than one costing 10 cents (Waber et al., 2008). To know how effective a therapy really is, researchers must control for a possible placebo effect.

placebo [pluh-SEE-bo; Latin for "I shall please"] **effect** experimental results caused by expectations alone; any effect on behavior caused by the administration of an inert substance or condition, which the recipient assumes is an active agent.

independent variable the experimental factor that is manipulated; the variable whose effect is being studied.

confounding variable a factor other than the independent variable that might produce an effect in an experiment.

dependent variable the outcome factor; the variable that may change in response to manipulations of the independent variable.

AP® Exam Tip

The identification of independent and dependent variables is the single most likely concept to be tested on the AP® exam. Experiments are critical to psychology, and independent and dependent variables are critical to experiments.

Independent and Dependent Variables

Here is a practical experiment: In a not yet published study, Victor Benassi and his colleagues gave college psychology students frequent in-class quizzes. Some items served merely as *review*—students were given questions with answers. Other *self-testing* items required students to actively produce the answers. When tested weeks later on a final exam, students did far better on material on which they had been tested (75 percent correct) rather than merely reviewed (51 percent correct). By a wide margin, testing beat restudy.

This simple experiment manipulated just one factor: the study procedure (reading answers versus self-testing). We call this experimental factor the **independent variable** because we can vary it *independently* of other factors, such as the students' memories, intelligence, and age. These other factors, which can potentially influence the results of the experiment, are called **confounding variables**. Random assignment controls for possible confounding variables.

Experiments examine the effect of one or more independent variables on some measurable behavior, called the **dependent variable** because it can vary *depending* on what takes place during the experiment. Both variables are given precise *operational definitions*, which specify the procedures that manipulate the independent variable (the review versus self-testing study method in this analysis) or measure the dependent variable (final exam performance). These definitions answer the "What do you mean?" question with a level of precision that enables others to repeat the study. (See **FIGURE 6.5** for the previously mentioned breast-milk experiment's design.)

Let's pause to check your understanding using a simple psychology experiment: To test the effect of perceived ethnicity on the availability of a rental house, researchers sent identically worded e-mail inquiries to 1115 Los Angeles-area landlords (Carpusor & Loges, 2006). The researchers varied the ethnic connotation of the sender's name and tracked the percentage of positive replies (invitations to view the apartment in person). "Patrick McDougall," "Said Al-Rahman," and "Tyrell Jackson" received, respectively, 89 percent, 66 percent, and 56 percent invitations. (In this experiment, what was the independent variable? The dependent variable?²)

Figure 6.5

Experimentation To discern causation, psychologists may randomly assign some participants to an experimental group, others to a control group. Measuring the dependent variable (intelligence score in later childhood) will determine the effect of the independent variable (whether breast feeding was promoted).

Random assignment
(controlling for other confounding variables,
such as parental intelligence and environment)

© Radius Images/Alamy

Group	Independent variable	Dependent variable
Experimental	Promoted breast feeding	Intelligence score, age 6
Control	Did not promote breast feeding	Intelligence score, age 6

A key goal of experimental design is **validity**, which means the experiment will test what it is supposed to test. In the rental housing experiment, we might ask, “Did the e-mail inquiries test the effect of perceived ethnicity? Did the landlords’ response actually vary with the ethnicity of the name?”

Experiments can also help us evaluate social programs. Do early childhood education programs boost impoverished children’s chances for success? What are the effects of different antismoking campaigns? Do school sex-education programs reduce teen pregnancies? To answer such questions, we can experiment: If an intervention is welcomed but resources are scarce, we could use a lottery to randomly assign some people (or regions) to experience the new program and others to a control condition. If later the two groups differ, the intervention’s effect will be supported (Passell, 1993).

Let’s recap. A *variable* is anything that can vary (infant nutrition, intelligence, TV exposure—anything within the bounds of what is feasible and ethical). Experiments aim to *manipulate* an *independent* variable, *measure* the *dependent* variable, and allow random assignment to *control* all other variables. An experiment has at least two different conditions: an *experimental condition* and a *comparison* or *control condition*. *Random assignment* works to equate the groups before any treatment effects occur. In this way, an experiment tests the effect of at least one independent variable (what we manipulate) on at least one dependent variable (the outcome we measure). **TABLE 6.3** compares the features of psychology’s research methods.

²The independent variable, which the researchers manipulated, was the ethnicity-related names. The dependent variable, which they measured, was the positive response rate.

validity the extent to which a test or experiment measures or predicts what it is supposed to.

AP[®] Exam Tip

Almost 15 pages of text are summarized in this one table. Spend some time with it, as it is information you will likely encounter on the AP[®] exam.

Table 6.3 Comparing Research Methods

Research Method	Basic Purpose	How Conducted	What Is Manipulated	Strengths	Weaknesses
<i>Descriptive</i>	To observe and record behavior	Do case studies, naturalistic observations, or surveys	Nothing	Case studies require only one participant; naturalistic observations may be done when it is not ethical to manipulate variables; surveys may be done quickly and inexpensively (compared with experiments)	Uncontrolled variables mean cause and effect cannot be determined; single cases may be misleading
<i>Correlational</i>	To detect naturally occurring relationships; to assess how well one variable predicts another	Collect data on two or more variables; no manipulation	Nothing	Works with large groups of data, and may be used in situations where an experiment would not be ethical or possible	Does not specify cause and effect
<i>Experimental</i>	To explore cause and effect	Manipulate one or more variables; use random assignment	The independent variable(s)	Specifies cause and effect, and variables are controlled	Sometimes not feasible; results may not generalize to other contexts; not ethical to manipulate certain variables

"If I don't think it's going to work, will it still work?"

Before You Move On

▶ ASK YOURSELF

If you were to become a research psychologist, what questions would you like to explore with experiments?

▶ TEST YOURSELF

Why, when testing a new drug to control blood pressure, would we learn more about its effectiveness from giving it to half of the participants in a group of 1000 than to all 1000 participants?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 6 Review

6-1

What are positive and negative correlations, and why do they enable prediction but not cause-effect explanation?

- In a positive correlation, two variables rise or fall together. In a negative correlation, one item rises as the other falls.
- *Scatterplots* can help us to see *correlations*.
- A *correlation coefficient* can describe the strength and direction of a relationship between two variables, from +1.00 (a perfect positive correlation) through zero (no correlation at all) to -1.00 (a perfect negative correlation).

6-2

What are illusory correlations?

- *Illusory correlations* are random events that we notice and falsely assume are related.
- Patterns or sequences occur naturally in sets of random data, but we tend to interpret these patterns as meaningful connections, perhaps in an attempt to make sense of the world around us.

6-3

What are the characteristics of experimentation that make it possible to isolate cause and effect?

- To discover cause-effect relationships, psychologists conduct *experiments*, manipulating one or more variables of interest and controlling other variables.
- Using *random assignment*, they can minimize *confounding variables*, such as preexisting differences between the *experimental group* (exposed to the treatment) and the *control group* (given a placebo or different version of the treatment).
- The *independent variable* is the factor the experimenter manipulates to study its effect; the *dependent variable* is the factor the experimenter measures to discover any changes occurring in response to the manipulation of the independent variable.
- Studies may use a *double-blind procedure* to avoid the *placebo effect* and researcher's bias.
- An experiment has *validity* if it tests what it is supposed to test.

Multiple-Choice Questions

1. Which of the following is an example of negative correlation?
 - a. People who spend more time exercising tend to weigh less.
 - b. Teenage females tend to have fewer speeding tickets than teenage males.
 - c. Students with low IQ scores tend to have lower grades.
 - d. As hours studying for a test decrease, so do grades on that test.
 - e. Students' shoe sizes are not related to their grades.

2. Which of the following is used only in correlation studies?
 - a. Double blind
 - b. Placebo
 - c. Random assignment
 - d. Scatterplot
 - e. Random sample
3. Researchers have discovered that individuals with lower income levels report having fewer hours of total sleep. Therefore,
 - a. income and sleep levels are positively correlated.
 - b. income and sleep levels are negatively correlated.
 - c. income and sleep levels are inversely correlated.
 - d. income and sleep levels are not correlated.
 - e. lower income levels cause individuals to have fewer hours of sleep.
4. Which of the following correlation coefficients represents the strongest relationship between two variables?
 - a. +.30
 - b. +.75
 - c. +1.3
 - d. $-.85$
 - e. -1.2
5. The purpose of random assignment is to
 - a. allow participants in both the experimental and control groups to be exposed to the independent variable.
 - b. ensure that every member of the population had an equal chance of being selected to participate in the research.
 - c. eliminate the placebo effect.
 - d. reduce potential confounding variables.
 - e. generate operational definitions for the independent and dependent variables.

Practice FRQs

1. Students with higher scores on anxiety scales were found to have lower scores on standardized tests. What research method would show this relationship? Why can no cause-effect conclusion be drawn from the results?

Answer

1 point: This research method is a correlation study.

1 point: There are three possibilities for causation: Anxiety could cause low test scores, low test scores could cause anxiety, or a third factor could cause both anxiety and low test scores. No conclusions can be drawn about causation because this is not an experiment.

2. Ms. Ledbetter wants to determine if the new review activity she developed will improve student performance on unit exams. She randomly separates 160 students into two groups. Group A reviews for the unit exam in the traditional manner they have always used. Group B participates in the new review activity. After reviewing, both groups are given the same unit exam and their scores are compared. Identify the independent and dependent variables for this experiment.

Module 7

Statistical Reasoning in Everyday Life

Module Learning Objectives

7-1

Describe the three measures of central tendency, and discuss the relative usefulness of the two measures of variation.

7-2

Explain how we know whether an observed difference can be generalized to other populations.

Norm Hall/Getty Images

FYI

Asked about the *ideal* wealth distribution in America, Democrats and Republicans were surprisingly similar. In the Democrats' ideal world, the richest 20 percent would possess 30 percent of the wealth. The Republicans' ideal world was similar, with the richest 20 percent possessing 35 percent of the wealth. (Norton & Ariely, 2011).

AP® Exam Tip

Do math and statistics scare you? Take a couple of deep breaths and relax before continuing. You will not be asked to do difficult computations on the AP® exam. Nothing will be beyond the scope of simple mental math. You need to focus on the concepts. Why do these statistics exist? How can they help us understand the real world?

In descriptive, correlational, and experimental research, statistics are tools that help us see and interpret what the unaided eye might miss. Sometimes the unaided eye misses badly. Researchers invited 5522 Americans to estimate the percentage of wealth possessed by the richest 20 percent in their country (Norton & Ariely, 2011). Their average person's guess—58 percent—"dramatically underestimated" the actual wealth inequality. (The wealthiest 20 percent possess 84 percent of the wealth.)

The Need for Statistics

Accurate statistical understanding benefits everyone. To be an educated person today is to be able to apply simple statistical principles to everyday reasoning. One needn't memorize complicated formulas to think more clearly and critically about data.

Off-the-top-of-the-head estimates often misread reality and then mislead the public. Someone throws out a big, round number. Others echo it, and before long the big, round number becomes public misinformation. A few examples:

- *Ten percent of people are lesbians or gay men.*
Or is it 2 to 3 percent, as suggested by various national surveys (Module 53)?
- *We ordinarily use but 10 percent of our brain.*
Or is it closer to 100 percent (Module 12)?
- *The human brain has 100 billion nerve cells.*
Or is it more like 40 billion, as suggested by extrapolation from sample counts (Module 10)?

The point to remember: Doubt big, round, undocumented numbers.

Statistical illiteracy also feeds needless health scares (Gigerenzer et al., 2008, 2009, 2010). In the 1990s, the British press reported a study showing

Patrick Hardin/cartoonstock

"Figures can be misleading—so I've written a song which I think expresses the real story of the firm's performance this quarter."

that women taking a particular contraceptive pill had a 100 percent increased risk of blood clots that could produce strokes. This caused thousands of women to stop taking the pill, leading to a wave of unwanted pregnancies and an estimated 13,000 additional abortions (which also are associated with increased blood clot risk). And what did the study find? A 100 percent increased risk, indeed—but only from 1 in 7000 women to 2 in 7000 women. Such false alarms underscore the need to teach statistical reasoning and to present statistical information more transparently.

Descriptive Statistics

7-1 How do we describe data using three measures of central tendency, and what is the relative usefulness of the two measures of variation?

Once researchers have gathered their data, they may use **descriptive statistics** to organize that data meaningfully. One way to do this is to convert the data into a simple *bar graph*, called a **histogram**, as in **FIGURE 7.1**, which displays a distribution of different brands of trucks still on the road after a decade. When reading statistical graphs such as this, take care. It's easy to design a graph to make a difference look big (Figure 7.1a) or small (Figure 7.1b). The secret lies in how you label the vertical scale (the *y-axis*).

The point to remember: Think smart. When viewing figures in magazines and on television, read the scale labels and note their range.

Measures of Central Tendency

The next step is to summarize the data using some *measure of central tendency*, a single score that represents a whole set of scores. The simplest measure is the **mode**, the most frequently occurring score or scores. The most commonly reported is the **mean**, or arithmetic average—the total sum of all the scores divided by the number of scores. On a divided highway, the median is the middle. So, too, with data: The **median** is the midpoint—the 50th percentile. If you arrange all the scores in order from the highest to the lowest, half will be above the median and half will be below it. In a symmetrical, bell-shaped distribution of scores, the mode, mean, and median scores may be the same or very similar.

descriptive statistics numerical data used to measure and describe characteristics of groups. Includes measures of central tendency and measures of variation.

histogram a bar graph depicting a frequency distribution.

mode the most frequently occurring score(s) in a distribution.

mean the arithmetic average of a distribution, obtained by adding the scores and then dividing by the number of scores.

median the middle score in a distribution; half the scores are above it and half are below it.

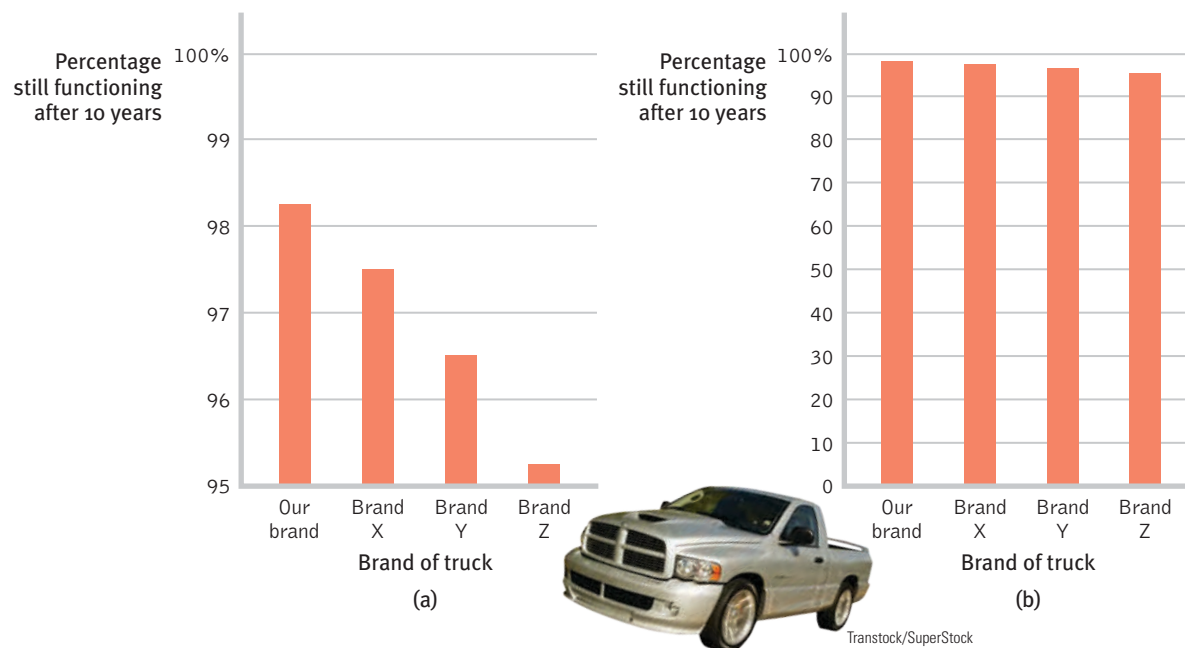

Figure 7.1
Read the scale labels An American truck manufacturer offered graph (a)—with actual brand names included—to suggest the much greater durability of its trucks. Note, however, how the apparent difference shrinks as the vertical scale changes in graph (b).

Transtock/SuperStock

Measures of central tendency neatly summarize data. But consider what happens to the mean when a distribution is lopsided, or **skewed**, by a few way-out scores. With income data, for example, the mode, median, and mean often tell very different stories (**FIGURE 7.2**). This happens because the mean is biased by a few extreme scores. When Microsoft co-founder Bill Gates sits down in an intimate café, its average (mean) customer instantly becomes a billionaire. But the customers' median wealth remains unchanged. Understanding this, you can see how a British newspaper could accurately run the headline "Income for 62% Is Below Average" (Waterhouse, 1993). Because the bottom *half* of British income earners receive only a *quarter* of the national income cake, most British people, like most people everywhere, make less than the mean. Mean and median tell different true stories.

The point to remember: Always note which measure of central tendency is reported. If it is a mean, consider whether a few atypical scores could be distorting it.

FYI

The average person has one ovary and one testicle.

Figure 7.2

A skewed distribution This graphic representation of the distribution of a village's incomes illustrates the three measures of central tendency—mode, median, and mean. Note how just a few high incomes make the mean—the fulcrum point that balances the incomes above and below—deceptively high.

Measures of Variation

Knowing the value of an appropriate measure of central tendency can tell us a great deal. But the single number omits other information. It helps to know something about the amount of *variation* in the data—how similar or diverse the scores are. Averages derived from scores with low variability are more reliable than averages based on scores with high variability. Consider a basketball player who scored between 13 and 17 points in each of her first 10 games in a season. Knowing this, we would be more confident that she would score near 15 points in her next game than if her scores had varied from 5 to 25 points.

The **range** of scores—the gap between the lowest and highest scores—provides only a crude estimate of variation. A couple of extreme scores in an otherwise uniform group, such as the \$950,000 and \$1,420,000 incomes in Figure 7.2, will create a deceptively large range.

The more useful standard for measuring how much scores deviate from one another is the **standard deviation**. It better gauges whether scores are packed together or dispersed, because it uses information from each score (**TABLE 7.1**). The computation assembles information about how much individual scores differ from the mean. If your high school serves a community where most families have similar incomes, family income data will have a relatively small standard deviation compared with the more diverse community population outside your school.

You can grasp the meaning of the standard deviation if you consider how scores tend to be distributed in nature. Large numbers of data—heights, weights, intelligence scores, grades (though not incomes)—often form a symmetrical, *bell-shaped* distribution.

skewed distribution a representation of scores that lack symmetry around their average value.

range the difference between the highest and lowest scores in a distribution.

standard deviation a computed measure of how much scores vary around the mean score.

Table 7.1 Standard Deviation Is Much More Informative Than Mean Alone

Note that the test scores in Class A and Class B have the same mean (80), but very different standard deviations, which tell us more about how the students in each class are really faring.

Test Scores in Class A			Test Scores in Class B		
Score	Deviation from the Mean	Squared Deviation	Score	Deviation from the Mean	Squared Deviation
72	-8	64	60	-20	400
74	-6	36	60	-20	400
77	-3	9	70	-10	100
79	-1	1	70	-10	100
82	+2	4	90	+10	100
84	+4	16	90	+10	100
85	+5	25	100	+20	400
<u>87</u>	<u>+7</u>	<u>49</u>	<u>100</u>	<u>+20</u>	<u>400</u>
Total = 640	Sum of (deviations) ² = 204		Total = 640	Sum of (deviations) ² = 2000	
Mean = 640 ÷ 8 = 80			Mean = 640 ÷ 8 = 80		
Standard deviation =			Standard deviation =		
$\sqrt{\frac{\text{Sum of (deviations)}^2}{\text{Number of scores}}} = \sqrt{\frac{204}{8}} = 5.0$			$\sqrt{\frac{\text{Sum of (deviations)}^2}{\text{Number of scores}}} = \sqrt{\frac{2000}{8}} = 15.8$		

Most cases fall near the mean, and fewer cases fall near either extreme. This bell-shaped distribution is so typical that we call the curve it forms the **normal curve**.

As **FIGURE 7.3** shows, a useful property of the normal curve is that roughly 68 percent of the cases fall within one standard deviation on either side of the mean. About 95 percent of cases fall within two standard deviations. Thus, as Module 61 notes, about 68 percent of people taking an intelligence test will score within ±15 points of 100. About 95 percent will score within ±30 points.

normal curve (*normal distribution*) a symmetrical, bell-shaped curve that describes the distribution of many types of data; most scores fall near the mean (about 68 percent fall within one standard deviation of it) and fewer and fewer near the extremes.

Figure 7.3

The normal curve Scores on aptitude tests tend to form a normal, or bell-shaped, curve. For example, the most commonly used intelligence test, the Wechsler Adult Intelligence Scale, calls the average score 100.

Inferential Statistics

7-2

How do we know whether an observed difference can be generalized to other populations?

Data are “noisy.” The average score in one group (breast-fed babies) could conceivably differ from the average score in another group (bottle-fed babies) not because of any real difference but merely because of chance fluctuations in the people sampled. How confidently, then, can we infer that an observed difference is not just a fluke—a chance result of your sampling? For guidance, we can ask how reliable and significant the differences are. These **inferential statistics** help us determine if results can be generalized to a larger population.

inferential statistics numerical data that allow one to generalize—to infer from sample data the probability of something being true of a population.

When Is an Observed Difference Reliable?

In deciding when it is safe to generalize from a sample, we should keep three principles in mind.

1. **Representative samples are better than biased samples.** As noted in Module 5, the best basis for generalizing is not from the exceptional and memorable cases one finds at the extremes but from a representative sample of cases. Research never randomly samples the whole human population. Thus, it pays to keep in mind what population a study has sampled.
2. **Less-variable observations are more reliable than those that are more variable.** As we noted in the example of the basketball player whose game-to-game points were consistent, an average is more reliable when it comes from scores with low variability.
3. **More cases are better than fewer.** An eager high school senior visits two university campuses, each for a day. At the first, the student randomly attends two classes and discovers both instructors to be witty and engaging. At the next campus, the two sampled instructors seem dull and uninspiring. Returning home, the student (discounting the small sample size of only two instructors at each institution) tells friends about the “great instructors” at the first school, and the “bores” at the second. Again, we know it but we ignore it: *Averages based on many cases are more reliable* (less variable) than averages based on only a few cases.

The point to remember: Smart thinkers are not overly impressed by a few anecdotes. Generalizations based on a few unrepresentative cases are unreliable.

When Is a Difference Significant?

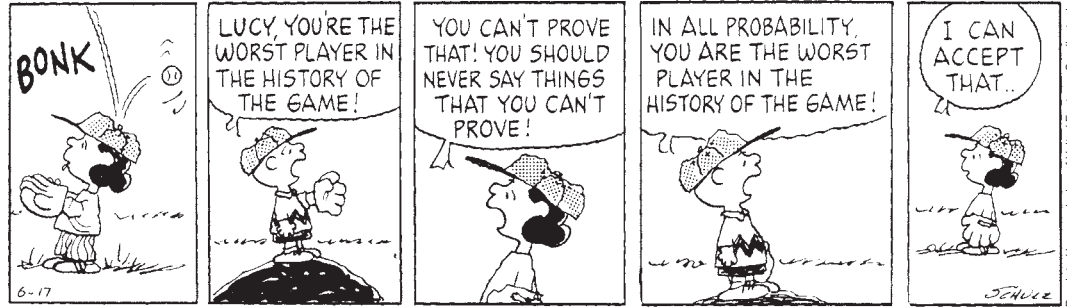

Perhaps you’ve compared men’s and women’s scores on a laboratory test of aggression, and found a gender difference. But individuals differ. How likely is it that the gender difference you found was just a fluke? Statistical testing can estimate the probability of the result occurring by chance.

Here is the underlying logic: When averages from two samples are each reliable measures of their respective populations (as when each is based on many observations that have small variability), then their *difference* is likely to be reliable as well. (Example: The less the variability in women’s and in men’s aggression scores, the more confidence we would have that any observed gender difference is reliable.) And when the difference between the sample averages is *large*, we have even more confidence that the difference between them reflects a real difference in their populations.

In short, when sample averages are reliable, and when the difference between them is relatively large, we say the difference has **statistical significance**. This means that the observed difference is probably not due to chance variation between the samples.

In judging statistical significance, psychologists are conservative. They are like juries who must presume innocence until guilt is proven. For most psychologists, proof beyond a

statistical significance a statistical statement of how likely it is that an obtained result occurred by chance.

PEANUTS

Reprinted by permission of United Features Syndicate, Inc.

reasonable doubt means not making much of a finding unless the odds of its occurring by chance, if no real effect exists, are less than 5 percent.

When reading about research, you should remember that, given large enough samples, a difference between them may be “statistically significant” yet have little practical significance. For example, comparisons of intelligence test scores among hundreds of thousands of first-born and later-born individuals indicate a highly significant tendency for first-born individuals to have higher average scores than their later-born siblings (Kristensen & Bjerkedal, 2007; Zajonc & Markus, 1975). But because the scores differ by only one to three points, the difference has little practical importance.

The point to remember: Statistical significance indicates the *likelihood* that a result will happen by chance. But this does not say anything about the *importance* of the result.

AP® Exam Tip

Sometimes a phrase that is frequently used in the media has a more specific meaning when used in psychology. That's the case with the phrase “statistically significant.” Make sure you know the precise meaning.

Before You Move On**▶ ASK YOURSELF**

Find a graph in a popular magazine ad. How does the advertiser use (or abuse) statistics to make a point?

▶ TEST YOURSELF

Can you solve this puzzle?

The registrar's office at the University of Michigan has found that usually about 100 students in Arts and Sciences have perfect grades at the end of their first term at the University. However, only about 10 to 15 students graduate with perfect grades. What do you think is the most likely explanation for the fact that there are more perfect grades after one term than at graduation (Jepson et al., 1983)?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 7 Review**7-1**

How do we describe data using three measures of central tendency, and what is the relative usefulness of the two measures of variation?

- A measure of central tendency is a single score that represents a whole set of scores. Three such measures are the *mode* (the most frequently occurring score), the *mean* (the arithmetic average), and the *median* (the middle score in a group of data).
- Measures of variation tell us how diverse data are. Two measures of variation are the *range* (which describes the gap between the highest and lowest scores) and the *standard deviation* (which states how much scores vary around the mean, or average, score).
- Scores often form a *normal* (or bell-shaped) *curve*.

7-2

How do we know whether an observed difference can be generalized to other populations?

- To feel confident about generalizing an observed difference to other populations, we would want to know that
 - the sample studied was representative of the larger population being studied;

- the observations, on average, had low variability;
- the sample consisted of more than a few cases; and
- the observed difference was *statistically significant*.

Multiple-Choice Questions

1. Which of the following is a measure of variation?
 - a. Range
 - b. Mean
 - c. Mode
 - d. Frequency
 - e. Median
2. Which statistical measure of central tendency is most affected by extreme scores?
 - a. Mean
 - b. Median
 - c. Mode
 - d. Skew
 - e. Correlation
3. A researcher calculates statistical significance for her study and finds a 5 percent chance that results are due to chance. Which of the following is an accurate interpretation of this finding?
 - a. This is well beyond the range of statistical significance.
 - b. This is the minimum result typically considered statistically significant.
 - c. This is not statistically significant.
 - d. There is no way to determine statistical significance without replication of the study.
 - e. Chance or coincidence is unrelated to statistical significance.
4. Descriptive statistics _____, while inferential statistics _____.
 - a. indicate the significance of the data; summarize the data
 - b. describe data from experiments; describe data from surveys and case studies
 - c. are measures of central tendency; are measures of variance
 - d. determine if data can be generalized to other populations; summarize data
 - e. summarize data; determine if data can be generalized to other populations
5. In a normal distribution, what percentage of the scores in the distribution falls within one standard deviation on either side of the mean?
 - a. 34 percent
 - b. 40 percent
 - c. 50 percent
 - d. 68 percent
 - e. 95 percent

Practice FRQs

1. Explain the difference between descriptive and inferential statistics in research.

Answer (2 points)

1 point: Descriptive statistics organize and summarize the data collected during research.

1 point: Inferential statistics are used to help determine whether results can be generalized to a larger population through the calculation of statistical significance.

2. The following data set includes information from survey research in a psychology course regarding how many hours each individual in the class spent preparing for the exam.

Student	Amount of hours reported studying
1	2
2	3
3	6
4	8
5	9
6	9
7	21

Examine the data and respond to the following:

- What is the middle score in this distribution? What term is used to describe the middle score?
- What would be the most useful statistic for measuring the variation of the hours spent studying? Why is this statistic a better measure of variation than the range?

(3 points)

Module 8

Frequently Asked Questions About Psychology

Module Learning Objectives

- 8-1** Explain the value of simplified laboratory conditions in illuminating everyday life.
- 8-2** Discuss whether psychological research can be generalized across cultures and genders.
- 8-3** Explain why psychologists study animals, and describe the ethical guidelines that safeguard animal research participants.
- 8-4** Describe the ethical guidelines that safeguard human research participants.
- 8-5** Examine whether psychology is free of value judgments.

We have reflected on how a scientific approach can restrain biases. We have seen how case studies, naturalistic observations, and surveys help us describe behavior. We have also noted that correlational studies assess the association between two variables, which indicates how well one thing predicts another. We have examined the logic that underlies experiments, which use control conditions and random assignment of participants to isolate the effects of an independent variable on a dependent variable. And we have considered how statistical tools can help us see and interpret the world around us.

Yet, even knowing this much, you may still be approaching psychology with a mixture of curiosity and apprehension. So before we plunge in, let's entertain some frequently asked questions.

Psychology Applied

- 8-1** Can laboratory experiments illuminate everyday life?

When you see or hear about psychological research, do you ever wonder whether people's behavior in the lab will predict their behavior in real life? For example, does detecting the blink of a faint red light in a dark room have anything useful to say about flying a plane at night? If, after playing violent video games in the lab, teens become more willing to push buttons that they think electrically shock someone, does this indicate that playing shooter games makes someone more likely to commit violence in everyday life?

Before you answer, consider: The experimenter *intends* the laboratory environment to be a simplified reality—one that simulates and controls important features of everyday life. Just as a wind tunnel lets airplane designers re-create airflow forces under controlled conditions, a laboratory experiment lets psychologists re-create psychological forces under controlled conditions.

An experiment's purpose is not to re-create the exact behaviors of everyday life but to test *theoretical principles* (Mook, 1983). In aggression studies, deciding whether to push a button that delivers a shock may not be the same as slapping someone in the face, but the principle is the same. *It is the resulting principles—not the specific findings—that help explain everyday behaviors.*

When psychologists apply laboratory research on aggression to actual violence, they are applying theoretical principles of aggressive behavior, principles they have refined through many experiments. Similarly, it is the principles of the visual system, developed from experiments in artificial settings (such as looking at red lights in the dark), that researchers apply to more complex behaviors such as night flying. And many investigations show that principles derived in the laboratory do typically generalize to the everyday world (Anderson et al., 1999).

The point to remember: Psychological science focuses less on particular behaviors than on seeking general principles that help explain many behaviors. And remember: Although psychological principles may help predict behaviors for groups of people, they minimally predict behavior for any individual. Knowing students' grade level may clue us to their average vocabulary level, but individual students' word power will vary.

8-2**Does behavior depend on one's culture and gender?**

What can psychological studies done in one time and place—often with people from what researchers call the WEIRD (*Western, Educated, Industrialized, Rich, and Democratic*) cultures (Henrich et al., 2010) really tell us about people in general? As we will see time and again, **culture**—shared ideas and behaviors that one generation passes on to the next—matters. Our culture shapes our behavior. It influences our standards of promptness and frankness, our attitudes toward premarital sex and varying body shapes, our tendency to be casual or formal, our willingness to make eye contact, our conversational distance, and much, much more. *Collectivist* cultures, for example, emphasize group goals, while *individualist* cultures put a priority on individual goals. Being aware of such differences, we can restrain our assumptions that others will think and act as we do. Given the growing mixing and clashing of cultures, our need for such awareness is urgent.

It is also true, however, that our shared biological heritage unites us as a universal human family. The same underlying processes guide people everywhere.

- People diagnosed with specific learning disorder (formerly called dyslexia) exhibit the same brain malfunction whether they are Italian, French, or British (Paulesu et al., 2001).
- Variation in languages may impede communication across cultures. Yet all languages share deep principles of grammar, and people from opposite hemispheres can communicate with a smile or a frown.
- People in different cultures vary in feelings of loneliness. But across cultures, loneliness is magnified by shyness, low self-esteem, and being unmarried (Jones et al., 1985; Rokach et al., 2002).

culture the enduring behaviors, ideas, attitudes, values, and traditions shared by a group of people and transmitted from one generation to the next.

Soccer shoes? Because culture shapes social behavior, actions that seem ordinary to some may seem odd to others. Yet underlying these differences are powerful similarities. Children everywhere love to play sports such as soccer. But many American children would only play with athletic shoes on a field, not barefoot in the street, as do these Burkina Faso boys.

Alistair Berg/Alamy

We are each in certain respects like all others, like some others, and like no other. Studying people of all races and cultures helps us discern our similarities and our differences, our human kinship and our diversity.

You will see throughout this book that *gender* matters, too. Researchers report gender differences in what we dream, in how we express and detect emotions, and in our risk for alcohol use disorder, depression, and eating disorders. Gender differences fascinate us, and studying them is potentially beneficial. For example, many researchers believe that women carry on conversations more readily to build relationships, while men talk more to give information and advice (Tannen, 2001). Knowing this difference can help us prevent conflicts and misunderstandings in everyday relationships.

But again, psychologically as well as biologically, women and men are overwhelmingly similar. Whether female or male, we learn to walk at about the same age. We experience the same sensations of light and sound. We feel the same pangs of hunger, desire, and fear. We exhibit similar overall intelligence and well-being.

The point to remember: Even when specific attitudes and behaviors vary by gender or across cultures, as they often do, the underlying processes are much the same.

“All people are the same; only their habits differ.” -CONFUCIUS, 551–479 B.C.E.

Ethics in Research

8-3

Why do psychologists study animals, and is it ethical to experiment on animals?

Many psychologists study animals because they find them fascinating. They want to understand how different species learn, think, and behave. Psychologists also study animals to learn about people. We humans are not *like* animals, we *are* animals, sharing a common biology. Animal experiments have therefore led to treatments for human diseases—insulin for diabetes, vaccines to prevent polio and rabies, transplants to replace defective organs.

Humans are complex. But the same processes by which we learn are present in rats, monkeys, and even sea slugs. The simplicity of the sea slug’s nervous system is precisely what makes it so revealing of the neural mechanisms of learning. Sharing such similarities, should we not respect our animal relatives? “We cannot defend our scientific work with animals on the basis of the similarities between them and ourselves and then defend it morally on the basis of differences,” noted Roger Ulrich (1991). The animal protection movement protests the use of animals in psychological, biological, and medical research. Researchers remind us that the animals used worldwide each year in research are but a fraction of 1 percent of the billions of animals killed annually for food. And yearly, for every dog or cat used in an experiment and cared for under humane regulations, 50 others are killed in humane animal shelters (Goodwin & Morrison, 1999).

Some animal protection organizations want to replace experiments on animals with naturalistic observation. Many animal researchers respond that this is not a question of good versus evil but of compassion for animals versus compassion for people. How many of us would have attacked Louis Pasteur’s experiments with rabies, which caused some dogs to suffer but led to a vaccine that spared millions of people (and dogs) from agonizing death? And would we really wish to have deprived ourselves of the animal research that led to effective methods of training children with mental disorders, of understanding aging, and of relieving fears and depression? The answers to such questions vary by culture. In Gallup surveys in Canada and the United States, about 60 percent of adults deem medical testing on animals “morally acceptable.” In Britain, only 37 percent do (Mason, 2003).

Out of this heated debate, two issues emerge. The basic one is whether it is right to place the well-being of humans above that of animals. In experiments on stress and cancer, is it right that mice get tumors in the hope that people might not? Should some monkeys be

“Rats are very similar to humans except that they are not stupid enough to purchase lottery tickets.” -DAVE BARRY, JULY 2, 2002

“Please do not forget those of us who suffer from incurable diseases or disabilities who hope for a cure through research that requires the use of animals.”
-PSYCHOLOGIST DENNIS FEENEY (1987)

exposed to an HIV-like virus in the search for an AIDS vaccine? Is our use and consumption of other animals as natural as the behavior of carnivorous hawks, cats, and whales? Defenders of research on animals argue that anyone who has eaten a hamburger, worn leather shoes, tolerated hunting and fishing, or supported the extermination of crop-destroying or plague-carrying pests has already agreed that, *yes*, it is sometimes permissible to sacrifice animals for the sake of human well-being.

Scott Plous (1993) notes, however, that our compassion for animals varies, as does our compassion for people—based on their perceived similarity to us. As Module 79 explains, we feel more attraction, give more help, and act less aggressively toward similar others. Likewise, we value animals according to their perceived kinship with us. Thus, primates and companion pets get top priority. (Western people raise or trap mink and foxes for their fur, but not dogs or cats.) Other mammals occupy the second rung on the privilege ladder, followed by birds, fish, and reptiles on the third rung, with insects at the bottom. In deciding which animals have rights, we each draw our own cut-off line somewhere across the animal kingdom.

If we give human life first priority, what safeguards should protect the well-being of animals in research? One survey of animal researchers gave an answer. Some 98 percent supported government regulations protecting primates, dogs, and cats, and 74 percent supported regulations providing for the humane care of rats and mice (Plous & Herzog, 2000). Many professional associations and funding agencies already have such guidelines. British Psychological Society guidelines call for housing animals under reasonably natural living conditions, with companions for social animals (Lea, 2000). American Psychological Association (APA) guidelines state that researchers must ensure the “comfort, health, and humane treatment” of animals and minimize “infection, illness, and pain” (APA, 2002). The European Parliament now mandates standards for animal care and housing (Vogel, 2010).

Animals have themselves benefited from animal research. One Ohio team of research psychologists measured stress hormone levels in samples of millions of dogs brought each year to animal shelters. They devised handling and stroking methods to reduce stress and ease the dogs’ transition to adoptive homes (Tuber et al., 1999). Other studies have helped improve care and management in animals’ natural habitats. By revealing our behavioral kinship with animals and the remarkable intelligence of chimpanzees, gorillas, and other animals, experiments have also led to increased empathy and protection for them. At its best, a psychology concerned for humans and sensitive to animals serves the welfare of both.

“The greatness of a nation can be judged by the way its animals are treated.” -MAHATMA GANDHI, 1869–1948

AP Photo/Mary Altafieri

Animal research benefiting animals

Thanks partly to research on the benefits of novelty, control, and stimulation, these gorillas are enjoying an improved quality of life in New York’s Bronx Zoo.

8-4 What ethical guidelines safeguard human participants?

Does the image of white-coated scientists delivering electric shocks trouble you? If so, you'll be relieved to know that most psychological studies are free of such stress. With people, blinking lights, flashing words, and pleasant social interactions are more common. Moreover, psychology's experiments are mild compared with the stress and humiliation often inflicted by reality TV shows. In one episode of *The Bachelor*, a man dumped his new fiancée—on camera, at the producers' request—for the woman who earlier had finished second (Collins, 2009).

Occasionally, though, researchers do temporarily stress or deceive people, but only when they believe it is essential to a justifiable end, such as understanding and controlling violent behavior or studying mood swings. Some experiments won't work if participants know everything beforehand. (Wanting to be helpful, the participants might try to confirm the researcher's predictions.)

Ethical principles developed by the American Psychological Association (2010), by the British Psychological Society (2009), and by psychologists internationally (Pettifor, 2004), urge researchers to (1) obtain potential participants' **informed consent**, (2) protect them from physical or emotional harm and discomfort, (3) keep information about individual participants confidential, and (4) fully **debrief** people (explain the research afterward). Moreover, most universities (where a great deal of research is conducted) now have an ethics committee—an Institutional Review Board (IRB)—that screens research proposals and safeguards participants' well-being.

The ideal is for a researcher to be sufficiently informative *and* considerate so that participants will leave feeling at least as good about themselves as when they came in. Better yet, they should be repaid by having learned something.

informed consent an ethical principle that research participants be told enough to enable them to choose whether they wish to participate.

debriefing the postexperimental explanation of a study, including its purpose and any deceptions, to its participants.

"It is doubtless impossible to approach any human problem with a mind free from bias."
—SIMONE DE BEAUVOIR, *THE SECOND SEX*, 1953

8-5 Is psychology free of value judgments?

Psychology is definitely not value-free. Values affect what we study, how we study it, and how we interpret results. Researchers' values influence their choice of topics. Should we study worker productivity or worker morale? Sex discrimination or gender differences? Conformity or independence? Values can also color "the facts." As we noted earlier, our preconceptions can bias our observations and interpretations; sometimes we see what we want or expect to see (**FIGURE 8.1**).

Even the words we use to describe something can reflect our values. In psychology and in everyday speech, labels describe and labels evaluate: One person's *rigidity* is another's *consistency*. One person's *faith* is another's *fanaticism*. One country's *enhanced interrogation techniques*, such as cold-water immersion, become *torture* when practiced by its enemies. Our labeling someone as *firm* or *stubborn*, *careful* or *picky*, *discreet* or *secretive* reveals our own attitudes.

Mike Kemp/Getty Images

Figure 8.1

What do you see? Our expectations influence what we perceive. Did you see a duck or a rabbit? Show some friends this image with the rabbit photo above covered up and see if they are more likely to perceive a duck head instead. (From Shepard, 1990.)

Popular applications of psychology also contain hidden values. If you defer to “professional” guidance about how to live—how to raise children, how to achieve self-fulfillment, what to do with sexual feelings, how to get ahead at work—you are accepting value-laden advice. A science of behavior and mental processes can help us reach our goals. But it cannot decide what those goals should be.

If some people see psychology as merely common sense, others have a different concern—that it is becoming dangerously powerful. Is it an accident that astronomy is the oldest science and psychology the youngest? To some, exploring the external universe seems far safer than exploring our own inner universe. Might psychology, they ask, be used to manipulate people?

Knowledge, like all power, can be used for good or evil. Nuclear power has been used to light up cities—and to demolish them. Persuasive power has been used to educate people—and to deceive them. Although psychology does indeed have the power to deceive, its purpose is to enlighten. Every day, psychologists are exploring ways to enhance learning, creativity, and compassion. Psychology speaks to many of our world’s great problems—war, overpopulation, prejudice, family crises, crime—all of which involve attitudes and behaviors. Psychology also speaks to our deepest longings—for nourishment, for love, for happiness. Psychology cannot address all of life’s great questions, but it speaks to some mighty important ones.

Psychology speaks In making its historic 1954 school desegregation decision, the U.S. Supreme Court cited the expert testimony and research of psychologists Kenneth Clark and Mamie Phipps Clark (1947). The Clarks reported that, when given a choice between Black and White dolls, most African-American children chose the White doll, which seemingly indicated internalized anti-Black prejudice.

Before You Move On

▶ ASK YOURSELF

Were any of this module’s Frequently Asked Questions your questions? Do you have other questions or concerns about psychology?

▶ TEST YOURSELF

How are human and animal research participants protected?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 8 Review

8-1

Can laboratory experiments illuminate everyday life?

- Researchers intentionally create a controlled, artificial environment in the laboratory in order to test general theoretical principles. These general principles help explain everyday behaviors.

8-2

Does behavior depend on one’s culture and gender?

- Attitudes and behaviors may vary somewhat by gender or across *cultures*, but because of our shared human kinship, the underlying processes and principles are more similar than different.

8-3

Why do psychologists study animals, and is it ethical to experiment on animals?

- Some psychologists are primarily interested in animal behavior; others want to better understand the physiological and psychological processes shared by humans and other species.
- Government agencies have established standards for animal care and housing. Professional associations and funding agencies also establish guidelines for protecting animals’ well-being.

8-4

What ethical guidelines safeguard human participants?

- The APA ethics code outlines standards for safeguarding human participants' well-being, including obtaining their *informed consent* and *debriefing* them later.

8-5

Is psychology free of value judgments?

- Psychologists' values influence their choice of research topics, their theories and observations, their labels for behavior, and their professional advice.
- Applications of psychology's principles have been used mainly in the service of humanity.

Multiple-Choice Questions

- Which of the following is more likely to be emphasized in individualist cultures than in collectivist cultures?
 - Gender differences
 - Shared goals
 - Personal achievement
 - Cooperation with the group
 - Preservation of tradition
- What must a researcher do to fulfill the ethical principle of informed consent?
 - Keep information about participants confidential.
 - Allow participants to choose whether to take part.
 - Protect participants from potential harm.
 - Provide participants with a pre-experimental explanation of the study.
 - Provide participants with a post-experimental explanation of the study.
- Which ethical principle requires that at the end of the study participants be told about the true purpose of the research?
 - Institutional Review Board approval
 - Informed consent
 - Confidentiality
 - Debriefing
 - Protection from physical harm
- Which of the following beliefs would most likely be held by an individual in a collectivist culture?
 - Children should be encouraged to focus on personal goals and aspirations.
 - Children should be encouraged to develop harmonious relationships.
 - It is important to be competitive and assertive in order to get ahead in life.
 - If you want something done well, you should do it yourself.
 - It is important to satisfy personal needs before those of the larger community.

Practice FRQs

- Provide three reasons why nonhuman animals are sometimes used in psychological research.

Answer

1 point: Some researchers use nonhuman animals because they are interested in understanding the animals themselves, including their thinking and behaviors.

1 point: Others use nonhuman animals to reduce the complexity that is part of human research. They hope to understand principles that may be similar to those that govern human psychological phenomena.

1 point: Researchers also study nonhuman animals in order to apply the findings in ways that will help both humans and the other animals themselves.

- Researchers interested in studying stress gave 150 high school seniors a very difficult math exam. After the test, the researchers measured stress by examining physiological changes with extensive medical testing that included drawing blood samples.

- What ethical principle governs what students must be told before the research takes place? What should the potential participants be told?
- What ethical principle governs the appropriate use of the results of the medical testing? What would that principle say about the use of these results?

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Which descriptive statistic would a researcher use to describe how close a student's SAT score is to a school's average SAT score?
 - Correlation coefficient
 - Mean
 - Median
 - Standard deviation
 - Range
- Which method should a psychology researcher use if she is interested in testing whether a specific reward in a classroom situation causes students to behave better?
 - Case study
 - Experiment
 - Survey
 - Naturalistic observation
 - Correlation
- When a distribution of scores is skewed, which of the following is the most representative measure of central tendency?
 - Inference
 - Standard deviation
 - Mean
 - Median
 - Correlation coefficient
- A researcher wants to conduct an experiment to determine if eating a cookie before class each day improves student grades. He uses two psychology classes for the experiment, providing daily cookies to one and nothing to the other. At the end of the semester, the researcher compares the final grades of students in the two classes. What is the independent variable for this experiment?
 - The students in the class that received cookies
 - The presence or absence of cookies
 - The students in the class that didn't receive cookies
 - The period of the day that the two classes met
 - Semester grades

5. Which of the following represents naturalistic observation?
- Researchers watch and record how elementary school children interact on the playground.
 - Researchers bring participants into a laboratory to see how they respond to a puzzle with no solution.
 - A principal looks at the relationship between the number of student absences and their grades.
 - A social worker visits a family home and gives feedback on family interactions.
 - Two grandparents sit in the front row to watch their grandson's first piano recital.
6. "Monday morning quarterbacks" rarely act surprised about the outcome of weekend football games. This tendency to believe they knew how the game would turn out is best explained by which psychological principle?
- Overconfidence
 - Hindsight bias
 - Intuition
 - Illusory correlation
 - Random sampling
7. Researchers studying gender have found that
- there are more similarities than differences between the genders.
 - there are no significant cognitive differences between the genders.
 - there are no significant emotional differences between the genders.
 - research tools are not capable of determining if there are true differences or not.
 - differences between the genders are becoming more pronounced over time.
8. A journalism student is writing an article about her school's new cell-phone policy, and she'd like to interview a random sample of students. Which of the following is the best example of a random sample?
- The writer arrives at school early and interviews the first five students who come through the main entrance.
 - The writer pulls the names of five students from a hat that contains all students' names. She interviews the five selected students.
 - The writer asks her teacher if she can distribute a brief survey to the students in her AP® Psychology class.
 - The writer passes out brief surveys to 50 students in the hall and uses the 18 surveys returned to her as the basis of her article.
 - The writer asks the principal for the names of 10 students who have had their cell phones confiscated for a day for violating the policy. She interviews these 10 students.
9. Which of the following is a positive correlation?
- As study time decreases, students achieve lower grades.
 - As levels of self-esteem decline, levels of depression increase.
 - People who exercise regularly are less likely to be obese.
 - Gas mileage decreases as vehicle weight increases.
 - Repeatedly shooting free throws in basketball is associated with a smaller percentage of missed free throws.
10. Why is random assignment of participants to groups an important aspect of a properly designed experiment?
- If the participants are randomly assigned, the researcher can assume that the people in each of the groups are pretty similar.
 - By randomly assigning participants, the researcher knows that whatever is learned from the experiment will also be true for the population from which the participants were selected.
 - Random assignment keeps expectations from influencing the results of the experiment.
 - If participants are not randomly assigned, it is impossible to replicate the experiment.
 - Statistical analysis cannot be performed on an experiment if random assignment is not used.
11. Which of the following demonstrates the need for psychological science?
- Psychology's methods are unlike those of any other science.
 - Psychological experiments are less valuable without psychological science.
 - Our intuitions about human thinking and behavior are not always accurate.
 - Intuition does not provide correct answers unless it is applied through the scientific method.
 - Psychological science research is superior to that of other sciences like biology and physics.
12. Which of the following is a potential problem with case studies?
- They provide too much detail and the researcher is likely to lose track of the most important facts.
 - They are generally too expensive to be economical.
 - They may be misleading because they don't fairly represent other cases.
 - They are technically difficult and most researchers don't have the skills to do them properly.
 - The dependent variable is difficult to operationally define in a case study.

- 13.** Which of the following is *not* an ethical principle regarding research on humans?
- Researchers must protect participants from needless harm and discomfort.
 - Participants must take part in the study on a voluntary basis.
 - Personal information about individual participants must be kept confidential.
 - Research studies must be fully explained to participants when the study is completed.
 - Participants should always be informed of the hypothesis of the study before they agree to participate.
- 14.** There is a negative correlation between TV watching and grades. What can we conclude from this research finding?
- We can conclude that a student who watches a lot of TV is likely to have lower grades.
 - We can conclude that TV watching leads to lower grades.
 - We can conclude that TV watching leads to higher grades.
 - We can conclude that the grades students get impact their TV watching habits.
 - We can conclude that this is an illusory correlation.
- 15.** A scientist's willingness to admit that she is wrong is an example of
- curiosity.
 - intelligence.
 - humility.
 - skepticism.
 - cynicism.

Free-Response Questions

- 1.** Sam Greene noticed an ad for an Internet dating service that claimed more people who used its service are in long-term relationships than people who didn't. Sam, a good critical thinker, knows this isn't enough to claim that the service causes people to find long-term love and wants to create an experiment to investigate. Use the following terms to describe an experiment that would support or dispute the ad's claim.

- Hypothesis
- Random sample
- Random assignment
- Operational definitions
- Independent variable
- Dependent variable
- Inferential statistics

Rubric for Free-Response Question 1

1 point: The hypothesis in this context is that the Internet dating service causes (or leads to) long-term relationships.

[↶](#) Page 38

1 point: Since the population of interest for this study should be people who are looking for long-term relationships, selecting a random sample of adults seeking relationships would help assure that the conclusions could be fairly generalized to the dating public. [↶](#) Page 43

1 point: In this case, participants should be randomly assigned to use of the Internet service (the experimental group) or not (the control group). [↶](#) Page 51

1 point: Sam would need to operationally define what is meant by use of the Internet service, possibly including a precise number of visits to the website or time spent on the website. The phrase *long-term relationship* would also need an operational definition, possibly by the number of months together or a formal commitment (like engagement or marriage). [↶](#) Page 39

1 point: In Sam's study, the use of the online dating service is the independent variable. [↶](#) Page 52

1 point: The number of long-term relationships is the dependent variable. [↶](#) Page 52

1 point: Sam will need to calculate statistical significance for the experimental findings. In order to claim support for the hypothesis, the results need to show that there is no more than a 5 percent chance the findings are due to chance.

[↶](#) Page 60

2. Dr. Tabor wanted to investigate the relationship between sleep and levels of alertness during a class for American university students. She gave surveys to 150 college freshmen in her introduction to psychology course, asking them to report how many hours they slept each night during a two-week period. Dr. Tabor also had the participants rate their level of alertness on a scale of 1 to 10, with 10 being the most alert each day at the end of class. Dr. Tabor compared the average amount of sleep reported by each participant along with their average score on the alertness scale on a graph to examine the data. The resulting correlation coefficient for Dr. Tabor's data was +0.89. Define each of the following terms and explain how each concept might apply to Dr. Tabor's research.

- Random sample
- Scatterplot
- Wording effects
- Positive correlation
- Operational definition

(10 points)

3. Find at least five problems in the research study described below. Identify the problem and explain how it is a violation of accepted research principles.

Dr. Pauling wanted to study whether vitamin C affects self-esteem. She recruited 200 respondents who arrived at her lab. Participants were told that they were about to participate in a harmless research study, and they needed to sign a release form in case there were harmful side effects from the vitamin C pills. The 100 participants on the right side of the room received a pill with vitamin C and the others on the left received a pill with caffeine. She then gave each group a list of questions to answer in essay form about their self-esteem. When they were finished, she thanked the participants and sent them on their way. After compiling her findings, Dr. Pauling printed the names of the students and their results in the campus newspaper so they would know what the results of the test were. Dr. Pauling concluded that vitamin C had a positive affect on self-esteem.

Unit III

Biological Bases of Behavior

Modules

- 9 Biological Psychology and Neurotransmission
- 10 The Nervous and Endocrine Systems
- 11 Studying the Brain, and Older Brain Structures
- 12 The Cerebral Cortex
- 13 Brain Hemisphere Organization and the Biology of Consciousness
- 14 Behavior Genetics: Predicting Individual Differences
- 15 Evolutionary Psychology: Understanding Human Nature

Imagine that just moments before your death, someone removed your brain from your body and kept it alive by floating it in a tank of fluid while feeding it enriched blood. Would you still be in there? Further imagine that your still-living brain was transplanted into the body of a person whose own brain had been severely damaged. To whose home should the recovered patient return? If you say the patient should return to your home, you illustrate what most of us believe—that we reside in our head. An acquaintance of mine received a new heart from a woman who had received a heart-lung transplant. When the two chanced to meet in their hospital ward, she introduced herself: “I think you have my heart.” But only her heart; herself, she assumed, still resided inside her skull. We rightly presume that our brain enables our mind. Indeed, no principle is more central to today’s psychology, or to this book, than this: *Everything psychological is simultaneously biological.*

Module 9

Biological Psychology and Neurotransmission

Module Learning Objectives

9-1

Explain why psychologists are concerned with human biology.

9-2

Describe the parts of a neuron, and explain how its impulses are generated.

9-3

Describe how nerve cells communicate with other nerve cells.

9-4

Describe how neurotransmitters influence behavior, and explain how drugs and other chemicals affect neurotransmission.

AP Photo/Fredrik Meijer Gardens & Sculpture Park, Chuck Heiney

Biology, Behavior, and Mind

9-1

Why are psychologists concerned with human biology?

Your every idea, every mood, every urge is a biological happening. You love, laugh, and cry with your body. Without your body—your genes, your brain, your appearance—you would, indeed, be nobody. Although we find it convenient to talk separately of biological and psychological influences on behavior, we need to remember: To think, feel, or act without a

body would be like running without legs.

Our understanding of how the brain gives birth to the mind has come a long way. The ancient Greek philosopher Plato correctly located the mind in the spherical head—his idea of the perfect form. His student, Aristotle, believed the mind was in the heart, which pumps warmth and vitality to the body. The heart remains our symbol for love, but science has long since overtaken philosophy on this issue. It's your brain, not your heart, that falls in love.

In the early 1800s, German physician Franz Gall proposed that *phrenology*, studying bumps on the skull, could reveal a person's mental abilities and character traits (**FIGURE 9.1**). At one point, Britain had 29 phrenological societies, and phrenologists traveled North America giving skull readings (Hunt, 1993).

"Then it's agreed—you can't have a mind without a brain, but you can have a brain without a mind."

Neural Communication

For scientists, it is a happy fact of nature that the information systems of humans and other animals operate similarly—so similarly that you could not distinguish between small samples of brain tissue from a human and a monkey. This similarity allows researchers to study relatively simple animals, such as squids and sea slugs, to discover how our neural systems operate. It allows them to study other mammals' brains to understand the organization of our own. Cars differ, but all have engines, accelerators, steering wheels, and brakes. An alien could study any one of them and grasp the operating principles. Likewise, animals differ, yet their nervous systems operate similarly. Though the human brain is more complex than a rat's, both follow the same principles.

neuron a nerve cell; the basic building block of the nervous system.

dendrites a neuron's bushy, branching extensions that receive messages and conduct impulses toward the cell body.

axon the neuron extension that passes messages through its branches to other neurons or to muscles or glands.

myelin [MY-uh-lin] sheath a fatty tissue layer segmentally encasing the axons of some neurons; enables vastly greater transmission speed as neural impulses hop from one sausage-like node to the next.

action potential a neural impulse; a brief electrical charge that travels down an axon.

"I sing the body electric." -WALT WHITMAN, "CHILDREN OF ADAM" (1855)

Neurons

9-2 What are the parts of a neuron, and how are neural impulses generated?

Our body's neural information system is complexity built from simplicity. Its building blocks are **neurons**, or nerve cells. To fathom our thoughts and actions, memories and moods, we must first understand how neurons work and communicate.

Neurons differ, but all are variations on the same theme (**FIGURE 9.2**). Each consists of a *cell body* and its branching fibers. The bushy **dendrite** fibers receive information and conduct it toward the cell body. From there, the cell's lengthy **axon** fiber passes the message through its terminal branches to other neurons or to muscles or glands. Dendrites listen. Axons speak.

Unlike the short dendrites, axons may be very long, projecting several feet through the body. A neuron carrying orders to a leg muscle, for example, has a cell body and axon roughly on the scale of a basketball attached to a rope 4 miles long. Much as home electrical wire is insulated, some axons are encased in a **myelin sheath**, a layer of fatty tissue that insulates them and speeds their impulses. As myelin is laid down up to about age 25, neural efficiency, judgment, and self-control grow (Fields, 2008). If the myelin sheath degenerates, *multiple sclerosis* results: Communication to muscles slows, with eventual loss of muscle control.

Neurons transmit messages when stimulated by signals from our senses or when triggered by chemical signals from neighboring neurons. In response, a neuron fires an impulse, called the **action potential**—a brief electrical charge that travels down its axon.

Depending on the type of fiber, a neural impulse travels at speeds ranging from a sluggish 2 miles per hour to a breakneck 180 miles per hour. But even this top speed is 3 million times slower than that of electricity through a wire. We measure brain activity in

Figure 9.2
A motor neuron

milliseconds (thousandths of a second) and computer activity in nanoseconds (billionths of a second). Thus, unlike the nearly instantaneous reactions of a high-speed computer, your reaction to a sudden event, such as a book slipping off your desk during class, may take a quarter-second or more. Your brain is vastly more complex than a computer, but slower at executing simple responses. And if you are an elephant—whose round-trip message travel time from a yank on the tail to the brain and back to the tail is 100 times longer than for a tiny shrew—reflexes are slower yet (More et al., 2010).

Like batteries, neurons generate electricity from chemical events. In the neuron's chemistry-to-electricity process, *ions* (electrically charged atoms) are exchanged. The fluid outside an axon's membrane has mostly positively charged ions; a resting axon's fluid interior has mostly negatively charged ions. This positive-outside/negative-inside state is called the *resting potential*. Like a tightly guarded facility, the axon's surface is very selective about what it allows through its gates. We say the axon's surface is *selectively permeable*.

When a neuron fires, however, the security parameters change: The first section of the axon opens its gates, rather like sewer covers flipping open, and positively charged sodium ions flood through the cell membrane (**FIGURE 9.3**). This *depolarizes* that axon section, causing another axon channel to open, and then another, like a line of falling dominos, each tripping the next.

During a resting pause called the **refractory period**, rather like a web page pausing to refresh, the neuron pumps the positively charged sodium ions back outside. Then it can fire again. (In myelinated neurons, as in Figure 9.2, the action potential speeds up by hopping from the end of one myelin "sausage" to the next.) The mind boggles when imagining this electrochemical process repeating up to 100 or even 1000 times a second. But this is just the first of many astonishments.

Each neuron is itself a miniature decision-making device performing complex calculations as it receives signals from hundreds, even thousands, of other neurons. Most signals are *excitatory*, somewhat like pushing a neuron's accelerator. Some are *inhibitory*, more like

refractory period a period of inactivity after a neuron has fired.

"What one neuron tells another neuron is simply how much it is excited." -FRANCIS CRICK, *THE ASTONISHING HYPOTHESIS*, 1994

threshold the level of stimulation required to trigger a neural impulse.

all-or-none response a neuron's reaction of either firing (with a full-strength response) or not firing.

AP® Exam Tip

Note the important shift here. So far, you have been learning about how just one neuron operates. The action potential is the mechanism for communication *within* a single neuron. Now you are moving on to a discussion of two neurons and how communication occurs *between* them. Very different, but equally important.

"All information processing in the brain involves neurons 'talking to' each other at synapses."
-NEUROSCIENTIST SOLOMON H. SNYDER (1984)

synapse [SIN-aps] the junction between the axon tip of the sending neuron and the dendrite or cell body of the receiving neuron. The tiny gap at this junction is called the *synaptic gap* or *synaptic cleft*.

neurotransmitters chemical messengers that cross the synaptic gaps between neurons. When released by the sending neuron, neurotransmitters travel across the synapse and bind to receptor sites on the receiving neuron, thereby influencing whether that neuron will generate a neural impulse.

reuptake a neurotransmitter's reabsorption by the sending neuron.

pushing its brake. If excitatory signals exceed inhibitory signals by a minimum intensity, or **threshold**, the combined signals trigger an action potential. (Think of it as a class vote: If the excitatory people with their hands up outvote the inhibitory people with their hands down, then the vote passes.) The action potential then travels down the axon, which branches into junctions with hundreds or thousands of other neurons or with the body's muscles and glands.

Increasing the level of stimulation above the threshold will not increase the neural impulse's intensity. The neuron's reaction is an **all-or-none response**: Like guns, neurons either fire or they don't. How, then, do we detect the intensity of a stimulus? How do we distinguish a gentle touch from a big hug? A strong stimulus can trigger *more* neurons to fire, and to fire more often. But it does not affect the action potential's strength or speed. Squeezing a trigger harder won't make a bullet go faster.

How Neurons Communicate

9-3 How do nerve cells communicate with other nerve cells?

Neurons interweave so intricately that even with a microscope you would have trouble seeing where one neuron ends and another begins. Scientists once believed that the axon of one cell fused with the dendrites of another in an uninterrupted fabric. Then British physiologist Sir Charles Sherrington (1857–1952) noticed that neural impulses were taking an unexpectedly long time to travel a neural pathway. Inferring that there must be a brief interruption in the transmission, Sherrington called the meeting point between neurons a **synapse**.

We now know that the axon terminal of one neuron is in fact separated from the receiving neuron by a *synaptic gap* (or *synaptic cleft*) less than 1 millionth of an inch wide. Spanish anatomist Santiago Ramón y Cajal (1852–1934) marveled at these near-unions of neurons, calling them "protoplasmic kisses." "Like elegant ladies air-kissing so as not to muss their makeup, dendrites and axons don't quite touch," notes poet Diane Ackerman (2004, p. 37). How do the neurons execute this protoplasmic kiss, sending information across the tiny synaptic gap? The answer is one of the important scientific discoveries of our age.

When an action potential reaches the knob-like terminals at an axon's end, it triggers the release of chemical messengers, called **neurotransmitters** (FIGURE 9.4). Within 1/10,000th of a second, the neurotransmitter molecules cross the synaptic gap and bind to receptor sites on the receiving neuron—as precisely as a key fits a lock. For an instant, the neurotransmitter unlocks tiny channels at the receiving site, and ions flow in, exciting or inhibiting the receiving neuron's readiness to fire. Then, in a process called **reuptake**, the sending neuron reabsorbs the excess neurotransmitters.

How Neurotransmitters Influence Us

9-4 How do neurotransmitters influence behavior, and how do drugs and other chemicals affect neurotransmission?

In their quest to understand neural communication, researchers have discovered dozens of different neurotransmitters and almost as many new questions: Are certain neurotransmitters found only in specific places? How do they affect our moods, memories, and mental abilities? Can we boost or diminish these effects through drugs or diet?

Later modules explore neurotransmitter influences on hunger and thinking, depression and euphoria, addictions and therapy. For now, let's glimpse how neurotransmitters influence our motions and our emotions. A particular brain pathway may use only one or two neurotransmitters (FIGURE 9.5), and particular neurotransmitters may affect specific

behaviors and emotions (**TABLE 9.1** on the next page). But neurotransmitter systems don't operate in isolation; they interact, and their effects vary with the receptors they stimulate. *Acetylcholine (ACh)*, which is one of the best-understood neurotransmitters, plays a role in learning and memory. In addition, it is the messenger at every junction between motor neurons (which carry information from the brain and spinal cord to the body's tissues) and skeletal muscles. When ACh is released to our muscle cell receptors, the muscle contracts. If ACh transmission is blocked, as happens during some kinds of anesthesia, the muscles cannot contract and we are paralyzed.

"When it comes to the brain, if you want to see the action, follow the neurotransmitters."
-NEUROSCIENTIST FLOYD BLOOM (1993)

Serotonin pathways

Dopamine pathways

Figure 9.5
Neurotransmitter pathways Each of the brain's differing chemical messengers has designated pathways where it operates, as shown here for serotonin and dopamine (Carter, 1998).

LiquidLibrary/Jupiterimages

AP[®] Exam Tip

As the text indicates, there are dozens of different neurotransmitters. Though there's no way to predict exactly which ones you'll see on the AP[®] exam, it's quite possible that the ones in Table 9.1 are ones you'll be asked about.

Physician Lewis Thomas, on the endorphins: "There it is, a biologically universal act of mercy. I cannot explain it, except to say that I would have put it in had I been around at the very beginning, sitting as a member of a planning committee." -*THE YOUNGEST SCIENCE*, 1983

endorphins [en-DOR-fins] "morphine within"—natural, opiate-like neurotransmitters linked to pain control and to pleasure.

agonist a molecule that, by binding to a receptor site, stimulates a response.

Table 9.1 Some Neurotransmitters and Their Functions

Neurotransmitter	Function	Examples of Malfunctions
<i>Acetylcholine (ACh)</i>	Enables muscle action, learning, and memory.	With Alzheimer's disease, ACh-producing neurons deteriorate.
<i>Dopamine</i>	Influences movement, learning, attention, and emotion.	Oversupply linked to schizophrenia. Undersupply linked to tremors and decreased mobility in Parkinson's disease.
<i>Serotonin</i>	Affects mood, hunger, sleep, and arousal.	Undersupply linked to depression. Some antidepressant drugs raise serotonin levels.
<i>Norepinephrine</i>	Helps control alertness and arousal.	Undersupply can depress mood.
<i>GABA (gamma-aminobutyric acid)</i>	A major inhibitory neurotransmitter.	Undersupply linked to seizures, tremors, and insomnia.
<i>Glutamate</i>	A major excitatory neurotransmitter; involved in memory.	Oversupply can overstimulate the brain, producing migraines or seizures (which is why some people avoid MSG, monosodium glutamate, in food).

Researchers made an exciting discovery about neurotransmitters when they attached a radioactive tracer to morphine, showing where it was taken up in an animal's brain (Pert & Snyder, 1973). The morphine, an opiate drug that elevates mood and eases pain, bound to receptors in areas linked with mood and pain sensations. But why would the brain have these "opiate receptors"? Why would it have a chemical lock, unless it also had a natural key to open it?

Researchers soon confirmed that the brain does indeed produce its own naturally occurring opiates. Our body releases several types of neurotransmitter molecules similar to morphine in response to pain and vigorous exercise. These **endorphins** (short for *endogenous* [produced within] *morphine*) help explain good feelings such as the "runner's high," the painkilling effects of acupuncture, and the indifference to pain in some severely injured people. But once again, new knowledge led to new questions.

HOW DRUGS AND OTHER CHEMICALS ALTER NEUROTRANSMISSION

If indeed the endorphins lessen pain and boost mood, why not flood the brain with artificial opiates, thereby intensifying the brain's own "feel-good" chemistry? One problem is that when flooded with opiate drugs such as heroin and morphine, the brain may stop producing its own natural opiates. When the drug is withdrawn, the brain may then be deprived of any form of opiate, causing intense discomfort. For suppressing the body's own neurotransmitter production, nature charges a price.

Drugs and other chemicals affect brain chemistry at synapses, often by either exciting or inhibiting neurons' firing. **Agonist** molecules may be similar enough to a neurotransmitter to bind to its receptor and mimic its effects. Some opiate drugs are agonists and produce a temporary "high" by amplifying normal sensations of arousal or pleasure.

Stephen VanHorn/Shutterstock

Antagonists also bind to receptors but their effect is instead to block a neurotransmitter's functioning. Botulin, a poison that can form in improperly canned food, causes paralysis by blocking ACh release. (Small injections of botulin—Botox—smooth wrinkles by paralyzing the underlying facial muscles.) These antagonists are enough like the natural neurotransmitter to occupy its receptor site and block its effect, as in **FIGURE 9.6**, but are not similar enough to stimulate the receptor (rather like foreign coins that fit into, but won't operate, a candy machine). Curare, a poison some South American Indians have applied to hunting-dart tips, occupies and blocks ACh receptor sites on muscles, producing paralysis in animals struck by the darts.

antagonist a molecule that, by binding to a receptor site, inhibits or blocks a response.

Before You Move On

▶ ASK YOURSELF

Can you recall a time when the endorphin response may have protected you from feeling extreme pain?

▶ TEST YOURSELF

How do neurons communicate with one another?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

AP® Exam Tip

Be very clear on this. Neurotransmitters are produced inside the body. They can excite and inhibit neural communication. Drugs and other chemicals come from outside the body. They can have an agonistic effect or an antagonistic effect on neurotransmission.

Module 9 Review

9-1 Why are psychologists concerned with human biology?

- Psychologists working from a *biological* perspective study the links between biology and behavior.
- We are biopsychosocial systems, in which biological, psychological, and social-cultural factors interact to influence behavior.

9-2 What are the parts of a neuron, and how are neural impulses generated?

- *Neurons* are the elementary components of the nervous system, the body's speedy electrochemical information system.
- A neuron receives signals through its branching *dendrites*, and sends signals through its *axons*.
- Some axons are encased in a *myelin sheath*, which enables faster transmission.
- If the combined received signals exceed a minimum *threshold*, the neuron fires, transmitting an electrical impulse (the *action potential*) down its axon by means of a chemistry-to-electricity process. The neuron's reaction is an *all-or-none process*.

9-3 How do nerve cells communicate with other nerve cells?

- When action potentials reach the end of an axon (the axon terminals), they stimulate the release of *neurotransmitters*.
- These chemical messengers carry a message from the sending neuron across a *synapse* to receptor sites on a receiving neuron.
- The sending neuron, in a process called *reuptake*, then reabsorbs the excess neurotransmitter molecules in the synaptic gap.
- If incoming signals are strong enough, the receiving neuron generates its own action potential and relays the message to other cells.

9-4 How do neurotransmitters influence behavior, and how do drugs and other chemicals affect neurotransmission?

- Neurotransmitters travel designated pathways in the brain and may influence specific behaviors and emotions.
- Acetylcholine (ACh) affects muscle action, learning, and memory.
- *Endorphins* are natural opiates released in response to pain and exercise.
- Drugs and other chemicals affect brain chemistry at synapses.
- *Agonists* excite by mimicking particular neurotransmitters or by blocking their reuptake.
- *Antagonists* inhibit a particular neurotransmitter's release or block its effect.

Multiple-Choice Questions

- Multiple sclerosis is a result of degeneration in the
 - dendrite.
 - axon.
 - myelin sheath.
 - terminal button.
 - neuron.
- Junita does not feel like getting out of bed, has lost her appetite, and feels tired for most of the day. Which of the following neurotransmitters likely is in short supply for Junita?

a. Dopamine	d. Acetylcholine
b. Serotonin	e. Glutamate
c. Norepinephrine	
- Which neurotransmitter inhibits CNS activity in order to calm a person down during stressful situations?

a. GABA	d. Dopamine
b. Norepinephrine	e. Serotonin
c. Acetylcholine	
- Phrenology has been discredited, but which of the following ideas has its origins in phrenology?
 - Brain lateralization
 - Brain cavities contributing to sense of humor
 - Bumps in the left hemisphere leading to emotional responses
 - Brain function localization
 - Belief that the mind pumps warmth and vitality into the body

5. When there is a negative charge inside an axon and a positive charge outside it, the neuron is
 - a. in the process of reuptake.
 - b. not in the refractory period.
 - c. said to have a resting potential.
 - d. said to have an action potential.
 - e. depolarizing.
6. Morphine elevates mood and eases pain, and is most similar to which of the following?
 - a. Dopamine
 - b. Serotonin
 - c. Endorphins
 - d. Acetylcholine
 - e. GABA
7. Neurotransmitters cross the _____ to carry information to the next neuron.
 - a. synaptic gap
 - b. axon
 - c. myelin sheath
 - d. dendrites
 - e. cell body
8. What neurotransmitters are most likely in undersupply in someone who is depressed?
 - a. Dopamine and GABA
 - b. ACh and norepinephrine
 - c. Dopamine and norepinephrine
 - d. Serotonin and norepinephrine
 - e. Serotonin and glutamate

Practice FRQs

1. While hiking, Ken stumbled and fell down a 10-foot drop-off. Upon landing, he sprained his ankle badly. Ken was surprised that he felt very little pain for the first half hour. Explain how the following helped Ken feel little pain in the moments after the injury.
 - Endorphins
 - The synapse
2. Explain the role each of the following plays in sending a message through a neuron.
 - Dendrites
 - Axon
 - Myelin sheath

(3 points)

Answer

1 point: Endorphins are natural, opiate-like neurotransmitters linked to controlling pain.

1 point: The synapse is the space between neurons where neurotransmitters like the endorphins carry information that influences how Ken feels.

Module 10

The Nervous and Endocrine Systems

Module Learning Objectives

- 10-1** Describe the functions of the nervous system's main divisions, and identify the three main types of neurons.
- 10-2** Describe the nature and functions of the endocrine system and its interaction with the nervous system.

nervous system the body's speedy, electrochemical communication network, consisting of all the nerve cells of the peripheral and central nervous systems.

central nervous system (CNS) the brain and spinal cord.

peripheral nervous system (PNS) the sensory and motor neurons that connect the central nervous system (CNS) to the rest of the body.

nerves bundled axons that form neural "cables" connecting the central nervous system with muscles, glands, and sense organs.

sensory (afferent) neurons neurons that carry incoming information from the sensory receptors to the brain and spinal cord.

motor (efferent) neurons neurons that carry outgoing information from the brain and spinal cord to the muscles and glands.

My nervous system recently gave me an emotional roller-coaster ride. Before sending me into an MRI machine for a routine shoulder scan, a technician asked if I had issues with claustrophobia (fear of enclosed spaces). "No, I'm fine," I assured her, with perhaps a hint of macho swagger. Moments later, as I found myself on my back, stuck deep inside a coffin-sized box and unable to move, my nervous system had a different idea. As claustrophobia overtook me, my heart began pounding and I felt a desperate urge to escape. Just as I was about to cry out for release, I suddenly felt my nervous system having a reverse calming influence. My heart rate slowed and my body relaxed, though my arousal surged again before the 20-minute confinement ended. "You did well!" the technician said, unaware of my roller-coaster ride.

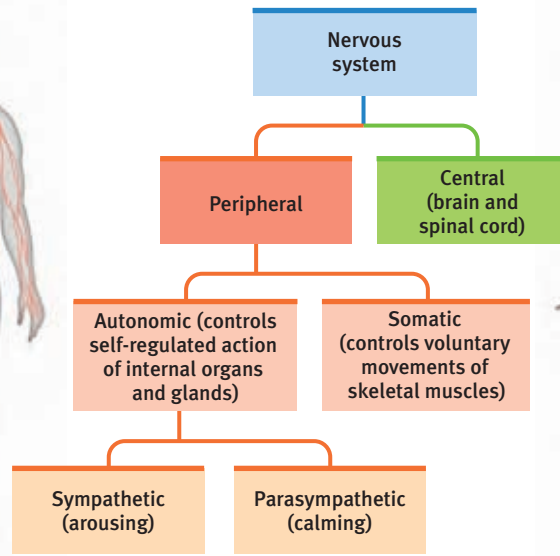

What happens inside our brains and bodies to produce such surging and subsiding emotions? Is the nervous system that stirs us the same nervous system that soothes us?

The Nervous System

- 10-1** What are the functions of the nervous system's main divisions, and what are the three main types of neurons?

To live is to take in information from the world and the body's tissues, to make decisions, and to send back information and orders to the body's tissues. All this happens thanks to our body's **nervous system (FIGURE 10.1)**. The brain and spinal cord form the **central nervous system (CNS)**, the body's decision maker. The **peripheral nervous system (PNS)** is responsible for gathering information and for transmitting CNS decisions to other body parts. **Nerves**, electrical cables formed of bundles of axons, link the CNS with the body's sensory receptors, muscles, and glands. The optic nerve, for example, bundles a million axons into a single cable carrying the messages each eye sends to the brain (Mason & Kandel, 1991).

Information travels in the nervous system through three types of neurons. **Sensory neurons** carry messages from the body's tissues and sensory receptors inward to the brain and spinal cord for processing. **Motor neurons** carry instructions from the central

Peripheral nervous system**Central nervous system****Figure 10.1**

The functional divisions of the human nervous system

nervous system out to the body's muscles and glands. Between the sensory input and motor output, information is processed in the brain's internal communication system via its **interneurons**. Our complexity resides mostly in our interneuron systems. Our nervous system has a few million sensory neurons, a few million motor neurons, and billions and billions of interneurons.

The Peripheral Nervous System

Our peripheral nervous system has two components—somatic and autonomic. Our **somatic nervous system** enables voluntary control of our skeletal muscles. As the bell signals the end of class, your somatic nervous system reports to your brain the current state of your skeletal muscles and carries instructions back, triggering your body to rise from your seat.

Our **autonomic nervous system (ANS)** controls our glands and the muscles of our internal organs, influencing such functions as glandular activity, heartbeat, and digestion. Like an automatic pilot, this system may be consciously overridden, but usually operates on its own (autonomously).

The autonomic nervous system serves two important, basic functions (**FIGURE 10.2** on the next page). The **sympathetic nervous system** arouses and expends energy. If something alarms or challenges you (such as taking the AP[®] Psychology exam, or being stuffed in an MRI machine), your sympathetic nervous system will accelerate your heartbeat, raise your blood pressure, slow your digestion, raise your blood sugar, and cool you with perspiration, making you alert and ready for action. When the stress subsides (the AP[®] exam or MRI is over), your **parasympathetic nervous system** will produce the opposite effects, conserving energy as it calms you by decreasing your heartbeat, lowering your blood sugar, and so forth. In everyday situations, the sympathetic and parasympathetic nervous systems work together to keep us in a steady internal state.

The Central Nervous System

From the simplicity of neurons “talking” to other neurons arises the complexity of the central nervous system's brain and spinal cord.

AP[®] Exam Tip

You've heard the word peripheral before, right? How does your knowledge of peripheral vision help you understand what the peripheral nervous system is? It's always good to create mental linkages between what you're learning and what you already know.

interneurons neurons within the brain and spinal cord that communicate internally and intervene between the sensory inputs and motor outputs.

somatic nervous system the division of the peripheral nervous system that controls the body's skeletal muscles. Also called the *skeletal nervous system*.

autonomic [aw-tuh-NAHM-ik] **nervous system (ANS)** the part of the peripheral nervous system that controls the glands and the muscles of the internal organs (such as the heart). Its sympathetic division arouses; its parasympathetic division calms.

sympathetic nervous system the division of the autonomic nervous system that arouses the body, mobilizing its energy in stressful situations.

parasympathetic nervous system the division of the autonomic nervous system that calms the body, conserving its energy.

Figure 10.2**The dual functions of the autonomic nervous system**

The autonomic nervous system controls the more autonomous (or self-regulating) internal functions. Its sympathetic division arouses and expends energy. Its parasympathetic division calms and conserves energy, allowing routine maintenance activity. For example, sympathetic stimulation accelerates heartbeat, whereas parasympathetic stimulation slows it.

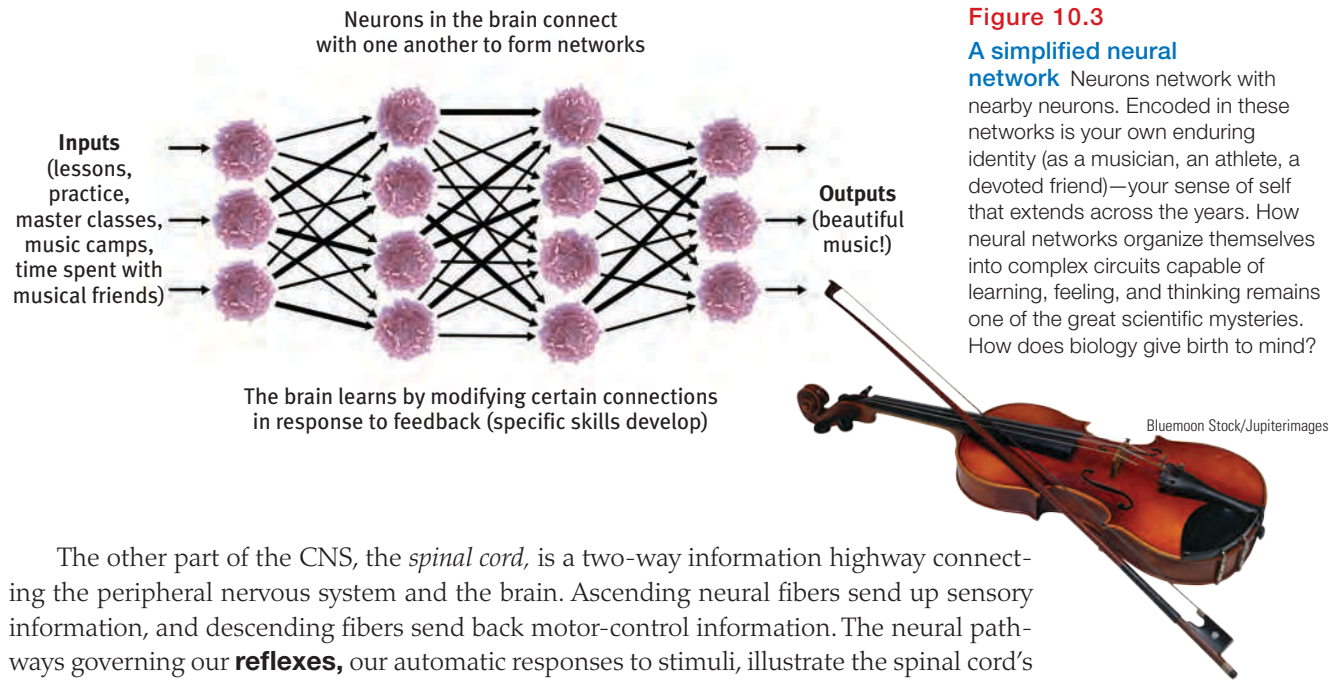

© Tom Swick

"The body is made up of millions and millions of crumbs."

It is the brain that enables our humanity—our thinking, feeling, and acting. Tens of billions of neurons, each communicating with thousands of other neurons, yield an everchanging wiring diagram. With some 40 billion neurons, each connecting with roughly 10,000 other neurons, we end up with perhaps 400 trillion synapses—places where neurons meet and greet their neighbors (de Courten-Myers, 2005).¹ A grain-of-sand-sized speck of your brain contains some 100,000 neurons and 1 billion "talking" synapses (Ramachandran & Blakeslee, 1998).

The brain's neurons cluster into work groups called *neural networks*. To understand why, Stephen Kosslyn and Olivier Koenig (1992, p. 12) have invited us to "think about why cities exist; why don't people distribute themselves more evenly across the countryside?" Like people networking with people, neurons network with nearby neurons with which they can have short, fast connections. As in **FIGURE 10.3**, each layer's cells connect with various cells in the neural network's next layer. Learning—to play the violin, speak a foreign language, solve a math problem—occurs as experience strengthens connections. Neurons that fire together wire together.

¹ Another research team, projecting from representative tissue samples, has estimated that the adult human male brain contains 86 billion neurons—give or take 8 billion (Azevedo et al., 2009). One moral: Distrust big round numbers, such as the familiar, undocumented claim that the human brain contains 100 billion neurons.

**Figure 10.3****A simplified neural network**

Neurons network with nearby neurons. Encoded in these networks is your own enduring identity (as a musician, an athlete, a devoted friend)—your sense of self that extends across the years. How neural networks organize themselves into complex circuits capable of learning, feeling, and thinking remains one of the great scientific mysteries. How does biology give birth to mind?

The other part of the CNS, the *spinal cord*, is a two-way information highway connecting the peripheral nervous system and the brain. Ascending neural fibers send up sensory information, and descending fibers send back motor-control information. The neural pathways governing our **reflexes**, our automatic responses to stimuli, illustrate the spinal cord's work. A simple spinal reflex pathway is composed of a single sensory neuron and a single motor neuron. These often communicate through an interneuron. The knee-jerk response, for example, involves one such simple pathway. A headless warm body could do it.

Another such pathway enables the pain reflex (**FIGURE 10.4**). When your finger touches a flame, neural activity (excited by the heat) travels via sensory neurons to interneurons in your spinal cord. These interneurons respond by activating motor neurons leading to the muscles in your arm. Because the simple pain-reflex pathway runs through the spinal cord and right back out, your hand jerks away from the candle's flame *before* your brain receives and responds to the information that causes you to feel pain. That's why it feels as if your hand jerks away not by your choice, but on its own.

Information travels to and from the brain by way of the spinal cord. Were the top of your spinal cord severed, you would not feel pain from your paralyzed body below. Nor would

reflex a simple, automatic response to a sensory stimulus, such as the knee-jerk response.

**Figure 10.4****A simple reflex**

"If the nervous system be cut off between the brain and other parts, the experiences of those other parts are nonexistent for the mind. The eye is blind, the ear deaf, the hand insensible and motionless." -WILLIAM JAMES, *PRINCIPLES OF PSYCHOLOGY*, 1890

you feel pleasure. With your brain literally out of touch with your body, you would lose all sensation and voluntary movement in body regions with sensory and motor connections to the spinal cord below its point of injury. You would exhibit the knee jerk without feeling the tap. To produce bodily pain or pleasure, the sensory information must reach the brain.

Before You Move On

▶ ASK YOURSELF

Does our nervous system's design—with its synaptic gaps that chemical messenger molecules cross in an imperceptibly brief instant—surprise you? Would you have designed yourself differently?

▶ TEST YOURSELF

How does information flow through your nervous system as you pick up a fork? Can you summarize this process?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

endocrine [EN-duh-krin]
system the body's "slow" chemical communication system; a set of glands that secrete hormones into the bloodstream.

hormones chemical messengers that are manufactured by the endocrine glands travel through the bloodstream and affect other tissues.

The Endocrine System

10-2

What is the nature and what are the functions of the endocrine system, and how does it interact with the nervous system?

So far we have focused on the body's speedy electrochemical information system. Interconnected with your nervous system is a second communication system, the **endocrine system (FIGURE 10.5)**. The endocrine system's glands secrete another form of chemical messengers, **hormones**, which travel through the bloodstream and affect other tissues, including the brain. When hormones act on the brain, they influence our interest in sex, food, and aggression.

Figure 10.5
The endocrine system

Some hormones are chemically identical to neurotransmitters (the chemical messengers that diffuse across a synapse and excite or inhibit an adjacent neuron). The endocrine system and nervous system are therefore close relatives: Both produce molecules that act on receptors elsewhere. Like many relatives, they also differ. The speedy nervous system zips messages from eyes to brain to hand in a fraction of a second. Endocrine messages trudge along in the bloodstream, taking several seconds or more to travel from the gland to the target tissue. If the nervous system's communication delivers messages with the speed of a text message, the endocrine system is more like sending a letter through the mail.

But slow and steady sometimes wins the race. Endocrine messages tend to outlast the effects of neural messages. That helps explain why upset feelings may linger beyond our awareness of what upset us. When this happens, it takes time for us to “simmer down.” In a moment of danger, for example, the ANS orders the **adrenal glands** on top of the kidneys to release *epinephrine* and *norepinephrine* (also called *adrenaline* and *noradrenaline*). These hormones increase heart rate, blood pressure, and blood sugar, providing us with a surge of energy, known as the *fight-or-flight* response. When the emergency passes, the hormones—and the feelings of excitement—linger a while.

The most influential endocrine gland is the **pituitary gland**, a pea-sized structure located in the core of the brain, where it is controlled by an adjacent brain area, the *hypothalamus* (more on that shortly). The pituitary releases certain hormones. One is a growth hormone that stimulates physical development. Another, oxytocin, enables contractions associated with birthing, milk flow during nursing, and orgasm. Oxytocin also promotes pair bonding, group cohesion, and social trust (De Dreu et al., 2010). During a laboratory game, those given a nasal squirt of oxytocin rather than a placebo were more likely to trust strangers with their money (Kosfeld et al., 2005).

Pituitary secretions also influence the release of hormones by other endocrine glands. The pituitary, then, is a sort of master gland (whose own master is the hypothalamus). For example, under the brain's influence, the pituitary triggers your sex glands to release sex hormones. These in turn influence your brain and behavior. So, too, with stress. A stressful event triggers your hypothalamus to instruct your pituitary to release a hormone that causes your adrenal glands to flood your body with cortisol, a stress hormone that increases blood sugar.

This feedback system (brain → pituitary → other glands → hormones → body and brain) reveals the intimate connection of the nervous and endocrine systems. The nervous system directs endocrine secretions, which then affect the nervous system. Conducting and coordinating this whole electrochemical orchestra is that maestro we call the brain.

adrenal [ah-DREEN-el] **glands**

a pair of endocrine glands that sit just above the kidneys and secrete hormones (epinephrine and norepinephrine) that help arouse the body in times of stress.

pituitary gland the endocrine system's most influential gland.

Under the influence of the hypothalamus, the pituitary regulates growth and controls other endocrine glands.

Before You Move On

▶ **ASK YOURSELF**

Can you remember feeling an extended period of discomfort after some particularly stressful event? How long did those feelings last?

▶ **TEST YOURSELF**

Why is the pituitary gland called the “master gland”?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 10 Review

10-1

What are the functions of the nervous system's main divisions, and what are the three main types of neurons?

- The *central nervous system (CNS)*—the brain and the spinal cord—is the *nervous system's* decision maker.
- The *peripheral nervous system (PNS)*, which connects the CNS to the rest of the body by means of *nerves*, gathers information and transmits CNS decisions to the rest of the body.
- The two main PNS divisions are the *somatic nervous system* (which enables voluntary control of the skeletal muscles) and the *autonomic nervous system* (which controls involuntary muscles and glands by means of its *sympathetic* and *parasympathetic divisions*).
- Neurons cluster into working networks.
- There are three types of neurons:
 - (1) *Sensory neurons* carry incoming information from sense receptors to the brain and spinal cord.

(2) *Motor neurons* carry information from the brain and spinal cord out to the muscles and glands.

(3) *Interneurons* communicate within the brain and spinal cord and between sensory and motor neurons.

10-2

What is the nature and what are the functions of the endocrine system, and how does it interact with the nervous system?

- The *endocrine system* is a set of glands that secrete *hormones* into the bloodstream, where they travel through the body and affect other tissues, including the brain. The *adrenal glands*, for example, release the hormones that trigger the fight-or-flight response.
- The endocrine system's master gland, the *pituitary*, influences hormone release by other glands. In an intricate feedback system, the brain's *hypothalamus* influences the pituitary gland, which influences other glands, which release hormones, which in turn influence the brain.

Multiple-Choice Questions

1. Which of the following carries the information necessary to activate withdrawal of the hand from a hot object?
 - a. Sensory neuron
 - b. Motor neuron
 - c. Interneuron
 - d. Receptor neuron
 - e. Reflex
2. Hormones are _____ released into the _____.
 - a. neurons; neurotransmitters
 - b. chemical messengers; bloodstream
 - c. electrical messengers; bloodstream
 - d. electrical messengers; synapse
 - e. chemical messengers; synapse
3. Which division of the nervous system produces the startle response?
 - a. Parasympathetic
 - b. Central
 - c. Somatic
 - d. Sympathetic
 - e. Autonomic
4. Which of the following endocrine glands may explain unusually tall height in a 12-year-old?
 - a. Pituitary
 - b. Adrenal
 - c. Pancreas
 - d. Parathyroid
 - e. Testes
5. Which of the following communicates with the pituitary, which in turn controls the endocrine system?
 - a. Parathyroids
 - b. Autonomic nervous system
 - c. Hypothalamus
 - d. Spinal cord
 - e. Pancreas
6. Which branch of the nervous system calms a person?
 - a. Central nervous system
 - b. Sympathetic
 - c. Parasympathetic
 - d. Somatic
 - e. Endocrine

- 7.** Epinephrine and norepinephrine increase energy and are released by the
- thyroid glands.
 - pituitary gland.
 - hypothalamus.
 - thalamus.
 - adrenal glands.
- 8.** Interneurons are said to
- send messages from specific body parts to the brain.
 - transmit and process information within the brain and spinal cord.
 - act as connectors, supporting other neurons in the brain.
 - send messages from the brain to body parts.
 - influence the pituitary gland.

Practice FRQs

- 1.** While walking barefoot, you step on a piece of glass. Before you have a chance to consciously process what has happened, you draw your foot away from the glass. Identify and explain the three types of neurons that deal with information regarding this painful stimulus.
- 2.** Name and describe the components and subcomponents of the peripheral nervous system.

(4 points)

Answer

1 point: Sensory neurons carry information from the point of the injury to the central nervous system.

1 point: Interneurons are neurons within the brain and spinal cord. Interneurons would help you interpret the pain and enable your brain to send out marching orders.

1 point: Motor neurons carry the instruction from the central nervous system to activate the muscles in your leg and foot.

Module 11

Studying the Brain, and Older Brain Structures

Module Learning Objectives

- 11-1** Describe several techniques for studying the brain's connections to behavior and mind.
- 11-2** Describe the components of the brainstem, and summarize the functions of the brainstem, thalamus, and cerebellum.
- 11-3** Describe the limbic system's structures and functions.

"I am a brain, Watson. The rest of me is a mere appendix."
 -SHERLOCK HOLMES, IN ARTHUR CONAN DOYLE'S "THE ADVENTURE OF THE MAZARIN STONE"

The brain enables the mind—seeing, hearing, smelling, feeling, remembering, thinking, speaking, dreaming, loving. Moreover, it is the brain that self-reflectively analyzes the brain. When we're thinking *about* our brain, we're thinking *with* our brain—by firing across millions of synapses and releasing billions of neurotransmitter molecules. Neuroscientists tell us that the *mind is what the brain does*. Brain, behavior, and cognition are an integrated whole. But precisely where and how are the mind's functions tied to the brain? Let's first see how scientists explore such questions.

The Tools of Discovery: Having Our Head Examined

- 11-1** How do neuroscientists study the brain's connections to behavior and mind?

A century ago, scientists had no tools high-powered yet gentle enough to explore the living human brain. Early case studies of patients by physicians and others helped localize some of the brain's functions. Damage to one side of the brain often caused numbness or paralysis on the body's opposite side, suggesting that the body's right side is wired to the brain's left side, and vice versa. Damage to the back of the brain disrupted vision, and to the left-front part of the brain produced speech difficulties. Gradually, these early explorers were mapping the brain.

Now, within a lifetime, a new generation of neural cartographers is probing and mapping the known universe's most amazing organ. Scientists can selectively **lesion** (destroy) tiny clusters of brain cells, leaving the surrounding tissue unharmed. In the laboratory, such studies have revealed, for example, that damage to one area of the hypothalamus in a rat's brain reduces eating, to the point of starvation, whereas damage in another area produces overeating.

lesion [LEE-zuhn] tissue destruction. A brain lesion is a naturally or experimentally caused destruction of brain tissue.

Today's neuroscientists can also electrically, chemically, or magnetically *stimulate* various parts of the brain and note the effect. Depending on the stimulated brain part, people may—to name a few examples—giggle, hear voices, turn their head, feel themselves falling, or have an out-of-body experience (Selimbeyoglu & Parvizi, 2010). Scientists can even snoop on the messages of individual neurons. With tips so small they can detect the electrical pulse in a single neuron, modern microelectrodes can, for example, now detect exactly where the information goes in a cat's brain when someone strokes its whisker. Researchers can also eavesdrop on the chatter of billions of neurons and can see color representations of the brain's energy-consuming activity.

Right now, your mental activity is emitting telltale electrical, metabolic, and magnetic signals that would enable neuroscientists to observe your brain at work. Electrical activity in your brain's billions of neurons sweeps in regular waves across its surface. An **electroencephalogram (EEG)** is an amplified readout of such waves. Researchers record the brain waves through a shower-cap-like hat that is filled with electrodes covered with a conductive gel. Studying an EEG of the brain's activity is like studying a car engine by listening to its hum. With no direct access to the brain, researchers present a stimulus repeatedly and have a computer filter out brain activity unrelated to the stimulus. What remains is the electrical wave evoked by the stimulus (**FIGURE 11.1**).

AJPhoto/Science Source

Figure 11.1
An electroencephalogram providing amplified tracings of waves of electrical activity in the brain Here it is displaying the brain activity of this 4-year-old who has epilepsy.

“You must look into people, as well as at them,” advised Lord Chesterfield in a 1746 letter to his son. Unlike EEGs, newer neuroimaging techniques give us that Superman-like ability to see inside the living brain. For example, the **CT (computed tomography) scan** examines the brain by taking X-ray photographs that can reveal brain damage. Even more dramatic is the **PET (positron emission tomography) scan** (**FIGURE 11.2** on the next page), which depicts brain activity by showing each brain area's consumption of its chemical fuel, the sugar glucose. Active neurons are glucose hogs, and after a person receives temporarily radioactive glucose, the PET scan can track the gamma rays released by this “food for thought” as the person performs a given task. Rather like weather radar showing rain activity, PET-scan “hot spots” show which brain areas are most active as the person does mathematical calculations, looks at images of faces, or daydreams.

In **MRI (magnetic resonance imaging)** brain scans, the person's head is put in a strong magnetic field, which aligns the spinning atoms of brain molecules. Then, a radio-wave pulse momentarily disorients the atoms. When the atoms return to their normal spin, they emit signals that provide a detailed picture of soft tissues, including the brain. MRI scans have revealed a larger-than-average neural area in the left hemisphere of musicians who display perfect pitch (Schlaug et al., 1995). They have also revealed enlarged *ventricles*—fluid-filled brain areas

electroencephalogram (EEG) an amplified recording of the waves of electrical activity sweeping across the brain's surface. These waves are measured by electrodes placed on the scalp.

CT (computed tomography) scan a series of X-ray photographs taken from different angles and combined by computer into a composite representation of a slice of the brain's structure. (Also called *CAT scan*.)

PET (positron emission tomography) scan a visual display of brain activity that detects where a radioactive form of glucose goes while the brain performs a given task.

MRI (magnetic resonance imaging) a technique that uses magnetic fields and radio waves to produce computer-generated images of soft tissue. MRI scans show brain anatomy.

Figure 11.2

The PET scan To obtain a PET scan, researchers inject volunteers with a low and harmless dose of a short-lived radioactive sugar. Detectors around the person's head pick up the release of gamma rays from the sugar, which has concentrated in active brain areas. A computer then processes and translates these signals into a map of the brain at work.

Figure 11.3

MRI scan of a healthy individual (left) and a person with schizophrenia (right) Note the enlarged ventricle, the fluid-filled brain region at the tip of the arrow in the image on the right.

(marked by the red arrows in **FIGURE 11.3**)—in some patients who have schizophrenia, a disabling psychological disorder.

A special application of MRI—**fMRI (functional MRI)**—can reveal the brain's functioning as well as its structure. Where the brain is especially active, blood goes. By comparing MRI scans taken less than a second apart, researchers can watch as specific brain areas activate, showing increased oxygen-laden bloodflow. As the person looks at a scene, for example, the fMRI machine detects blood rushing to the back of the brain, which processes visual information (see Figure 12.5, in the discussion of cortex functions in Module 12).

Such snapshots of the brain's changing activity are providing new insights—albeit sometimes overstated (Vul et al., 2009a,b)—into how the brain divides its labor. A mountain of recent fMRI studies suggests which brain areas are most active when people feel pain or rejection, listen to angry voices, think about scary things, feel happy, or become sexually excited. The technology enables a very crude sort of mind reading. After scanning 129 people's brains as they did eight different mental tasks (such as reading, gambling, or rhyming), neuroscientists were able, with 80 percent accuracy, to predict which of these mental activities people were doing (Poldrack et al., 2009). Other studies have explored brain activity associated with religious experience, though without settling the question of whether the brain is producing or perceiving God (Fingelkurts & Fingelkurts, 2009; Inzlicht et al., 2009; Kapogiannis et al., 2009).

* * *

Today's techniques for peering into the thinking, feeling brain are doing for psychology what the microscope did for biology and the telescope did for astronomy. From them we have learned more about the brain in the last 30 years than in the previous 30,000. To be learning about the neurosciences now is like studying world geography while Magellan was exploring the seas. This truly is the golden age of brain science.

Older Brain Structures

11-2

What structures make up the brainstem, and what are the functions of the brainstem, thalamus, and cerebellum?

An animal's capacities come from its brain structures. In primitive animals, such as sharks, a not-so-complex brain primarily regulates basic survival functions: breathing, resting, and feeding. In lower mammals, such as rodents, a more complex brain enables emotion and greater memory. In advanced mammals, such as humans, a brain that processes more information enables increased foresight as well.

fMRI (functional MRI) a

technique for revealing bloodflow and, therefore, brain activity by comparing successive MRI scans. fMRI scans show brain function as well as its structure.

AP® Exam Tip

Your author, David Myers, is about to take you on a journey through your brain. Focus on the name of each part, its location within the brain, and what it does. Then it's time to practice, practice, practice.

Figure 11.4
The brainstem and thalamus The brainstem, including the pons and medulla, is an extension of the spinal cord. The thalamus is attached to the top of the brainstem. The reticular formation passes through both structures.

This increasing complexity arises from new brain systems built on top of the old, much as the Earth's landscape covers the old with the new. Digging down, one discovers the fossil remnants of the past—brainstem components performing for us much as they did for our distant ancestors. Let's start with the brain's basement and work up to the newer systems.

The Brainstem

The brain's oldest and innermost region is the **brainstem**. It begins where the spinal cord swells slightly after entering the skull. This slight swelling is the **medulla** (**FIGURE 11.4**). Here lie the controls for your heartbeat and breathing. As some brain-damaged patients in a vegetative state illustrate, we need no higher brain or conscious mind to orchestrate our heart's pumping and lungs' breathing. The brainstem handles those tasks.

Just above the medulla sits the *pons*, which helps coordinate movements. If a cat's brainstem is severed from the rest of the brain above it, the animal will still breathe and live—and even run, climb, and groom (Klemm, 1990). But cut off from the brain's higher regions, it won't *purposefully* run or climb to get food.

The brainstem is a crossover point, where most nerves to and from each side of the brain connect with the body's opposite side (**FIGURE 11.5**). This peculiar cross-wiring is but one of the brain's many surprises.

The Thalamus

Sitting atop the brainstem is the **thalamus**, a pair of egg-shaped structures that act as the brain's sensory control center (Figure 11.4). The thalamus receives information from all the senses except smell and routes it to the higher brain regions that deal with seeing, hearing, tasting, and touching. The thalamus also receives some of the higher brain's replies, which it then directs to the medulla and to the cerebellum (see the next page). Think of the thalamus as being to sensory information what London is to England's trains: a hub through which traffic passes en route to various destinations.

Figure 11.5
The body's wiring Nerves from the left side of the brain are mostly linked to the right side of the body, and vice versa.

Andrew Swift

brainstem the oldest part and central core of the brain, beginning where the spinal cord swells as it enters the skull; the brainstem is responsible for automatic survival functions.

medulla [muh-DUL-uh] the base of the brainstem; controls heartbeat and breathing.

thalamus [THAL-uh-muss] the brain's sensory control center, located on top of the brainstem; it directs messages to the sensory receiving areas in the cortex and transmits replies to the cerebellum and medulla.

reticular formation a nerve network that travels through the brainstem and thalamus and plays an important role in controlling arousal.

Figure 11.6
The brain's organ of agility Hanging at the back of the brain, the cerebellum coordinates our voluntary movements.

cerebellum [sehr-uh-BELL-um] the “little brain” at the rear of the brainstem; functions include processing sensory input, coordinating movement output and balance, and enabling nonverbal learning and memory.

limbic system neural system (including the *hippocampus*, *amygdala*, and *hypothalamus*) located below the cerebral hemispheres; associated with emotions and drives.

The Reticular Formation

Inside the brainstem, between your ears, lies the **reticular** (“netlike”) **formation**, a neuron network that extends from the spinal cord right up through the thalamus. As the spinal cord’s sensory input flows up to the thalamus, some of it travels through the reticular formation, which filters incoming stimuli and relays important information to other brain areas.

In 1949, Giuseppe Moruzzi and Horace Magoun discovered that electrically stimulating the reticular formation of a sleeping cat almost instantly produced an awake, alert animal. When Magoun *severed* a cat’s reticular formation without damaging the nearby sensory pathways, the effect was equally dramatic: The cat lapsed into a coma from which it never awakened. The conclusion? The reticular formation enables arousal.

The Cerebellum

Extending from the rear of the brainstem is the baseball-sized **cerebellum**, meaning “little brain,” which is what its two wrinkled halves resemble (**FIGURE 11.6**). As you will see in Module 32, the cerebellum enables nonverbal learning and memory. It also helps us judge time, modulate our emotions, and discriminate sounds and textures (Bower & Parsons, 2003). And it coordinates voluntary movement (with assistance from

the pons). When a soccer player executes a perfect bicycle kick (above), give his cerebellum some credit. If you injured your cerebellum, you would have difficulty walking, keeping your balance, or shaking hands. Your movements would be jerky and exaggerated. Gone would be any dreams of being a dancer or guitarist. Under alcohol’s influence on the cerebellum, coordination suffers, as many a driver has learned after being pulled over and given a roadside test.

* * *

Note: These older brain functions all occur without any conscious effort. This illustrates another of our recurring themes: *Our brain processes most information outside of our awareness.* We are aware of the *results* of our brain’s labor (say, our current visual experience) but not of *how* we construct the visual image. Likewise, whether we are asleep or awake, our brainstem manages its life-sustaining functions, freeing our newer brain regions to think, talk, dream, or savor a memory.

The Limbic System

11-3 What are the limbic system’s structures and functions?

We’ve considered the brain’s oldest parts, but we’ve not yet reached its newest and highest regions, the *cerebral hemispheres* (the two halves of the brain). Between the oldest and newest brain areas lies the **limbic system** (*limbus* means “border”). This system contains the *amygdala*, the *hypothalamus*, and the *hippocampus* (**FIGURE 11.7**). The hippocampus processes conscious memories. Animals or humans who lose their hippocampus to surgery or injury also lose their ability to form new memories of facts and events. Module 31 explains how our two-track mind processes our memories. For now, let’s look at the limbic system’s links to emotions such as fear and anger, and to basic motives such as those for food and sex.

**Figure 11.7**

The limbic system This neural system sits between the brain's older parts and its cerebral hemispheres. The limbic system's hypothalamus controls the nearby pituitary gland.

amygdala [uh-MIG-duh-la] two lima-bean-sized neural clusters in the limbic system; linked to emotion.

hypothalamus [hi-po-THAL-uh-muss] a neural structure lying below (*hypo*) the thalamus; it directs several maintenance activities (eating, drinking, body temperature), helps govern the endocrine system via the pituitary gland, and is linked to emotion and reward.

THE AMYGDALA

Research has linked the **amygdala**, two lima-bean-sized neural clusters, to aggression and fear. In 1939, psychologist Heinrich Klüver and neurosurgeon Paul Bucy surgically removed a rhesus monkey's amygdala, turning the normally ill-tempered animal into the most mellow of creatures. In studies with other wild animals, including the lynx, wolverine, and wild rat, researchers noted the same effect.

What then might happen if we electrically stimulated the amygdala of a normally placid domestic animal, such as a cat? Do so in one spot and the cat prepares to attack, hissing with its back arched, its pupils dilated, its hair on end. Move the electrode only slightly within the amygdala, cage the cat with a small mouse, and now it cowers in terror.

These and other experiments have confirmed the amygdala's role in rage and fear, including the perception of these emotions and the processing of emotional memories (Anderson & Phelps, 2000; Poremba & Gabriel, 2001). But we must be careful. The brain is not neatly organized into structures that correspond to our behavior categories. When we feel or act in aggressive or fearful ways, there is neural activity in many levels of our brain. Even within the limbic system, stimulating structures other than the amygdala can evoke aggression or fear. If you charge your cell phone's dead battery, you can activate the phone and make a call. Yet the battery is merely one link in an integrated system.

Jane Burton/Dorling Kindersley/Getty Images

Aggression as a brain state

Back arched and fur fluffed, this fierce cat is ready to attack. Electrical stimulation of a cat's amygdala provokes angry reactions, suggesting the amygdala's role in aggression. Which ANS division is activated by such stimulation?

ANSWER: The cat would be aroused via its sympathetic nervous system.

THE HYPOTHALAMUS

Just below (*hypo*) the thalamus is the **hypothalamus** (FIGURE 11.8 on the next page), an important link in the command chain governing bodily maintenance. Some neural clusters in the hypothalamus influence hunger; others regulate thirst, body temperature, and sexual behavior. Together, they help maintain a steady internal state.

As the hypothalamus monitors the state of your body, it tunes into your blood chemistry and any incoming orders from other brain parts. For example, picking up signals from your brain's cerebral cortex that you are thinking about sex, your hypothalamus will secrete hormones. These hormones will in turn trigger the adjacent "master gland," your pituitary (see Figure 11.7), to influence your sex glands to release their hormones. These will intensify the thoughts of sex in your cerebral cortex. (Once again, we see the interplay between the nervous and endocrine systems: The brain influences the endocrine system, which in turn influences the brain.)

AP® Exam Tip

If you ever have to make a guess about brain parts on the AP® exam, the hypothalamus isn't a bad bet. Even though it's small, it has many functions.

ISM/Phototake

Figure 11.8

The hypothalamus This small but important structure, colored yellow/orange in this MRI scan photograph, helps keep the body's internal environment in a steady state.

"If you were designing a robot vehicle to walk into the future and survive, . . . you'd wire it up so that behavior that ensured the survival of the self or the species—like sex and eating—would be naturally reinforcing."
—CANDACE PERT (1986)

A remarkable discovery about the hypothalamus illustrates how progress in science often occurs—when curious, open-minded investigators make an unexpected observation. Two young McGill University neuropsychologists, James Olds and Peter Milner (1954), were trying to implant an electrode in a rat's reticular formation when they made a magnificent mistake: They placed the electrode incorrectly (Olds, 1975). Curiously, as if seeking more stimulation, the rat kept returning to the location where it had been stimulated by this misplaced electrode. On discovering that they had actually placed the device in a region of the hypothalamus, Olds and Milner realized they had stumbled upon a brain center that provides pleasurable rewards (Olds, 1975).

In a meticulous series of experiments, Olds (1958) went on to locate other "pleasure centers," as he called them. (What the rats actually experience only they know, and they aren't telling. Rather than attribute human feelings to rats, today's scientists refer to *reward centers*, not "pleasure centers.") When allowed to press pedals to trigger their own stimulation in these areas, rats would sometimes do so at a feverish pace—up to 7000 times per hour—until they dropped from exhaustion. Moreover, to get this stimulation, they would even cross an electrified floor that a starving rat would not cross to reach food (**FIGURE 11.9**).

Other limbic system reward centers, such as the *nucleus accumbens* in front of the hypothalamus, were later discovered in many other species, including dolphins and monkeys. In fact, animal research has revealed both a general dopamine-related reward system and specific centers associated with the pleasures of eating, drinking, and sex. Animals, it seems, come equipped with built-in systems that reward activities essential to survival.

Contemporary researchers are experimenting with new ways of using limbic stimulation to control animals' actions in future applications, such as search-and-rescue operations. By rewarding rats for turning left or right, one research team trained previously caged rats to navigate natural environments (Talwar et al., 2002; **FIGURE 11.10**). By pressing buttons on a laptop, the researchers were then able to direct the rat—which carried a receiver, power source, and video camera on a backpack—to turn on cue, climb trees, scurry along branches, and turn around and come back down.

Do humans have limbic centers for pleasure? Indeed we do. To calm violent patients, one neurosurgeon implanted electrodes in such areas. Stimulated patients reported mild pleasure; unlike Olds' rats, however, they were not driven to a frenzy (Deutsch, 1972; Hooper & Teresi, 1986).

Experiments have also revealed the effects of a dopamine-related reward system in people. One research team had people rate the desirability of different vacation destinations. Then, after receiving either a dopamine-increasing drug or a sugar pill, they imagined themselves vacationing at half the locations. A day later, when presented with pairs of vacation spots they

**Figure 11.9**

Rat with an implanted electrode With an electrode implanted in a reward center of its hypothalamus, the rat readily crosses an electrified grid, accepting the painful shocks, to press a pedal that sends electrical impulses to that center.

**Figure 11.10**

Ratbot on a pleasure cruise When stimulated by remote control, a rat could be guided to navigate across a field and even up a tree.

Figure 11.11
Review: Brain structures and their functions

had initially rated equally, only the dopamine takers preferred the places they had imagined under dopamine's influence (Sharot et al., 2009). The participants, it seems, associated the imagined experiences with dopamine-induced pleasant feelings.

Some researchers believe that addictive disorders, such as substance use disorders and binge eating, may stem from malfunctions in natural brain systems for pleasure and well-being. People genetically predisposed to this *reward deficiency syndrome* may crave whatever provides that missing pleasure or relieves negative feelings (Blum et al., 1996).

* * *

FIGURE 11.11 locates the brain areas we've discussed, as well as the *cerebral cortex*, our next topic.

Before You Move On

▶ ASK YOURSELF

If one day researchers discover how to stimulate human limbic centers to produce as strong a reaction as found in other animals, do you think this process could be used to reduce the incidence of substance use? Could such use have any negative consequences?

▶ TEST YOURSELF

Within what brain region would damage be most likely to disrupt your ability to skip rope? Your ability to sense tastes or sounds? In what brain region would damage perhaps leave you in a coma? Without the very breath and heartbeat of life?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 11 Review

11-1

How do neuroscientists study the brain's connections to behavior and mind?

- Case studies and *lesioning* first revealed the general effects of brain damage.
- Modern electrical, chemical, or magnetic stimulation has also revealed aspects of information processing in the brain.
- *CT* and *MRI* scans show anatomy. *EEG*, *PET*, and *fMRI* (*functional MRI*) recordings reveal brain function.

11-2

What structures make up the brainstem, and what are the functions of the brainstem, thalamus, and cerebellum?

- The *brainstem*, the oldest part of the brain, is responsible for automatic survival functions. Its components are the *medulla* (which controls heartbeat and breathing), the *pons* (which helps coordinate movements), and the *reticular formation* (which affects arousal).

- The *thalamus*, sitting above the brainstem, acts as the brain's sensory control center. The *cerebellum*, attached to the rear of the brainstem, coordinates muscle movement and balance and also helps process sensory information.

11-3

What are the limbic system's structures and functions?

- The *limbic system* is linked to emotions, memory, and drives.
- Its neural centers include the hippocampus (which processes conscious memories); the *amygdala* (involved in responses of aggression and fear); and the *hypothalamus* (involved in various bodily maintenance functions, pleasurable rewards, and the control of the endocrine system).
- The pituitary (the "master gland") controls the hypothalamus by stimulating it to trigger the release of hormones.

Multiple-Choice Questions

- Computer-enhanced X-rays used to create brain images are known as
 - position emission tomography scans.
 - functional magnetic resonance images.
 - computed tomography scans.
 - electroencephalograms.
 - magnetic resonance images.
- What part of the brain triggers the release of adrenaline to boost heart rate when you're afraid?
 - Amygdala
 - Thalamus
 - Medulla
 - Hippocampus
 - Hypothalamus
- A gymnast falls and hits her head on the floor. She attempts to continue practicing, but has trouble maintaining balance. What part of her brain has probably been affected?
 - Reticular formation
 - Cerebellum
 - Amygdala
 - Frontal lobe
 - Brainstem
- Which of the following scanning techniques measures glucose consumption as an indicator of brain activity?
 - CT
 - MRI
 - fMRI
 - PET
 - EEG
- Which of the following is sometimes referred to as the brain's train hub, because it directs incoming sensory messages (with the exception of smell) to their proper places in the brain?
 - Hypothalamus
 - Pituitary
 - Cerebellum
 - Limbic system
 - Thalamus
- Which of the following brain areas is responsible for regulating thirst?
 - Reticular activating system
 - Amygdala
 - Hypothalamus
 - Hippocampus
 - Brainstem

7. The hypothalamus is a(n) _____ center for the brain.
- positioning
 - aggression
 - balance
 - memory
 - reward
8. Which of the following's primary function is processing memories?
- Cerebral cortex
 - Medulla
 - Corpus callosum
 - Hippocampus
 - Hypothalamus

Practice FRQs

1. Following a brain injury, Mike struggles to control his emotions and has difficulty establishing new memories. What parts of Mike's brain have most likely been affected by his injury?
2. Identify the role of each of the following in listening to and taking notes during a psychology lecture.
- Hippocampus
 - Cerebellum
 - Cerebral cortex

Answer

1 point: Damage to the amygdala would make it difficult for Mike to control his emotions.

1 point: Damage to the hippocampus would affect Mike's ability to establish new memories.

(3 points)

Module 12

The Cerebral Cortex

Module Learning Objectives

- 12-1** Identify the various regions of the cerebral cortex, and describe their functions.
- 12-2** Discuss the brain's ability to reorganize itself, and define neurogenesis.

12-1 What are the functions of the various cerebral cortex regions?

Older brain networks sustain basic life functions and enable memory, emotions, and basic drives. Newer neural networks within the *cerebrum*—the hemispheres that contribute 85 percent of the brain's weight—form specialized work teams that enable our perceiving, thinking, and speaking. Like other structures above the brainstem (including the thalamus, hippocampus, and amygdala), the cerebral hemispheres come as a pair. Covering those hemispheres, like bark on a tree, is the **cerebral cortex**, a thin surface layer of interconnected neural cells. It is your brain's thinking crown, your body's ultimate control and information-processing center.

As we move up the ladder of animal life, the cerebral cortex expands, tight genetic controls relax, and the organism's adaptability increases. Frogs and other small-cortex amphibians operate extensively on preprogrammed genetic instructions. The larger cortex of mammals offers increased capacities for learning and thinking, enabling them to be more adaptable. What makes us distinctively human mostly arises from the complex functions of our cerebral cortex.

FYI

The people who first dissected and labeled the brain used the language of scholars—Latin and Greek. Their words are actually attempts at graphic description: For example, *cortex* means “bark,” *cerebellum* is “little brain,” and *thalamus* is “inner chamber.”

cerebral [seh-REE-bruhl] **cortex** the intricate fabric of interconnected neural cells covering the cerebral hemispheres; the body's ultimate control and information-processing center.

glial cells (glia) cells in the nervous system that support, nourish, and protect neurons; they may also play a role in learning and thinking.

Structure of the Cortex

If you opened a human skull, exposing the brain, you would see a wrinkled organ, shaped somewhat like the meat of an oversized walnut. Without these wrinkles, a flattened cerebral cortex would require triple the area—roughly that of a large pizza. The brain's left and right hemispheres are filled mainly with axons connecting the cortex to the brain's other regions. The cerebral cortex—that thin surface layer—contains some 20 to 23 billion nerve cells and 300 trillion synaptic connections (de Courten-Myers, 2005). Being human takes a lot of nerve.

Supporting these billions of nerve cells are nine times as many spidery **glial cells** (“glue cells”). Neurons are like queen bees; on their own they cannot feed or sheathe themselves. Glial cells are worker bees. They provide nutrients and insulating myelin, guide neural connections, and mop up ions and neurotransmitters. Glia may also play a role in learning and thinking. By “chatting” with neurons they may participate in information transmission and memory (Fields, 2009; Miller, 2005).

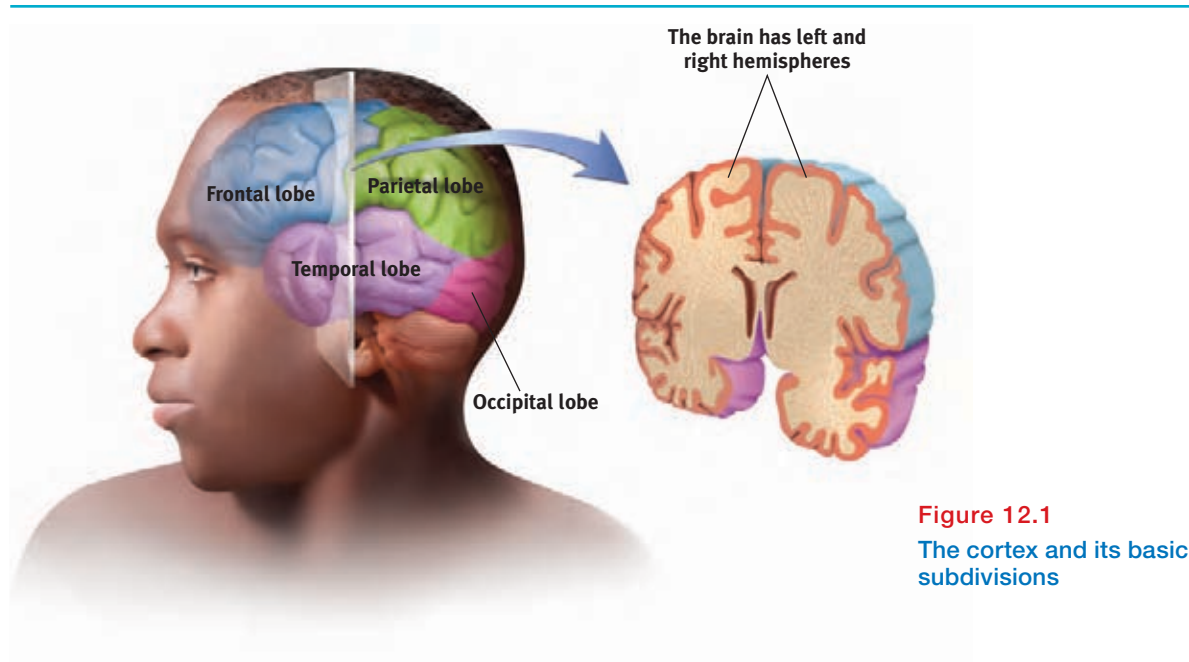

Figure 12.1
The cortex and its basic subdivisions

In more complex animal brains, the proportion of glia to neurons increases. A postmortem analysis of Einstein’s brain did not find more or larger-than-usual neurons, but it did reveal a much greater concentration of glial cells than found in an average Albert’s head (Fields, 2004).

Each hemisphere’s cortex is subdivided into four *lobes*, separated by prominent *fissures*, or folds (**FIGURE 12.1**). Starting at the front of your brain and moving over the top, there are the **frontal lobes** (behind your forehead), the **parietal lobes** (at the top and to the rear), and the **occipital lobes** (at the back of your head). Reversing direction and moving forward, just above your ears, you find the **temporal lobes**. Each of the four lobes carries out many functions, and many functions require the interplay of several lobes.

Functions of the Cortex

More than a century ago, surgeons found damaged cortical areas during autopsies of people who had been partially paralyzed or speechless. This rather crude evidence did not prove that specific parts of the cortex control complex functions like movement or speech. After all, if the entire cortex controlled speech and movement, damage to almost any area might produce the same effect. A TV with its power cord cut would go dead, but we would be fooling ourselves if we thought we had “localized” the picture in the cord.

Motor Functions

Scientists had better luck in localizing simpler brain functions. For example, in 1870, German physicians Gustav Fritsch and Eduard Hitzig made an important discovery: Mild electrical stimulation to parts of an animal’s cortex made parts of its body move. The effects were selective: Stimulation caused movement only when applied to an arch-shaped region at the back of the frontal lobe, running roughly ear-to-ear across the top of the brain. Moreover, stimulating parts of this region in the left or right hemisphere caused movements of specific body parts on the *opposite* side of the body. Fritsch and Hitzig had discovered what is now called the **motor cortex**.

MAPPING THE MOTOR CORTEX

Lucky for brain surgeons and their patients, the brain has no sensory receptors. Knowing this, Otfrid Foerster and Wilder Penfield were able to map the motor cortex in hundreds of wide-awake patients by stimulating different cortical areas and observing the body’s responses.

frontal lobes portion of the cerebral cortex lying just behind the forehead; involved in speaking and muscle movements and in making plans and judgments.

parietal [puh-RYE-uh-tuhl] **lobes** portion of the cerebral cortex lying at the top of the head and toward the rear; receives sensory input for touch and body position.

occipital [ahk-SIP-uh-tuhl] **lobes** portion of the cerebral cortex lying at the back of the head; includes areas that receive information from the visual fields.

temporal lobes portion of the cerebral cortex lying roughly above the ears; includes the auditory areas, each receiving information primarily from the opposite ear.

motor cortex an area at the rear of the frontal lobes that controls voluntary movements.

Figure 12.2

Left hemisphere tissue devoted to each body part in the motor cortex and the somatosensory cortex

As you can see from this classic though inexact representation, the amount of cortex devoted to a body part in the motor cortex (in the frontal lobes) or in the somatosensory cortex (in the parietal lobes) is not proportional to that body part's size. Rather, the brain devotes more tissue to sensitive areas and to areas requiring precise control. Thus, the fingers have a greater representation in the cortex than does the upper arm.

They discovered that body areas requiring precise control, such as the fingers and mouth, occupy the greatest amount of cortical space (**FIGURE 12.2**).

In one of his many demonstrations of motor behavior mechanics, Spanish neuroscientist José Delgado stimulated a spot on a patient's left motor cortex, triggering the right hand to make a fist. Asked to keep the fingers open during the next stimulation, the patient, whose fingers closed despite his best efforts, remarked, "I guess, Doctor, that your electricity is stronger than my will" (Delgado, 1969, p. 114).

More recently, scientists were able to predict a monkey's arm motion a tenth of a second *before* it moved—by repeatedly measuring motor cortex activity preceding specific arm movements (Gibbs, 1996). Such findings have opened the door to research on brain-controlled computers.

BRAIN-COMPUTER INTERFACES

By eavesdropping on the brain, could we enable someone—perhaps a paralyzed person—to move a robotic limb? Could a *brain-computer interface* command a cursor to write an e-mail or search the Internet? To find out, Brown University brain researchers implanted 100 tiny recording electrodes in the motor cortexes of three monkeys (Nicolelis & Chapin, 2002; Serruya et al., 2002). As the monkeys used a joystick to move a cursor to follow a moving red target (to gain rewards), the researchers matched the brain signals with the arm movements. Then they programmed a computer to monitor the signals and operate the joystick. When a monkey merely thought about a move, the mind-reading computer moved the cursor with nearly the same proficiency as had the reward-seeking monkey. In follow-up experiments, two monkeys were trained to control a robot arm that could grasp and deliver food (Velliste et al., 2008), and then a human did the same (**FIGURE 12.3**).

Hochberg et al., 2012. Reach and grasp by people with tetraplegia using a neurally controlled robotic arm. Nature, 485, pp. 372–375

Figure 12.3

Mind over matter A series of strokes left Cathy paralyzed for 15 years, unable to make even simple arm movements. Now, thanks to a tiny, 96-electrode implant in her brain's motor cortex, she is learning to direct a robotic arm with her thoughts (Hochberg et al., 2012).

Clinical trials of such *cognitive neural prosthetics* are now under way with people who have suffered paralysis or amputation (Andersen et al., 2010; Nurmikko et al., 2010). The first patient, a paralyzed 25-year-old man, was able to mentally control a TV, draw shapes on a computer screen, and play video games—all thanks to an aspirin-sized chip with 100 microelectrodes recording activity in his motor cortex (Hochberg et al., 2006). If everything psychological is also biological—if, for example, every thought is also a neural event—then microelectrodes perhaps could detect thoughts well enough to enable people to control events, as suggested by **FIGURE 12.4** on the next page.

Sensory Functions

If the motor cortex sends messages out to the body, where does the cortex receive the incoming messages? Wilder Penfield also identified the cortical area that specializes in receiving information from the skin senses and from the movement of body parts. This area at the front of the parietal lobes, parallel to and just behind the motor cortex, we now call the **somatosensory cortex** (Figure 12.2). Stimulate a point on the top of this band of tissue and a person may report being touched on the shoulder; stimulate some point on the side and the person may feel something on the face.

The more sensitive the body region, the larger the somatosensory cortex area devoted to it (Figure 12.2). Your supersensitive lips project to a larger brain area than do your toes, which is one reason we kiss with our lips rather than touch toes. Rats have a large area of the brain devoted to their whisker sensations, and owls to their hearing sensations.

Scientists have identified additional areas where the cortex receives input from senses other than touch. At this moment, you are receiving visual information in the visual cortex in your occipital lobes, at the very back of your brain (**FIGURES 12.5** and **12.6** on the next page). A bad enough bash there would make you blind. Stimulated there, you might see flashes of light or dashes of color. (In a sense, we *do* have eyes in the back of our head!) From your occipital lobes, visual information goes to other areas that specialize in tasks such as identifying words, detecting emotions, and recognizing faces.

Any sound you now hear is processed by your auditory cortex in your temporal lobes (just above your ears; see Figure 12.6). Most of this auditory information travels

somatosensory cortex area at the front of the parietal lobes that registers and processes body touch and movement sensations.

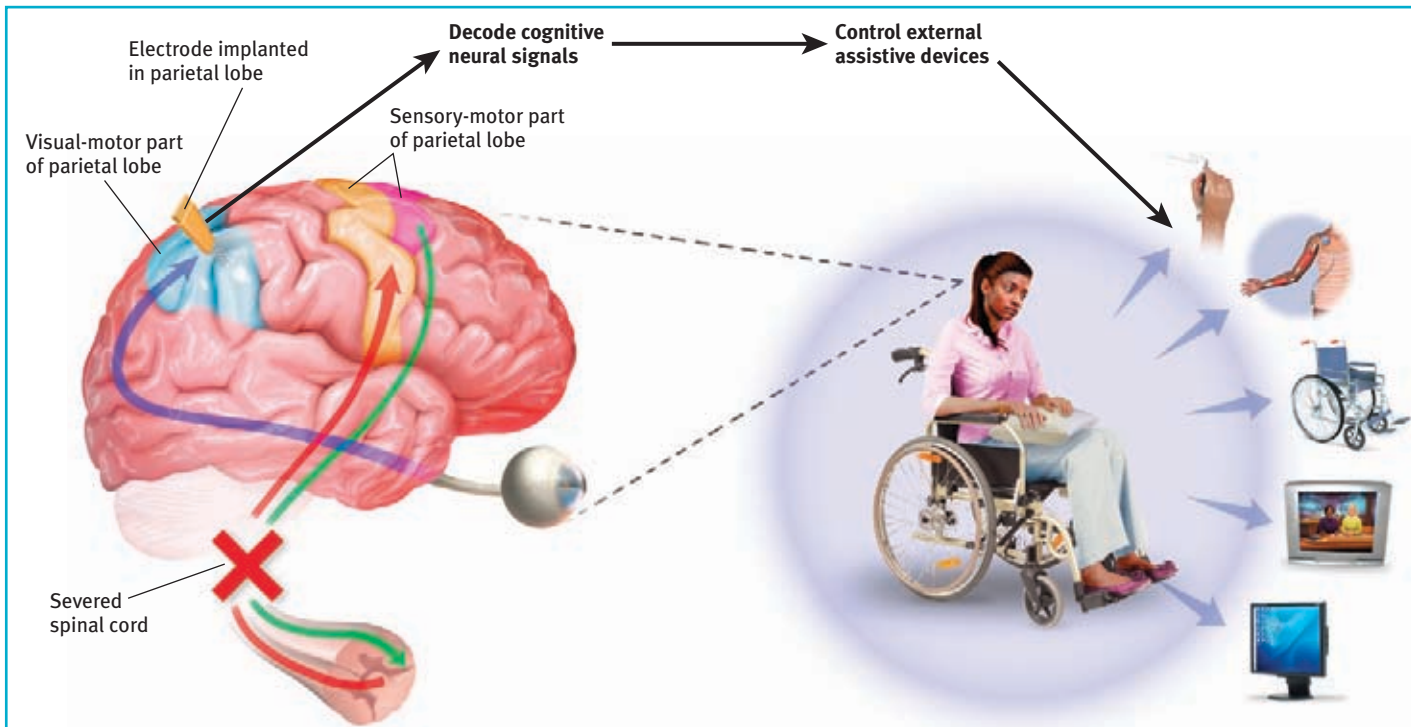

Figure 12.4

Brain-computer interaction A patient with a severed spinal cord has electrodes planted in a parietal lobe region involved with planning to reach out one's arm. The resulting signal can enable the patient to move a robotic limb, stimulate muscles that activate a paralyzed limb, navigate a wheelchair, control a TV, and use the Internet. (Graphic adapted from Andersen et al., 2010.)

a circuitous route from one ear to the auditory receiving area above your opposite ear. If stimulated there, you might hear a sound. MRI scans of people with schizophrenia reveal active auditory areas in the temporal lobes during auditory hallucinations (Lennox et al., 1999). Even the phantom ringing sound experienced by people with hearing loss is—if heard in one ear—associated with activity in the temporal lobe on the brain's opposite side (Muhlneckel, 1998).

Figure 12.5

The brain in action This fMRI (functional MRI) scan shows the visual cortex in the occipital lobes activated (color representation of increased bloodflow) as a research participant looks at a photo. When the person stops looking, the region instantly calms down.

Figure 12.6

The visual cortex and auditory cortex The visual cortex of the occipital lobes at the rear of your brain receives input from your eyes. The auditory cortex, in your temporal lobes—above your ears—receives information from your ears.

Association Areas

So far, we have pointed out small cortical areas that either receive sensory input or direct muscular output. Together, these occupy about one-fourth of the human brain's thin, wrinkled cover. What, then, goes on in the vast regions of the cortex? In these **association areas** (the peach-colored areas in **FIGURE 12.7**), neurons are busy with higher mental functions—many of the tasks that make us human.

Electrically probing an association area won't trigger any observable response. So, unlike the sensory and motor areas, association area functions cannot be neatly mapped. Their silence has led to what Donald McBurney (1996, p. 44) has called "one of the hardest weeds in the garden of psychology": the claim that we ordinarily use only 10 percent of our brains. (If true, wouldn't this imply a 90 percent chance that a bullet to your brain would land in an unused area?) Surgically lesioned animals and brain-damaged humans bear witness that association areas are not dormant. Rather, these areas interpret, integrate, and act on sensory information and link it with stored memories—a very important part of thinking.

Association areas are found in all four lobes. The *prefrontal cortex* in the forward part of the frontal lobes enables judgment, planning, and processing of new memories. People with damaged frontal lobes may have intact memories, high scores on intelligence tests, and great cake-baking skills. Yet they would not be able to plan ahead to *begin* baking a cake for a birthday party (Huey et al., 2006).

association areas areas of the cerebral cortex that are not involved in primary motor or sensory functions; rather, they are involved in higher mental functions such as learning, remembering, thinking, and speaking.

Figure 12.7

Areas of the cortex in four mammals

More intelligent animals have increased "uncommitted" or association areas of the cortex. These vast areas of the brain are responsible for interpreting, integrating, and acting on sensory information and linking it with stored memories.

Frontal lobe damage also can alter personality and remove a person's inhibitions. Consider the classic case of railroad worker Phineas Gage. One afternoon in 1848, Gage, then 25 years old, was packing gunpowder into a rock with a tamping iron. A spark ignited the gunpowder, shooting the rod up through his left cheek and out the top of his skull, leaving his frontal lobes massively damaged (**FIGURE 12.8** on the next page). To everyone's amazement, he was immediately able to sit up and speak, and after the wound healed he returned to work. But the affable, soft-spoken man was now irritable, profane, and dishonest. This person, said his friends, was "no longer Gage." Although his mental abilities and memories were intact, his personality was not. (Although Gage lost his job, he did, over time, adapt to his injury and find work as a stagecoach driver [Macmillan & Lena, 2010].)

More recent studies of people with damaged frontal lobes have revealed similar impairments. Not only may they become less inhibited (without the frontal lobe brakes on their impulses), but their moral judgments may seem unrestrained by normal emotions. Would you advocate pushing someone in front of a runaway boxcar to save five others? Most people do not, but those with damage to a brain area behind the eyes often do (Koenigs et al., 2007). With their frontal lobes ruptured, people's moral compass seems to disconnect from their behavior.

Figure 12.8**A blast from the past**

(a) Gage's skull was kept as a medical record. Using measurements and modern neuroimaging techniques, researchers have reconstructed the probable path of the rod through Gage's brain (Damasio et al., 1994). (b) This recently discovered photo shows Gage after his accident. The image has been reversed to show the features correctly. (Early photos, such as this one, were actually mirror images.)

(b)

Association areas also perform other mental functions. In the parietal lobes, parts of which were large and unusually shaped in Einstein's normal-weight brain, they enable mathematical and spatial reasoning (Witelson et al., 1999). In patients undergoing brain surgery, stimulation of one parietal lobe area produced a feeling of wanting to move an upper limb, the lips, or the tongue (but without any actual movement). With increased stimulation, patients falsely believed they actually had moved. Curiously, when surgeons stimulated a different association area near the motor cortex in the frontal lobes, the patients did move but had no awareness of doing so (Desmurget et al., 2009). These head-scratching findings suggest that our perception of moving flows not from the movement itself, but rather from our intention and the results we expected.

Yet another association area, on the underside of the right temporal lobe, enables us to recognize faces. If a stroke or head injury destroyed this area of your brain, you would still be able to describe facial features and to recognize someone's gender and approximate age, yet be strangely unable to identify the person as, say, Lady Gaga, or even your grandmother.

Nevertheless, we should be wary of using pictures of brain "hot spots" to create a new phrenology that locates complex functions in precise brain areas (Uttal, 2001). Complex mental functions don't reside in any one place. There is no one spot in a rat's small association cortex that, when damaged, will obliterate its ability to learn or remember a maze.

Similarly, the acquisition, development, and use of language depends on both specialized neural networks and their integration. Nineteenth-century research by French physician Paul Broca and German investigator Carl Wernicke led to the discovery of specialized language brain areas. Damage to *Broca's area* disrupts speaking, while damage to *Wernicke's area* disrupts understanding. Today's neuroscience has shown that language functions are distributed across other brain areas as well.

Memory, language, and attention result from the synchronized activity among distinct brain areas (Knight, 2007). Ditto for religious experience. Reports of more than 40 distinct brain regions becoming active in different religious states, such as praying and meditating, indicate that there is no simple "God spot" (Fingelkurts & Fingelkurts, 2009). The big lesson: *Our mental experiences arise from coordinated brain activity.*

FYI

For information on how distinct neural networks in your brain coordinate to enable language, see Module 36.

The Brain's Plasticity

12-2

To what extent can a damaged brain reorganize itself, and what is neurogenesis?

Our brains are sculpted not only by our genes but also by our experiences. MRI scans show that well-practiced pianists have a larger-than-usual auditory cortex area that encodes piano sounds (Bavelier et al., 2000; Pantev et al., 1998). In Unit IX, we'll focus more on how

experience molds the brain. For now, let's turn to another aspect of the brain's **plasticity**: its ability to modify itself after damage.

Some of the effects of brain damage described earlier can be traced to two hard facts: (1) Severed neurons, unlike cut skin, usually do not regenerate. (If your spinal cord were severed, you would probably be permanently paralyzed.) And (2) some brain functions seem preassigned to specific areas. One newborn who suffered damage to temporal lobe facial recognition areas later remained unable to recognize faces (Farah et al., 2000). But there is good news: Some of the brain's neural tissue can *reorganize* in response to damage. Under the surface of our awareness, the brain is constantly changing, building new pathways as it adjusts to little mishaps and new experiences.

Plasticity may also occur after serious damage, especially in young children (Kolb, 1989; see also **FIGURE 12.9**). Constraint-induced therapy aims to rewire brains and improve the dexterity of a brain-damaged child or even an adult stroke victim (Taub, 2004). By restraining a fully functioning limb, therapists force patients to use the "bad" hand or leg, gradually reprogramming the brain. One stroke victim, a surgeon in his fifties, was put to work cleaning tables, with his good arm and hand restrained. Slowly, the bad arm recovered its skills. As damaged-brain functions migrated to other brain regions, he gradually learned to write again and even to play tennis (Doidge, 2007).

The brain's plasticity is good news for those who are blind or deaf. Blindness or deafness makes unused brain areas available for other uses (Amedi et al., 2005). If a blind person uses one finger to read Braille, the brain area dedicated to that finger expands as the sense of touch invades the visual cortex that normally helps people see (Barinaga, 1992a; Sadato et al., 1996). Plasticity also helps explain why some studies find that deaf people have enhanced peripheral vision (Bosworth & Dobkins, 1999). In those people whose native language is sign, the temporal lobe area normally dedicated to hearing waits in vain for stimulation. Finally, it looks for other signals to process, such as those from the visual system.

Similar reassignment may occur when disease or damage frees up other brain areas normally dedicated to specific functions. If a slow-growing left hemisphere tumor disrupts language (which resides mostly in the left hemisphere), the right hemisphere may compensate (Thiel et al., 2006). If a finger is amputated, the somatosensory cortex that received its input will begin to receive input from the adjacent fingers, which then become more sensitive (Fox, 1984).

Although the brain often attempts self-repair by reorganizing existing tissue, it sometimes attempts to mend itself by producing new brain cells. This process, known as

plasticity the brain's ability to change, especially during childhood, by reorganizing after damage or by building new pathways based on experience.

Figure 12.9

Brain plasticity Although the brains of young children show the greatest ability to reorganize and adapt to damage, adult brains also have some capacity for self-repair. Former Arizona Congresswoman Gabrielle Giffords lost her ability to speak after suffering a left-hemisphere gunshot wound. Her medical care included music therapy, where she worked on forming words to familiar songs such as "Happy Birthday." Giffords has since partly recovered her speaking ability. Two years after the shooting, she was able to speak as a surprise witness at a 2013 U.S. Senate hearing on gun legislation.

neurogenesis the formation of new neurons.

neurogenesis, has been found in adult mice, birds, monkeys, and humans (Jessberger et al., 2008). These baby neurons originate deep in the brain and may then migrate elsewhere and form connections with neighboring neurons (Aimone et al., 2010; Gould, 2007).

Master stem cells that can develop into any type of brain cell have also been discovered in the human embryo. If mass-produced in a lab and injected into a damaged brain, might neural stem cells turn themselves into replacements for lost brain cells? Might we someday be able to rebuild damaged brains, much as we reseed damaged lawns? Might new drugs spur the production of new nerve cells? Stay tuned. Today's biotech companies are hard at work on such possibilities. In the meantime, we can all benefit from other natural promoters of neurogenesis, such as exercise, sleep, and nonstressful but stimulating environments (Iso et al., 2007; Pereira et al., 2007; Stranahan et al., 2006).

Before You Move On

▶ ASK YOURSELF

Has what you have learned about how our brains enable our minds affected your view of human nature?

▶ TEST YOURSELF

Try moving your right hand in a circular motion, as if polishing a table. Then start your right foot doing the same motion, synchronized with your hand. Now reverse the right foot's motion, but not the hand's. Finally, try moving the *left* foot opposite to the right hand.

1. Why is reversing the right foot's motion so hard?
2. Why is it easier to move the left foot opposite to the right hand?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 12 Review

12-1

What are the functions of the various cerebral cortex regions?

- The *cerebral cortex* has two hemispheres, and each hemisphere has four lobes: the *frontal*, *parietal*, *occipital*, and *temporal*. Each lobe performs many functions and interacts with other areas of the cortex.
- *Glial cells* support, nourish, and protect neurons and may also play a role in learning and thinking.
- The *motor cortex*, at the rear of the frontal lobes, controls voluntary movements.
- The *somatosensory cortex*, at the front of the parietal lobes, registers and processes body touch and movement sensations.
- Body parts requiring precise control or those that are especially sensitive occupy the greatest amount of space in the motor cortex and somatosensory cortex, respectively.

- Most of the brain's cortex—the major portion of each of the four lobes—is devoted to uncommitted *association areas*, which integrate information involved in learning, remembering, thinking, and other higher-level functions.
- Our mental experiences arise from coordinated brain activity.

12-2

To what extent can a damaged brain reorganize itself, and what is neurogenesis?

- If one hemisphere is damaged early in life, the other will pick up many of its functions by reorganizing or building new pathways. This *plasticity* diminishes later in life.
- The brain sometimes mends itself by forming new neurons, a process known as *neurogenesis*.

Multiple-Choice Questions

1. Damage to which of the following could interfere with the ability to plan for the future?
 - a. Frontal lobe
 - b. Temporal lobe
 - c. Parietal lobe
 - d. Occipital lobe
 - e. Somatosensory cortex
2. In general, damage to _____ disrupts speaking, while damage to _____ disrupts understanding of language.
 - a. the frontal lobe; the occipital lobe
 - b. the temporal lobe; the frontal lobe
 - c. the occipital lobe; the temporal lobe
 - d. Wernicke's area; Broca's area
 - e. Broca's area; Wernicke's area
3. Stimulation at a point on which of the following may cause a person to report being touched on the knee?
 - a. Motor cortex
 - b. Cerebellum
 - c. Somatosensory cortex
 - d. Temporal lobe
 - e. Thalamus
4. George can move his hand to sign a document because the _____, located in the _____ lobe of the brain, allows him to activate the proper muscles.
 - a. somatosensory cortex; temporal
 - b. somatosensory cortex; parietal
 - c. motor cortex; parietal
 - d. somatosensory cortex; frontal
 - e. motor cortex; frontal
5. The most noticeable difference between human brains and other mammalian brains is the size of the
 - a. association areas.
 - b. frontal lobe.
 - c. glial cells.
 - d. reticular activating system.
 - e. visual cortex.
6. Cognitive neural prosthetics are placed in the brain to help control parts of the
 - a. motor cortex.
 - b. auditory cortex.
 - c. somatosensory cortex.
 - d. visual cortex.
 - e. parietal lobe.

Practice FRQs

1. Doctors sometimes have to remove a portion of the brain to control life-threatening seizures. Describe what the results of the removal of a portion of the motor cortex would be and explain how this procedure might be affected by brain plasticity.
2. Anthony attends a high school band concert. First, identify and explain which two lobes of his brain are most important for watching and listening to the concert. Second, explain which lobe of the brain is most responsible for analyzing the music and finding personal meaning.

Answer

1 point: Removing part of the motor cortex will result in paralysis in the parts of the body associated with the removed tissue.

1 point: Because of brain plasticity, the person's brain may be able to change and reorganize new pathways based on experience. This is more likely if the person is a child.

(3 points)

Module 13

Brain Hemisphere Organization and the Biology of Consciousness

Module Learning Objectives

- 13-1** Explain how split-brain research helps us understand the functions of our two brain hemispheres.
- 13-2** Explain what is meant by “dual processing,” as revealed by today’s cognitive neuroscience.

Monica Murphy/Getty Images

Our Divided Brain

- 13-1** What do split brains reveal about the functions of our two brain hemispheres?

Our brain’s look-alike left and right hemispheres serve differing functions. This *lateralization* is apparent after brain damage. Research collected over more than a century has shown that accidents, strokes, and tumors in the left hemisphere can impair reading, writing, speaking, arithmetic reasoning, and understanding. Similar lesions in the right hemisphere have effects that are less visibly dramatic.

Does this mean that the right hemisphere is just along for the ride—a silent, “subordinate” or “minor” hemisphere? Many believed this was the case until 1960, when researchers found that the “minor” right hemisphere was not so limited after all. The story of this discovery is a fascinating episode in psychology’s history.

Splitting the Brain

In 1961, two Los Angeles neurosurgeons, Philip Vogel and Joseph Bogen, speculated that major epileptic seizures were caused by an amplification of abnormal brain activity bouncing back and forth between the two cerebral hemispheres. If so, they wondered, could they put an end to this biological tennis game by severing the **corpus callosum** (see **FIGURE 13.1**)? This wide band of axon fibers connects the two hemispheres and carries messages between them. Vogel and Bogen knew that psychologists Roger Sperry, Ronald Myers, and Michael Gazzaniga had divided the brains of cats and monkeys in this manner, with no serious ill effects.

So the surgeons operated. The result? The seizures all but disappeared. The patients with these **split brains** were surprisingly normal, their personality and intellect hardly affected. Waking from surgery, one even joked that he had a “splitting headache” (Gazzaniga, 1967). By sharing their experiences, these patients have greatly expanded our understanding of interactions between the intact brain’s two hemispheres.

corpus callosum [KOR-pus kah-LOW-sum] the large band of neural fibers connecting the two brain hemispheres and carrying messages between them.

split brain a condition resulting from surgery that isolates the brain’s two hemispheres by cutting the fibers (mainly those of the corpus callosum) connecting them.

Martin M. Rotker/Science Source

Figure 13.1

The corpus callosum This large band of neural fibers connects the two brain hemispheres. To photograph this half brain, a surgeon separated the hemispheres by cutting through the corpus callosum and lower brain regions.

AP® Exam Tip

The classic split-brain studies are famous in psychology, which means they are likely to show up on the AP® exam.

To appreciate these findings, we need to focus for a minute on the peculiar nature of our visual wiring. As **FIGURE 13.2** illustrates, information from the left half of your field of vision goes to your right hemisphere, and information from the right half of your visual field goes to your left hemisphere, which usually controls speech. (Note, however, that each eye receives sensory information from both the right and left visual fields.) Data received by either hemisphere are quickly transmitted to the other across the corpus callosum. In a person with a severed corpus callosum, this information-sharing does not take place.

Knowing these facts, Sperry and Gazzaniga could send information to a patient's left or right hemisphere. As the person stared at a spot, they flashed a stimulus to its right or left. They could do this with you, too, but in your intact brain, the hemisphere receiving the information would instantly pass the news to the other side. Because the split-brain surgery had cut the communication lines between the hemispheres, the researchers could, with these patients, quiz each hemisphere separately.

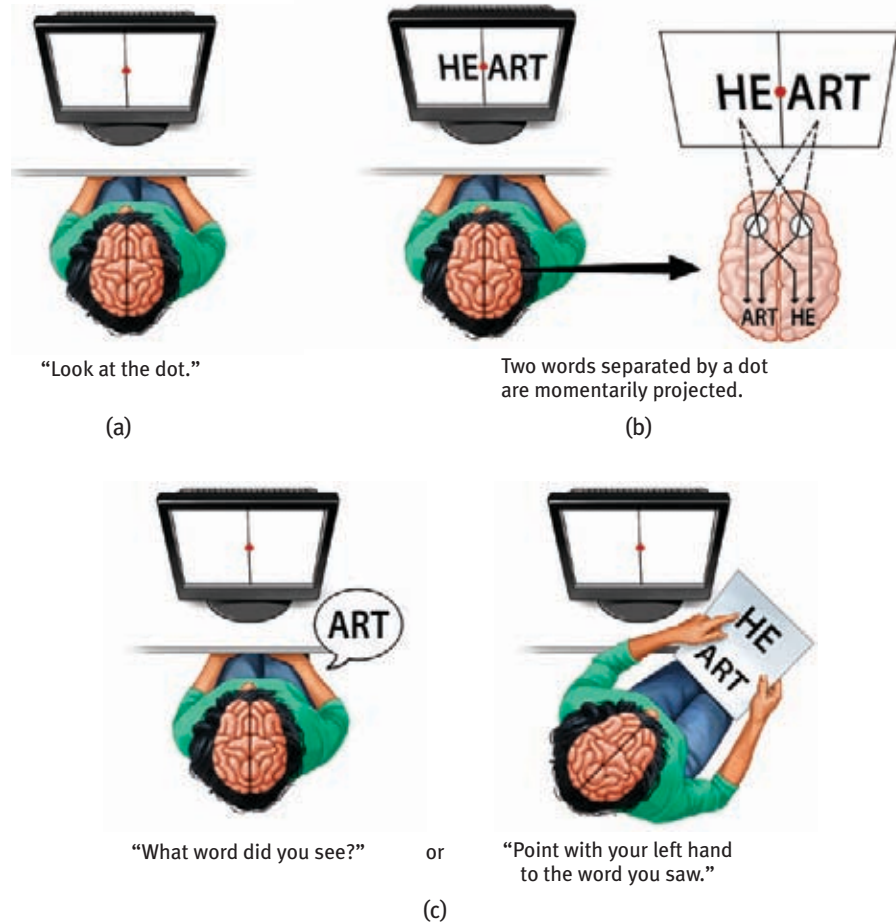

In an early experiment, Gazzaniga (1967) asked these people to stare at a dot as he flashed HE·ART on a screen (**FIGURE 13.3** on the next page). Thus, HE appeared in their left visual field (which transmits to the right hemisphere) and ART in the right field (which transmits to the left hemisphere). When he then asked them to *say* what they had seen, the patients reported that they had seen ART. But when asked to *point* to the word they had seen, they were startled when their left hand (controlled by the right hemisphere) pointed to HE. Given an opportunity to express itself, each hemisphere reported what it had seen. The right hemisphere (controlling the left hand) intuitively knew what it could not verbally report.

**Figure 13.2**

The information highway from eye to brain

Figure 13.3

Testing the divided brain When an experimenter flashes the word HEART across the visual field, a woman with a split brain reports seeing the portion of the word transmitted to her left hemisphere. However, if asked to indicate with her left hand what she saw, she points to the portion of the word transmitted to her right hemisphere. (From Gazzaniga, 1983.)

"Do not let your left hand know what your right hand is doing."
-MATTHEW 6:3

When a picture of a spoon was flashed to their right hemisphere, the patients could not *say* what they had viewed. But when asked to *identify* what they had viewed by feeling an assortment of hidden objects with their left hand, they readily selected the spoon. If the experimenter said, "Correct!" the patient might reply, "What? Correct? How could I possibly pick out the correct object when I don't know what I saw?" It is, of course, the left hemisphere doing the talking here, bewildered by what the nonverbal right hemisphere knows.

A few people who have had split-brain surgery have been for a time bothered by the unruly independence of their left hand, which might unbutton a shirt while the right hand buttoned it, or put grocery store items back on the shelf after the right hand put them in the

cart. It was as if each hemisphere was thinking "I've half a mind to wear my green (blue) shirt today." Indeed, said Sperry (1964), split-brain surgery leaves people "with two separate minds." With a split brain, both hemispheres can comprehend and follow an instruction to copy—*simultaneously*—different figures with the left and right hands (Franz et al., 2000; see also **FIGURE 13.4**). (Reading these reports, I fantasize a patient enjoying a solitary game of "rock, paper, scissors"—left versus right hand.)

Figure 13.4

Try this! A person who has undergone split-brain surgery can simultaneously draw two different shapes.

When the “two minds” are at odds, the left hemisphere does mental gymnastics to rationalize reactions it does not understand. If a patient follows an order sent to the right hemisphere (“Walk”), a strange thing happens. Unaware of the order, the left hemisphere doesn’t know why the patient begins walking. Yet, when asked why, the patient doesn’t say “I don’t know.” Instead, the interpretive left hemisphere improvises—“I’m going into the house to get a Coke.” Gazzaniga (1988), who considers these patients “the most fascinating people on earth,” concluded that the conscious left hemisphere is an “interpreter” or press agent that instantly constructs theories to explain our behavior.

Right-Left Differences in the Intact Brain

So, what about the 99.99+ percent of us with undivided brains? Does each of *our* hemispheres also perform distinct functions? Several different types of studies indicate they do. When a person performs a *perceptual* task, for example, brain waves, bloodflow, and glucose consumption reveal increased activity in the *right* hemisphere. When the person speaks or calculates, activity increases in the *left* hemisphere.

A dramatic demonstration of hemispheric specialization happens before some types of brain surgery. To locate the patient’s language centers, the surgeon injects a sedative into the neck artery feeding blood to the left hemisphere, which usually controls speech. Before the injection, the patient is lying down, arms in the air, chatting with the doctor. Can you predict what probably happens when the drug puts the left hemisphere to sleep? Within seconds, the person’s right arm falls limp. If the left hemisphere is controlling language, the patient will be speechless until the drug wears off. If the drug is injected into the artery to the right hemisphere, the *left* arm will fall limp, but the person will still be able to speak.

To the brain, language is language, whether spoken or signed. Just as hearing people usually use the left hemisphere to process speech, deaf people use the left hemisphere to process sign language (Corina et al., 1992; Hickok et al., 2001). Thus, a left-hemisphere stroke disrupts a deaf person’s signing, much as it would disrupt a hearing person’s speaking. The same brain area is involved in both (Corina, 1998). (For more on how the brain enables language, see Module 36.)

Although the left hemisphere is adept at making quick, literal interpretations of language, the right hemisphere

- *excels in making inferences* (Beeman & Chiarello, 1998; Bowden & Beeman, 1998; Mason & Just, 2004). Primed with the flashed word *foot*, the left hemisphere will be especially quick to recognize the closely associated word *heel*. But if primed with *foot*, *cry*, and *glass*, the right hemisphere will more quickly recognize another word distantly related to all three (*cut*). And if given an insight-like problem—“What word goes with *boot*, *summer*, and *ground*?”—the right hemisphere more quickly than the left recognizes the solution: *camp*. As one patient explained after a right-hemisphere stroke, “I understand words, but I’m missing the subtleties.”
- *helps us modulate our speech* to make meaning clear—as when we ask “What’s that in the road ahead?” instead of “What’s that in the road, a head?” (Heller, 1990).
- *helps orchestrate our sense of self*. People who suffer partial paralysis will sometimes obstinately deny their impairment—strangely claiming they can move a paralyzed limb—if the damage is to the right hemisphere (Berti et al., 2005).

Simply looking at the two hemispheres, so alike to the naked eye, who would suppose they contribute uniquely to the harmony of the whole? Yet a variety of observations—of people with split brains, of people with normal brains, and even of other species’ brains—converge beautifully, leaving little doubt that we have unified brains with specialized parts (Hopkins & Cantalupo, 2008; MacNeilage et al., 2009; and see Close-up: Handedness on the next page).

AP® Exam Tip

Notice that David Myers never refers to your left brain or your right brain. You have two brain hemispheres, each with its own responsibilities, *but you only have one brain*. It’s very misleading when the media refers to the left brain and the right brain, and this happens frequently.

Close-up

Handedness

Nearly 90 percent of us are primarily right-handed (Leask & Beaton, 2007; Medland et al., 2004; Peters et al., 2006). Some 10 percent of us (somewhat more among males, somewhat less among females) are left-handed. (A few people write with their right hand and throw a ball with their left, or vice versa.) Almost all right-handers (96 percent) process speech primarily in the left hemisphere, which tends to be the slightly larger hemisphere (Hopkins, 2006). Left-handers are more diverse. Seven in ten process speech in the left hemisphere, as right-handers do. The rest either process language in the right hemisphere or use both hemispheres.

IS HANDEDNESS INHERITED?

Judging from prehistoric human cave drawings, tools, and hand and arm bones, this veer to the right occurred long ago (Corballis, 1989; MacNeilage et al., 2009). Right-handedness prevails in all human cultures, and even in monkeys and apes. Moreover, it appears prior to culture's impact: More than 9 in 10 fetuses suck the right hand's thumb (Hepper et al., 1990, 2004). Twin studies indicate only a small genetic influence on individual handedness (Vuoksimaa et al., 2009). But the universal prevalence of right-handers in humans and other primates suggests that either genes or some prenatal factors influence handedness.

Most people also kick with their right foot, look through a microscope with their right eye, and (had you noticed?) kiss the right way—with their head tilted right (Güntürkün, 2003).

SO, IS IT ALL RIGHT TO BE LEFT-HANDED?

Judging by our everyday conversation, left-handedness is not all right. To be “coming out of left field” is hardly better than to be “gauche” (derived from the French word for “left”). On the other hand, right-handedness is “right on,” which any “righteous,” “right-hand man” “in his right mind” usually is.

Left-handers are more numerous than usual among those with reading disabilities, allergies, and migraine headaches (Geschwind & Behan, 1984). But in Iran, where students report which hand they write with when taking the university

Both photos Mike Janes/Four Seam Images via AP Images

The rarest of baseball players: an ambidextrous pitcher

Using a glove with two thumbs, Minor League New York Yankees pitcher Pat Venditte, shown here in 2012, pitches to right-handed batters with his right hand, then switches to face left-handed batters with his left hand. During his college career at Creighton University, after one switch-hitter switched sides of the plate, Venditte switched pitching arms, which triggered the batter to switch again, and so on. The umpires ultimately ended the comedy routine by applying a little-known rule: A pitcher must declare which arm he will use before throwing his first pitch to a batter (Schwarz, 2007).

entrance exam, lefties have outperformed righties in all subjects (Noroozian et al., 2003). Left-handedness is also more common among musicians, mathematicians, professional baseball and cricket players, architects, and artists, including such luminaries as Michelangelo, Leonardo da Vinci, and Picasso.¹ Although left-handers must tolerate elbow jostling at the dinner table, right-handed desks, and awkward scissors, the pros and cons of being a lefty seem roughly equal.

¹ Strategic factors explain the higher-than-normal percentage of lefties in sports. For example, it helps a soccer team to have left-footed players on the left side of the field (Wood & Aggleton, 1989). In golf, however, no left-hander won the Masters tournament until Canadian Mike Weir did so in 2003.

consciousness our awareness of ourselves and our environment.

The Biology of Consciousness

13-2

What is the “dual processing” being revealed by today’s cognitive neuroscience?

Today’s science explores the biology of **consciousness**. Evolutionary psychologists speculate that consciousness must offer a reproductive advantage (Barash, 2006). Consciousness helps us act in our long-term interests (by considering consequences) rather than merely seeking short-term pleasure and avoiding pain. Consciousness also promotes our survival by anticipating how we seem to others and helping us read their minds: “He looks really angry! I’d better run!”

Such explanations still leave us with the “hard problem”: How do brain cells jabbering to one another create our awareness of the taste of a taco, the idea of infinity, the feeling of fright? Today’s scientists are pursuing answers.

Cognitive Neuroscience

Scientists assume, in the words of neuroscientist Marvin Minsky (1986, p. 287), that “the mind is what the brain does.” We just don’t know *how* it does it. Even with all the world’s chemicals, computer chips, and energy, we still don’t have a clue *how* to make a conscious robot. Yet today’s **cognitive neuroscience**—the interdisciplinary study of the brain activity linked with our mental processes—is taking the first small step by relating specific brain states to conscious experiences.

A stunning demonstration of consciousness appeared in brain scans of a noncommunicative patient—a 23-year-old woman who had been in a car accident and showed no outward signs of conscious awareness (Owen et al., 2006). When researchers asked her to *imagine* playing tennis, fMRI scans revealed brain activity in a brain area that normally controls arm and leg movements (**FIGURE 13.5**). Even in a motionless body, the researchers concluded, the brain—and the mind—may still be active. A follow-up study of 22 other “vegetative” patients revealed 3 more who also showed meaningful brain responses to questions (Monti et al., 2010).

Many cognitive neuroscientists are exploring and mapping the conscious functions of the cortex. Based on your cortical activation patterns, they can now, in limited ways, read your mind (Bor, 2010). They can, for example, tell which of 10 similar objects (hammer, drill, and so forth) you are viewing (Shinkareva et al., 2008).

Despite such advances, much disagreement remains. One view sees conscious experiences as produced by the synchronized activity across the brain (Gaillard et al., 2009; Koch & Greenfield, 2007; Schurger et al., 2010). If a stimulus activates enough brainwide coordinated neural activity—with strong signals in one brain area triggering activity elsewhere—it crosses a threshold for consciousness. A weaker stimulus—perhaps a word flashed too briefly to consciously perceive—may trigger localized visual cortex activity that quickly dies out. A stronger stimulus will engage other brain areas, such as those involved with language, attention, and memory. Such reverberating activity (detected by brain scans) is a telltale sign of conscious awareness. How the synchronized activity produces awareness—how matter makes mind—remains a mystery.

Dual Processing: The Two-Track Mind

Many cognitive neuroscience discoveries tell us of a particular brain region (such as the visual cortex mentioned above) that becomes active with a particular conscious experience. Such findings strike many people as interesting but not mind-blowing. (If everything psychological is simultaneously biological, then our ideas, emotions, and spirituality must all, somehow, be embodied.) What *is* mind-blowing to many of us is the growing evidence that we have, so to speak, two minds, each supported by its own neural equipment.

At any moment, you and I are aware of little more than what’s on the screen of our consciousness. But beneath the surface, unconscious information processing occurs simultaneously on many parallel tracks. When we look at a bird flying, we are consciously aware of the result of our cognitive processing (“It’s a hummingbird!”) but not of our subprocessing of the bird’s color, form, movement, and distance. One of the grand ideas of recent cognitive neuroscience is that much of our brain work occurs off stage, out of sight. Perception, memory, thinking, language, and attitudes all operate on two levels—a conscious, deliberate

cognitive neuroscience the interdisciplinary study of the brain activity linked with cognition (including perception, thinking, memory, and language).

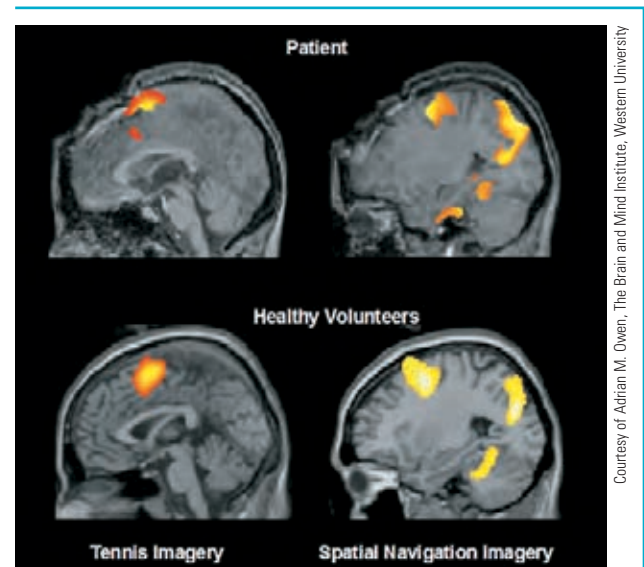

Figure 13.5
Evidence of awareness? When asked to imagine playing tennis or navigating through her home, a vegetative patient’s brain (top) exhibited activity similar to a healthy person’s brain (bottom). Researchers wonder if such fMRI scans might enable a “conversation” with some unresponsive patients, by instructing them, for example, to answer yes to a question by imagining playing tennis and *no* by imagining walking around their home.

AP® Exam Tip

Dual processing is another one of those big ideas that shows up in several units. Pay attention!

dual processing the principle that information is often simultaneously processed on separate conscious and unconscious tracks.

adapted from: Milner, A. D., & Goodale, M.A. (2006). *The Visual Brain in Action*: 2nd Edition/ Oxford: Oxford University Press, 297 pp. (paperback 2006)

Figure 13.6
When the blind can “see” In a compelling demonstration of blindsight and the two-track mind, a researcher trails a blindsight patient down a cluttered hallway. Although told the hallway was empty, the patient meandered around all the obstacles without any awareness of them.

“high road” and an unconscious, automatic “low road.” Today’s researchers call this **dual processing**. We know more than we know we know.

Sometimes science confirms widely held beliefs. Other times, as this next story illustrates, science is stranger than science fiction.

During my sojourns at Scotland’s University of St. Andrews, I came to know cognitive neuroscientists David Milner and Melvyn Goodale (2008). When overcome by carbon monoxide, a local woman, whom they call D. F., suffered brain damage that left her unable to recognize and discriminate objects visually. Consciously she could see nothing. Yet she exhibited *blindsight*—she would act as if she could see. Asked to slip a postcard into a vertical or horizontal mail slot, she could do so without error. Although unable to report the width of a block in front of her, she could grasp it with just the right finger-thumb distance. If you were to experience temporary blindness (with magnetic pulses to your brain’s primary visual cortex area) this, too, would create blindsight—as you correctly guess the color or orientation of an object that you cannot consciously see (Boyer et al., 2005).

How could this be? Don’t we have one visual system? Goodale and Milner knew from animal research that the eye sends information simultaneously to different brain areas, which support different tasks (Weiskrantz, 2009, 2010). Sure enough, a scan of D. F.’s brain activity revealed normal activity in the area concerned with reaching for, grasping, and navigating objects, but damage in the area concerned with consciously recognizing objects. (See another example in **FIGURE 13.6**.)

So, would the reverse damage lead to the opposite symptoms? Indeed, there are a few such patients—who can see and recognize objects but have difficulty pointing toward or grasping them.

How strangely intricate is this thing we call vision, conclude Goodale and Milner in their aptly titled book, *Sight Unseen*. We may think of our vision as one system controlling our visually guided actions, but it is actually a dual-processing system. A *visual perception track* enables us “to think about the world”—to recognize things and to plan future actions. A *visual action track* guides our moment-to-moment movements.

On rare occasions, the two conflict. Shown the *hollow face illusion*, people will mistakenly perceive the inside of a mask as a protruding face (**FIGURE 13.7**). Yet they will unhesitatingly and accurately reach into the inverted mask to flick off a buglike target stuck on the face (Króliczak et al., 2006). What their conscious mind doesn’t know, their hand does.

Figure 13.7

The hollow face illusion We tend to see an illusory protruding face even on an inverted mask (right). Yet research participants will accurately reach for a speck on the face inside the inverted mask, suggesting that our unconscious mind seems to know the truth of the illusion.

David Mack/Science Source

Another patient, who lost all his left visual cortex—leaving him blind to objects presented on the right side of his field of vision—can nevertheless sense the emotion expressed in faces he does not consciously perceive (De Gelder, 2010). The same is true of normally sighted people whose visual cortex has been disabled with magnetic stimulation. This suggests that brain areas below the cortex are processing emotion-related information.

People often have trouble accepting that much of our everyday thinking, feeling, and acting operates outside our conscious awareness (Bargh & Chartrand, 1999). We are understandably biased to believe that our intentions and deliberate choices rule our lives. But consciousness, though enabling us to exert voluntary control and to communicate our mental states to others, is but the tip of the information-processing iceberg. Being intensely focused on an activity (such as reading this module, I'd love to think) increases your total brain activity no more than 5 percent above its baseline rate. And even when you rest, “hubs of dark energy” are whirling inside your head (Raichle, 2010).

Experiments show that when you move your wrist at will, you consciously experience the decision to move it about 0.2 seconds before the actual movement (Libet, 1985, 2004). No surprise there. But your brain waves jump about 0.35 seconds before you consciously perceive your decision to move (**FIGURE 13.8**)! This readiness potential has enabled researchers (using fMRI brain scans) to predict—with 60 percent accuracy and up to 7 seconds ahead—participants' decisions to press a button with their left or right finger (Soon et al., 2008). The startling conclusion: Consciousness sometimes arrives late to the decision-making party.

Running on automatic pilot allows our consciousness—our mind's CEO—to monitor the whole system and deal with new challenges, while neural assistants automatically take care of routine business. Walking the familiar path to your next class, your feet do the work while your mind rehearses the presentation you're about to give. A skilled tennis player's brain and body respond automatically to an oncoming serve before becoming consciously aware of the ball's trajectory (which takes about three-tenths of a second). Ditto for other skilled athletes, for whom action precedes awareness. *The bottom line:* In everyday life, we mostly function like an automatic point-and-shoot camera, but with a manual (conscious) override.

Our unconscious parallel processing is faster than sequential conscious processing, but both are essential. Sequential processing is skilled at solving new problems, which require our focused attention. Try this: If you are right-handed, you can move your right foot in a smooth counterclockwise circle, and you can write the number 3 repeatedly with your right hand—but probably not at the same time. (Try something equally difficult: Tap a steady beat three times with your left hand while tapping four times with your right hand.) Both tasks require conscious attention, which can be in only one place at a time. If time is nature's way of keeping everything from happening at once, then consciousness is nature's way of keeping us from thinking and doing everything at once.

Figure 13.8

Is the brain ahead of the mind?

In this study, volunteers watched a computer clock sweep through a full revolution every 2.56 seconds. They noted the time at which they decided to move their wrist. About one-third of a second before that decision, their brain-wave activity jumped, indicating a *readiness potential* to move. Watching a slow-motion replay, the researchers were able to predict when a person was about to decide to move (following which, the wrist did move) (Libet, 1985, 2004). Other researchers, however, question the clock measurement procedure (Miller et al., 2011).

Before You Move On

▶ ASK YOURSELF

What are some examples of things you do on “automatic pilot”? What behaviors require your conscious attention?

▶ TEST YOURSELF

What are the mind's two tracks, and what is “dual processing”?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 13 Review

13-1 What do split brains reveal about the functions of our two brain hemispheres?

- *Split-brain* research (experiments on people with a severed *corpus callosum*) has confirmed that in most people, the left hemisphere is the more verbal, and that the right hemisphere excels in visual perception and the recognition of emotion.
- Studies of healthy people with intact brains confirm that each hemisphere makes unique contributions to the integrated functioning of the brain.

13-2 What is the “dual processing” being revealed by today’s cognitive neuroscience?

- *Cognitive neuroscientists* and others studying the brain mechanisms underlying consciousness and cognition have discovered that the mind processes information on two separate tracks, one operating at an explicit, conscious level and the other at an implicit, unconscious level. This *dual processing* affects our perception, memory, attitudes, and other cognitions.

Multiple-Choice Questions

1. A split-brain patient has a picture of a dog flashed to his right hemisphere and a cat to his left hemisphere. He will be able to identify the
 - a. cat using his right hand.
 - b. dog using his right hand.
 - c. dog using either hand.
 - d. cat using either hand.
 - e. cat using his left hand.
2. You are aware that a dog is viciously barking at you, but you are not aware of the type of dog. Later, you are able to describe the type and color of the dog. This ability to process information without conscious awareness best exemplifies which of the following?
 - a. Split brain
 - b. Blindsight
 - c. Consciousness
 - d. Cognitive neuroscience
 - e. Dual processing
3. Which of the following is most likely to be a function of the left hemisphere?
 - a. Speech
 - b. Evaluating perceptual tasks
 - c. Making inferences
 - d. Identifying emotion in other people’s faces
 - e. Identifying one’s sense of self
4. The dual-processing model refers to which of the following ideas?
 - a. The right and left hemispheres of the brain both process incoming messages.
 - b. Incoming information is processed by both conscious and unconscious tracks.
 - c. Each lobe of the brain processes incoming information.
 - d. The brain first processes emotional information and then processes analytical information.
 - e. The thalamus and hypothalamus work together to analyze incoming sensory information.

Practice FRQs

1. Brain lateralization means that each hemisphere has its own functions. Give an example of both a left hemisphere and a right hemisphere function. Then explain how the two hemispheres communicate with one another.
2. Because Jerry suffered severe seizures, his neurosurgeon decided to “split his brain.” What does this mean? How might a psychologist use people who have had split-brain surgery to determine the location of speech control?

(3 points)

Answer

1 point: Left hemisphere functions include language, math, and logic.

1 point: Right hemisphere functions include spatial relationships, facial recognition, and patterns.

1 point: The corpus callosum carries information back and forth between the two hemispheres.

Module 14

Behavior Genetics: Predicting Individual Differences

Module Learning Objectives

- 14-1** Define *genes*, and describe how behavior geneticists explain our individual differences.
- 14-2** Identify the potential uses of molecular genetics research.
- 14-3** Explain what is meant by heritability, and discuss how it relates to individuals and groups.
- 14-4** Discuss the interaction of heredity and environment.

Michael Tullberg/Getty Images

Behind the story of our human brain—surely the most awesome thing on Earth—is the essence of our universal human attributes and our individual traits. What makes you *you*? In important ways, we are each unique. We look different. We sound different. We have varying personalities, interests, and cultural and family backgrounds.

We are also the leaves of one tree. Our human family shares not only a common biological heritage—cut us and we bleed—but also common behavioral tendencies. Our shared brain architecture predisposes us to sense the world, develop language, and feel hunger through identical mechanisms. Whether we live in the Arctic or the tropics, we prefer sweet tastes to sour. We divide the color spectrum into similar colors. And we feel drawn to behaviors that produce and protect offspring.

Our kinship appears in our social behaviors as well. Whether named Wong, Nkomo, Smith, or Gonzales, we start fearing strangers at about eight months, and as adults we prefer the company of those with attitudes and attributes similar to our own. Coming from different parts of the globe, we know how to read one another's smiles and frowns. As members of one species, we affiliate, conform, return favors, punish offenses, organize hierarchies of status, and grieve a child's death. A visitor from outer space could drop in anywhere and find humans dancing and feasting, singing and worshipping, playing sports and games, laughing and crying, living in families and forming groups. Taken together, such universal behaviors define our human nature.

What causes our striking diversity, and also our shared human nature? How much are human differences shaped by our differing genes? And how much by our *environment*—by every external influence, from maternal nutrition while in the womb to social support while nearing the tomb? To what extent are we formed by our upbringing? By our culture? By our current circumstances? By people's reactions to our genetic dispositions? This module and the next begin to tell the complex story of how our genes (nature) and environments (nurture) define us.

Courtesy of Kevin Feyen

The nurture of nature Parents everywhere wonder: Will my baby grow up to be peaceful or aggressive? Homely or attractive? Successful or struggling at every step? What comes built in, and what is nurtured—and how? Research reveals that nature and nurture together shape our development—every step of the way.

behavior genetics the study of the relative power and limits of genetic and environmental influences on behavior.

environment every external influence, from prenatal nutrition to the people and things around us.

chromosomes threadlike structures made of DNA molecules that contain the genes.

DNA (deoxyribonucleic acid) a complex molecule containing the genetic information that makes up the chromosomes.

genes the biochemical units of heredity that make up the chromosomes; segments of DNA capable of synthesizing proteins.

genome the complete instructions for making an organism, consisting of all the genetic material in that organism's chromosomes.

"Your DNA and mine are 99.9 percent the same. . . . At the DNA level, we are clearly all part of one big worldwide family." -FRANCIS COLLINS, HUMAN GENOME PROJECT DIRECTOR, 2007

Genes: Our Codes for Life

14-1

What are genes, and how do behavior geneticists explain our individual differences?

If Jaden Agassi, son of tennis stars Andre Agassi and Steffi Graf, grows up to be a tennis star, should we attribute his superior talent to his Grand Slam genes? To his growing up in a tennis-rich environment? To high expectations? Such questions intrigue **behavior geneticists**, who study our differences and weigh the effects and interplay of heredity and **environment**.

Barely more than a century ago, few would have guessed that every cell nucleus in your body contains the genetic master code for your entire body. It's as if every room in Dubai's Burj Khalifa (the world's tallest building) had a book containing the architect's plans for the entire structure. The plans for your own book of life run to 46 chapters—23 donated by your mother's egg and 23 by your father's sperm. Each of these 46 chapters, called a **chromosome**, is composed of a coiled chain of the molecule **DNA (deoxyribonucleic acid)**. **Genes**, small segments of the giant DNA molecules, form the words of those chapters (**FIGURE 14.1**). All told, you have 20,000 to 25,000 genes. Genes can be either active (*expressed*) or inactive. Environmental events "turn on" genes, rather like hot water enabling a tea bag to express its flavor. When turned on, genes provide the code for creating *protein molecules*, our body's building blocks.

Genetically speaking, every other human is nearly your identical twin. Human **genome** researchers have discovered the common sequence within human DNA. It is this shared genetic profile that makes us humans, rather than chimpanzees or tulips.

Actually, we aren't all that different from our chimpanzee cousins; with them we share about 96 percent of our DNA sequence (Mikkelsen et al., 2005). At "functionally important" DNA sites, reported one molecular genetics team, the human-chimpanzee DNA similarity is 99.4 percent (Wildman et al., 2003). Yet that wee difference matters. Despite

Figure 14.1

The human building blocks The nucleus of every human cell contains chromosomes, each of which is made up of two strands of DNA connected in a double helix.

"Thanks for almost everything, Dad."

some remarkable abilities, chimpanzees grunt. Shakespeare intricately wove 17,677 words to form his literary masterpieces.

Small differences matter among chimpanzees, too. Two species, common chimpanzees and bonobos, differ by much less than 1 percent of their genomes, yet they display markedly differing behaviors. Chimpanzees are aggressive and male dominated. Bonobos are peaceable and female led.

Geneticists and psychologists are interested in the occasional variations found at particular gene sites in human DNA. Slight person-to-person variations from the common pattern give clues to our uniqueness—why one person has a disease that another does not, why one person is short and another tall, why one is outgoing and another shy.

Most of our traits are influenced by many genes. How tall you are, for example, reflects the size of your face, vertebrae, leg bones, and so forth—each of which may be influenced by different genes interacting with your environment. Complex traits such as intelligence, happiness, and aggressiveness are similarly influenced by groups of genes. Thus our genetic predispositions—our genetically influenced traits—help explain both our shared human nature and our human diversity.

“We share half our genes with the banana.” -EVOLUTIONARY BIOLOGIST ROBERT MAY, PRESIDENT OF BRITAIN’S ROYAL SOCIETY, 2001

Twin and Adoption Studies

To scientifically tease apart the influences of environment and heredity, behavior geneticists would need to design two types of experiments. The first would control the home environment while varying heredity. The second would control heredity while varying the home environment. Such experiments with human infants would be unethical, but happily for our purposes, nature has done this work for us.

Identical Versus Fraternal Twins

Identical (*monozygotic*) twins develop from a single fertilized egg that splits in two. Thus they are *genetically* identical—nature’s own human clones (**FIGURE 14.2**). Indeed, they are clones who share not only the same genes but the same conception and uterus, and usually the same birth date and cultural history. Two slight qualifications:

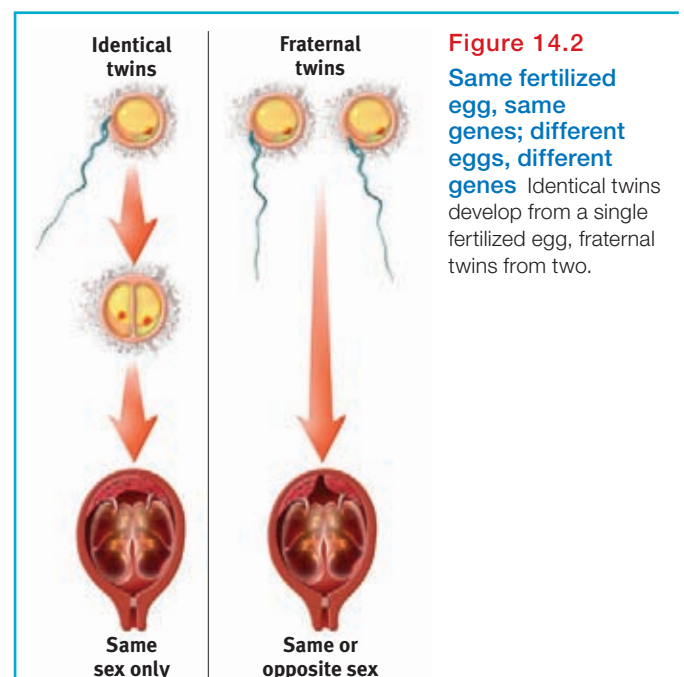

- Although identical twins have the same genes, they don’t always have the same *number of copies* of those genes. That helps explain why one twin may be more at risk for certain illnesses (Bruder et al., 2008).
- Most identical twins share a placenta during prenatal development, but one of every three sets has two separate placentas. One twin’s placenta may provide slightly better nourishment, which may contribute to identical twin differences (Davis et al., 1995; Phelps et al., 1997; Sokol et al., 1995).

Fraternal (*dizygotic*) twins develop from separate fertilized eggs. As womb-mates, they share a fetal environment, but they are genetically no more similar than ordinary brothers and sisters.

Shared genes can translate into shared experiences. A person whose identical twin has Alzheimer’s disease, for example, has a 60 percent risk of getting the disease; if the affected twin is fraternal, the risk is 30 percent (Plomin et al., 1997). To study the effects of genes and environments, hundreds of researchers have studied some 800,000 identical and fraternal twin pairs (Johnson et al., 2009).

identical twins (*monozygotic twins*) twins who develop from a single fertilized egg that splits in two, creating two genetically identical organisms.

fraternal twins (*dizygotic twins*) twins who develop from separate fertilized eggs. They are genetically no closer than brothers and sisters, but they share a fetal environment.

Belinda Images/SuperStock

More twins Curiously, twinning rates vary by race. The rate among Caucasians is roughly twice that of Asians and half that of Africans. In Africa and Asia, most twins are identical. In Western countries, most twins are fraternal, and fraternal twins are increasing with the use of fertility drugs (Hall, 2003; Steinhauer, 1999).

Are identical twins, being genetic clones of each other, also behaviorally more similar than fraternal twins? Studies of thousands of twin pairs in Sweden, Finland, and Australia find that on both extraversion (outgoingness) and neuroticism (emotional instability), identical twins are much more similar than fraternal twins. If genes influence traits such as emotional instability, might they also influence the social effects of such traits? To find out, researchers studied divorce rates among 1500 same-sex, middle-aged twin pairs (McGue & Lykken, 1992). Their result: If you have a fraternal twin who has divorced, the odds of your divorcing are 1.6 times greater than if you have a not-divorced twin. If you have an identical twin who has divorced, the odds of your divorcing are 5.5 times greater. From such data, the researchers estimate that people's differing divorce risks are about 50 percent attributable to genetic factors.

Identical twins, more than fraternal twins, also report being treated alike. So, do their experiences rather than their genes account for their similarity? *No*. Studies have shown that identical twins whose parents treated them alike were not psychologically more alike than identical twins who were treated less similarly (Loehlin & Nichols, 1976). In explaining individual differences, genes matter.

Separated Twins

Imagine the following science fiction experiment: A mad scientist decides to separate identical twins at birth, then rear them in differing environments. Better yet, consider a *true* story:

On a chilly February morning in 1979, some time after divorcing his first wife, Linda, Jim Lewis awoke in his modest home next to his second wife, Betty. Determined that this marriage would work, Jim made a habit of leaving love notes to Betty around the house. As he lay in bed he thought about others he had loved, including his son, James Alan, and his faithful dog, Toy.

Jim was looking forward to spending part of the day in his basement woodworking shop, where he had put in many happy hours building furniture, picture frames, and other items, including a white bench now circling a tree in his front yard. Jim also liked to spend free time driving his Chevy, watching stock-car racing, and drinking Miller Lite beer.

Jim was basically healthy, except for occasional half-day migraine headaches and blood pressure that was a little high, perhaps related to his chain-smoking habit. He had become overweight a while back but had shed some of the pounds. Having undergone a vasectomy, he was done having children.

What was extraordinary about Jim Lewis, however, was that at that same moment (I am not making this up) there existed another man—also named Jim—for whom all these things (right down to the dog's name) were also true.¹ This other Jim—Jim Springer—just happened, 38 years earlier, to have been his fetal partner. Thirty-seven days after their birth, these genetically identical twins were separated, adopted by blue-collar families, and reared with no contact or knowledge of each other's whereabouts until the day Jim Lewis received a call from his genetic clone (who, having been told he had a twin, set out to find him).

FYI

Sweden has the world's largest national twin registry—140,000 living and dead twin pairs—which forms part of a massive registry of 600,000 twins currently being sampled in the world's largest twin study (Wheelwright, 2004; www.genomeutwin.org).

FYI

Twins Lorraine and Levinia Christmas, driving to deliver Christmas presents to each other near Flitcham, England, collided (Shepherd, 1997).

"In some domains it looks as though our identical twins reared apart are . . . just as similar as identical twins reared together. Now that's an amazing finding and I can assure you none of us would have expected that degree of similarity."
—THOMAS BOUCHARD (1981)

¹ Actually, this description of the two Jims errs in one respect: Jim Lewis named his son James Alan. Jim Springer named his James Allan.

One month later, the brothers became the first twin pair tested by University of Minnesota psychologist Thomas Bouchard and his colleagues, beginning a study of separated twins that extends to the present (Holden, 1980a,b; Wright, 1998). Their voice intonations and inflections were so similar that, hearing a playback of an earlier interview, Jim Springer guessed “That’s me.” Wrong—it was his brother. Given tests measuring their personality, intelligence, heart rate, and brain waves, the Jim twins—despite 38 years of separation—were virtually as alike as the same person tested twice. Both married women named Dorothy Jane Scheckelburger. Okay, the last item is a joke. But as Judith Rich Harris (2006) notes, it is hardly weirder than some other reported similarities.

Aided by publicity in magazine and newspaper stories, Bouchard (2009) and his colleagues located and studied 74 pairs of identical twins reared apart. They continued to find similarities not only of tastes and physical attributes but also of personality (characteristic patterns of thinking, feeling, and acting), abilities, attitudes, interests, and even fears.

In Sweden, Nancy Pedersen and her co-workers (1988) identified 99 separated identical twin pairs and more than 200 separated fraternal twin pairs. Compared with equivalent samples of identical twins reared together, the separated identical twins had somewhat less identical personalities. Still, separated twins were more alike if genetically identical than if fraternal. And separation shortly after birth (rather than, say, at age 8) did not amplify their personality differences.

Stories of startling twin similarities do not impress Bouchard’s critics, who remind us that “the plural of *anecdote* is not *data*.” They contend that if any two strangers were to spend hours comparing their behaviors and life histories, they would probably discover many coincidental similarities. If researchers created a control group of biologically unrelated pairs of the same age, sex, and ethnicity, who had not grown up together but who were as similar to one another in economic and cultural background as are many of the separated twin pairs, wouldn’t these pairs also exhibit striking similarities (Joseph, 2001)? Bouchard replies that separated fraternal twins do not exhibit similarities comparable to those of separated identical twins.

Even the more impressive data from personality assessments are clouded by the reunion of many of the separated twins some years before they were tested. Moreover, identical twins share an appearance, and the responses it evokes. Adoption agencies also tend to place separated twins in similar homes. Despite these criticisms, the striking twin-study results helped shift scientific thinking toward a greater appreciation of genetic influences.

FYI

Bouchard’s famous twin research was, appropriately enough, conducted in Minneapolis, the “Twin City” (with St. Paul), and home to the Minnesota Twins baseball team.

FYI

Coincidences are not unique to twins. Patricia Kern of Colorado was born March 13, 1941, and named Patricia Ann Campbell. Patricia DiBiasi of Oregon also was born March 13, 1941, and named Patricia Ann Campbell. Both had fathers named Robert, worked as bookkeepers, and at the time of this comparison had children ages 21 and 19. Both studied cosmetology, enjoyed oil painting as a hobby, and married military men, within 11 days of each other. They are not genetically related. (From an AP report, May 2, 1983.)

St. Bonaventure University

The twin friars Julian and Adrian Reister—two “quiet, gentle souls”—both died of heart failure, at age 92, on the same day in 2011.

Biological Versus Adoptive Relatives

For behavior geneticists, nature's second real-life experiment—adoption—creates two groups: *genetic relatives* (biological parents and siblings) and *environmental relatives* (adoptive parents and siblings). For any given trait, we can therefore ask whether adopted children are more like their biological parents, who contributed their genes, or their adoptive parents, who contribute a home environment. While sharing that home environment, do adopted siblings also come to share traits?

The stunning finding from studies of hundreds of adoptive families is that people who grow up together, whether biologically related or not, do not much resemble one another in personality (McGue & Bouchard, 1998; Plomin, 2011; Rowe, 1990). In traits such as extraversion and agreeableness, adoptees are more similar to their biological parents than to their caregiving adoptive parents.

The finding is important enough to bear repeating: *The environment shared by a family's children has virtually no discernible impact on their personalities.* Two adopted children reared in the same home are no more likely to share personality traits with each other than with the child down the block. Heredity shapes other primates' personalities, too. Macaque monkeys raised by foster mothers exhibit social behaviors that resemble their biological, rather than foster, mothers (Maestripieri, 2003). Add all this to the similarity of identical twins, whether they grow up together or apart, and the effect of a shared rearing environment seems shockingly modest.

What we have here is perhaps “the most important puzzle in the history of psychology,” contended Steven Pinker (2002): *Why are children in the same family so different? Why does shared family environment have so little effect on children's personalities? Is it because each sibling experiences unique peer influences and life events? Because sibling relationships ricochet off each other, amplifying their differences? Because siblings—despite sharing half their genes—have very different combinations of genes and may evoke very different kinds of parenting? Such questions fuel behavior geneticists' curiosity.*

The minimal shared-environment effect does not mean that adoptive parenting is a fruitless venture. The genetic leash may limit the family environment's influence on personality, but parents do influence their children's attitudes, values, manners, faith, and politics (Reifman & Cleveland, 2007). A pair of adopted children or identical twins *will*, especially during adolescence, have more similar religious beliefs if reared together (Koenig et al., 2005). Parenting matters!

Moreover, in adoptive homes, child neglect and abuse and even parental divorce are rare. (Adoptive parents are carefully screened; natural parents are not.) So it is not surprising that, despite a somewhat greater risk of psychological disorder, most adopted children thrive, especially when adopted as infants (Loehlin et al., 2007; van IJzendoorn & Juffer, 2006; Wierzbicki, 1993). Seven in eight report feeling strongly attached to one or both adoptive parents. As children of self-giving parents, they grow up to be more self-giving and altruistic than average (Sharma et al., 1998). Many score higher than their biological parents on intelligence tests, and most grow into happier and more stable adults. In one Swedish study, infant adoptees grew up with fewer problems than were experienced by children whose biological mothers had initially registered them for adoption but then decided to raise the children themselves (Bohman & Sigvardsson, 1990). Regardless of personality differences between parents and their adoptees, most children benefit from adoption.

“We carry to our graves the essence of the zygote that was first us.” -MARY PIPHER, *SEEKING PEACE: CHRONICLES OF THE WORST BUDDHIST IN THE WORLD*, 2009

“Mom may be holding a full house while Dad has a straight flush, yet when Junior gets a random half of each of their cards his poker hand may be a loser.” -DAVID LYKKEN (2001)

FYI

The greater uniformity of adoptive homes—mostly healthy, nurturing homes—helps explain the lack of striking differences when comparing child outcomes of different adoptive homes (Stoolmiller, 1999).

Nature or nurture or both? When talent runs in families, as with the Williams sisters for tennis, how do heredity and environment together do their work?

The New Frontier: Molecular Genetics

14-2 What is the promise of molecular genetics research?

Behavior geneticists have progressed beyond asking, “Do genes influence behavior?” The new frontier of behavior-genetics research draws on “bottom-up” **molecular genetics** as it seeks to identify *specific genes* influencing behavior.

As we have already seen, most human traits are influenced by teams of genes. For example, twin and adoption studies tell us that heredity influences body weight, but there is no single “obesity gene.” More likely, some genes influence how quickly the stomach tells the brain, “I’m full.” Others might dictate how much fuel the muscles need, how many calories are burned off by fidgeting, and how efficiently the body converts extra calories into fat (Vogel, 1999). Given that genes typically are not solo players, a goal of *molecular behavior genetics* is to find some of the many genes that together orchestrate traits such as body weight, sexual orientation, and extraversion (Holden, 2008; Tsankova et al., 2007).

Genetic tests can now reveal at-risk populations for many dozens of diseases. The search continues in labs worldwide, where molecular geneticists are teaming with psychologists to pinpoint genes that put people at risk for such genetically influenced disorders as learning disorder, depression, schizophrenia, and alcohol use disorder. (In Module 67, for example, we will take note of a worldwide research effort to sleuth the genes that make people vulnerable to the emotional swings of bipolar disorder, formerly called manic-depressive disorder.) To tease out the implicated genes, molecular behavior geneticists find families that have had the disorder across several generations. They draw blood or take cheek swabs from both affected and unaffected family members. Then they examine their DNA, looking for differences. “The most powerful potential for DNA,” note Robert Plomin and John Crabbe (2000), “is to predict risk so that steps can be taken to prevent problems before they happen.”

Aided by inexpensive DNA-scanning techniques, medical personnel are becoming able to give would-be parents a readout on how their fetus’ genes differ from the normal pattern and what this might mean. With this benefit come risks. Might labeling a fetus “at risk for a learning disorder” lead to discrimination? Prenatal screening poses ethical dilemmas. In China and India, where boys are highly valued, testing for an offspring’s sex has enabled selective abortions resulting in millions—yes, millions—of “missing women.”

Assuming it were possible, should prospective parents take their eggs and sperm to a genetics lab for screening before combining them to produce an embryo? Should we enable parents to screen their fertilized eggs for health—and for brains or beauty? Progress is a double-edged sword, raising both hopeful possibilities and difficult problems. By selecting out certain traits, we may deprive ourselves of future Handels and van Goghs, Churchills and Lincolns, Tolstoy and Dickinsons—troubled people all.

molecular genetics the subfield of biology that studies the molecular structure and function of genes.

“I thought that sperm-bank donors remained anonymous.”

Heritability

14-3 What is heritability, and how does it relate to individuals and groups?

Using twin and adoption studies, behavior geneticists can mathematically estimate the **heritability** of a trait—the extent to which variation among individuals can be attributed to their differing genes. As Modules 63 and 64 will emphasize, if the heritability of intelligence is, say, 50 percent, this does *not* mean that *your* intelligence is 50 percent genetic. (The heritability of height is 90 percent, but this does not mean that a 60-inch-tall woman can credit

heritability the proportion of variation among individuals that we can attribute to genes. The heritability of a trait may vary, depending on the range of populations and environments studied.

AP® Exam Tip

Heritability is likely to show up on the AP® exam because it's confusing. The key thing to remember is that heritability refers to variation within a group. It does not refer to the impact of nature on an individual. Be clear on both what it is and what it isn't.

© The New Yorker Collection, 2003. Michael Shaw from cartoonbank.com. All Rights Reserved.

"The title of my science project is 'My Little Brother: Nature or Nurture.'"

her genes for 54 inches and her environment for the other 6 inches.) Rather, it means that genetic influence explains 50 percent of the observed *variation among people*. This point is so often misunderstood that I repeat: We can never say what percentage of an *individual's* personality or intelligence is inherited. It makes no sense to say that your personality is due x percent to your heredity and y percent to your environment. Heritability refers instead to the extent to which *differences among people* are attributable to genes.

Even this conclusion must be qualified, because heritability can vary from study to study. Consider humorist Mark Twain's (1835–1910) fantasy of raising boys in barrels to age 12, feeding them through a hole. If we were to follow his suggestion, the boys would all emerge with lower-than-normal intelligence scores at age 12. Yet, given their equal environments, their test score differences could be explained only by their heredity. In this case, heritability—differences due to genes—would be near 100 percent.

As environments become more similar, heredity as a source of differences necessarily becomes more important. If all schools were of uniform quality, all families equally loving, and all neighborhoods equally healthy, then heritability would *increase* (because differences due to environment would *decrease*). At the other extreme, if all people had similar heredities but were raised in drastically different environments (some in barrels, some in luxury homes), heritability would be much lower.

Can we extend this thinking to differences between groups? If genetic influences help explain individual diversity in traits such as aggressiveness, for example, can the same be said of group differences between men and women, or between people of different races? Not necessarily. Individual differences in height and weight, for example, are highly heritable; yet nutritional rather than genetic influences explain why, as a group, today's adults are taller and heavier than those of a century ago. The two groups differ, but not because human genes have changed in a mere century's eye-blink of time. Although height is 90 percent heritable, South Koreans, with their better diets, average six inches taller than North Koreans, who come from the same genetic stock (Johnson et al., 2009).

As with height and weight, so with personality and intelligence scores: Heritable individual differences need not imply heritable group differences. If some individuals are genetically disposed to be more aggressive than others, that needn't explain why some groups are more aggressive than others. Putting people in a new social context can change their aggressiveness. Today's peaceful Scandinavians carry many genes inherited from their Viking warrior ancestors.

Gene-Environment Interaction

14-4 How do heredity and environment work together?

Among our similarities, the most important—the behavioral hallmark of our species—is our enormous adaptive capacity. Some human traits, such as having two eyes, develop the same in virtually every environment. But other traits are expressed only in particular environments. Go barefoot for a summer and you will develop toughened, callused feet—a biological adaptation to friction. Meanwhile, your shod neighbor will remain a tenderfoot. The difference between the two of you is, of course, an effect of environment. But it is also the product of a biological mechanism—adaptation. Our shared biology enables our developed diversity (Buss, 1991).

An analogy may help: Genes and environment—nature and nurture—work together like two hands clapping. Genes are *self-regulating*. Rather than acting as blueprints that lead to the same result no matter the context, genes react. An African butterfly that is green in summer turns brown in fall, thanks to a temperature-controlled genetic switch. The genes

"Men's natures are alike; it is their habits that carry them far apart."
—CONFUCIUS, *ANALECTS*, 500 B.C.E.

that produce brown in one situation produce green in another. So, too, people with identical genes but differing experiences will have similar but not identical minds. One twin may fall in love with someone quite different from the co-twin's love.

Asking whether our personality is more a product of our genes or our environment is like asking whether the area of a field is more the result of its length or its width. We could, however, ask whether the differing areas of various fields are more the result of *differences* in their length or their width, and also whether person-to-person personality differences are influenced more by nature or nurture.

To say that genes and experience are *both* important is true. But more precisely, they **interact**. Imagine two babies, one genetically predisposed to be attractive, sociable, and easygoing, the other less so. Assume further that the first baby attracts more affectionate and stimulating care and so develops into a warmer and more outgoing person. As the two children grow older, the more naturally outgoing child more often seeks activities and friends that encourage further social confidence.

What has caused their resulting personality differences? Neither heredity nor experience dances alone. Environments trigger gene activity. And our genetically influenced traits *evoke* significant responses in others. Thus, a child's impulsivity and aggression may evoke an angry response from a teacher who reacts warmly to the child's model classmates. Parents, too, may treat their own children differently; one child elicits punishment, another does not. In such cases, the child's nature and the parents' nurture interact. Neither operates apart from the other. Gene and scene dance together.

Evocative interactions may help explain why identical twins reared in different families recall their parents' warmth as remarkably similar—almost as similar as if they had had the same parents (Plomin et al., 1988, 1991, 1994). Fraternal twins have more differing recollections of their early family life—even if reared in the same family! "Children experience us as different parents, depending on their own qualities," noted Sandra Scarr (1990). Moreover, a selection effect may be at work. As we grow older, we select environments well suited to our natures.

Recall that genes can be either active (expressed, as the hot water activates the tea bag) or inactive. A new field, **epigenetics** (meaning "in addition to" or "above and beyond" genetics), is studying the molecular mechanisms by which environments trigger genetic expression. Although genes have the potential to influence development, environmental triggers can switch them on or off, much as your computer's software directs your printer. One such *epigenetic mark* is an organic methyl molecule attached to part of a DNA strand (**FIGURE 14.3**). It instructs the cell to ignore any gene present in that DNA segment, thereby preventing the DNA from producing the proteins coded by that gene.

Environmental factors such as diet, drugs, and stress can affect the epigenetic molecules that regulate gene expression. In one experiment, infant rats deprived of their mothers' normal licking had more molecules that blocked

"Heredity deals the cards; environment plays the hand."
-PSYCHOLOGIST CHARLES L. BREWER (1990)

interaction the interplay that occurs when the effect of one factor (such as environment) depends on another factor (such as heredity).

epigenetics the study of environmental influences on gene expression that occur without a DNA change.

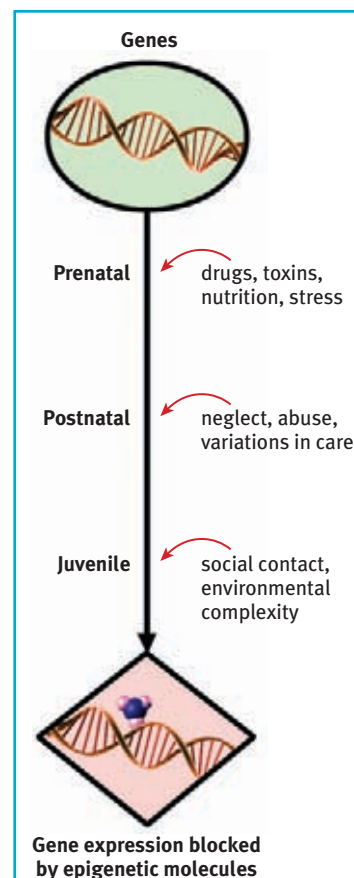

Figure 14.3
Epigenetics influences gene expression Life experiences beginning in the womb lay down *epigenetic marks*—often organic methyl molecules—that can block the expression of any gene in the associated DNA segment (from Champagne, 2010).

Gene-environment interaction

Biological appearances have social consequences. People respond differently to recording artist Nicki Minaj and concert violinist Hilary Hahn.

Saveirkin Alexander/TAR-TASS/Landov

access to the “on” switch for developing the brain’s stress hormone receptors. When stressed, the animals had more free-floating stress hormones and were more stressed out (Champagne et al., 2003; Champagne & Mashoodh, 2009). Child abuse may similarly affect its victims. Humans who have committed suicide exhibit the same epigenetic effect if they had suffered a history of child abuse (McGowan et al., 2009). Researchers now wonder if epigenetics might help solve some scientific mysteries, such as why only one member of an identical twin pair may develop a genetically influenced mental disorder, and how experience leaves its fingerprints in our brains.

So, from conception onward, we are the product of a cascade of interactions between our genetic predispositions and our surrounding environments (McGue, 2010). Our genes affect how people react to and influence us. Biological appearances have social consequences. So, forget nature *versus* nurture; think nature *via* nurture.

Before You Move On

▶ ASK YOURSELF

Would you want genetic tests on your unborn offspring? What would you do if you knew your child would be destined for hemophilia (a medical condition that interferes with blood clotting)? A specific learning disorder? A high risk of depression? Do you think society would benefit or lose if such embryos were aborted?

▶ TEST YOURSELF

What is *heritability*?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 14 Review

14-1 What are genes, and how do behavior geneticists explain our individual differences?

- *Genes* are the biochemical units of heredity that make up *chromosomes*, the threadlike coils of *DNA*.
- When genes are “turned on” (expressed), they provide the code for creating the proteins that form our body’s building blocks.
- Most human traits are influenced by many genes acting together.
- *Behavior geneticists* seek to quantify genetic and *environmental* influences on our traits, in part through studies of *identical* (monozygotic) *twins*, *fraternal* (dizygotic) *twins*, and adoptive families.
- Shared family environments have little effect on personality, and the stability of personality suggests a genetic predisposition.

14-2 What is the promise of molecular genetics research?

- *Molecular geneticists* study the molecular structure and function of genes, including those that affect behavior.

- Psychologists and molecular geneticists are cooperating to identify specific genes—or more often, teams of genes—that put people at risk for disorders.

14-3 What is heritability, and how does it relate to individuals and groups?

- *Heritability* describes the extent to which variation among members of a group can be attributed to genes.
- Heritable individual differences (in traits such as height or intelligence) do not necessarily imply heritable group differences. Genes mostly explain why some people are taller than others, but not why people are taller today than they were a century ago.

14-4 How do heredity and environment work together?

- Our genetic predispositions and our surrounding environments *interact*. Environments can trigger gene activity, and genetically influenced traits can evoke responses from others.
- The field of *epigenetics* studies the influences on gene expression that occur without changes in DNA.

Multiple-Choice Questions

- Human genome (DNA) researchers have discovered that
 - chimpanzees are completely different than humans, sharing a small DNA sequence percentage.
 - the occasional variations found at particular gene sites in human DNA are of no interest to science.
 - many genes do not influence most of our traits.
 - nearly every other human is your genetically identical twin.
 - genetic predispositions do not help explain our shared human nature and our human diversity.
- One reason that identical twins might show slight differences at birth is
 - they did not develop from a single fertilized egg.
 - one twin’s placenta may have provided slightly better nourishment.
 - they develop from different sperm.
 - one twin gestated much longer in the uterus than the other.
 - their relative positions in the uterus.
- Generally speaking, heritability is the extent to which
 - differences among people are accounted for by genes.
 - an individual’s specific traits are due to genes or the environment.
 - differences among people are due to the environment.
 - differences among people are due to their cultural heritage.
 - an individual’s height is related to the height of his or her parents.
- Which of the following is most closely associated with the idea of epigenetics?
 - Eye color
 - Gene display based on environmental factors
 - IQ as a function of educational experiences
 - Height at birth
 - Shoe size

5. Which of the following is an example of gene-environment interaction?
- Yeh Lin experiences flushing syndrome, which mostly occurs in those of Asian heritage.
 - Alfonso gets food poisoning from eating undercooked meat.
 - Ted gets diabetes, which runs in his family, because he eats too much sugary food.
 - Samantha has a food allergy to shellfish.
 - Jordan has an autoimmune disorder that causes him to lose hair.

Practice FRQs

1. Explain the two positions in the nature–nurture debate.

Answer (2 points)

1 point: Nature refers to the contributions of heredity and inborn, biologically determined aspects of behavior and mental processes.

1 point: Nurture refers to the contributions of environment and the way individuals are raised.

2. What does it mean to say that the heritability of height is 90 percent? What does that tell us about the contribution of genetics to any one person's height?

(2 points)

Module 15

Evolutionary Psychology: Understanding Human Nature

Module Learning Objectives

- 15-1** Describe evolutionary psychologists' use of natural selection to explain behavior tendencies.
- 15-2** Discuss evolutionary explanations for gender differences in sexuality and mating preferences.
- 15-3** Summarize the key criticisms of evolutionary psychology, and describe how evolutionary psychologists respond.
- 15-4** Describe the biopsychosocial approach to individual development.

- 15-1** How do evolutionary psychologists use natural selection to explain behavior tendencies?

Behavior geneticists explore the genetic and environmental roots of human differences. **Evolutionary psychologists** instead focus mostly on what makes us so much alike. They use Charles Darwin's principle of natural selection to understand the roots of behavior and mental processes. Richard Dawkins (2007) calls **natural selection** "arguably the most momentous idea ever to occur to a human mind." The idea, simplified, is this:

- Organisms' varied offspring compete for survival.
- Certain biological and behavioral variations increase organisms' reproductive and survival chances in their particular environment.
- Offspring that survive are more likely to pass their genes to ensuing generations.
- Thus, over time, population characteristics may change.

To see these principles at work, let's consider a straightforward example in foxes.

Natural Selection and Adaptation

A fox is a wild and wary animal. If you capture a fox and try to befriend it, be careful. Stick your hand in the cage and, if the timid fox cannot flee, it may snack on your fingers. Russian scientist Dmitry Belyaev wondered how our human ancestors had domesticated dogs from their equally wild wolf forebears. Might he, within a comparatively short stretch of time, accomplish a similar feat by transforming the fearful fox into a friendly fox?

evolutionary psychology the study of the evolution of behavior and the mind, using principles of natural selection.

natural selection the principle that, among the range of inherited trait variations, those contributing to reproduction and survival will most likely be passed on to succeeding generations.

To find out, Belyaev set to work with 30 male and 100 female foxes. From their offspring he selected and mated the tamest 5 percent of males and 20 percent of females. (He measured tameness by the foxes' responses to attempts to feed, handle, and stroke them.) Over more than 30 generations of foxes, Belyaev and his successor, Lyudmila Trut, repeated that simple procedure. Forty years and 45,000 foxes later, they had a new breed of foxes that, in Trut's (1999) words, are "docile, eager to please, and unmistakably domesticated. . . . Before our eyes, 'the Beast' has turned into 'beauty,' as the aggressive behavior of our herd's wild [ancestors] entirely disappeared." So friendly and eager for human contact are they, so inclined to whimper to attract attention and to lick people like affectionate dogs, that the cash-strapped institute seized on a way to raise funds—marketing its foxes to people as house pets.

Over time, traits that are *selected* confer a reproductive advantage on an individual or a species and will prevail. Animal breeding experiments manipulate genetic selection and show its powers. Dog breeders have given us sheepdogs that herd, retrievers that retrieve, trackers that track, and pointers that point (Plomin et al., 1997). Psychologists, too, have bred animals to be serene or reactive, quick learners or slow.

Does the same process work with naturally occurring selection? Does natural selection explain our human tendencies? Nature has indeed selected advantageous variations from the new gene combinations produced at each human conception and the **mutations** (random errors in gene replication) that sometimes result. But the tight genetic leash that predisposes a dog's retrieving, a cat's pouncing, or an ant's nest building is looser on humans. The genes selected during our ancestral history provide more than a long leash; they endow us with a great capacity to learn and therefore to *adapt* to life in varied environments, from the tundra to the jungle. Genes and experience together wire the brain. Our adaptive flexibility in responding to different environments contributes to our *fitness*—our ability to survive and reproduce.

mutation a random error in gene replication that leads to a change.

Evolutionary Success Helps Explain Similarities

Although our person-to-person differences grab attention, we humans are also strikingly alike. As brothers and sisters in one great human family, we all wake and sleep, think and speak, hunger and thirst. We smile when happy and favor what's familiar more than what is foreign. We return favors, fear snakes, grieve death, and, as social animals, have a need to belong. Beneath our differing skin, we all are kin. Evolutionary psychologist Steven Pinker (2002, p. 73) has noted that it is no wonder our emotions, drives, and reasoning "have a common logic across cultures": Our shared human traits "were shaped by natural selection acting over the course of human evolution."

Our Genetic Legacy

Our behavioral and biological similarities arise from our shared human *genome*, our common genetic profile. No more than 5 percent of the genetic differences among humans arise from population group differences. Some 95 percent of genetic variation exists *within* populations (Rosenberg et al., 2002). The typical genetic difference between two Icelandic villagers or between two Kenyans is much greater than the *average* difference between the two groups. Thus, if after a worldwide catastrophe only Icelanders or Kenyans survived, the human species would suffer only "a trivial reduction" in its genetic diversity (Lewontin, 1982).

And how did we develop this shared human genome? At the dawn of human history, our ancestors faced certain questions: Who is my ally, who my foe? What food should I eat? With whom should I mate? Some individuals answered those questions more successfully than others. For example, women who experienced nausea in the critical first three months of pregnancy were predisposed to avoid certain bitter, strongly flavored, and novel foods. Avoiding such foods has survival value, since they are the very foods most often toxic to

embryonic development (Schmitt & Pilcher, 2004). Early humans disposed to eat nourishing rather than poisonous foods survived to contribute their genes to later generations. Those who deemed leopards “nice to pet” often did not.

Similarly successful were those whose mating helped them produce and nurture offspring. Over generations, the genes of individuals not so disposed tended to be lost from the human gene pool. As success-enhancing genes continued to be selected, behavioral tendencies and thinking and learning capacities emerged that prepared our Stone Age ancestors to survive, reproduce, and send their genes into the future, and into you.

Across our cultural differences, we even share “a universal moral grammar,” notes evolutionary psychologist Marc Hauser (2006, 2009). Men and women, young and old, liberal and conservative, living in Sydney or Seoul, all respond negatively when asked, “If a lethal gas is leaking into a vent and is headed toward a room with seven people, is it okay to push someone into the vent—saving the seven but killing the one?” And they all respond more approvingly when asked if it’s okay to allow someone to fall into the vent, again sacrificing one life but saving seven. Our shared moral instincts survive from a distant past where we lived in small groups in which direct harm-doing was punished, argues Hauser. For all such universal human tendencies, from our intense need to give parental care to our shared fears and lusts, evolutionary theory proposes a one-stop shopping explanation (Schloss, 2009).

As inheritors of this prehistoric genetic legacy, we are predisposed to behave in ways that promoted our ancestors’ surviving and reproducing. But in some ways, we are biologically prepared for a world that no longer exists. We love the taste of sweets and fats, which prepared our ancestors to survive famines, and we heed their call from school cafeterias, fast-food outlets, and vending machines. With famine now rare in Western cultures, obesity is truly a growing problem. Our natural dispositions, rooted deep in history, are mismatched with today’s junk-food environment and today’s threats such as climate change (Colarelli & Dettman, 2003).

Evolutionary Psychology Today

Darwin’s theory of evolution has been an organizing principle for biology for a long time. Jared Diamond (2001) noted, “Virtually no contemporary scientists believe that Darwin was basically wrong.” Today, Darwin’s theory lives on in the *second Darwinian revolution*: the application of evolutionary principles to psychology. In concluding *On the Origin of Species*, Darwin anticipated this, foreseeing “open fields for far more important researches. Psychology will be based on a new foundation” (1859, p. 346).

In modules to come, we’ll address questions that intrigue evolutionary psychologists, such as why infants start to fear strangers about the time they become mobile. Why are biological fathers so much less likely than unrelated boyfriends to abuse and murder the children with whom they share a home? Why do so many more people have phobias about spiders, snakes, and heights than about more dangerous threats, such as guns and electricity? And why do we fear air travel so much more than driving?

To see how evolutionary psychologists think and reason, let’s pause now to explore their answers to these two questions: How are men and women alike? How and why does men’s and women’s sexuality differ?

An Evolutionary Explanation of Human Sexuality

15-2

How might an evolutionary psychologist explain gender differences in sexuality and mating preferences?

Having faced many similar challenges throughout history, men and women have adapted in similar ways. Whether male or female, we eat the same foods, avoid the same predators, and perceive, learn, and remember similarly. It is only in those domains where we have faced differing adaptive challenges—most obviously in behaviors related to reproduction—that we differ, say evolutionary psychologists.

FYI

Despite high infant mortality and rampant disease in past millennia, not one of your countless ancestors died childless.

FYI

Those who are troubled by an apparent conflict between scientific and religious accounts of human origins may find it helpful to recall from Module 2 that different perspectives of life can be complementary. For example, the scientific account attempts to tell us *when* and *how*; religious creation stories usually aim to tell about an ultimate *who* and *why*. As Galileo explained to the Grand Duchess Christina, “The Bible teaches how to go to heaven, not how the heavens go.”

There is a principle at work here, say evolutionary psychologists: Nature selects behaviors that increase the likelihood of sending one's genes into the future. As mobile gene machines, we are designed to prefer whatever worked for our ancestors in their environments. They were predisposed to act in ways that would produce grandchildren—had they not been, we wouldn't be here. And as carriers of their genetic legacy, we are similarly predisposed.

Without disputing nature's selection of traits that enhance gene survival, critics see some problems with this explanation of our mating preferences. They believe that the evolutionary perspective overlooks some important influences on human sexuality (see Thinking Critically About: The Evolutionary Perspective on Human Sexuality).

Thinking Critically About

The Evolutionary Perspective on Human Sexuality

15-3

What are the key criticisms of evolutionary psychology, and how do evolutionary psychologists respond?

Evolutionary psychology, say some critics, starts with an effect (such as the gender sexuality difference) and works backward to propose an explanation. They invite us to imagine a different result and reason backward. If men were uniformly loyal to their mates, might we not reason that the children of these committed, supportive fathers would more often survive to perpetuate their genes? Might not men also be better off bonded to one woman—both to increase their odds of impregnation and to keep her from the advances of competing men? Might not a ritualized bond—a marriage—also spare women from chronic male harassment? Such suggestions are, in fact, evolutionary explanations for why humans tend to pair off monogamously (Gray & Anderson, 2010). One can hardly lose at hindsight explanation, which is, said paleontologist Stephen Jay Gould (1997), mere “speculation [and] guesswork in the cocktail party mode.”

Some also worry about the social consequences of evolutionary psychology. Does it suggest a genetic determinism that strikes at the heart of progressive efforts to remake society (Rose, 1999)? Does it undercut moral responsibility (Buller, 2005, 2009)? Could it be used to rationalize “high-status men marrying a series of young, fertile women” (Looy, 2001)?

Others argue that evolutionary explanations blur the line between genetic legacy and social-cultural tradition. Show Alice Eagly and Wendy Wood (1999; Eagly, 2009) a culture with gender inequality—where men are providers and women are homemakers—and they will show you a culture where men strongly desire youth and domestic skill in their potential mates, and where women seek status and earning potential in their mates. Show Eagly and Wood a culture with gender equality, and they will show you a culture with smaller gender differences in mate preferences.

Much of who we are is *not* hard-wired, agree evolutionary psychologists. “Evolution forcefully rejects a genetic determinism,” insists one research team (Confer et al., 2010). Evolutionary psychologists reassure us that men and women, having faced similar adaptive problems, are far more alike than different, and that humans have a great capacity for learning and social progress. Indeed, natural selection has prepared us to flexibly adjust and respond to varied environments, to adapt and survive, whether we live in igloos or tree houses. Further, they agree that cultures vary, cultures change, and cultural expectations can bend the genders. If socialized to value lifelong commitment, men may sexually bond with one partner; if socialized to accept casual sex, women may willingly have sex with many partners.

Evolutionary psychologists acknowledge struggling to explain some traits and behaviors such as same-sex attraction and suicide (Confer et al., 2010). But they also point to the explanatory and predictive power of evolutionary principles. Evolutionary psychologists predict, and have confirmed, that we tend to favor others to the extent that they share our genes or can later return our favors. They predict, and have confirmed, that human memory should be well-suited to retaining survival-relevant information (such as food locations, for which females exhibit superiority). They predict, and have confirmed, various other male and female mating strategies.

Evolutionary psychologists also remind us that the study of how we came to be need not dictate how we ought to be. Understanding our propensities sometimes helps us overcome them.

“It is dangerous to show a man too clearly how much he resembles the beast, without at the same time showing him his greatness. It is also dangerous to allow him too clear a vision of his greatness without his baseness. It is even more dangerous to leave him in ignorance of both.” -BLAISE PASCAL, PENSEES, 1659

Before You Move On

▶ ASK YOURSELF

Whose reasoning do you find most persuasive—that of evolutionary psychologists or their critics? Why?

▶ TEST YOURSELF

What are the three main criticisms of evolutionary psychology's explanations?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Reflections on Nature and Nurture

15-4 What is included in the biopsychosocial approach to individual development?

“There are trivial truths and great truths,” the physicist Niels Bohr reportedly said in reflecting on the paradoxes of science. “The opposite of a trivial truth is plainly false. The opposite of a great truth is also true.” It appears true that our ancestral history helped form us as a species. Where there is variation, natural selection, and heredity, there will be evolution.

The unique gene combination created when our mother’s egg engulfed our father’s sperm predisposed both our shared humanity and our individual differences. This is a great truth about human nature. Genes form us.

But it also is true that our experiences form us. In our families and in our peer relationships, we learn ways of thinking and acting. Differences initiated by our nature may be amplified by our nurture. If genes and hormones predispose males to be more physically aggressive than females, culture may magnify this gender difference through norms that encourage males to be macho and females to be the kinder, gentler sex. If men are encouraged toward roles that demand physical power, and women toward more nurturing roles, each may then exhibit the actions expected of them and find themselves shaped accordingly. Roles remake their players. Presidents in time become more presidential, servants more servile. Gender roles similarly shape us.

But gender roles are converging. Brute strength has become increasingly irrelevant to power and status (think Bill Gates and Hillary Clinton). Thus both women and men are now seen as “fully capable of effectively carrying out organizational roles at all levels,” note Wendy Wood and Alice Eagly (2002). And as women’s employment in formerly male occupations has increased, gender differences in traditional masculinity or femininity and in what one seeks in a mate have diminished (Twenge, 1997). As the roles we play change over time, we change with them.

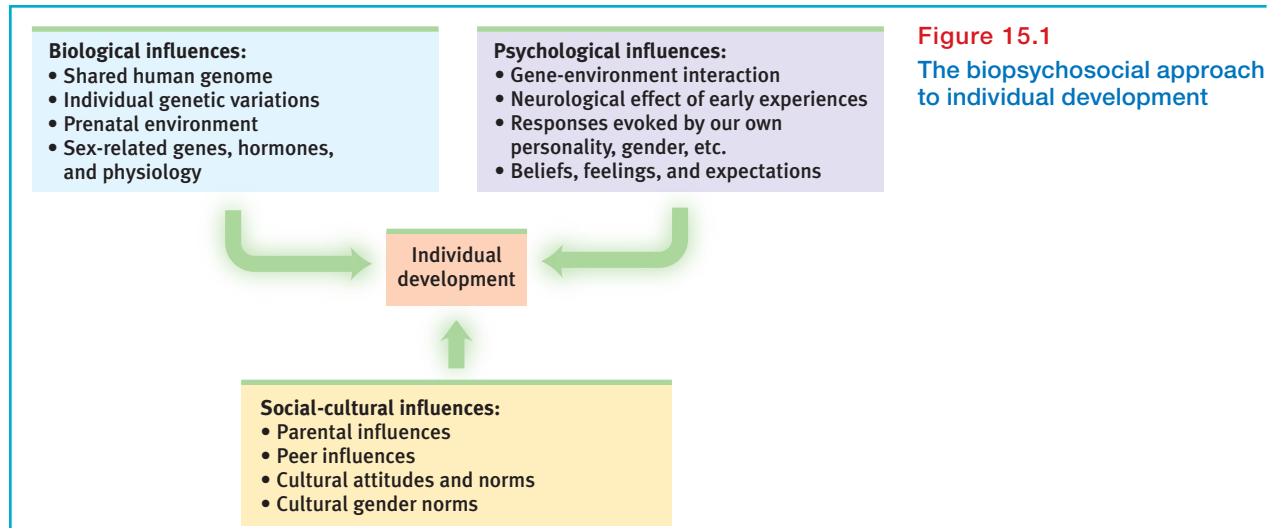

* * *

If nature and nurture jointly form us, are we “nothing but” the product of nature and nurture? Are we rigidly determined?

We are the product of nature and nurture (**FIGURE 15.1**), but we are also an open system, as suggested by the biopsychosocial approach (see Module 2). Genes are all pervasive but not all powerful; people may defy their genetic bent to reproduce by electing celibacy. Culture, too, is all pervasive but not all powerful; people may defy peer pressures and do the opposite of the expected. To excuse our failings by blaming our nature and nurture is what philosopher-novelist Jean-Paul Sartre called “bad faith”—attributing responsibility for one’s fate to bad genes or bad influences.

Culture matters As this exhibit at San Diego’s Museum of Man illustrates, children learn their culture. A baby’s foot can step into any culture.

In reality, we are both the creatures and the creators of our worlds. We are—it is a great truth—the products of our genes and environments. Nevertheless (another great truth), the stream of causation that shapes the future runs through our present choices. Our decisions today design our environments tomorrow. Mind matters. The human environment is not like the weather—something that just happens. We are its architects. Our hopes, goals, and expectations influence our future. And that is what enables cultures to vary and to change so quickly.

* * *

I know from my mail and from public opinion surveys that some readers feel troubled by the naturalism and evolutionism of contemporary science. Readers from other nations bear with me, but in the United States there is a wide gulf between scientific and lay thinking about evolution. “The idea that human minds are the product of evolution is . . . unassailable fact,” declared a 2007 editorial in *Nature*, a leading science magazine. That sentiment concurs with a 2006 statement of “evidence-based facts” about evolution jointly issued by the national science academies of 66 nations (IAP, 2006). In *The Language of God*, Human Genome Project director Francis Collins (2006, pp. 141, 146), a self-described evangelical Christian, compiles the “utterly compelling” evidence that leads him to conclude that Darwin’s big idea is “unquestionably correct.” Yet Gallup reports that half of U.S. adults do not believe in evolution’s role in “how human beings came to exist on Earth” (Newport, 2007). Many of those who dispute the scientific story worry that a science of behavior (and evolutionary science in particular) will destroy our sense of the beauty, mystery, and spiritual significance of the human creature. For those concerned, I offer some reassuring thoughts.

When Isaac Newton explained the rainbow in terms of light of differing wavelengths, the poet Keats feared that Newton had destroyed the rainbow’s mysterious beauty. Yet, noted Richard Dawkins (1998) in *Unweaving the Rainbow*, Newton’s analysis led to an even deeper mystery—Einstein’s theory of special relativity. Moreover, nothing about Newton’s optics need diminish our appreciation for the dramatic elegance of a rainbow arching across a brightening sky.

Tatyana Kochneva | Dreamstime.com

“Let’s hope that it’s not true; but if it is true, let’s hope that it doesn’t become widely known.” -LADY ASHLEY, COMMENTING ON DARWIN’S THEORY

“Is it not stirring to understand how the world actually works—that white light is made of colors, that color measures light waves, that transparent air reflects light . . . ? It does no harm to the romance of the sunset to know a little about it.” —CARL SAGAN, *SKIES OF OTHER WORLDS*, 1988

When Galileo assembled evidence that the Earth revolved around the Sun, not vice versa, he did not offer irrefutable proof for his theory. Rather, he offered a coherent explanation for a variety of observations, such as the changing shadows cast by the Moon’s mountains. His explanation eventually won the day because it described and explained things in a way that made sense, that hung together. Darwin’s theory of evolution likewise is a coherent view of natural history. It offers an organizing principle that unifies various observations.

Collins is not the only person of faith to find the scientific idea of human origins congenial with his spirituality. In the fifth century, St. Augustine (quoted by Wilford, 1999) wrote, “The universe was brought into being in a less than fully formed state, but was gifted with the capacity to transform itself from unformed matter into a truly marvelous array of structures and life forms.” Some 1600 years later, Pope John Paul II in 1996 welcomed a science-religion dialogue, finding it noteworthy that evolutionary theory “has been progressively accepted by researchers, following a series of discoveries in various fields of knowledge.”

Meanwhile, many people of science are awestruck at the emerging understanding of the universe and the human creature. It boggles the mind—the entire universe popping out of a point some 14 billion years ago, and instantly inflating to cosmological size. Had the energy of this Big Bang been the tiniest bit less, the universe would have collapsed back on itself. Had it been the tiniest bit more, the result would have been a soup too thin to support life. Astronomer Sir Martin Rees has described *Just Six Numbers* (1999), any one of which, if changed ever so slightly, would produce a cosmos in which life could not exist. Had gravity been a tad bit stronger or weaker, or had the weight of a carbon proton been a wee bit different, our universe just wouldn’t have worked.

What caused this almost-too-good-to-be-true, finely tuned universe? Why is there something rather than nothing? How did it come to be, in the words of Harvard-Smithsonian astrophysicist Owen Gingerich (1999), “so extraordinarily right, that it seemed the universe had been expressly designed to produce intelligent, sentient beings”? Is there a benevolent superintelligence behind it all? Have there instead been an infinite number of universes born and we just happen to be the lucky inhabitants of one that, by chance, was exquisitely fine-tuned to give birth to us? Or does that idea violate *Occam’s razor*, the principle that we should prefer the simplest of competing explanations? On such matters, a humble, awed, scientific silence is appropriate, suggested philosopher Ludwig Wittgenstein: “Whereof one cannot speak, thereof one must be silent” (1922, p. 189).

Rather than fearing science, we can welcome its enlarging our understanding and awakening our sense of awe. In *The Fragile Species*, Lewis Thomas (1992) described his utter amazement that the Earth in time gave rise to bacteria and eventually to Bach’s Mass in B Minor. In a short 4 billion years, life on Earth has come from nothing to structures as complex as a 6-billion-unit strand of DNA and the incomprehensible intricacy of the human brain. Atoms no different from those in a rock somehow formed dynamic entities that became conscious. Nature, says cosmologist Paul Davies (2007), seems cunningly and ingeniously devised to produce extraordinary, self-replicating, information-processing systems—us. Although we appear to have been created from dust, over eons of time, the end result is a priceless creature, one rich with potential beyond our imagining.

“The causes of life’s history [cannot] resolve the riddle of life’s meaning.” —STEPHEN JAY GOULD, *ROCKS OF AGES: SCIENCE AND RELIGION IN THE FULLNESS OF LIFE*, 1999

Before You Move On

▶ ASK YOURSELF

How have your heredity and your environment influenced who you are today? Can you recall an important time when you determined your own fate in a way that was at odds with pressure you felt from either your heredity or your environment?

▶ TEST YOURSELF

How does the biopsychosocial approach explain our individual development?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

* * *

In this unit we have glimpsed an overriding principle: Everything psychological is simultaneously biological. We have focused on how our thoughts, feelings, and actions arise from our specialized yet integrated brain. In modules to come, we will further explore the significance of the biological revolution in psychology.

From nineteenth-century phrenology to today's neuroscience, we have come a long way. Yet what is unknown still dwarfs what is known. We can describe the brain. We can learn the functions of its parts. We can study how the parts communicate. But how do we get mind out of meat? How does the electrochemical whirl in a hunk of tissue the size of a head of lettuce give rise to elation, a creative idea, or that memory of Grandmother?

Much as gas and air can give rise to something different—fire—so also, believed Roger Sperry, does the complex human brain give rise to something different: *consciousness*. The mind, he argued, emerges from the brain's dance of ions, yet is not reducible to it. Cells cannot be fully explained by the actions of atoms, nor minds by the activity of cells. Psychology is rooted in biology, which is rooted in chemistry, which is rooted in physics. Yet psychology is more than applied physics. As Jerome Kagan (1998) reminded us, the meaning of the Gettysburg Address is not reducible to neural activity. Communication is more than air flowing over our vocal cords. Morality and responsibility become possible when we understand the mind as a "holistic system," said Sperry (1992) (**FIGURE 15.2**). We are not mere jabbering robots.

The mind seeking to understand the brain—that is indeed among the ultimate scientific challenges. And so it will always be. To paraphrase cosmologist John Barrow, a brain simple enough to be understood is too simple to produce a mind able to understand it.

**Figure 15.2**

Mind and brain as holistic system In Roger Sperry's view, the brain creates and controls the emergent mind, which in turn influences the brain. (Think vividly about biting into a lemon and you may salivate.)

Module 15 Review

15-1

How do evolutionary psychologists use natural selection to explain behavior tendencies?

- *Evolutionary psychologists* seek to understand how our traits and behavior tendencies are shaped by *natural selection*, as genetic variations increasing the odds of reproducing and surviving are most likely to be passed on to future generations.
- Some genetic variations arise from *mutations* (random errors in gene replication), others from new gene combinations at conception.
- Humans share a genetic legacy and are predisposed to behave in ways that promoted our ancestors' surviving and reproducing.
- Charles Darwin's theory of evolution is an organizing principle in biology. He anticipated today's application of evolutionary principles in psychology.

15-2

How might an evolutionary psychologist explain gender differences in sexuality and mating preferences?

- Men tend to have a recreational view of sexual activity; women tend to have a relational view.
- Evolutionary psychologists reason that men's attraction to multiple healthy, fertile-appearing partners increases their chances of spreading their genes widely.
- Because women incubate and nurse babies, they increase their own and their children's chances of survival by searching for mates with the potential for long-term investment in their joint offspring.

15-3

What are the key criticisms of evolutionary psychology, and how do evolutionary psychologists respond?

- Critics argue that evolutionary psychologists (1) start with an effect and work backward to an explanation, (2) do not recognize social and cultural influences, and (3) absolve people from taking responsibility for their sexual behavior.
- Evolutionary psychologists respond that understanding our predispositions can help us overcome them. They also cite the value of testable predictions based on evolutionary principles, as well as the coherence and explanatory power of those principles.

15-4

What is included in the biopsychosocial approach to individual development?

- Individual development results from the interaction of biological, psychological, and social-cultural influences.
- Biological influences include our shared human *genome*; individual variations; prenatal environment; and sex-related genes, hormones, and physiology.
- Psychological influences include gene-environment interactions; the effect of early experiences on neural networks; responses evoked by our own characteristics, such as gender and personality; and personal beliefs, feelings, and expectations.
- Social-cultural influences include parental and peer influences; cultural traditions and values; and cultural gender norms.

Multiple-Choice Questions

1. Which of the following refers to an effect of life experience that leaves a molecular mark that affects gene expression?
 - a. Epigenetics
 - b. Adaptation
 - c. Evolution
 - d. Natural selection
 - e. Universal moral grammar
2. Which of the following best describes genetic mutation?
 - a. Random errors in gene replication
 - b. The study of the mind's evolution
 - c. The study of behavioral evolution
 - d. Passing on successful, inherited traits
 - e. Survival of the genetically successful
3. Which of the following is true regarding the initiation of sexual activity?
 - a. Men are more likely to initiate sexual activity than women.
 - b. Women are more likely to initiate sexual activity than men.
 - c. The initiation of sexual activity for both men and women correlates with how many television sitcoms they viewed as children.
 - d. Men and women are equally likely to initiate sexual activity.
 - e. Who initiates sexual activity is largely determined by culture.

Practice FRQs

1. Explain four of the important ideas behind natural selection.
2. Explain the three major influences on individual development, according to the biopsychosocial approach.

(3 points)

Answer

1 point: Organisms' varied offspring compete for survival.

1 point: Certain biological and behavioral variations increase an organism's reproductive and survival chances in a particular environment.

1 point: Offspring that survive are more likely to pass their genes to ensuing generations.

1 point: Over time, population characteristics may change.

Unit III Review

Key Terms and Concepts to Remember

- biological psychology, p. 77
- neuron, p. 78
- dendrites, p. 78
- axon, p. 78
- myelin [MY-uh-lin] sheath, p. 78
- action potential, p. 78
- refractory period, p. 79
- threshold, p. 80
- all-or-none response, p. 80
- synapse [SIN-aps], p. 80
- neurotransmitters, p. 80
- reuptake, p. 80
- endorphins [en-DOR-fins], p. 82
- agonist, p. 82
- antagonist, p. 83
- nervous system, p. 86
- central nervous system (CNS), p. 86
- peripheral nervous system (PNS), p. 86
- nerves, p. 86
- sensory (afferent) neurons, p. 86
- motor (efferent) neurons, p. 86
- interneurons, p. 87
- somatic nervous system, p. 87
- autonomic [aw-tuh-NAHM-ik] nervous system (ANS), p. 87
- sympathetic nervous system, p. 87
- parasympathetic nervous system, p. 87
- reflex, p. 89

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Why do researchers study the brains of nonhuman animals?
 - It is not ethical to study human brains.
 - Human brains are too complex to study meaningfully.
 - The same principles govern neural functioning in all species.
 - It is too expensive to study human brains.
 - The technology is still being developed for the study of human brains.
- What is the brief electrical charge that travels down an axon called?
 - Action potential
 - Resting potential
 - All-or-none impulse
 - Refractory period
 - Myelination response
- An individual is having trouble with cognitive tasks related to learning and memory. Which of the following neurotransmitters is most likely to be involved with the problem?
 - Acetylcholine
 - Dopamine
 - Serotonin
 - The endorphins
 - GABA
- Which is the most influential of the endocrine glands?
 - Pituitary gland
 - Adrenal glands
 - Dendrites
 - Threshold glands
 - Parasympathetic
- What is the purpose of the myelin sheath?
 - Make the transfer of information across a synapse more efficient
 - Increase the amount of neurotransmitter available in the neuron
 - Reduce the antagonistic effect of certain drugs
 - Establish a resting potential in the axon
 - Speed the transmission of information within a neuron
- The peripheral nervous system
 - connects the brain to the spinal cord.
 - calms the body after an emergency.
 - is limited to the control of voluntary movement.
 - controls only the arms and the legs.
 - is the part of the nervous system that does not include the brain and the spinal cord.
- To walk across a street, a person would rely most directly on which division of the nervous system?
 - Central nervous system
 - Sympathetic nervous system
 - Peripheral nervous system
 - Autonomic nervous system
 - Parasympathetic nervous system
- Opiate drugs such as morphine are classified as what?
 - Antagonists, because they block neurotransmitter receptors for pain
 - Agonists, because they mimic other neurotransmitters' pain-diminishing effects
 - Excitatory neurotransmitters, because they activate pain-control mechanisms
 - Sympathetic nervous system agents, because they prepare the body for a challenge
 - Parasympathetic nervous system agents, because they calm the body
- Which region of the brain controls our breathing and heartbeat?
 - Pons
 - Corpus callosum
 - Parietal lobe
 - Hippocampus
 - Medulla
- Which of the following does a PET scan best allow researchers to examine?
 - The presence of tumors in the brain
 - Electrical activity on the surface of the brain
 - The size of the internal structures of the brain
 - The location of strokes
 - The functions of various brain regions

11. A researcher interested in determining the size of a particular area of the brain would be most likely to use what kind of test?
 - a. Lesion
 - b. EEG
 - c. MRI
 - d. fMRI
 - e. PET scan
12. Damage to the hippocampus would result in what?
 - a. Difficulties with balance and coordination
 - b. Memory problems
 - c. The false sensation of burning in parts of the body
 - d. Emotional outbursts
 - e. Death
13. Surgical stimulation of the somatosensory cortex might result in the false sensation of what?
 - a. Music
 - b. Flashes of colored light
 - c. Someone whispering your name
 - d. Someone tickling you
 - e. A bad odor
14. During which task might the right hemisphere of the brain be most active?
 - a. Solving a mathematical equation
 - b. Reading
 - c. Making a brief oral presentation to a class
 - d. Imagining what a dress would look like on a friend
 - e. Solving a logic problem
15. Brain plasticity refers to which of the following?
 - a. Healthy human brain tissue
 - b. The ability of the brain to transfer information from one hemisphere to the other
 - c. How a brain gets larger as a child grows
 - d. A wide variety of functions performed by the human brain
 - e. The ability of brain tissue to take on new functions
16. When Klüver and Bucy surgically lesioned the amygdala of a rhesus monkey's brain, what was the impact on the monkey's behavior?
 - a. Lost its ability to coordinate movement
 - b. Died because its heartbeat became irregular
 - c. Became less aggressive
 - d. Lost its memory of where food was stored
 - e. Sank into an irreversible coma
17. An individual experiences brain damage that produces a coma. Which part of the brain was probably damaged?
 - a. Corpus callosum
 - b. Reticular formation
 - c. Frontal lobe
 - d. Cerebellum
 - e. Limbic system
18. Evolutionary psychologists seek to understand how traits and behavioral tendencies have been shaped by what?
 - a. Natural selection
 - b. Genes
 - c. Prenatal nutrition
 - d. DNA
 - e. Chromosomes
19. Which is one of the major criticisms of the evolutionary perspective in psychology?
 - a. It analyzes after the fact using hindsight.
 - b. It attempts to extend a biological theory into a psychological realm.
 - c. There is very little evidence to support it.
 - d. It has not been around long enough to "stand the test of time."
 - e. It seems to apply in certain cultures but not in others.
20. What was one of the major findings of Thomas Bouchard's study of twins?
 - a. It demonstrated that peer influence is more important than parental influence in the development of personality traits.
 - b. It proved that the influence of parental environment becomes more and more important as children grow into adults.
 - c. He discovered almost unbelievable similarities between adult identical twins who had been separated near birth.
 - d. Fraternal twins showed almost as much similarity as identical twins when they reached adulthood.
 - e. It provided evidence that heritability is less important than researchers previously suspected.
21. Which of the following statements has been supported by the research of evolutionary psychologists?
 - a. Women are attracted to men who appear virile.
 - b. Men are attracted to women who appear fertile and capable of bearing children.
 - c. The connection between sex and pleasure is mostly determined by culture.
 - d. The same factors determine sexual attraction in both males and females.
 - e. Most adults are attracted to partners that in some way remind them of their parents.

- 22.** Why do researchers find the study of fraternal twins important?
- They share similar environments and the same genetic code.
 - Data collected concerning their similarities is necessary for calculating heritability.
 - They are the same age and are usually raised in similar environments, but they do not have the same genetic code.
 - Results allow us to determine exactly how disorders ranging from heart disease to schizophrenia are inherited.
 - They are typically raised in less similar environments than nontwin siblings.
- 23.** Heritability refers to the percentage of what?
- Group variation in a trait that can be explained by environment
 - Traits shared by identical twins
 - Traits shared by fraternal twins
 - Traits shared by adopted children and their birth parents
 - Group variation in a trait that can be explained by genetics
- 24.** What is the study of specific genes and teams of genes that influence behavior called?
- Molecular genetics
 - Evolutionary psychology
 - Behavior genetics
 - Heritability
 - Natural selection
- 25.** In an effort to reveal genetic influences on personality, researchers use adoption studies mainly for what purpose?
- To compare adopted children with nonadopted children
 - To study the effect of prior neglect on adopted children
 - To study the effect of a child's age at adoption
 - To evaluate whether adopted children more closely resemble their adoptive parents or their biological parents
 - To consider the effects of adoption on a child's manners and values

Free-Response Questions

1. Charlotte is 88 years old and is feeling the effects of her long life. She suffered a stroke five years ago, which left the right side of her body limp. She also sometimes has trouble understanding when she is asked questions. Her doctors believe that she also may be suffering from the beginning stages of Alzheimer's disease. Define each of the following terms and explain how each might contribute to Charlotte's current circumstance.

- Motor cortex
- Acetylcholine
- Association areas
- Plasticity
- Epigenetics

Rubric for Free Response Question 1

1 point: The motor cortex is responsible for directing movements. The left motor cortex controls the right side of the body while the right motor cortex controls the left side of the body.  Page 105

1 point: Because Charlotte's right side is limp, the damage from her stroke most likely occurred in the left hemisphere and potentially in her left motor cortex, which would leave her with little muscular control over the right side of her body.  Page 105

1 point: Acetylcholine is a neurotransmitter that plays a role in muscle action, learning, and memory.  Page 81

1 point: If Charlotte suffers from Alzheimer's disease, it is possible that the neurons responsible for producing acetylcholine have deteriorated.  Page 81

1 point: Association areas are the areas of the cerebral cortex not directly involved in motor or sensory functions; rather they are involved in higher-order thought processes such as learning, memory, and thinking.  Page 109

1 point: If Charlotte's association areas have been damaged, it may be difficult for her to integrate new ideas. She may also have trouble retrieving memories that were once easily recalled.  Page 109

1 point: Plasticity is the brain's ability to create new neural pathways. This often occurs in response to brain injuries and occurs most efficiently in children.  Page 111

1 point: Because of Charlotte's age, her brain will not have the ability to build an abundance of new neural networks, and if she has not recovered from her injury in a few months time, she is likely to make little progress in her recovery.

 Page 111

1 point: Epigenetics is the study of environmental influences on gene expression, which occur without DNA change.

 Page 131

1 point: Perhaps Charlotte has a predisposition for Alzheimer's disease. If she was in an environment which was not enriching and cognitively engaging, it may have made Alzheimer's disease more likely. On the other hand, despite having a genetic predisposition for Alzheimer's disease, if Charlotte was exposed to an enriching environment, her disposition may not have been expressed.  Page 125

2. If a person accidentally touches a pan filled with hot water on the stove, they will immediately move their hand away from the hot pan before yelling out in pain. Use the following terms to explain what is involved in this reaction.

- Neurotransmitters
- The endocrine system
- Thalamus
- Amygdala
- Sensory cortex
- Pain reflex

(6 points)

3. Dr. Nation is a biopsychologist interested in studying genetic influences on brain development. Briefly describe a twin study Dr. Nation might design to investigate the research question: "How do genetics and early environmental influences interact to impact how brains develop?" Use the following terms in context in your description:

- Genes
- Heritability
- Epigenetics
- Fraternal or identical twins
- fMRI

Unit IV

Sensation and Perception

Modules

16 Basic Principles of Sensation and Perception

17 Influences on Perception

18 Vision

19 Visual Organization and Interpretation

20 Hearing

21 The Other Senses

“I have perfect vision,” explains my colleague, Heather Sellers, an acclaimed writer and teacher. Her vision may be fine, but there is a problem with her perception. She cannot recognize faces.

In her memoir, *You Don't Look Like Anyone I Know*, Sellers (2010) tells of awkward moments resulting from her lifelong *prosopagnosia*—face blindness.

In college, on a date at the Spaghetti Station, I returned from the bathroom and plunked myself down in the wrong booth, facing the wrong man. I remained unaware he was not my date even as my date (a stranger to me) accosted Wrong Booth Guy, and then stormed out of the Station. I can't distinguish actors in movies and on television. I do not recognize myself in photos or videos. I can't recognize my stepsons in the soccer pick-up line; I failed to determine which husband was mine at a party, in the mall, at the market.

Her inability to recognize faces means that people sometimes perceive her as snobby or aloof. “Why did you walk past me?” a neighbor might later ask. Similar to those of us with hearing loss who fake hearing during trite social conversation, Sellers sometimes fakes recognition. She often smiles at people she passes, in case she knows them. Or she pretends to know the person with whom she is talking. (To avoid the stress associated with such perception failures, people with serious hearing loss or with *prosopagnosia* often shy away from busy social situations.) But

there is an upside: When encountering someone who previously irritated her, she typically won't feel ill will, because she doesn't recognize the person.

Unlike Sellers, most of us have (as Module 18 explains) a functioning area on the underside of our brain's right hemisphere that helps us recognize a familiar human face as soon as we detect it—in only one-seventh of a second (Jacques & Rossion, 2006). This ability illustrates a broader principle. *Nature's sensory gifts enable each animal to obtain essential information.* Some examples:

- Frogs, which feed on flying insects, have cells in their eyes that fire only in response to small, dark, moving objects. A frog could starve to death knee-deep in motionless flies. But let one zoom by and the frog's "bug detector" cells snap awake.
- Male silkworm moths' odor receptors can detect one-billionth of an ounce of sex attractant per second released by a female one mile away. That is why silkworms continue to be.
- Human ears are most sensitive to sound frequencies that include human voices, especially a baby's cry.

In this unit, we'll look more closely at what psychologists have learned about how we sense and perceive the world around us.

Module 16

Basic Principles of Sensation and Perception

Module Learning Objectives

- 16-1** Contrast *sensation* and *perception*, and explain the difference between *bottom-up* and *top-down* processing.
- 16-2** Discuss how much information we can consciously attend to at once.
- 16-3** Identify the three steps that are basic to all our sensory systems.
- 16-4** Distinguish between *absolute* and *difference thresholds*, and discuss whether we can sense and be affected by stimuli below the absolute threshold.
- 16-5** Explain the function of sensory adaptation.

sensation the process by which our sensory receptors and nervous system receive and represent stimulus energies from our environment.

perception the process of organizing and interpreting sensory information, enabling us to recognize meaningful objects and events.

bottom-up processing analysis that begins with the sensory receptors and works up to the brain's integration of sensory information.

top-down processing information processing guided by higher-level mental processes, as when we construct perceptions drawing on our experience and expectations.

selective attention the focusing of conscious awareness on a particular stimulus.

16-1 What are sensation and perception? What do we mean by *bottom-up processing* and *top-down processing*?

Sellers' curious mix of "perfect vision" and face blindness illustrates the distinction between sensation and perception. When she looks at a friend, her **sensation** is normal: Her senses detect the same information yours would, and they transmit that information to her brain. And her **perception**—the processes by which her brain organizes and interprets sensory input—is almost normal. Thus, she may recognize people from their hair, gait, voice, or particular physique, just not their face. Her experience is much like the struggle you or I would have trying to recognize a specific penguin in a group of waddling penguins.

In our everyday experiences, sensation and perception blend into one continuous process. In this module, we slow down that process to study its parts, but in real life, our sensory and perceptual processes work together to help us decipher the world around us.

- Our **bottom-up processing** starts at the sensory receptors and works up to higher levels of processing.
- Our **top-down processing** constructs perceptions from the sensory input by drawing on our experience and expectations.

As our brain absorbs the information in **FIGURE 16.1**, bottom-up processing enables our sensory systems to detect the lines, angles, and colors that form the flower and leaves. Using top-down processing we interpret what our senses detect.

But *how* do we do it? How do we create meaning from the blizzard of sensory stimuli bombarding our bodies 24 hours a day? Meanwhile, in a silent, cushioned, inner world, our brain floats in utter darkness. By itself, it sees nothing. It hears nothing. It feels nothing. *So, how does the world out there get in?* To phrase the question scientifically: How do we construct our representations of the external world? How do a campfire's flicker, crackle, and smoky scent activate neural connections? And how, from this living neurochemistry, do we create our conscious experience of the fire's motion and temperature, its aroma and beauty? In search of answers to such questions, let's look at some processes that cut across all our sensory systems. To begin, where is the border between our conscious and unconscious awareness, and what stimuli cross that threshold?

Figure 16.1

What's going on here? Our sensory and perceptual processes work together to help us sort out the complex images, including the hidden couple in Sandro Del-Prete's drawing, *The Flowering of Love*.

Sandro Del-Prete

Selective Attention

16-2 How much information do we consciously attend to at once?

Through **selective attention**, your awareness focuses, like a flashlight beam, on a minute aspect of all that you experience. By one estimate, your five senses take in 11,000,000 bits of information per second, of which you consciously process about 40 (Wilson, 2002). Yet your mind's unconscious track intuitively makes great use of the other 10,999,960 bits. Until reading this sentence, for example, you have been unaware that your shoes are pressing against your feet or that your nose is in your line of vision. Now, suddenly, your attentional spotlight shifts. Your feet feel encased, your nose stubbornly intrudes on the words before you. While focusing on these words, you've also been blocking other parts of your environment from awareness, though your peripheral vision would let you see them easily. You can change that. As you stare at the X below, notice what surrounds these sentences (the edges of the page, the desktop, the floor).

X

A classic example of selective attention is the *cocktail party effect*—your ability to attend to only one voice among many (while also being able to detect your own name in an unattended voice). This effect might have prevented an embarrassing and dangerous situation in

2009, when two commercial airline pilots “lost track of time.” Focused on their laptops and conversation, they ignored alarmed air traffic controllers’ attempts to reach them as they overflew their Minneapolis destination by 150 miles. If only the controllers had known and spoken the pilots’ names.

Selective Attention and Accidents

Text or talk on the phone while driving, or attend to a music player or GPS, and your selective attention will shift back and forth between the road and its electronic competition. But when a demanding situation requires it, you’ll probably give the road your full attention. You’ll probably also blink less. When focused on a task, such as reading, people blink less than when their mind is wandering (Smilek et al., 2010). If you want to know whether your dinner companion is focused on what you’re saying, watch for eyeblinks and hope there won’t be too many.

We pay a toll for switching attentional gears, especially when we shift to complex tasks, like noticing and avoiding cars around us. The toll is a slight and sometimes fatal delay in coping (Rubenstein et al., 2001). About 28 percent of traffic accidents occur when people are chatting on cell phones or texting (National Safety Council, 2010). One study tracked long-haul truck drivers for 18 months. The video cameras mounted in their cabs showed they were at 23 times greater risk of a collision while texting (VTI, 2009). Mindful of such findings, the United States in 2010 banned truckers and bus drivers from texting while driving (Halsey, 2010).

It’s not just truck drivers who are at risk. One in four teen drivers with cell phones admit to texting while driving (Pew, 2009). Multitasking comes at a cost: fMRI scans offer a biological account of how multitasking distracts from brain resources allocated to driving. They show that brain activity in areas vital to driving decreases an average 37 percent when a driver is attending to conversation (Just et al., 2008).

Even hands-free cell-phone talking is more distracting than a conversation with passengers, who can see the driving demands and pause the conversation. When University of Sydney researchers analyzed phone records for the moments before a car crash, they found that cell-phone users (even with hands-free sets) were four times more at risk (McEvoy et al., 2005, 2007). Having a passenger increased risk only 1.6 times. This risk difference also appeared in an experiment that asked drivers to pull off at a freeway rest stop 8 miles ahead. Of drivers conversing with a passenger, 88 percent did so. Of those talking on a cell phone, 50 percent drove on by (Strayer & Drews, 2007).

“I wasn’t texting. I was building this ship in a bottle.”

SALLY FORTH

Driven to distraction

In driving-simulation experiments, people whose attention is diverted by cell-phone conversation make more driving errors.

AP® Exam Tip

You may wish to think about how the information on selective attention relates to something a little less dangerous: studying. The same principles apply. The more time you spend texting, tweeting, and Facebooking, the less focused you’ll be on the material you’re trying to master. A better strategy is to spend 25 minutes doing schoolwork and schoolwork alone. Then you can reward yourself with a few minutes of social networking.

Most European countries and American states now ban hand-held cell phones while driving (Rosenthal, 2009). Engineers are also devising ways to monitor drivers' gaze and to direct their attention back to the road (Lee, 2009).

Selective Inattention

At the level of conscious awareness, we are “blind” to all but a tiny sliver of visual stimuli. Researchers demonstrated this **inattentional blindness** dramatically by showing people a 1-minute video in which images of three black-shirted men tossing a basketball were superimposed over the images of three white-shirted players (Neisser, 1979; Becklen & Cervone, 1983). The viewers' supposed task was to press a key every time a black-shirted player passed the ball. Most focused their attention so completely on the game that they failed to notice a young woman carrying an umbrella saunter across the screen midway through the video (**FIGURE 16.2**). Seeing a replay of the video, viewers were astonished to see her (Mack & Rock, 2000). This inattentional blindness is a by-product of what we are really good at: focusing attention on some part of our environment.

In a repeat of the experiment, smart-aleck researchers Daniel Simons and Christopher Chabris (1999) sent a gorilla-suited assistant through the swirl of players. During its 5- to 9-second cameo appearance, the gorilla paused to thump its chest. Still, half the conscientious pass-counting viewers failed to see it. In another follow-up experiment, only 1 in 4 students engrossed in a cell-phone conversation while crossing a campus square noticed a clown-suited unicyclist in their midst (Hyman et al., 2010). (Most of those not on the phone *did* notice.) Attention is powerfully selective. Your conscious mind is in one place at a time.

Given that most people miss someone in a gorilla or clown suit while their attention is riveted elsewhere, imagine the fun that magicians can have by manipulating our selective attention. Misdirect people's attention and they will miss the hand slipping into the pocket. “Every time you perform a magic trick, you're engaging in experimental psychology,” says Teller, a magician and master of mind-messing methods (2009).

Magicians also exploit a form of inattentional blindness called **change blindness**. By selectively riveting our attention on their left hand's dramatic act, we fail to notice changes made with their other hand. In laboratory experiments, viewers didn't notice that, after a brief visual interruption, a big Coke bottle had disappeared, a railing had risen, or clothing color had changed (Chabris & Simons, 2010; Resnick et al., 1997). Focused on giving directions to a construction worker, two out of three people also failed to notice when he was replaced by another worker during a staged interruption (**FIGURE 16.3**). Out of sight, out of mind.

inattentional blindness failing to see visible objects when our attention is directed elsewhere.

change blindness failing to notice changes in the environment.

Figure 16.2

Testing selective attention In this classic experiment, viewers who were attending to basketball tosses among the black-shirted players usually failed to notice the umbrella-toting woman sauntering across the screen. (From Neisser, 1979.)

**Figure 16.3**

Change blindness While a man (white hair) provides directions to a construction worker, two experimenters rudely pass between them. During this interruption, the original worker switches places with another person wearing different-colored clothing. Most people, focused on their direction giving, do not notice the switch.

An equally astonishing form of inattention is *choice blindness*. At one Swedish supermarket, people tasted two jams, indicated their preference, and then tasted again their preferred jam and explained their preference. Fooled by trick jars (see **FIGURE 16.4**) most people didn't notice that they were actually "retasting" their *non*preferred jam.

Image is from the research paper by Lars Hall, Petter Johansson, and colleagues (2010).

**Figure 16.4**

Marketplace magic Prankster researchers Lars Hall, Petter Johansson, and colleagues (2010) invited people to sample two jams and pick one to retaste. By flipping the jars after putting the lids back on, the researchers actually induced people to "resample" their nonchosen jam. Yet, even when asked whether they noticed anything odd, most tasters were choice blind. Even when given markedly different jams, they usually failed to notice the switch.

Some stimuli, however, are so powerful, so strikingly distinct, that we experience *pop-out*, as when we notice an angry face in a crowd. We don't choose to attend to these stimuli; they draw our eye and demand our attention.

Our selective attention extends even into our sleep, as we will see.

Transduction

16-3 What three steps are basic to all our sensory systems?

Every second of every day, our sensory systems perform an amazing feat: They convert one form of energy into another. Vision processes light energy. Hearing processes sound waves. All our senses

- *receive* sensory stimulation, often using specialized receptor cells.
- *transform* that stimulation into neural impulses.
- *deliver* the neural information to our brain.

The process of converting one form of energy into another that your brain can use is called **transduction**. Later in this unit, we'll focus on individual sensory systems. How do we see? Hear? Feel pain? Taste? Smell? Keep our balance? In each case, we'll consider these three steps—receiving, transforming, and delivering the information to the brain. We'll also see what **psychophysics** has discovered about the physical energy we can detect and its effects on our psychological experiences.

First, though, let's explore some strengths and weaknesses in our ability to detect and interpret stimuli in the vast sea of energy around us.

transduction conversion of one form of energy into another. In sensation, the transforming of stimulus energies, such as sights, sounds, and smells, into neural impulses our brain can interpret.

psychophysics the study of relationships between the physical characteristics of stimuli, such as their intensity, and our psychological experience of them.

Thresholds

16-4

What are the *absolute* and *difference thresholds*, and do stimuli below the absolute threshold have any influence on us?

At this moment, you and I are being struck by X-rays and radio waves, ultraviolet and infrared light, and sound waves of very high and very low frequencies. To all of these we are blind and deaf. Other animals with differing needs detect a world that lies beyond our experience. Migrating birds stay on course aided by an internal magnetic compass. Bats and dolphins locate prey using sonar, bouncing echoing sound off objects. Bees navigate on cloudy days by detecting invisible (to us) polarized light.

The shades on our own senses are open just a crack, allowing us a restricted awareness of this vast sea of energy. But for our needs, this is enough.

Absolute Thresholds

To some kinds of stimuli we are exquisitely sensitive. Standing atop a mountain on an utterly dark, clear night, most of us could see a candle flame atop another mountain 30 miles away. We could feel the wing of a bee falling on our cheek. We could smell a single drop of perfume in a three-room apartment (Galanter, 1962).

German scientist and philosopher Gustav Fechner (1801–1887) studied our awareness of these faint stimuli and called them our **absolute thresholds**—the minimum stimulation necessary to detect a particular light, sound, pressure, taste, or odor 50 percent of the time. To test your absolute threshold for sounds, a hearing specialist would expose each of your ears to varying sound levels. For each tone, the test would define where half the time you could detect the sound and half the time you could not. That 50–50 point would define your absolute threshold.

Detecting a weak stimulus, or signal, depends not only on the signal's strength (such as a hearing-test tone) but also on our psychological state—our experience, expectations, motivation, and alertness. **Signal detection theory** predicts when we will detect weak signals (measured as our ratio of “hits” to “false alarms”) (**FIGURE 16.5**). Signal detection theorists seek to understand why people respond differently to the same stimuli (have you ever noticed that some teachers are much more likely than others to detect students texting during class?) and why the same person's reactions vary as circumstances change. Exhausted parents will notice the faintest whimper from a newborn's cradle while failing to notice louder, unimportant sounds. Lonely, anxious people at speed-dating events also respond with a low threshold and thus tend to be unselective in reaching out to potential dates (McClure et al., 2010).

absolute threshold the minimum stimulation needed to detect a particular stimulus 50 percent of the time.

signal detection theory a theory predicting how and when we detect the presence of a faint stimulus (*signal*) amid background stimulation (*noise*). Assumes that there is no single absolute threshold and that detection depends partly on a person's experience, expectations, motivation, and alertness.

Try This

Try out this old riddle on a couple of friends. “You're driving a bus with 12 passengers. At your first stop, 6 passengers get off. At the second stop, 3 get off. At the third stop, 2 more get off but 3 new people get on. What color are the bus driver's eyes?” Do your friends detect the signal—who is the bus driver?—amid the accompanying noise?

Figure 16.5

Signal detection What three factors will make it more likely that you correctly detect a text message?

ANSWER: (1) You are expecting a text message. (2) It is important that you see the text message and respond. (3) You are alert.

© Inspirestock/Corbis

AJ Photo/Science Source

**Figure 16.6**

Absolute threshold Can I detect this sound? An *absolute threshold* is the intensity at which a person can detect a stimulus half the time. Hearing tests locate these thresholds for various frequency levels. Stimuli below your absolute threshold are subliminal.

Stimuli you cannot detect 50 percent of the time are **subliminal**—below your absolute threshold (**FIGURE 16.6**). Under certain conditions, you can be affected by stimuli so weak that you don't consciously notice them. An unnoticed image or word can reach your visual cortex and briefly **prime** your response to a later question. In a typical experiment, the image or word is quickly flashed, then replaced by a *masking stimulus* that interrupts the brain's processing before conscious perception (Van den Bussche et al., 2009). For example, one experiment subliminally flashed either emotionally positive scenes (kittens, a romantic couple) or negative scenes (a werewolf, a dead body) an instant before participants viewed slides of people (Krosnick et al., 1992). The participants consciously perceived either scene as only a flash of light. Yet the people somehow looked nicer if their image immediately followed unperceived kittens rather than an unperceived werewolf. As other experiments confirm, we can evaluate a stimulus even when we are not aware of it—and even when we are unaware of our evaluation (Ferguson & Zayas, 2009).

How do we feel or respond to what we do not know and cannot describe? An imperceptibly brief stimulus often triggers a weak response that *can* be detected by brain scanning (Blankenburg et al., 2003; Haynes & Rees, 2005, 2006). Only when the stimulus triggers synchronized activity in several brain areas does it reach consciousness (Dehaene, 2009). Once again we see the dual-track mind at work: *Much of our information processing occurs automatically, out of sight, off the radar screen of our conscious mind.*

So can we be controlled by subliminal messages? For more on that question, see Thinking Critically About: Can Subliminal Messages Control Our Behavior? on the next page.

Difference Thresholds

To function effectively, we need absolute thresholds low enough to allow us to detect important sights, sounds, textures, tastes, and smells. We also need to detect small differences among stimuli. A musician must detect minute discrepancies when tuning an instrument. Students in the hallway must detect the sound of their friends' voices amid all the other voices. Even after living two years in Scotland, sheep *baa*'s all sound alike to my ears. But not to those of ewes, which I have observed streaking, after shearing, directly to the *baa* of their lamb amid the chorus of other distressed lambs.

subliminal below one's absolute threshold for conscious awareness.

priming the activation, often unconsciously, of certain associations, thus predisposing one's perception, memory, or response.

"The heart has its reasons which reason does not know." -PASCAL, *PENSÉES*, 1670

Thinking Critically About

Can Subliminal Messages Control Our Behavior?

Hoping to penetrate our unconscious, entrepreneurs offer audio and video programs to help us lose weight, stop smoking, or improve our memories. Soothing ocean sounds may mask messages we cannot consciously hear: “I am thin”; “Smoke tastes bad”; or “I do well on tests—I have total recall of information.” Such claims make two assumptions: (1) We can unconsciously sense subliminal (literally, “below threshold”) stimuli. (2) Without our awareness, these stimuli have extraordinary suggestive powers. Can we? Do they?

As we have seen, subliminal *sensation* is a fact. Remember that an “absolute” threshold is merely the point at which we can detect a stimulus *half the time*. At or slightly below this threshold, we will still detect the stimulus some of the time.

But does this mean that claims of subliminal *persuasion* are also facts? The near-consensus among researchers is *No*. The laboratory research reveals a *subtle, fleeting* effect. Priming thirsty people with the subliminal word *thirst* might therefore, for a moment, make a thirst-quenching beverage ad more persuasive (Strahan et al., 2002). Likewise, priming thirsty people with Lipton Iced Tea may increase their choosing the primed brand (Karremans et al., 2006; Veltkamp et al., 2011; Verwijmeren et al., 2011a,b). But the subliminal-message hucksters claim something different: a *powerful, enduring* effect on behavior.

To test whether subliminal recordings have this enduring effect, researchers randomly assigned university students to listen daily for 5 weeks to commercial subliminal messages claiming to improve either self-esteem or memory (Greenwald et al., 1991, 1992). But the researchers played a practical joke and switched half the labels. Some students who thought they were receiving affirmations of self-esteem were actually hearing the memory-enhancement message. Others got the self-esteem message but thought their memory was being recharged.

Were the recordings effective? Students’ test scores for self-esteem and memory, taken before and after the 5 weeks,

Babas Reingold for Worth Publishers

Subliminal persuasion?

Although subliminally presented stimuli *can* subtly influence people, experiments discount attempts at subliminal advertising and self-improvement. (The playful message here is not actually subliminal—because you can easily perceive it.)

revealed no effects. Yet the students *perceived* themselves receiving the benefits they *expected*. Those who *thought* they had heard a memory recording *believed* their memories had improved. Those who thought they had heard a self-esteem recording believed their self-esteem had grown. (Reading this research, one hears echoes of the testimonies that ooze from ads for such products. Some customers, having bought what is not supposed to be heard [and having indeed not heard it!] offer testimonials like, “I really know that your recordings were invaluable in reprogramming my mind.”)

Over a decade, Greenwald conducted 16 double-blind experiments evaluating subliminal self-help recordings. His results were uniform: Not one of the recordings helped more than a placebo (Greenwald, 1992). And placebos, you may remember, work only because we *believe* they will work.

The difference threshold

In this computer-generated copy of the Twenty-third Psalm, each line of the typeface increases slightly. How many lines are required for you to experience a just noticeable difference?

The LORD is my shepherd;
I shall not want.
He maketh me to lie down
in green pastures:
he leadeth me
beside the still waters.
He restoreth my soul:
he leadeth me
in the paths of righteousness
for his name's sake.
Yea, though I walk through the valley
of the shadow of death,
I will fear no evil:
for thou art with me;
thy rod and thy staff
they comfort me.
Thou preparest a table before me
in the presence of mine enemies:
thou anointest my head with oil,
my cup runneth over.
Surely goodness and mercy
shall follow me
all the days of my life:
and I will dwell
in the house of the LORD
for ever.

The **difference threshold** (or the *just noticeable difference [jnd]*) is the minimum difference a person can detect between any two stimuli half the time. That difference threshold increases with the size of the stimulus. Thus, if you add 1 ounce to a 10-ounce weight, you will detect the difference; add 1 ounce to a 100-ounce weight and you probably will not.

In the nineteenth century, Ernst Weber noted something so simple and so widely applicable that we still refer to it as **Weber's law**. This law states that for an average person to perceive a difference, two stimuli must differ by a constant minimum *percentage* (not a

constant *amount*). The exact proportion varies, depending on the stimulus. Two lights, for example, must differ in intensity by 8 percent. Two objects must differ in weight by 2 percent. And two tones must differ in frequency by only 0.3 percent (Teghtsoonian, 1971). For example, to be perceptibly different, a 50-ounce weight must differ from another by about an ounce, a 100-ounce weight by about 2 ounces.

Sensory Adaptation

16-5 What is the function of sensory adaptation?

Entering your neighbors' living room, you smell a musty odor. You wonder how they can stand it, but within minutes you no longer notice it. **Sensory adaptation** has come to your rescue. When we are constantly exposed to a stimulus that does not change, we become less aware of it because our nerve cells fire less frequently. (To experience sensory adaptation, move your watch up your wrist an inch: You will feel it—but only for a few moments.)

Why, then, if we stare at an object without flinching, does it *not* vanish from sight? Because, unnoticed by us, our eyes are always moving. This continual flitting from one spot to another ensures that stimulation on the eyes' receptors continually changes (**FIGURE 16.7**).

What if we actually could stop our eyes from moving? Would sights seem to vanish, as odors do? To find out, psychologists have devised ingenious instruments that maintain a constant image on the eye's inner surface. Imagine that we have fitted a volunteer, Mary, with one of these instruments—a miniature projector mounted on a contact lens (**FIGURE 16.8a** on the next page). When Mary's eye moves, the image from the projector moves as well. So everywhere that Mary looks, the scene is sure to go.

If we project images through this instrument, what will Mary see? At first, she will see the complete image. But within a few seconds, as her sensory system begins to fatigue, things get weird. Bit by bit, the image vanishes, only to reappear and then disappear—often in fragments (Figure 16.8b).

Although sensory adaptation reduces our sensitivity, it offers an important benefit: freedom to focus on *informative* changes in our environment without being distracted by background chatter. Stinky or heavily perfumed classmates don't notice their odor because, like you and me, they adapt to what's constant and detect only change. Our sensory receptors

difference threshold the minimum difference between two stimuli required for detection 50 percent of the time. We experience the difference threshold as a *just noticeable difference* (or *jnd*).

Weber's law the principle that, to be perceived as different, two stimuli must differ by a constant minimum percentage (rather than a constant amount).

sensory adaptation diminished sensitivity as a consequence of constant stimulation.

"We need above all to know about changes; no one wants or needs to be reminded 16 hours a day that his shoes are on."
-NEUROSCIENTIST DAVID HUBEL (1979)

Figure 16.7

The jumpy eye Our gaze jumps from one spot to another every third of a second or so, as eye-tracking equipment illustrated in this photograph of Edinburgh's Princes Street Gardens (Henderson, 2007). The circles represent fixations, and the numbers indicate the time of fixation in milliseconds (300 milliseconds = three-tenths of a second).

Figure 16.8**Sensory adaptation: Now you see it, now you don't!**

(a) A projector mounted on a contact lens makes the projected image move with the eye. (b) Initially, the person sees the stabilized image, but soon she sees fragments fading and reappearing. (a)

(b)

are alert to novelty; bore them with repetition and they free our attention for more important things. We will see this principle again and again: *We perceive the world not exactly as it is, but as it is useful for us to perceive it.*

Our sensitivity to changing stimulation helps explain television's attention-grabbing power. Cuts, edits, zooms, pans, sudden noises—all demand attention. The phenomenon is irresistible even to TV researchers. One noted that even during interesting conversations, "I cannot for the life of me stop from periodically glancing over to the screen" (Tannenbaum, 2002).

Sensory adaptation even influences our perceptions of emotions. By creating a 50-50 morphed blend of an angry and a scared face, researchers showed that our visual system adapts to a static facial expression by becoming less responsive to it (Butler et al., 2008) (**FIGURE 16.9**).

Sensory adaptation and sensory thresholds are important ingredients in our perceptions of the world around us. Much of what we perceive comes not just from what's "out there" but also from what's behind our eyes and between our ears.

Figure 16.9

Emotion adaptation Gaze at the angry face on the left for 20 to 30 seconds, then look at the center face (looks scared, yes?). Then gaze at the scared face on the right for 20 to 30 seconds, before returning to the center face (now looks angry, yes?).

Reprinted from *Brain Research*, Vol 1191, Andrea Butler, Ipek Onuc, Christopher J. Fox, Jason J. S. Barton. Factors contributing to the adaptation after effects of facial expression, Pg 116–126, 2008, with permission from Elsevier.

Before You Move On

▶ ASK YOURSELF

Can you recall a recent time when, your attention focused on one thing, you were oblivious to something else (perhaps to pain, to someone's approach, or to background music)?

▶ TEST YOURSELF

Explain how Heather Sellers' experience of prosopagnosia illustrates the difference between sensation and perception.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 16 Review

16-1 What are *sensation* and *perception*? What do we mean by *bottom-up processing* and *top-down processing*?

- *Sensation* is the process by which our sensory receptors and nervous system receive and represent stimulus energies from our environment. *Perception* is the process of organizing and interpreting this information, enabling recognition of meaningful events. Sensation and perception are actually parts of one continuous process.
- *Bottom-up processing* is sensory analysis that begins at the entry level, with information flowing from the sensory receptors to the brain. *Top-down processing* is information processing guided by high-level mental processes, as when we construct perceptions by filtering information through our experience and expectations.

16-2 How much information do we consciously attend to at once?

- We *selectively attend* to, and process, a very limited portion of incoming information, blocking out much and often shifting the spotlight of our attention from one thing to another.
- Focused intently on one task, we often display *inattentional blindness* (including *change blindness*) to other events and changes around us.

16-3 What three steps are basic to all our sensory systems?

- Our senses (1) receive sensory stimulation (often using specialized receptor cells); (2) transform that stimulation into neural impulses; and (3) deliver the neural information to the brain. *Transduction* is the process of converting one form of energy into another.

- Researchers in *psychophysics* study the relationships between stimuli's physical characteristics and our psychological experience of them.

16-4 What are the *absolute* and *difference thresholds*, and do stimuli below the absolute threshold have any influence on us?

- Our *absolute threshold* for any stimulus is the minimum stimulation necessary for us to be consciously aware of it 50 percent of the time. *Signal detection theory* predicts how and when we will detect a faint stimulus amid background noise. Individual absolute thresholds vary, depending on the strength of the signal and also on our experience, expectations, motivation, and alertness.
- Our *difference threshold* (also called *just noticeable difference*, or *jnd*) is the difference we can discern between two stimuli 50 percent of the time. *Weber's law* states that two stimuli must differ by a constant percentage (not a constant amount) to be perceived as different.
- *Priming* shows that we can process some information from stimuli below our absolute threshold for conscious awareness. But the effect is too fleeting to enable people to exploit us with *subliminal* messages.

16-5 What is the function of sensory adaptation?

- *Sensory adaptation* (our diminished sensitivity to constant or routine odors, sights, sounds, and touches) focuses our attention on informative changes in our environment.

Multiple-Choice Questions

1. What occurs when experiences influence our interpretation of data?
 - a. Selective attention
 - b. Transduction
 - c. Bottom-up processing
 - d. Top-down processing
 - e. Signal detection theory
2. What principle states that to be perceived as different, two stimuli must differ by a minimum percentage rather than a constant amount?
 - a. Absolute threshold
 - b. Different threshold
 - c. Signal detection theory
 - d. Priming
 - e. Weber's law

3. What do we call the conversion of stimulus energies, like sights and sounds, into neural impulses?
 - a. Transduction
 - b. Perception
 - c. Priming
 - d. Signal detection theory
 - e. Threshold
4. Natalia is washing her hands and adjusts the faucet handle until the water feels just slightly hotter than it did before. Natalia's adjustment until she feels a difference is an example of
 - a. a subliminal stimulus.
 - b. an absolute threshold.
 - c. a difference threshold.
 - d. signal detection.
 - e. Weber's law.
5. Tyshane went swimming with friends who did not want to get into the pool because the water felt cold. Tyshane jumped in and after a few minutes declared, "It was cold when I first got in, but now my body is used to it. Come on in!" Tyshane's body became accustomed to the water due to
 - a. perceptual set.
 - b. absolute threshold.
 - c. difference threshold.
 - d. selective attention.
 - e. sensory adaptation.

Practice FRQs

1. Explain how bottom-up and top-down processes work together to help us decipher the world around us..

Answer

1 point: Bottom-up processing starts at the sensory receptors and works up to higher levels of processing.

1 point: Top-down processing constructs perceptions from the sensory input by drawing on our experience and expectations.

2. Marisol is planning a ski trip for spring break. Define absolute threshold and difference threshold, and explain how each one might play a role in her perception of the winter weather she will experience.

(4 points)

Module 17

Influences on Perception

Module Learning Objectives

- 17-1** Explain how our expectations, contexts, emotions, and motivation influence our perceptions.
- 17-2** List the claims of ESP, and discuss the conclusions of most research psychologists after putting these claims to the test.

Perceptual Set

- 17-1** How do our expectations, contexts, emotions, and motivation influence our perceptions?

As everyone knows, to see is to believe. As we less fully appreciate, to believe is to see. Through experience, we come to expect certain results. Those expectations may give us a **perceptual set**, a set of mental tendencies and assumptions that greatly affects (top-down) what we perceive. Perceptual set can influence what we hear, taste, feel, and see.

Consider: Is the image in the center picture of **FIGURE 17.1** a young woman's profile or an old woman? What we see in such a drawing can be influenced by first looking at either of the two unambiguous versions (Boring, 1930).

Everyday examples of perceptual set abound. In 1972, a British newspaper published unretouched photographs of a "monster" in Scotland's Loch Ness—"the most amazing

perceptual set a mental predisposition to perceive one thing and not another.

Figure 17.1
Perceptual set Show a friend either the left or right image. Then show the center image and ask, "What do you see?" Whether your friend reports seeing a young woman's profile or an old woman may depend on which of the other two drawings was viewed first. In each of those images, the meaning is clear, and it will establish perceptual expectations.

© The New Yorker Collection, 2002, Leo Cullum from cartoonbank.com. All Rights Reserved.

pictures ever taken,” stated the paper. If this information creates in you the same expectations it did in most of the paper’s readers, you, too, will see the monster in a similar photo in **FIGURE 17.2**. But when a skeptical researcher approached the photos with different expectations, he saw a curved tree limb—as had others the day the photo was shot (Campbell, 1986). With this different perceptual set, you may now notice that the object is floating motionless, with ripples outward in all directions—hardly what we would expect of a lively monster. Once we have formed a wrong idea about reality, we have more difficulty seeing the truth.

Perceptual set can also affect what we hear. Consider the kindly airline pilot who, on a takeoff run, looked over at his depressed co-pilot and said, “Cheer up.” Expecting to hear the usual “Gear up,” the co-pilot promptly raised the wheels—before they left the ground (Reason & Mycielska, 1982).

Figure 17.2

Believing is seeing What do you perceive? Is this Nessie, the Loch Ness monster, or a log?

Hulton Archive/Getty Images

Try This

When shown the phrase
*Mary had a
 a little lamb*
 many people perceive what they expect, and miss the repeated word. Did you?

“We hear and apprehend only what we already half know.”
 —HENRY DAVID THOREAU, *JOURNAL*, 1860

Perceptual set similarly affects taste. One experiment invited some bar patrons to sample free beer (Lee et al., 2006). When researchers added a few drops of vinegar to a brand-name beer, the tasters preferred it—unless they had been told they were drinking vinegar-laced beer. Then they expected, and usually experienced, a worse taste. In another experiment, preschool children, by a 6-to-1 margin, thought french fries tasted better when served in a McDonald’s bag rather than a plain white bag (Robinson et al., 2007).

What determines our perceptual set? As Module 47 will explain, through experience we form concepts, or *schemas*, that organize and allow us to interpret unfamiliar information. Our pre-existing schemas for old women and young women, for monsters and tree limbs, all influence how we interpret ambiguous sensations with top-down processing.

In everyday life, stereotypes about gender (another instance of perceptual set) can color perception. Without the obvious cues of pink or blue, people will struggle over whether to call the new baby “he” or “she.” But told an infant is “David,” people (especially children) may perceive “him” as bigger and stronger than if the same infant is called “Diana” (Stern & Karraker, 1989). Some differences, it seems, exist merely in the eyes of their beholders.

Context Effects

A given stimulus may trigger radically different perceptions, partly because of our differing perceptual set, but also because of the immediate context. Some examples:

Culture and context effects

What is above the woman's head? In a classic study from nearly a half-century ago, most East Africans perceived the woman as balancing a metal box or can on her head and the family as sitting under a tree. Westerners, for whom corners and boxlike architecture were more common, were more likely to perceive the family as being indoors, with the woman sitting under a window. (Adapted from Gregory & Gombrich, 1973.)

- Imagine hearing a noise interrupted by the words “eel is on the wagon.” Likely, you would actually perceive the first word as *wheel*. Given “eel is on the orange,” you would hear *peel*. This curious phenomenon, discovered by Richard Warren, suggests that the brain can work backward in time to allow a later stimulus to determine how we perceive an earlier one. The context creates an expectation that, top-down, influences our perception (Grossberg, 1995).
- Does the pursuing dog in **FIGURE 17.3** look bigger than the one being pursued? If so, you are experiencing a context effect.
- How tall is the shorter player in **FIGURE 17.4**?

Figure 17.3

The interplay between context and emotional perception The context makes the pursuing dog look bigger than the pursued. It isn't.

Dennis Geppert/Holland Sentinel

Figure 17.4

Big and “little” The “little guy” shown here is actually a 6'9" former Hope College basketball center who would tower over most of us. But he seemed like a short player when matched in a semi-pro game against the world's tallest basketball player at that time, 7'9" Sun Ming Ming from China.

Emotion and Motivation

Perceptions are influenced, top-down, not only by our expectations and by the context, but also by our emotions and motivation.

Hearing sad rather than happy music can predispose people to perceive a sad meaning in spoken homophonic words—*mourning* rather than *morning*, *die* rather than *dye*, *pain* rather than *pane* (Halberstadt et al., 1995).

Researchers (Proffitt, 2006a,b; Schnall et al., 2008) have demonstrated the power of emotions with other clever experiments showing that

- walking destinations look farther away to those who have been fatigued by prior exercise.
- a hill looks steeper to those who are wearing a heavy backpack or have just been exposed to sad, heavy classical music rather than light, bouncy music. As with so many of life’s challenges, a hill also seems less steep to those with a friend beside them.
- a target seems farther away to those throwing a heavy rather than a light object at it.

Even a softball appears bigger when you are hitting well, observed other researchers, after asking players to choose a circle the size of the ball they had just hit well or poorly (Witt & Proffitt, 2005). When angry, people more often perceive neutral objects as guns (Bauman & DeSteno, 2010).

Motives also matter. Desired objects, such as a water bottle when thirsty, seem closer (Balcetis & Dunning, 2010). This perceptual bias energizes our going for it. Our motives also direct our perception of ambiguous images.

Emotions color our social perceptions, too. Spouses who feel loved and appreciated perceive less threat in stressful marital events—“He’s just having a bad day” (Murray et al., 2003). Professional referees, if told a soccer team has a history of aggressive behavior, will assign more penalty cards after watching videotaped fouls (Jones et al., 2002).

* * *

Emotion and motivation clearly influence how we perceive sensations. But what to make of extrasensory perception, which claims that perception can occur apart from sensory input? For more on that question, see Thinking Critically About: ESP—Perception Without Sensation?

Before You Move On

▶ ASK YOURSELF

Can you recall a time when your expectations have predisposed how you perceived a person (or group of people)?

▶ TEST YOURSELF

What type of evidence shows that, indeed, “there is more to perception than meets the senses”?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

“When you’re hitting the ball,
it comes at you looking like a
grapefruit. When you’re not,
it looks like a blackeyed pea.”
-FORMER MAJOR LEAGUE BASEBALL
PLAYER GEORGE SCOTT

Thinking Critically About

ESP—Perception Without Sensation?

17-2

What are the claims of ESP, and what have most research psychologists concluded after putting these claims to the test?

Without sensory input, are we capable of **extrasensory perception (ESP)**? Are there indeed people—any people—who can read minds, see through walls, or foretell the future? Nearly half of Americans believe there are (AP, 2007; Moore, 2005).

The most testable and, for this unit, most relevant parapsychological concepts are

- *telepathy*: mind-to-mind communication.
- *clairvoyance*: perceiving remote events, such as a house on fire in another state.
- *precognition*: perceiving future events, such as an unexpected death in the next month.

Closely linked is *psychokinesis*, or “mind over matter,” such as levitating a table or influencing the roll of a die. (The claim is illustrated by the wry request, “Will all those who believe in psychokinesis please raise my hand?”)

If ESP is real, we would need to overturn the scientific understanding that we are creatures whose minds are tied to our physical brains and whose perceptual experiences of the world are built of sensations. Sometimes new evidence does overturn our scientific preconceptions. Science, as we will see throughout this book, offers us various surprises—about the extent of the unconscious mind, about the effects of emotions on health, about what heals and what doesn’t, and much more.

Most research psychologists and scientists—including 96 percent of the scientists in the U.S. National Academy of Sciences—are skeptical that paranormal phenomena exist (McConnell, 1991). But reputable universities in many locations, including Great Britain, the Netherlands, and Australia, have added faculty chairs or research units in **parapsychology** (Turpin, 2005). These researchers perform scientific experiments searching for possible ESP and other paranormal phenomena. Before seeing how parapsychologists do research on ESP, let’s consider some popular beliefs.

PREMONITIONS OR PRETENSIONS?

Can psychics see into the future? Although one might wish for a psychic stock forecaster, the tallied forecasts of “leading psychics” reveal meager accuracy. During the 1990s, the tabloid psychics were all wrong in predicting surprising events. (Madonna did not become a gospel singer, the Statue of Liberty did not lose both its arms in a terrorist blast, Queen Elizabeth did not abdicate her throne to enter a convent.) And the new-century psychics have missed the big-news events. Where were the psychics on 9/10 when we needed them? Why, despite a \$50 million reward offered, could none of them help locate terrorist Osama bin Laden after the horror of 9/11, or step forward to predict the impending stock crashes in 2008? In 30 years, unusual predictions have almost never come true, and psychics have virtually never anticipated any of the year’s headline events (Emory, 2004, 2006). In 2010, when a mine collapse trapped 33 miners, the Chilean government reportedly consulted four psychics. Their verdict? “They’re all dead” (Kraul, 2010). But 69 days later, all 33 were rescued.

Moreover, the hundreds of psychic visions offered to police departments have been no more accurate than guesses made by others (Nickell, 1994, 2005; Radford, 2010; Reiser, 1982). But their sheer volume does increase the odds of an occasional correct guess, which psychics can then report to the media. Police departments are wise to all this. When researchers asked the police departments of America’s 50 largest cities whether they ever had used psychics, 65 percent said *No* (Sweat & Durm, 1993). Of those that had, not one had found them helpful. Vague predictions can also later be interpreted (“retrofitted”)

extrasensory perception (ESP) the controversial claim that perception can occur apart from sensory input; includes telepathy, clairvoyance, and precognition.

parapsychology the study of paranormal phenomena, including ESP and psychokinesis.

(continued on next page)

Thinking Critically About *(continued)*

to match events that provide a perceptual set for “understanding” them. Nostradamus, a sixteenth-century French psychic, explained in an unguarded moment that his ambiguous prophecies “could not possibly be understood till they were interpreted after the event and by it.”

Are the spontaneous “visions” of everyday people any more accurate? Do dreams, for example, foretell the future, as people from both Eastern and Western cultures tend to believe—making some people more reluctant to fly after dreaming of a plane crash (Morewedge & Norton, 2009)? Or do they only seem to do so when we recall or reconstruct them in light of what has already happened? Two Harvard psychologists tested the prophetic power of dreams after superhero aviator Charles Lindbergh’s baby son was kidnapped and murdered in 1932, but before the body was discovered (Murray & Wheeler, 1937). When invited to report their dreams about the child, 1300 visionaries submitted dream reports. How many accurately envisioned the child dead? Five percent. And how many also correctly anticipated the body’s location—buried among trees? Only 4 of the 1300. Although this number was surely no better than chance, to those 4 dreamers the accuracy of their apparent precognitions must have seemed uncanny.

Given the billions of events in the world each day, and given enough days, some stunning coincidences are sure to occur. By one careful estimate, chance alone would predict that more than a thousand times a day someone on Earth will think of another person and then within the next five minutes will learn of that person’s death (Charpak & Broch, 2004). Thus, when explaining an astonishing event, we should “give chance a chance” (Lilienfeld, 2009). With enough time and people, the improbable becomes inevitable.

“To be sure of hitting the target, shoot first and call whatever you hit the target.” -WRITER-ARTIST ASHLEIGH BRILLIANT, 1933

“A person who talks a lot is sometimes right.” -SPANISH PROVERB

PUTTING ESP TO EXPERIMENTAL TEST

When faced with claims of mind reading or out-of-body travel or communication with the dead, how can we separate bizarre ideas from those that sound strange but are true? At the heart of science is a simple answer: *Test them to see if they work.* If they do, so much the better for the ideas. If they don’t, so much the better for our skepticism.

This scientific attitude has led both believers and skeptics to agree that what parapsychology needs is a reproducible phenomenon and a theory to explain it. Parapsychologist Rhea White (1998) spoke for many in saying that “the image of parapsychology that comes to my mind, based on nearly 44 years in the field, is that of a small airplane [that] has been perpetually taxiing down the runway of the Empirical Science Airport since 1882 . . . its movement punctuated occasionally by lifting a few feet off the ground only to bump back down on the tarmac once again. It has never taken off for any sustained flight.”

How might we test ESP claims in a controlled, reproducible experiment? An experiment differs from a staged demonstration. In the laboratory, the experimenter controls what the “psychic” sees and hears. On stage, the psychic controls what the audience sees and hears.

The search for a valid and reliable test of ESP has resulted in thousands of experiments. After digesting data from 30 such studies, parapsychologist Lance Storm and his colleagues (2010a,b) concluded that, given participants with experience or belief in ESP, there is “consistent and reliable” parapsychological evidence. Psychologist Ray Hyman (2010), who has been scrutinizing parapsychological research since 1957, replies that if this is the best evidence, it fails to impress: “Parapsychology will achieve scientific acceptability only when it provides a positive theory with . . . independently replicable evidence. This is something it has yet to achieve after more than a century.”

Daryl Bem (2011), a respected social psychologist, has been a skeptic of stage psychics; he once quipped that “a psychic is an actor playing the role of a psychic” (1984). Yet he has reignited hopes for replicable evidence with nine experiments that seemed to show people anticipating future events. In one,

“At the heart of science is an essential tension between two seemingly contradictory attitudes—an openness to new ideas, no matter how bizarre or counterintuitive they may be, and the most ruthless skeptical scrutiny of all ideas, old and new.”
-CARL SAGAN (1987)

Magician Harry Houdini after fooling Sir Arthur Conan Doyle with a pseudo-psychic trick: “Now I beg of you, Sir Arthur, do not jump to the conclusion that certain things you see are necessarily ‘supernatural,’ or with the work of ‘spirits,’ just because you cannot explain them.” -QUOTED BY WILLIAM KALUSH AND LARRY SLOMAN, *THE SECRET LIFE OF HOUDINI*, 2007

Thinking Critically About *(continued)*

when an erotic scene was about to appear on a screen in one of two randomly selected positions, Cornell University participants guessed right 53.1 percent of the time (beating 50 percent by a small but statistically significant margin). In another, people viewed a set of words, took a recall test of those words, and then rehearsed a randomly selected subset of those words. People better remembered the rehearsed words—even when the rehearsal took place *after* the recall test. The upcoming rehearsal—a future event—apparently affected their ability to recall words.

Bem wonders if his “anomalous” findings reflect an evolutionary advantage to those who can precognitively anticipate future dangers. Critics scoff. “If any of his claims were true,” wrote cognitive scientist Douglas Hofstadter (2011), “then all of the bases underlying contemporary science would be toppled, and we would have to rethink everything about the nature of the universe.” Moreover, if future events retroactively affect present feelings, then why can’t people intuitively predict casino outcomes or stock market futures?

Despite Bem’s research having survived critical reviews by a top-tier journal, other critics found the methods “badly flawed” (Alcock, 2011) or the statistical analyses “biased” (Wagenmakers et al., 2011). “A result—especially one of this importance—must recur several times in tests by independent and skeptical researchers to gain scientific credibility,” observed astronomer David Helfand (2011). “I have little doubt that Professor Bem’s experiments will fail this test.”

Anticipating such skepticism, Bem has made his computer materials available to anyone who wishes to replicate his studies, and replications are now under way. One research team has already conducted five replications of Bem’s recall experiments at various universities and found no precognition (Galak et al., 2011). Regardless of the outcomes, science will have done its work. It will have been open to a finding that challenges its own worldview, and then, through follow-up research, it will have assessed its validity. And that is how science sifts crazy-sounding ideas, leaving most on the historical waste heap while occasionally surprising us.

One skeptic, magician James Randi, has had a longstanding offer of \$1 million to be given “to anyone who proves a genuine psychic power under proper observing conditions” (Randi, 1999; Thompson, 2010). French, Australian, and Indian groups have made similar offers of up to 200,000 euros (CFI, 2003). Large as these sums are, the scientific seal of approval would be worth far more. To refute those who say there is no ESP,

Courtesy of Claire Cole

Testing psychic powers in the British population

University of Hertfordshire psychologists created a “mind machine” to see if people can influence or predict a coin toss (Wiseman & Greening, 2002). Using a touch-sensitive screen, visitors to festivals around the country were given four attempts to call heads or tails. Using a random-number generator, a computer then decided the outcome. When the experiment concluded in January 2000, nearly 28,000 people had predicted 110,959 tosses—with 49.8 percent correct.

one need only produce a single person who can demonstrate a single, reproducible ESP event. (To refute those who say pigs can’t talk would take but one talking pig.) So far, no such person has emerged.

Before You Move On

▶ ASK YOURSELF

Have you ever had what felt like an ESP experience? Can you think of an explanation other than ESP for that experience?

▶ TEST YOURSELF

What is the field of study that researches claims of extrasensory perception (ESP)?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 17 Review

17-1

How do our expectations, contexts, emotions, and motivation influence our perceptions?

- *Perceptual set* is a mental predisposition that functions as a lens through which we perceive the world.
- Our learned concepts (schemas) prime us to organize and interpret ambiguous stimuli in certain ways.
- Our physical and emotional context, as well as our motivation, can create expectations and color our interpretation of events and behaviors.

17-2

What are the claims of ESP, and what have most research psychologists concluded after putting these claims to the test?

- *Parapsychology* is the study of paranormal phenomena, including *extrasensory perception (ESP)* and psychokinesis.
- The three most testable forms of ESP are telepathy (mind-to-mind communication), clairvoyance (perceiving remote events), and precognition (perceiving future events).
- Skeptics argue that (1) to believe in ESP, you must believe the brain is capable of perceiving without sensory input, and (2) researchers have been unable to replicate ESP phenomena under controlled conditions.

Multiple-Choice Questions

1. What do we call a mental predisposition that influences our interpretation of a stimulus?
 - a. A context effect
 - b. Perceptual set
 - c. Extrasensory perception
 - d. Emotion
 - e. Motivation
2. Kimberly tells her brother to put on a suit on a warm summer day. Kimberly's brother knows to put on a swimsuit instead of a business suit because of
 - a. context.
 - b. ESP.
 - c. precognition.
 - d. bottom-up processing.
 - e. clairvoyance.
3. Which of the following is produced by perceptual set?
 - a. Not noticing that the songs change in a restaurant
 - b. Noticing a difference in the weight of a friend from one week to the next
 - c. Moving an arm quickly so that a mosquito flies away
 - d. Surprise at hearing an Oklahoma cowboy speak with a British accent
 - e. Not noticing a watch on your wrist as the day goes on

Practice FRQs

1. Martha is convinced she has extrasensory perception. Explain what Martha's specific abilities would be if she had each of the following forms of ESP:
 - Telepathy
 - Clairvoyance
 - Precognition
 Then, briefly explain why you should doubt her claims.

Answer

1 point: Telepathy: Martha would be able to use mind-to-mind communication; that is, she is able to read someone's mind.

1 point: Clairvoyance: Martha would be able to perceive things happening at a distance; that is, a cousin who lives in another state just burnt her hand on the oven, and Martha feels it.

1 point: Precognition: Martha would be able to see future events happen; that is, she knows a pop quiz will take place next week.

1 point: There has never been a conclusive scientific demonstration of extrasensory ability.

2. How can context effects, emotions, and motivation trigger different perceptions of a single stimulus?

(3 points)

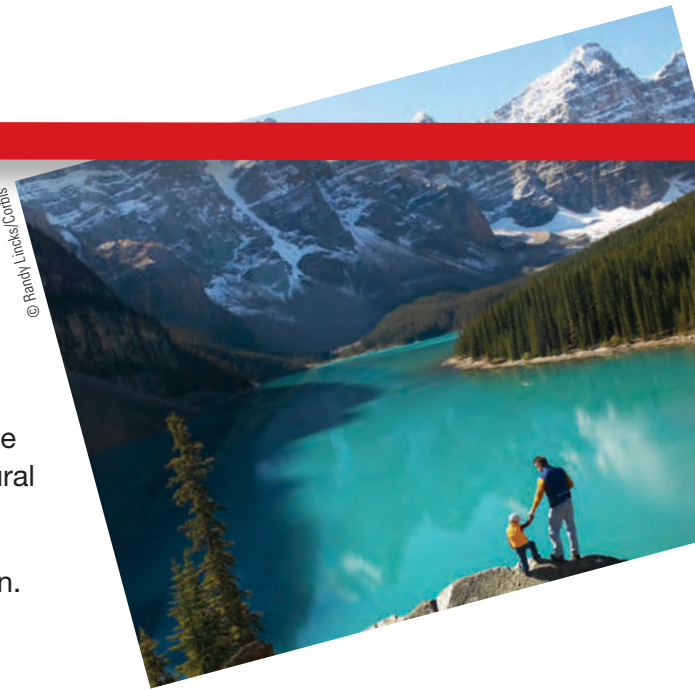

Module 18

Vision

Module Learning Objectives

- 18-1** Describe the characteristics of visible light, and explain the process by which the eye transforms light energy into neural messages.
- 18-2** Describe how the eye and brain process visual information.
- 18-3** Discuss the theories that help us understand color vision.

© Randy Lincks/Corbis

- 18-1** What is the energy that we see as visible light, and how does the eye transform light energy into neural messages?

Our eyes receive light energy and transduce (transform) it into neural messages that our brain then processes into what we consciously see. How does such a taken-for-granted yet remarkable thing happen?

The Stimulus Input: Light Energy

When you look at a bright red tulip, what strikes your eyes is not particles of the color red but pulses of electromagnetic energy that your visual system perceives as red. What we see as visible light is but a thin slice of the whole spectrum of electromagnetic energy, ranging from imperceptibly short gamma waves to the long waves of radio transmission (**FIGURE 18.1**). Other organisms are sensitive to differing portions of the spectrum. Bees, for instance, cannot see what we perceive as red but can see ultraviolet light.

Two physical characteristics of light help determine our sensory experience of them. Light's **wavelength**—the distance from one wave peak to the next

wavelength the distance from the peak of one light or sound wave to the peak of the next. Electromagnetic wavelengths vary from the short blips of cosmic rays to the long pulses of radio transmission.

Figure 18.2

The physical properties of waves (a) Waves vary in *wavelength* (the distance between successive peaks). *Frequency*, the number of complete wavelengths that can pass a point in a given time, depends on the wavelength. The shorter the wavelength, the higher the frequency. Wavelength determines the perceived color of light (and also the *pitch* of sound). (b) Waves also vary in *amplitude* (the height from peak to trough). Wave amplitude determines the *brightness* of colors (and also the loudness of sounds).

hue the dimension of color that is determined by the wavelength of light; what we know as the color names *blue*, *green*, and so forth.

intensity the amount of energy in a light or sound wave, which we perceive as brightness or loudness, as determined by the wave's amplitude.

pupil the adjustable opening in the center of the eye through which light enters.

iris a ring of muscle tissue that forms the colored portion of the eye around the pupil and controls the size of the pupil opening.

lens the transparent structure behind the pupil that changes shape to help focus images on the retina.

retina the light-sensitive inner surface of the eye, containing the receptor rods and cones plus layers of neurons that begin the processing of visual information.

accommodation the process by which the eye's lens changes shape to focus near or far objects on the retina.

(**FIGURE 18.2a**)—determines its **hue** (the color we experience, such as the tulip's red petals or green leaves). **Intensity**, the amount of energy in light waves (determined by a wave's *amplitude*, or height), influences brightness (Figure 18.2b). To understand *how* we transform physical energy into color and meaning, we first need to understand vision's window, the eye.

The Eye

Light enters the eye through the *cornea*, which protects the eye and bends light to provide focus (**FIGURE 18.3**). The light then passes through the **pupil**, a small adjustable opening. Surrounding the pupil and controlling its size is the **iris**, a colored muscle that dilates or constricts in response to light intensity and even to inner emotions. (When we're feeling amorous, our telltale dilated pupils and dark eyes subtly signal our interest.) Each iris is so distinctive that an iris-scanning machine can confirm your identity.

Behind the pupil is a **lens** that focuses incoming light rays into an image on the **retina**, a multilayered tissue on the eyeball's sensitive inner surface. The lens focuses the rays by changing its curvature in a process called **accommodation**.

For centuries, scientists knew that when an image of a candle passes through a small opening, it casts an inverted mirror image on a dark wall behind. If the retina receives this sort of upside-down image, as in Figure 18.3, how can we see the world right side up? The ever-curious Leonardo da Vinci had an idea: Perhaps the eye's watery fluids bend the light rays, reinverting the image to the upright position as it reaches the retina. But then in 1604, the astronomer and optics expert Johannes Kepler showed that the retina does receive upside-down images of the world (Crombie, 1964). And how could we understand such a world? "I leave it," said the befuddled Kepler, "to natural philosophers."

Figure 18.3

The eye Light rays reflected from a candle pass through the cornea, pupil, and lens. The curvature and thickness of the lens change to bring nearby or distant objects into focus on the retina. Rays from the top of the candle strike the bottom of the retina, and those from the left side of the candle strike the right side of the retina. The candle's image on the retina thus appears upside down and reversed.

Eventually, the answer became clear: The retina doesn't "see" a whole image. Rather, its millions of receptor cells convert particles of light energy into neural impulses and forward those to the brain. *There*, the impulses are reassembled into a perceived, upright-seeming image.

The Retina

If you could follow a single light-energy particle into your eye, you would first make your way through the retina's outer layer of cells to its buried receptor cells, the **rods** and **cones** (FIGURE 18.4). There, you would see the light energy trigger chemical changes that would spark neural signals, activating nearby *bipolar cells*. The bipolar cells in turn would activate the neighboring *ganglion cells*, whose axons twine together like the strands of a rope to form the **optic nerve**. That nerve will carry the information to your brain, where your thalamus stands ready to distribute the information. The optic nerve can send nearly 1 million messages at once through its nearly 1 million ganglion fibers. (The auditory nerve, which enables hearing, carries much less information through its mere 30,000 fibers.) We pay a small price for this eye-to-brain highway. Where the optic nerve leaves the eye, there are no receptor cells—creating a **blind spot** (FIGURE 18.5 on the next page). Close one eye and you won't see a black hole, however. Without seeking your approval, your brain fills in the hole.

Rods and cones differ in where they're found and in what they do (TABLE 18.1 on the next page). *Cones* cluster in and around the **fovea**, the retina's area of central focus (see Figure 18.3). Many have their own hotline to the brain: Each one transmits to a single bipolar cell that helps relay the cone's individual message to the visual cortex, which devotes a large area to input from the fovea. These direct connections preserve the cones' precise information, making them better able to detect fine detail.

Rods have no such hotline; they share bipolar cells with other rods, sending combined messages. To experience this rod-cone difference in sensitivity to details, pick a word in this sentence and stare directly at it, focusing its image on the cones in your fovea. Notice that

AP® Exam Tip

There's a lot of vocabulary here. Make sure you understand the name and the function of each of the parts of the eye. To learn how all the parts fit together, it may help to make rough sketches (you don't need to be an artist to try this!) and then compare your sketches with Figures 18.3 and 18.4. You'll be better off making several quick, rough sketches than one time-consuming, nicely drawn one.

rods retinal receptors that detect black, white, and gray; necessary for peripheral and twilight vision, when cones don't respond.

cones retinal receptor cells that are concentrated near the center of the retina and that function in daylight or in well-lit conditions. The cones detect fine detail and give rise to color sensations.

optic nerve the nerve that carries neural impulses from the eye to the brain.

blind spot the point at which the optic nerve leaves the eye, creating a "blind" spot because no receptor cells are located there.

fovea the central focal point in the retina, around which the eye's cones cluster.

Figure 18.5

The blind spot There are no receptor cells where the optic nerve leaves the eye. This creates a blind spot in your vision. To demonstrate, first close your left eye, look at the spot, and move the page to a distance from your face at which one of the cars disappears (which one do you predict it will be?). Repeat with the other eye closed—and note that now the other car disappears. Can you explain why?

words a few inches off to the side appear blurred? Their image strikes the outer regions of your retina, where rods predominate. Thus, when driving or biking, you can detect a car in your peripheral vision well before perceiving its details.

Cones also enable you to perceive color. In dim light they become ineffectual, so you see no colors. Rods, which enable black-and-white vision, remain sensitive in dim light. Several rods will funnel their faint energy output onto a single bipolar cell. Thus, cones and rods each provide a special sensitivity—cones to detail and color, and rods to faint light.

Table 18.1 Receptors in the Human Eye: Rod-Shaped Rods and Cone-Shaped Cones

	Cones	Rods
<i>Number</i>	6 million	120 million
<i>Location in retina</i>	Center	Periphery
<i>Sensitivity in dim light</i>	Low	High
<i>Color sensitivity</i>	High	Low
<i>Detail sensitivity</i>	High	Low

When you enter a darkened theater or turn off the light at night, your eyes adapt. Your pupils dilate to allow more light to reach your retina, but it typically takes 20 minutes or more before your eyes fully adapt. You can demonstrate dark adaptation by closing or covering one eye for up to 20 minutes. Then make the light in the room not quite bright enough to read this book with your open eye. Now open the dark-adapted eye and read (easily). This period of dark adaptation matches the average natural twilight transition between the Sun's setting and darkness. How wonderfully made we are.

Visual Information Processing

18-2

How do the eye and the brain process visual information?

Visual information percolates through progressively more abstract levels on its path through the thalamus and on to the visual cortex. At the entry level, information processing begins in the retina's neural layers, which are actually brain tissue that has migrated to the eye during early fetal development. These layers don't just pass along electrical impulses; they also help to encode and analyze sensory information. The third neural layer in a frog's eye, for example, contains the "bug detector" cells that fire only in response to moving fly-like stimuli.

After processing by your retina's nearly 130 million receptor rods and cones, information travels to your bipolar cells, then to your million or so ganglion cells, and through their axons making up the optic nerve to your brain. Any given retinal area relays its information to a corresponding location in the visual cortex, in the occipital lobe at the back of your brain (**FIGURE 18.6**).

The same sensitivity that enables retinal cells to fire messages can lead them to misfire, as you can demonstrate for yourself. Turn your eyes to the left, close them, and then gently rub the right side of your right eyelid with your fingertip. Note the patch of light to the left, moving as your finger moves. Why do you see light? Why at the left?

Your retinal cells are so responsive that even pressure triggers them. But your brain interprets their firing as light. Moreover, it interprets the light as coming from the left—the normal direction of light that activates the right side of the retina.

Figure 18.6

Pathway from the eyes to the visual cortex Ganglion axons forming the optic nerve run to the thalamus, where they synapse with neurons that run to the visual cortex.

Feature Detection

David Hubel and Torsten Wiesel (1979) received a Nobel Prize for their work on **feature detectors**. These specialized neurons in the occipital lobe's visual cortex receive information from individual ganglion cells in the retina. Feature detector cells derive their name from their ability to respond to a scene's specific features—to particular edges, lines, angles, and movements. These cells pass this information to other cortical areas, where teams of cells (*supercell clusters*) respond to more complex patterns. As we noted in Module 12, one temporal lobe area by your right ear (**FIGURE 18.7** on the next page) enables you to perceive faces and, thanks to a specialized neural network, to recognize them from varied viewpoints (Connor, 2010). If this region were damaged, you might recognize other forms and objects, but, like Heather Sellers, not familiar faces. When researchers temporarily disrupt the brain's face-processing areas with magnetic pulses, people are unable to recognize faces.

They will, however, be able to recognize houses, because the brain's face-perception occurs separately from its object-perception (McKone et al., 2007; Pitcher et al., 2007). Thus, functional MRI (fMRI) scans show different brain areas activating when people

feature detectors nerve cells in the brain that respond to specific features of the stimulus, such as shape, angle, or movement.

AP® Exam Tip

Warning! Sometimes students spend so much time mastering the parts of the eye that they skim over the part you're about to read. Do not forget that you see with your brain as much as you see with your eyes.

Figure 18.7

Face recognition processing In social animals such as humans, a dedicated brain system (shown here in a right-facing brain) assigns considerable neural bandwidth to the crucial task of face recognition.

**Figure 18.8**

The telltale brain Looking at faces, houses, and chairs activates different brain areas in this right-facing brain.

view varied objects (Downing et al., 2001). Brain activity is so specific (**FIGURE 18.8**) that, with the help of brain scans, “we can tell if a person is looking at a shoe, a chair, or a face, based on the pattern of their brain activity,” noted one researcher (Haxby, 2001).

Research shows that for biologically important objects and events, monkey brains (and surely ours as well) have a “vast visual encyclopedia” distributed as specialized cells (Perrett et al., 1988, 1992, 1994). These cells respond to one type of stimulus, such as a specific gaze, head angle, posture, or body movement. Other supercell clusters integrate this information and fire only when the cues collectively indicate the direction of someone’s attention and approach. This instant analysis, which aided our ancestors’ survival, also helps a soccer goal-keeper anticipate the direction of an impending kick, and a driver anticipate a pedestrian’s next movement.

Well-developed supercells

In this 2011 World Cup match, USA’s Abby Wambach instantly processed visual information about the positions and movements of Brazil’s defenders and goalkeeper and somehow managed to get the ball around them all and into the net.

FFA via Getty Images

parallel processing the processing of many aspects of a problem simultaneously; the brain’s natural mode of information processing for many functions, including vision. Contrasts with the step-by-step (serial) processing of most computers and of conscious problem solving.

Parallel Processing

Our brain achieves these and other remarkable feats by means of **parallel processing**: doing many things at once. To analyze a visual scene, the brain divides it into subdimensions—motion, form, depth, color—and works on each aspect simultaneously (Livingstone & Hubel, 1988). We then construct our perceptions by integrating the separate but parallel work of these different visual teams (**FIGURE 18.9**).

**Figure 18.9**

Parallel processing Studies of patients with brain damage suggest that the brain delegates the work of processing motion, form, depth, and color to different areas. After taking a scene apart, the brain integrates these subdimensions into the perceived image. How does the brain do this? The answer to this question is the Holy Grail of vision research.

To recognize a face, your brain integrates information projected by your retinas to several visual cortex areas, compares it with stored information, and enables you to recognize the face: *Grandmother!* Scientists are debating whether this stored information is contained in a single cell or distributed over a network. Some supercells—“grandmother cells”—do appear to respond very selectively to 1 or 2 faces in 100 (Bowers, 2009). The whole facial recognition process requires tremendous brain power—30 percent of the cortex (10 times the brain area devoted to hearing).

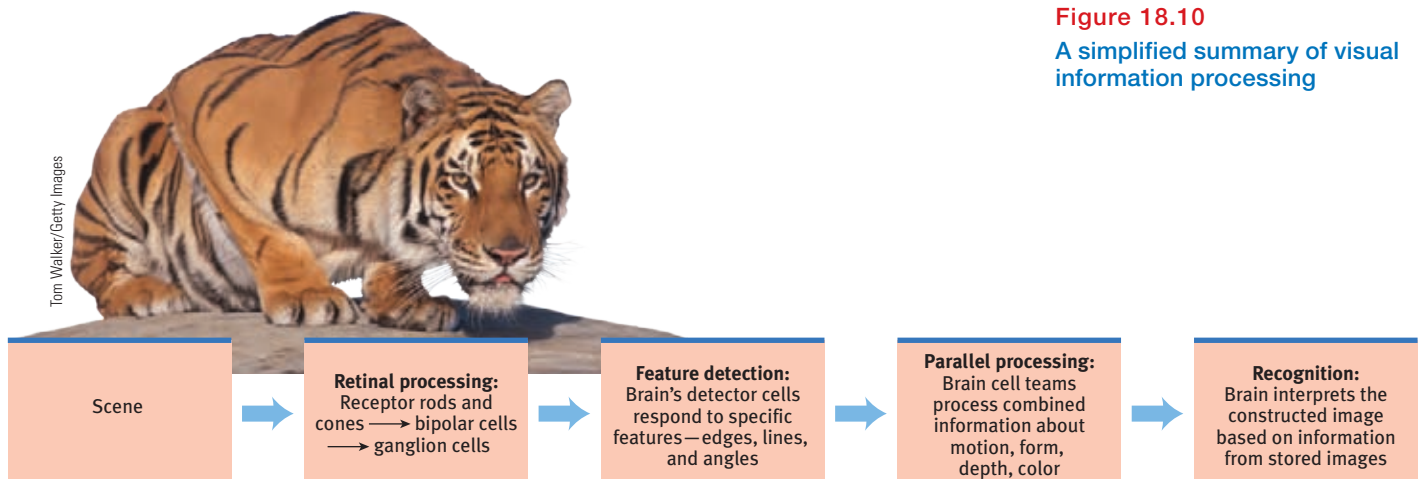

Destroy or disable a neural workstation for a visual subtask, and something peculiar results, as happened to “Mrs. M.” (Hoffman, 1998). Since a stroke damaged areas near the rear of both sides of her brain, she has been unable to perceive movement. People in a room seem “suddenly here or there but I have not seen them moving.” Pouring tea into a cup is a challenge because the fluid appears frozen—she cannot perceive it rising in the cup.

After stroke or surgery damage to the brain’s visual cortex, others have experienced *blind-sight* (a phenomenon we met in Module 13). Shown a series of sticks, they report seeing nothing. Yet when asked to guess whether the sticks are vertical or horizontal, their visual intuition typically offers the correct response. When told, “You got them all right,” they are astounded. There is, it seems, a second “mind”—a parallel processing system—operating unseen. These separate visual systems for perception and action illustrate dual processing—the two-track mind.

* * *

Think about the wonders of visual processing. As you look at that tiger in the zoo, information enters your eyes, is transduced, and is sent to your brain as millions of neural impulses. As your brain buzzes with activity, various areas focus on different aspects of the tiger’s image. Finally, in some as yet mysterious way, these separate teams pool their work to produce a meaningful image, which you compare with previously stored images and recognize: a crouching tiger (**FIGURE 18.10**).

“I am . . . wonderfully made.”
-KING DAVID, PSALM 139:14

**Figure 18.10**

A simplified summary of visual information processing

Think, too, about what is happening as you read this page. The printed squiggles are transmitted by reflected light rays onto your retina, which triggers a process that sends formless nerve impulses to several areas of your brain, which integrates the information and decodes meaning, thus completing the transfer of information across time and space from my mind to your mind. That all of this happens instantly, effortlessly, and continuously is indeed awesome. As Roger Sperry (1985) observed, the “insights of science give added, not lessened, reasons for awe, respect, and reverence.”

Color Vision

18-3 What theories help us understand color vision?

We talk as though objects possess color: “A tomato is red.” Perhaps you have pondered the old question, “If a tree falls in the forest and no one hears it, does it make a sound?” We can ask the same of color: If no one sees the tomato, is it red?

The answer is *No*. First, the tomato is everything *but* red, because it *rejects* (reflects) the long wavelengths of red. Second, the tomato’s color is our mental construction. As Isaac Newton (1704) noted, “The [light] rays are not colored.” Color, like all aspects of vision, resides not in the object but in the theater of our brain, as evidenced by our dreaming in color.

One of vision’s most basic and intriguing mysteries is how we see the world in color. How, from the light energy striking the retina, does the brain manufacture our experience of color—and of such a multitude of colors? Our difference threshold for colors is so low that we can discriminate more than 1 million different color variations (Neitz et al., 2001). At least most of us can. For about 1 person in 50, vision is color deficient—and that person is usually male, because the defect is genetically sex-linked.

Why is some people’s vision deficient? To answer that question, we need to understand how normal color vision works. Modern detective work on this mystery began in the nineteenth century, when Hermann von Helmholtz built on the insights of an English physicist, Thomas Young. Knowing that any color can be created by combining the light waves of three primary colors—red, green, and blue—Young and von Helmholtz inferred that the eye must have three corresponding types of color receptors. Years later, researchers measured the response of various cones to different color stimuli and confirmed the **Young-Helmholtz trichromatic (three-color) theory**, which implies that the receptors do their color magic in teams of three. Indeed, the retina has three types of color receptors, each especially sensitive to one of three colors. And those colors are, in fact, red, green, and blue. When we stimulate combinations of these cones, we see other colors. For example, there are no receptors especially sensitive to yellow. We see yellow when mixing red and green light, which stimulates both red-sensitive and green-sensitive cones.

Most people with color-deficient vision are not actually “colorblind.” They simply lack functioning red- or green-sensitive cones, or sometimes both. Their vision—perhaps unknown to them, because their lifelong vision *seems* normal—is monochromatic (one-color) or dichromatic (two-color) instead of trichromatic, making it impossible to distinguish the red and green in **FIGURE 18.11** (Boynton, 1979). Dogs, too, lack receptors for the wavelengths of red, giving them only limited, dichromatic color vision (Neitz et al., 1989).

“Only mind has sight and hearing; all things else are deaf and blind.”
-EPICHRMUS, *FRAGMENTS*, 550 B.C.E.

Young-Helmholtz trichromatic (three-color) theory the theory that the retina contains three different color receptors—one most sensitive to red, one to green, one to blue—which, when stimulated in combination, can produce the perception of any color.

Figure 18.11

Color-deficient vision

People who suffer red-green deficiency have trouble perceiving the number within the design.

Amabilia Bluesky/Science Source

**Figure 18.12**

Afterimage effect Stare at the center of the flag for a minute and then shift your eyes to the dot in the white space beside it. What do you see? (After tiring your neural response to black, green, and yellow, you should see their opponent colors.) Stare at a white wall and note how the size of the flag grows with the projection distance.

But how is it that people blind to red and green can often still see yellow? And why does yellow appear to be a pure color and not a mixture of red and green, the way purple is of red and blue? As Ewald Hering soon noted, trichromatic theory leaves some parts of the color vision mystery unsolved.

Hering, a physiologist, found a clue in *afterimages*. Stare at a green square for a while and then look at a white sheet of paper, and you will see red, green's *opponent color*. Stare at a yellow square and its opponent color, blue, will appear on the white paper. (To experience this, try the flag demonstration in **FIGURE 18.12**.) Hering surmised that there must be two additional color processes, one responsible for red-versus-green perception, and one for blue-versus-yellow.

Indeed, a century later, researchers also confirmed Hering's **opponent-process theory**. Three sets of opponent retinal processes—*red-green*, *yellow-blue*, and *white-black*—enable color vision. In the retina and in the thalamus (where impulses from the retina are relayed en route to the visual cortex), some neurons are turned “on” by red but turned “off” by green. Others are turned on by green but off by red (DeValois & DeValois, 1975). Like red and green marbles sent down a narrow tube, “red” and “green” messages cannot both travel at once. So we do not experience a reddish green. (Red and green are thus opponents.) But red and blue travel in separate channels, so we *can* see a reddish-blue magenta.

So how do we explain afterimages, such as in the flag demonstration? By staring at green, we tire our green response. When we then stare at white (which contains all colors, including red), only the red part of the green-red pairing will fire normally.

The present solution to the mystery of color vision is therefore roughly this: Color processing occurs in two stages. The retina's red, green, and blue cones respond in varying degrees to different color stimuli, as the Young-Helmholtz trichromatic theory suggested. Their signals are then processed by the nervous system's opponent-process cells, as Hering's theory proposed.

opponent-process theory

the theory that opposing retinal processes (red-green, yellow-blue, white-black) enable color vision. For example, some cells are stimulated by green and inhibited by red; others are stimulated by red and inhibited by green.

Before You Move On

▶ ASK YOURSELF

If you were forced to give up one sense, which would it be? Why?

▶ TEST YOURSELF

What is the rapid sequence of events that occurs when you see and recognize a friend?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 18 Review

18-1

What is the energy that we see as visible light, and how does the eye transform light energy into neural messages?

- The *hue* we perceive in light depends on its *wavelength*, and its brightness depends on its *intensity*.
- After entering the eye and being focused by the *lens*, light energy particles (from a thin slice of the broad spectrum of electromagnetic energy) strike the eye's inner surface, the *retina*. The retina's light-sensitive *rods* and color-sensitive *cones* convert the light energy into neural impulses.

18-2

How do the eye and the brain process visual information?

- After processing by bipolar and ganglion cells in the eyes' retina, neural impulses travel through the *optic nerve*, to the thalamus, and on to the visual cortex. In the visual cortex, *feature detectors* respond to specific features of the visual stimulus. Supercell clusters in other critical brain areas respond to more complex patterns.
- Through *parallel processing*, the brain handles many aspects of vision (color, movement, form, and depth) simultaneously. Other neural teams integrate the results, comparing them with stored information and enabling perceptions.

18-3

What theories help us understand color vision?

- The *Young-Helmholtz trichromatic (three-color) theory* proposed that the retina contains three types of color receptors. Contemporary research has found three types of cones, each most sensitive to the wavelengths of one of the three primary colors of light (red, green, or blue).
- Hering's *opponent-process theory* proposed three additional color processes (red-versus-green, blue-versus-yellow, black-versus-white). Contemporary research has confirmed that, en route to the brain, neurons in the retina and the thalamus code the color-related information from the cones into pairs of opponent colors.
- These two theories, and the research supporting them, show that color processing occurs in two stages.

Multiple-Choice Questions

1. Light's _____ is the distance from one wave peak to the next. This dimension determines the _____ we experience.
 - a. hue; wavelength
 - b. wavelength; hue
 - c. hue; intensity
 - d. wavelength; intensity
 - e. intensity; wavelength
2. What do we call the specialized neurons in the occipital lobe's visual cortex that respond to particular edges, lines, angles, and movements?
 - a. Rods
 - b. Cones
 - c. Foveas
 - d. Feature detectors
 - e. Ganglion cells
3. Which of the following explains reversed-color afterimages?
 - a. Young-Helmholtz trichromatic theory
 - b. The blind spot
 - c. Hering's opponent-process theory
 - d. Feature detectors
 - e. Parallel processing
4. Your best friend decides to paint her room an extremely bright electric blue. Which of the following best fits the physical properties of the color's light waves?
 - a. No wavelength; large amplitude
 - b. Short wavelength; large amplitude
 - c. Short wavelength; small amplitude
 - d. Long wavelength; large amplitude
 - e. No wavelength; small amplitude

5. What do we call the transparent, protective layer that light passes through as it enters the eye?
- Pupil
 - Iris
 - Cornea
 - Lens
 - Fovea

Practice FRQs

1. As light reflected off an object reaches your eye, it passes through several structures before it reaches the retina. Describe three of these structures, including the function of each.

2. Explain two theories of color vision in humans. How does one of them explain color deficiency?

(3 points)

Answer

1 point: The cornea is at the front of the eye. It bends and focuses the light waves.

1 point: The pupil is the opening through which light enters the eyeball. It is surrounded by the iris, which can expand or contract to allow more or less light to pass through the pupil.

1 point: The lens is the transparent structure behind the pupil that changes shape to help focus images on the retina.

Module 19

Visual Organization and Interpretation

Module Learning Objectives

- 19-1** Describe Gestalt psychologists' understanding of perceptual organization, and explain how figure-ground and grouping principles contribute to our perceptions.
- 19-2** Explain how we use binocular and monocular cues to perceive the world in three dimensions and perceive motion.
- 19-3** Explain how perceptual constancies help us organize our sensations into meaningful perceptions.
- 19-4** Describe what research on restored vision, sensory restriction, and perceptual adaptation reveals about the effects of experience on perception.

Visual Organization

- 19-1** How did the Gestalt psychologists understand perceptual organization, and how do figure-ground and grouping principles contribute to our perceptions?

It's one thing to understand how we see shapes and colors. But how do we organize and interpret those sights (or sounds or tastes or smells) so that they become meaningful perceptions—a rose in bloom, a familiar face, a sunset?

Early in the twentieth century, a group of German psychologists noticed that when given a cluster of sensations, people tend to organize them into a **gestalt**, a German word meaning a “form” or a “whole.” For example, look at **FIGURE 19.1**. Note that the individual elements of this figure, called a *Necker cube*, are really nothing but eight blue circles, each containing three converging white lines. When we view these elements all together, however, we see a cube that sometimes reverses direction. This phenomenon nicely illustrates a favorite saying of Gestalt psychologists: In perception, the whole may exceed the sum of its parts. If we combine sodium (a corrosive metal) with chlorine (a poisonous gas), something very different emerges—table salt. Likewise, a unique perceived form emerges from a stimulus' components (Rock & Palmer, 1990).

Over the years, the Gestalt psychologists demonstrated many principles we use to organize our sensations into perceptions. Underlying all of them is a fundamental truth: *Our brain does more than register information about the world.* Perception is not just opening a shutter and letting a picture print itself on the brain. We filter incoming information and construct perceptions. Mind matters.

gestalt an organized whole. Gestalt psychologists emphasized our tendency to integrate pieces of information into meaningful wholes.

AP® Exam Tip

The Necker cube is an excellent vehicle for understanding the distinction between sensation and perception. The only visual stimuli are the blue wedges. The circles, lines, and cube are all the products of perception—they are in your mind and not on the page.

**Figure 19.1**

A Necker cube What do you see: circles with white lines, or a cube? If you stare at the cube, you may notice that it reverses location, moving the tiny X in the center from the front edge to the back. At times, the cube may seem to float in front of the page, with circles behind it. At other times, the circles may become holes in the page through which the cube appears, as though it were floating behind the page. There is far more to perception than meets the eye. (From Bradley et al., 1976.)

**Figure 19.2**
Reversible figure and ground

Form Perception

Imagine designing a video-computer system that, like your eye-brain system, can recognize faces at a glance. What abilities would it need?

FIGURE AND GROUND

To start with, the video-computer system would need to separate faces from their backgrounds. Likewise, in our eye-brain system, our first perceptual task is to perceive any object (the *figure*) as distinct from its surroundings (the *ground*). Among the voices you hear at a party, the one you attend to becomes the figure; all others are part of the ground. As you read, the words are the figure; the white paper is the ground. Sometimes the same stimulus can trigger more than one perception. In **FIGURE 19.2**, the **figure-ground** relationship continually reverses—but always we organize the stimulus into a figure seen against a ground.

GROUPING

Having discriminated figure from ground, we (and our video-computer system) must also organize the figure into a *meaningful* form. Some basic features of a scene—such as color, movement, and light-dark contrast—we process instantly and automatically (Treisman, 1987). Our minds bring order and form to stimuli by following certain rules for **grouping**. These rules, identified by the Gestalt psychologists and applied even by infants, illustrate how the perceived whole differs from the sum of its parts (Quinn et al., 2002; Rock & Palmer, 1990). Three examples:

PROXIMITY We group nearby figures together. We see not six separate lines, but three sets of two lines.

CONTINUITY We perceive smooth, continuous patterns rather than discontinuous ones. This pattern could be a series of alternating semicircles, but we perceive it as two continuous lines—one wavy, one straight.

CLOSURE We fill in gaps to create a complete, whole object. Thus we assume that the circles on the right are complete but partially blocked by the (illusory) triangle. Add nothing more than little line segments to close off the circles and your brain stops constructing a triangle. Such principles usually help us construct reality.

figure-ground the organization of the visual field into objects (the *figures*) that stand out from their surroundings (the *ground*).

grouping the perceptual tendency to organize stimuli into coherent groups.

Depth Perception

19-2 How do we use binocular and monocular cues to perceive the world in three dimensions and perceive motion?

From the two-dimensional images falling on our retinas, we somehow organize three-dimensional perceptions. **Depth perception** enables us to estimate an object's distance from us. At a glance, we can estimate the distance of an oncoming car or the height of a house. Depth perception is partly innate, as Eleanor Gibson and Richard Walk (1960) discovered using a model of a cliff with a drop-off area (which was covered by sturdy glass). Gibson's inspiration for these **visual cliff** experiments occurred while she was picnicking on the rim of the Grand Canyon. She wondered: Would a toddler peering over the rim perceive the dangerous drop-off and draw back?

Figure 19.3

Visual cliff Eleanor Gibson and Richard Walk devised a miniature cliff with a glass-covered drop-off to determine whether crawling infants can perceive depth. Even when coaxed, infants are reluctant to venture onto the glass over the cliff (Gibson & Walk, 1960).

Back in their Cornell University laboratory, Gibson and Walk placed 6- to 14-month-old infants on the edge of a safe canyon and had the infants' mothers coax them to crawl out onto the glass (**FIGURE 19.3**). Most infants refused to do so, indicating that they could perceive depth.

Had they *learned* to perceive depth? Learning seems to be part of the answer because crawling, no matter when it begins, seems to increase infants' wariness of heights (Campos et al., 1992). Yet, the researchers observed, mobile newborn animals come prepared to perceive depth. Even those with virtually no visual experience—

including young kittens, a day-old goat, and newly hatched chicks—will not venture across the visual cliff. Thus, it seems that biology predisposes us to be wary of heights and experience amplifies that fear.

How do we perceive depth? *How* do we transform two differing two-dimensional (2-D) retinal images into a single three-dimensional (3-D) perception? Our brain constructs these perceptions using information supplied by one or both eyes.

BINOCULAR CUES

Try this: With both eyes open, hold two pens or pencils in front of you and touch their tips together. Now do so with one eye closed. With one eye, the task becomes noticeably more difficult, demonstrating the importance of **binocular cues** in judging the distance of nearby objects. Two eyes are better than one.

Because your eyes are about 2½ inches apart, your retinas receive slightly different images of the world. By comparing these two images, your brain can judge how close an object is to you. The greater the **retinal disparity**, or difference between the two images, the closer the object. Try it. Hold your two index fingers, with the tips about half an inch apart, directly in front of your nose, and your retinas will receive quite different views. If you close one eye and then the other, you can see the difference. (You may also create a finger sausage, as in **FIGURE 19.4**.) At a greater distance—say, when you hold your fingers at arm's length—the disparity is smaller.

We could easily build this feature into our video-computer system. Moviemakers can simulate or exaggerate retinal disparity by filming a scene with two cameras placed a few inches apart. Viewers then wear glasses that allow the left eye to see only the image from the left camera, and the right eye to see only the image from the right camera.

depth perception the ability to see objects in three dimensions although the images that strike the retina are two-dimensional; allows us to judge distance.

visual cliff a laboratory device for testing depth perception in infants and young animals.

binocular cues depth cues, such as retinal disparity, that depend on the use of two eyes.

retinal disparity a binocular cue for perceiving depth: By comparing images from the retinas in the two eyes, the brain computes distance—the greater the disparity (difference) between the two images, the closer the object.

**Figure 19.4**

The floating finger sausage Hold your two index fingers about 5 inches in front of your eyes, with their tips half an inch apart. Now look beyond them and note the weird result. Move your fingers out farther and the retinal disparity—and the finger sausage—will shrink.

The resulting 3-D effect, as 3-D movie fans know, mimics or exaggerates normal retinal disparity. Similarly, twin cameras in airplanes can take photos of terrain for integration into 3-D maps.

MONOCULAR CUES

How do we judge whether a person is 10 or 100 meters away? Retinal disparity won't help us here, because there won't be much difference between the images cast on our right and left retinas. At such distances, we depend on **monocular cues** (depth cues available to each eye separately). See **FIGURE 19.5** on the next page for some examples.

Motion Perception

Imagine that you could perceive the world as having color, form, and depth but that you could not see motion. Not only would you be unable to bike or drive, you would have trouble writing, eating, and walking.

Normally your brain computes motion based partly on its assumption that shrinking objects are retreating (not getting smaller) and enlarging objects are approaching. But you are imperfect at motion perception. Large objects, such as trains, appear to move more slowly than smaller objects, such as cars, moving at the same speed. (Perhaps at an airport you've noticed that jumbo jets seem to land more slowly than little jets.)

To catch a fly ball, softball or cricket players (unlike drivers) want to achieve a collision—with the ball that's flying their way. To accomplish that, they follow an unconscious rule—one they can't explain but know intuitively: Run to keep the ball at a constantly increasing angle of gaze (McBeath et al., 1995). A dog catching a Frisbee does the same (Shaffer et al., 2004).

The brain also perceives continuous movement in a rapid series of slightly varying images (a phenomenon called *stroboscopic movement*). As film animation artists know well, you can create this illusion by flashing 24 still pictures a second. The motion we then see in popular action adventures is not in the film, which merely presents a superfast slide show. We construct that motion in our heads, just as we construct movement in blinking marquees and holiday lights. When two adjacent stationary lights blink on and off in quick succession, we perceive a single light moving back and forth between them. Lighted signs exploit this **phi phenomenon** with a succession of lights that creates the impression of, say, a moving arrow.

FYI

Carnivorous animals, including humans, have eyes that enable forward focus on a prey and offer binocular vision-enhanced depth perception. Grazing herbivores, such as horses and sheep, typically have eyes on the sides of their skull. Although lacking binocular depth perception, they have sweeping peripheral vision.

monocular cues depth cues, such as interposition and linear perspective, available to either eye alone.

phi phenomenon an illusion of movement created when two or more adjacent lights blink on and off in quick succession.

"Sometimes I wonder: Why is that Frisbee getting bigger? And then it hits me." -ANONYMOUS

"From there to here, from here to there, funny things are everywhere." -DR. SEUSS, *ONE FISH, TWO FISH, RED FISH, BLUE FISH*, 1960

Relative height We perceive objects higher in our field of vision as farther away. Because we assume the lower part of a figure-ground illustration is closer, we perceive it as figure (Vecera et al., 2002). Invert this illustration and the black will become ground, like a night sky.

Relative motion As we move, objects that are actually stable may appear to move. If while riding on a bus you fix your gaze on some point—say, a house—the objects beyond the fixation point will appear to move with you. Objects in front of the point will appear to move backward. The farther an object is from the fixation point, the faster it will seem to move.

Direction of passenger's motion →

Figure 19.5
Monocular depth cues

Relative size If we assume two objects are similar in size, most people perceive the one that casts the smaller retinal image as farther away.

© Philipp Mugridge/Alamy

Interposition *Interpose* means “to come between.” If one object partially blocks our view of another, we perceive it as closer.

Linear perspective Parallel lines appear to meet in the distance. The sharper the angle of convergence, the greater the perceived distance.

Perceptual Constancy

19-3

How do perceptual constancies help us organize our sensations into meaningful perceptions?

AP® Exam Tip

The illustrations in Figure 19.5 provide you with excellent opportunities to practice identifying monocular depth cues. To really demonstrate your understanding, look for these cues in other drawings and photographs. There are almost always cues to identify.

So far, we have noted that our video-computer system must perceive objects as we do—as having a distinct form, location, and perhaps motion. Its next task is to recognize objects without being deceived by changes in their color, brightness, shape, or size—a top-down process called **perceptual constancy**. Regardless of the viewing angle, distance, and illumination, we can identify people and things in less time than it takes to draw a breath, a feat that would be a monumental challenge for even advanced computers and that has intrigued researchers for decades.

COLOR AND BRIGHTNESS CONSTANCIES

Color does not reside in an object. Our experience of color depends on the object's *context*. If you view an isolated tomato through a paper tube, its color would seem to change as the light—and thus the wavelengths reflected from its surface—changed. But if you viewed that tomato as one item in a bowl of fresh fruit and vegetables, its color would remain roughly constant as the lighting shifts. This perception of consistent color is known as **color constancy**.

Though we take color constancy for granted, this ability is truly remarkable. A blue poker chip under indoor lighting reflects wavelengths that match those reflected by a sunlit gold chip (Jameson, 1985). Yet bring a bluebird indoors and it won't look like a goldfinch. The color is not in the bird's feathers. You and I see color thanks to our brain's computations of the light reflected by an object *relative to the objects surrounding it*. (But only if we grew up with normal light, it seems. Monkeys raised under a restricted range of wavelengths later have great difficulty recognizing the same color when illumination varies [Sugita, 2004].) **FIGURE 19.6** dramatically illustrates the ability of a blue object to appear very different in three different contexts. Yet we have no trouble seeing these disks as blue.

perceptual constancy perceiving objects as unchanging (having consistent shapes, size, brightness, and color) even as illumination and retinal images change.

color constancy perceiving familiar objects as having consistent color, even if changing illumination alters the wavelengths reflected by the object.

(a)

(b)

Figure 19.6

Color depends on context

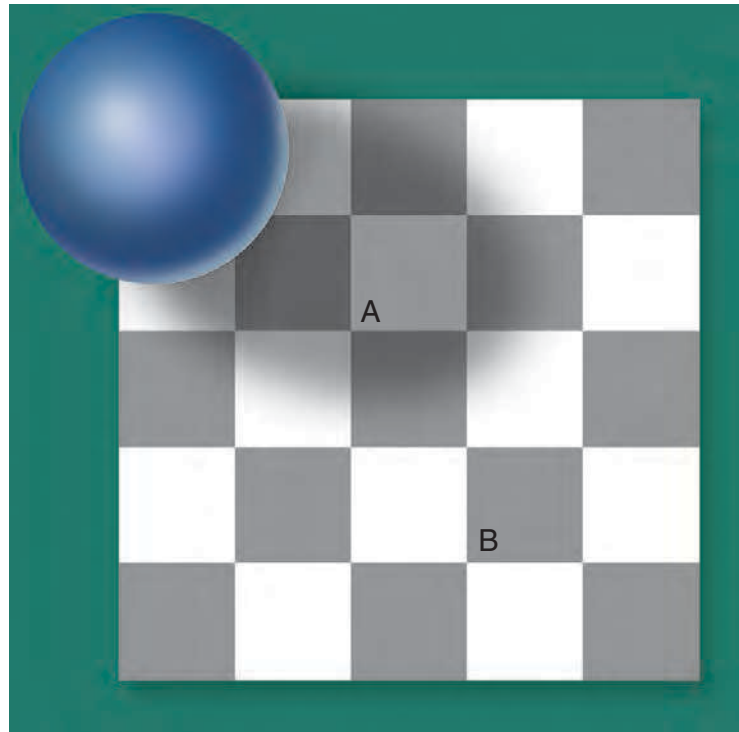

- (a) Believe it or not, these three blue disks are identical in color.
 (b) Remove the surrounding context and see what results.

Similarly, *brightness constancy* (also called *lightness constancy*) depends on context. We perceive an object as having a constant brightness even while its illumination varies. This perception of constancy depends on *relative luminance*—the amount of light an object reflects *relative to its surroundings* (**FIGURE 19.7** on the next page). White paper reflects 90 percent of the light falling on it; black paper, only 10 percent. Although a black paper viewed in sunlight may reflect 100 times more light than does a white paper viewed indoors, it will still look black (McBurney & Collings, 1984). But if you view sunlit black paper through a narrow tube so nothing else is visible, it may look gray, because in bright sunshine it reflects a fair amount of light. View it without the tube and it is again black, because it reflects much less light than the objects around it.

This principle—that we perceive objects not in isolation but in their environmental context—matters to artists, interior decorators, and clothing designers. Our perception of the color and brightness of a wall or of a streak of paint on a canvas is determined not just by the paint in the can but by the surrounding colors. The take-home lesson: *Comparisons govern our perceptions*.

Figure 19.7

Relative luminance Squares A and B are identical in color, believe it or not. (If you don't believe me, photocopy the illustration, cut out the squares, and compare.) But we perceive A as lighter, thanks to its surrounding context.

SHAPE AND SIZE CONSTANCIES

Sometimes an object whose actual shape cannot change *seems* to change shape with the angle of our view (**FIGURE 19.8**). More often, thanks to *shape constancy*, we perceive the form of familiar objects, such as the door in **FIGURE 19.9**, as constant even while our retinas receive changing images of them. Our brain manages this feat thanks to visual cortex neurons that rapidly learn to associate different views of an object (Li & DiCarlo, 2008).

Thanks to *size constancy*, we perceive objects as having a constant size, even while our distance from them varies. We assume a car is large enough to carry people, even when we see its tiny image from two blocks away. This assumption also illustrates the close connection between perceived *distance* and perceived *size*. Perceiving an object's distance gives us cues to its size. Likewise, knowing its general size—that the object is a car—provides us with cues to its distance.

**Figure 19.8**

Perceiving shape Do the tops of these tables have different dimensions? They appear to. But—believe it or not—they are identical. (Measure and see.) With both tables, we adjust our perceptions relative to our viewing angle.

**Figure 19.9**

Shape constancy A door casts an increasingly trapezoidal image on our retinas as it opens, yet we still perceive it as rectangular.

Even in size-distance judgments, however, we consider an object's context. The dogs in Module 17's Figure 17.3 cast identical images on our retinas. Using linear perspective as a cue (see Figure 19.5), our brain assumes that the pursuing dog is farther away. We therefore perceive it as larger. It isn't.

This interplay between perceived size and perceived distance helps explain several well-known illusions, including the *Moon illusion*: The Moon looks up to 50 percent larger when near the horizon than when high in the sky. Can you imagine why? For at least 22 centuries, scholars have debated this question (Hershenson, 1989). One reason is that cues to objects' distances make the horizon Moon—like the distant dog in Figure 17.3—appear farther away. If it's farther away, our brain assumes, it must be larger than the Moon high in the night sky (Kaufman & Kaufman, 2000). Take away the distance cue, by looking at the horizon Moon (or each dog) through a paper tube, and the object will immediately shrink.

Size-distance relationships also explain why in **FIGURE 19.10** the two same-age girls seem so different in size. As the diagram reveals, the girls are actually about the same size, but the room is distorted. Viewed with one eye through a peephole, the room's trapezoidal walls produce the same images you would see in a normal rectangular room viewed with both eyes. Presented with the camera's one-eyed view, your brain makes the reasonable assumption that the room *is* normal and each girl is therefore the same distance from you. Given the different sizes of the girls' images on your retinas, your brain ends up calculating that the girls must be very different in size.

Perceptual illusions reinforce a fundamental lesson: Perception is not merely a projection of the world onto our brain. Rather, our sensations are disassembled into information bits that our brain, using both bottom-up and top-down processing, then reassembles into its own functional model of the external world. During this reassembly process, our assumptions—such as the usual relationship between distance and size—can lead us astray. *Our brain constructs our perceptions.*

* * *

Form perception, depth perception, motion perception, and perceptual constancies illuminate how we organize our visual experiences. Perceptual organization applies to our other senses, too. It explains why we perceive a clock's steady tick not as a *tick-tick-tick-tick* but as grouped sounds, say, *TICK-tick, TICK-tick*. Listening to an unfamiliar language, we have trouble hearing where one word stops and the next one begins. Listening to our own language, we automatically hear distinct words. This, too, reflects perceptual organization. But it is more, for we even organize a string of letters—**THEDOGATEMEAT**—into words that make an intelligible phrase, more likely "The dog ate meat" than "The do gate me at" (McBurney & Collings, 1984). This process involves not only the organization we've been discussing, but also interpretation—discerning meaning in what we perceive.

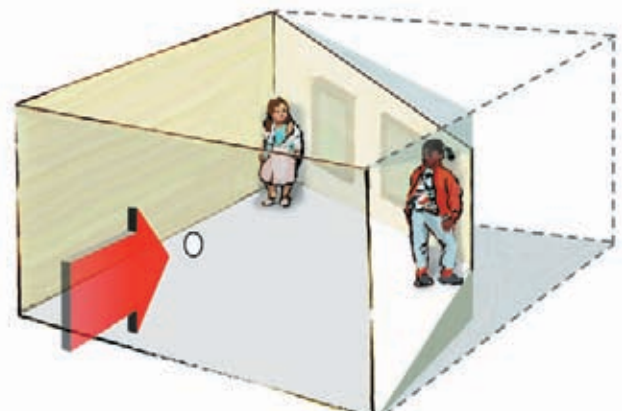

Figure 19.10

The illusion of the shrinking and growing girls

This distorted room, designed by Adelbert Ames, appears to have a normal rectangular shape when viewed through a peephole with one eye. The girl in the right corner appears disproportionately large because we judge her size based on the false assumption that she is the same distance away as the girl in the left corner.

S. Schwartzberg/The Exploratorium

“Let us then suppose the mind to be, as we say, white paper void of all characters, without any ideas: How comes it to be furnished? . . . To this I answer, in one word, from EXPERIENCE.” -JOHN LOCKE, *AN ESSAY CONCERNING HUMAN UNDERSTANDING*, 1690

Learning to see: At age 3, Mike May lost his vision in an explosion. Decades later, after a new cornea restored vision to his right eye, he got his first look at his wife and children. Alas, although signals were now reaching his visual cortex, it lacked the experience to interpret them. May could not recognize expressions, or faces, apart from features such as hair. Yet he can see an object in motion and to marvel at such things as dust floating in sunlight (Abrams, 2002).

AP Photo/Marcio Jose Sanchez

Visual Interpretation

Philosophers have debated whether our perceptual abilities should be credited to our nature or our nurture. To what extent do we *learn* to perceive? German philosopher Immanuel Kant (1724–1804) maintained that knowledge comes from our *inborn* ways of organizing sensory experiences. Indeed, we come equipped to process sensory information. But British philosopher John Locke (1632–1704) argued that through our experiences we also *learn* to perceive the world. Indeed, we learn to link an object’s distance with its size. So, just how important is experience? How radically does it shape our perceptual interpretations?

Experience and Visual Perception

19-4

What does research on restored vision, sensory restriction, and perceptual adaptation reveal about the effects of experience on perception?

RESTORED VISION AND SENSORY RESTRICTION

Writing to John Locke, William Molyneux wondered whether “a man *born* blind, and now adult, taught by his *touch* to distinguish between a cube and a sphere” could, if made to see, visually distinguish the two. Locke’s answer was *No*, because the man would never have *learned* to see the difference.

Molyneux’s hypothetical case has since been put to the test with a few dozen adults who, though blind from birth, have gained sight (Gregory, 1978; von Senden, 1932). Most had been born with cataracts—clouded lenses that allowed them to see only diffused light, rather as someone might see a foggy image through a Ping-Pong ball sliced in half. After cataract surgery, the patients could distinguish figure from ground and could sense colors—suggesting that these aspects of perception are innate. But much as Locke supposed, they often could not visually recognize objects that were familiar by touch.

Seeking to gain more control than is provided by clinical cases, researchers have outfitted infant kittens and monkeys with goggles through which they could see only diffuse, unpatterned light (Wiesel, 1982). After infancy, when the goggles were removed, these animals exhibited perceptual limitations much like those of humans born with cataracts. They could distinguish color and brightness, but not the form of a circle from that of a square. Their eyes had not degenerated; their retinas still relayed signals to their visual cortex. But lacking stimulation, the cortical cells had not developed normal connections. Thus, the animals remained functionally blind to shape. Experience guides, sustains, and maintains the brain’s neural organization as it forms the pathways that affect our perceptions.

In both humans and animals, similar sensory restrictions later in life do no permanent harm. When researchers cover the eye of an adult animal for several months, its vision will be unaffected after the eye patch is removed. When surgeons remove cataracts that develop during late adulthood, most people are thrilled at the return to normal vision.

The effect of sensory restriction on infant cats, monkeys, and humans suggests there is a *critical period* for normal sensory and perceptual development. Nurture sculpts what nature has endowed. In less dramatic ways, it continues to do so throughout our lives. Despite concerns about their social costs (more on this in Module 78), action video games sharpen spatial skills such as visual attention, eye-hand coordination and speed, and tracking multiple objects (Spence & Feng, 2010).

Experiments on early sensory deprivation provide a partial answer to the enduring question about experience: Does the effect of early experience last a lifetime? For some aspects of perception, the answer is clearly *Yes*: “Use it *soon* or lose it.” We retain the imprint of some early sensory experiences far into the future.

PERCEPTUAL ADAPTATION

Given a new pair of glasses, we may feel slightly disoriented, even dizzy. Within a day or two, we adjust. Our **perceptual adaptation** to changed visual input makes the world seem normal again. But imagine a far more dramatic new pair of glasses—one that shifts the apparent location of objects 40 degrees to the left. When you first put them on and toss a ball to a friend, it sails off to the left. Walking forward to shake hands with the person, you veer to the left.

Could you adapt to this distorted world? Baby chicks cannot. When fitted with such lenses, they continue to peck where food grains *seem* to be (Hess, 1956; Rossi, 1968). But we humans adapt to distorting lenses quickly. Within a few minutes your throws would again be accurate, your stride on target. Remove the lenses and you would experience an aftereffect: At first your throws would err in the *opposite* direction, sailing off to the right; but again, within minutes you would readapt.

Indeed, given an even more radical pair of glasses—one that literally turns the world upside down—you could still adapt. Psychologist George Stratton (1896) experienced this when he invented, and for eight days wore, optical headgear that flipped left to right *and* up to down, making him the first person to experience a right-side-up retinal image while standing upright. The ground was up, the sky was down.

At first, when Stratton wanted to walk, he found himself searching for his feet, which were now “up.” Eating was nearly impossible. He became nauseated and depressed. But he persisted, and by the eighth day he could comfortably reach for an object in the right direction and walk without bumping into things. When Stratton finally removed the headgear, he readapted quickly.

In later experiments, people wearing the optical gear have even been able to ride a motorcycle, ski the Alps, and fly an airplane (Dolezal, 1982; Kohler, 1962). The world around them still seemed above their heads or on the wrong side. But by actively moving about in these topsy-turvy worlds, they adapted to the context and learned to coordinate their movements.

perceptual adaptation in vision, the ability to adjust to an artificially displaced or even inverted visual field.

Courtesy of Hubert Dolezal

Perceptual adaptation “Oops, missed,” thought researcher Hubert Dolezal as he viewed the world through inverting goggles. Yet, believe it or not, kittens, monkeys, and humans can adapt to an inverted world.

Before You Move On

▶ ASK YOURSELF

Try drawing a realistic depiction of the scene from your window. Which monocular cues will you use in your drawing?

▶ TEST YOURSELF

What do we mean when we say that, in perception, “the whole is greater than the sum of its parts”?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 19 Review

19-1 How did the Gestalt psychologists understand perceptual organization, and how do figure-ground and grouping principles contribute to our perceptions?

- Gestalt psychologists searched for rules by which the brain organizes fragments of sensory data into *gestalts* (from the German word for “whole”), or meaningful forms. In pointing out that the whole may exceed the sum of its parts, they noted that we filter sensory information and construct our perceptions.
- To recognize an object, we must first perceive it (see it as a *figure*) as distinct from its surroundings (the *ground*). We bring order and form to stimuli by organizing them into meaningful *groups*, following such rules as proximity, continuity, and closure.

19-2 How do we use binocular and monocular cues to perceive the world in three dimensions and perceive motion?

- *Depth perception* is our ability to see objects in three dimensions and judge distance. The *visual cliff* and other research demonstrate that many species perceive the world in three dimensions at, or very soon after, birth.
- *Binocular cues*, such as *retinal disparity*, are depth cues that rely on information from both eyes.
- *Monocular cues* (such as relative size, interposition, relative height, relative motion, linear perspective, and light and shadow) let us judge depth using information transmitted by only one eye.
- As objects move, we assume that shrinking objects are retreating and enlarging objects are approaching.
- A quick succession of images on the retina can create an illusion of movement, as in stroboscopic movement or the *phi phenomenon*.

19-3 How do perceptual constancies help us organize our sensations into meaningful perceptions?

- *Perceptual constancy* enables us to perceive objects as stable despite the changing image they cast on our retinas.
 - *Color constancy* is our ability to perceive consistent color in objects, even though the lighting and wavelengths shift.
 - Brightness (or lightness) constancy is our ability to perceive an object as having a constant lightness even when its illumination—the light cast upon it—changes.
 - Our brain constructs our experience of an object’s color or brightness through comparisons with other surrounding objects.
 - Shape constancy is our ability to perceive familiar objects (such as an opening door) as unchanging in shape.
 - Size constancy is perceiving objects as unchanging in size despite their changing retinal images.
- Knowing an object’s size gives us clues to its distance; knowing its distance gives clues about its size, but we sometimes misread monocular distance cues and reach the wrong conclusions, as in the Moon illusion.

19-4 What does research on restored vision, sensory restriction, and perceptual adaptation reveal about the effects of experience on perception?

- Experience guides our perceptual interpretations. People blind from birth who gained sight after surgery lack the experience to visually recognize shapes, forms, and complete faces.
- Sensory restriction research indicates that there is a critical period for some aspects of sensory and perceptual development. Without early stimulation, the brain’s neural organization does not develop normally.
- People given glasses that shift the world slightly to the left or right, or even upside down, experience *perceptual adaptation*. They are initially disoriented, but they manage to adapt to their new context.

Multiple-Choice Questions

1. A teacher used distortion goggles, which shifted the wearer's gaze 20 degrees, to demonstrate an altered perception. A student wearing the goggles initially bumped into numerous desks and chairs while walking around, but chose to wear the goggles for a half hour. After 30 minutes, the student was able to smoothly avoid obstacles, illustrating the concept of
 - a. perceptual adaptation.
 - b. visual interpretation.
 - c. sensory restriction.
 - d. perceptual constancy.
 - e. binocular cues.
2. What do we call the illusion of movement that results from two or more stationary, adjacent lights blinking on and off in quick succession?
 - a. Phi phenomenon
 - b. Perceptual constancy
 - c. Binocular cues
 - d. Retinal disparity
 - e. Depth perception
3. Bryanna and Charles are in a dancing competition. It is easy for spectators to see them against the dance floor because of
 - a. the visual cliff.
 - b. the phi phenomenon.
 - c. color constancy.
 - d. sensory restriction.
 - e. figure-ground relationships.
4. The view from Narmeen's left eye is slightly different from the view from her right eye. This is due to which depth cue?
 - a. Retinal disparity
 - b. Relative size
 - c. Linear perspective
 - d. Relative motion
 - e. Convergence
5. Bringing order and form to stimuli, which illustrates how the whole differs from the sum of its parts, is called
 - a. grouping.
 - b. monocular cue.
 - c. binocular cue.
 - d. disparity.
 - e. motion.

Practice FRQs

1. Look at the **relative size** cartoon in Figure 19.5. Describe how the artist who drew this cartoon incorporated relative size, linear perspective, and interposition to create depth.
2. Explain the meaning of the word *gestalt* as it applies to perception. Then, apply any two gestalt principles to the perception of food on a plate.

(3 points)

Answer

Specific explanations may utilize different aspects of the cartoon.

1 point: Relative size: We know the woman is closer to us than the police officer, because she is drawn larger.

1 point: Linear perspective: We can tell that the sidewalk is receding into the distance, because its sides pinch closer together in the distance.

1 point: Interposition: We know the woman is closer to us than the police officer, because our view of her partially blocks our view of him.

Module 20

Hearing

Module Learning Objectives

- 20-1** Describe the characteristics of air pressure waves, and explain the process by which the ear transforms sound energy into neural messages.
- 20-2** Discuss the theories that help us understand pitch perception.
- 20-3** Describe how we locate sounds.

Leland Bobbie/CORBIS

- 20-1** What are the characteristics of air pressure waves that we hear as sound, and how does the ear transform sound energy into neural messages?

Like our other senses, our **audition**, or hearing, is highly adaptive. We hear a wide range of sounds, but the ones we hear best are those sounds with frequencies in a range corresponding to that of the human voice. Those with normal hearing are acutely sensitive to faint sounds, an obvious boon for our ancestors' survival when hunting or being hunted, or for detecting a child's whimper. (If our ears were much more sensitive, we would hear a constant hiss from the movement of air molecules.)

We are also remarkably attuned to variations in sounds. We easily detect differences among thousands of possible human voices: Walking between classes, we immediately recognize the voice of a friend behind us. A fraction of a second after a spoken word stimulates the ear's receptors, millions of neurons have simultaneously coordinated in extracting the essential features, comparing them with past experience, and identifying the stimulus (Freeman, 1991).

But not everyone has this ability. Some years ago, on a visit to my childhood home, I communicated with my then 80-year-old mother by writing on her erasable "magic pad." Four years earlier she had transitioned from hearing loss to complete deafness by giving up her now useless hearing aids.

"Do you hear anything?" I wrote.

"No," she answered, her voice still strong although she could not hear it. "Last night your Dad came in and found the TV blasting. Someone had left the volume way up; I didn't hear a thing." (Indeed, my father later explained, he recently tested her by sneaking up while she was reading and giving a loud clap just behind her ear. Her eye never wavered from the page.)

What is it like, I wondered. "A silent world?"

"Yes," she replied. "It's a silent world."

audition the sense or act of hearing.

AP[®] Exam Tip

Pay attention to how many pages are devoted to each of the senses. Not only does this represent the complexity of the sensory system, it also represents how likely you are to find questions about that system on the AP[®] exam. More pages are devoted to vision than hearing, and vision questions are somewhat more likely to appear on the exam.

And for her, with human connections made difficult, it became a socially isolated world. “Not having understood what was said in a group,” she reminisced, “I would chime in and say the same thing someone else had just said—and everyone would laugh. I would be so embarrassed, I wanted to fall through the floor.” Increasingly, her way of coping was to avoid getting out onto the floor in the first place. She shied away from public events and found excuses to avoid people who didn’t understand.

Our exchange left me wondering: Will I—having inherited her progressive hearing loss—also become socially isolated? Or, aided by today’s better technology, can I keep my private vow not to repeat her past? Hearing allows mind-to-mind communication and enables connection. Yet many of us can and do connect despite hearing loss—with help from technology, lip-reading, and signing. For me, it’s worth the effort. Communicating with others affirms our humanity as social creatures.

So, how does hearing normally work? How do we harvest meaning from the air pressure waves sent from another’s mouth?

The Stimulus Input: Sound Waves

Draw a bow across a violin, and you will unleash the energy of sound waves. Jostling molecules of air, each bumping into the next, create waves of compressed and expanded air, like the ripples on a pond circling out from a tossed stone. As we swim in our ocean of moving air molecules, our ears detect these brief air pressure changes. (Exposed to a loud, low bass sound—perhaps from a bass guitar or a cello—we can also *feel* the vibration. We hear by both air and bone conduction.)

Like light waves, sound waves vary in shape. The *amplitude* of sound waves determines their *loudness*. Their length, or **frequency**, determines the **pitch** we experience. Long waves have low frequency—and low pitch. Short waves have high frequency—and high pitch. Sound waves produced by a violin are much shorter and faster than those produced by a cello or a bass guitar.

We measure sounds in *decibels*, with zero decibels representing the absolute threshold for hearing. Every 10 decibels correspond to a tenfold increase in sound intensity. Thus, normal conversation (60 decibels) is 10,000 times more intense than a 20-decibel whisper. And a temporarily tolerable 100-decibel passing subway train is 10 billion times more intense than the faintest detectable sound.

The Ear

The intricate process that transforms vibrating air into nerve impulses, which our brain decodes as sounds, begins when sound waves enter the outer ear. A mechanical chain reaction begins as the visible *outer ear* channels the waves through the auditory canal to the *eardrum*, a tight membrane, causing it to vibrate (**FIGURE 20.1** on the next page). In the **middle ear** three tiny bones (the *hammer*, *anvil*, and *stirrup*) pick up the vibrations and transmit them to the **cochlea**, a snail-shaped tube in the **inner ear**. The incoming vibrations cause the cochlea’s membrane (the *oval window*) to vibrate, jostling the fluid that fills the tube. This motion causes ripples in the *basilar membrane*, bending the *hair cells* lining its surface, not unlike the wind bending a wheat field. Hair cell movement triggers impulses in the adjacent nerve cells. Axons of those cells converge to form the *auditory nerve*, which sends neural messages (via the thalamus) to the *auditory cortex* in the brain’s temporal lobe. From vibrating air to fluid waves to electrical impulses to the brain: Voila! We hear.

The sounds of music A violin’s short, fast waves create a high pitch, a cello’s longer, slower waves a lower pitch. Differences in the waves’ height, or amplitude, also create differing degrees of loudness. (To review the physical properties of light and sound waves, see Figure 18.2 in Module 18.)

Dennis MacDonald/Photo Edit

AP[®] Exam Tip

Note that both light and sound travel in waves. In each case, the amplitude and length of the waves are important.

frequency the number of complete wavelengths that pass a point in a given time (for example, per second).

pitch a tone’s experienced highness or lowness; depends on frequency.

middle ear the chamber between the eardrum and cochlea containing three tiny bones (hammer, anvil, and stirrup) that concentrate the vibrations of the eardrum on the cochlea’s oval window.

cochlea [KOHK-lee-uh] a coiled, bony, fluid-filled tube in the inner ear; sound waves traveling through the cochlear fluid trigger nerve impulses.

inner ear the innermost part of the ear, containing the cochlea, semicircular canals, and vestibular sacs.

Figure 20.1

Hear here: How we transform sound waves into nerve impulses that our brain interprets

(a) The outer ear funnels sound waves to the eardrum. The bones of the middle ear (hammer, anvil, and stirrup) amplify and relay the eardrum's vibrations through the oval window into the fluid-filled cochlea. (b) As shown in this detail of the middle and inner ear, the resulting pressure changes in the cochlear fluid cause the basilar membrane to ripple, bending the hair cells on its surface. Hair cell movements trigger impulses at the base of the nerve cells, whose fibers converge to form the auditory nerve. That nerve sends neural messages to the thalamus and on to the auditory cortex.

My vote for the most intriguing part of the hearing process is the hair cells—“quivering bundles that let us hear” thanks to their “extreme sensitivity and extreme speed” (Goldberg, 2007). A cochlea has 16,000 of them, which sounds like a lot until we compare that with an eye’s 130 million or so photoreceptors. But consider their responsiveness. Deflect the tiny bundles of *cilia* on the tip of a hair cell by the width of an atom—the equivalent of displacing the top of the Eiffel Tower by half an inch—and the alert hair cell, thanks to a special protein at its tip, triggers a neural response (Corey et al., 2004).

Susumu Nishimaga/Science Source

Be kind to your inner ear's hair cells When vibrating in response to sound, the hair cells shown here lining the cochlea produce an electrical signal.

Damage to the cochlea's hair cell receptors or their associated nerves can cause **sensorineural hearing loss** (or nerve deafness). (A less common form of hearing loss is **conduction hearing loss**, caused by damage to the mechanical system that conducts sound waves to the cochlea.) Occasionally, disease causes sensorineural hearing loss, but more often the culprits are biological changes linked with heredity, aging, and prolonged exposure to ear-splitting noise or music.

Hair cells have been likened to carpet fibers. Walk around on them and they will spring back with a quick vacuuming. But leave a heavy piece of furniture on them for a long time and they may never rebound. As a general rule, if we cannot talk over a noise, it is potentially harmful, especially if prolonged and repeated (Roesser, 1998). Such experiences are common when sound exceeds 100 decibels, as happens in venues from frenzied sports arenas to bagpipe bands to personal music coming through our earphones near maximum volume (**FIGURE 20.2**). Ringing of the ears after exposure to loud machinery or music indicates that we have been bad to our unhappy hair cells. As pain alerts us to possible bodily harm, ringing of the ears alerts us to possible hearing damage. It is hearing's equivalent of bleeding.

The rate of teen hearing loss, now 1 in 5, has risen by one-third since the early 1990s (Shargorodsky et al., 2010). Teen boys more than teen girls or adults blast themselves with loud volumes for long periods (Zogby, 2006). Males' greater noise exposure may help explain why men's hearing tends to be less acute than women's. But male or female, those who spend many hours in a loud nightclub, behind a power mower, or above a jackhammer should wear earplugs. "Condoms or, safer yet, abstinence," say sex educators. "Earplugs or walk away," say hearing educators.

Hardware for hearing Cochlear implants work by translating sounds into electrical signals that are transmitted to the cochlea and, via the auditory nerve, on to the brain.

cochlear implant a device for converting sounds into electrical signals and stimulating the auditory nerve through electrodes threaded into the cochlea.

For now, the only way to restore hearing for people with nerve deafness is a sort of bionic ear—a **cochlear implant**, which, by 2009, had been given to 188,000 people worldwide (NIDCD, 2011). This electronic device translates sounds into electrical signals that, wired into the cochlea’s nerves, convey information about sound to the brain. Cochlear implants given to deaf kittens and human infants seem to trigger an “awakening” of the pertinent brain area (Klinke et al., 1999; Sirenteanu, 1999). They can help children become proficient in oral communication (especially if they receive them as preschoolers or even before age 1) (Dettman et al., 2007; Schorr et al., 2005).

The latest cochlear implants also can help restore hearing for most adults. However, the implants will not enable normal hearing in adults if their brain never learned to process sound during childhood. Similarly, cochlear implants did not enable hearing in deaf-from-birth cats that received them when fully grown rather than as 8-week-old kittens (Ryugo et al., 2010).

Perceiving Loudness

How do we detect loudness? It is not, as I would have guessed, from the intensity of a hair cell’s response. Rather, a soft, pure tone activates only the few hair cells attuned to its frequency. Given louder sounds, neighboring hair cells also respond. Thus, the brain can interpret loudness from the *number* of activated hair cells.

If a hair cell loses sensitivity to soft sounds, it may still respond to loud sounds. This helps explain another surprise: Really loud sounds may seem loud to people with or without normal hearing. As a person with hearing loss, I used to wonder what really loud music must sound like to people with normal hearing. Now I realize it sounds much the same; where we differ is in our sensation of soft sounds. This is why we hard-of-hearing people do not want *all* sounds (loud and soft) amplified. We like sound *compressed*—which means harder-to-hear sounds are amplified more than loud sounds (a feature of today’s digital hearing aids).

FYI

Experiments are also under way to restore vision—with a bionic retina (a 2-millimeter-diameter microchip with photoreceptors that stimulate damaged retinal cells), and with a video camera and computer that stimulate the visual cortex. In test trials, both devices have enabled blind people to gain partial sight (Boahen, 2005; Steenhuisen, 2002).

Perceiving Pitch

20-2 What theories help us understand pitch perception?

How do we know whether a sound is the high-frequency, high-pitched chirp of a bird or the low-frequency, low-pitched roar of a truck? Current thinking on how we discriminate pitch, like current thinking on how we discriminate color, combines two theories.

- Hermann von Helmholtz’s **place theory** presumes that we hear different pitches because different sound waves trigger activity at different places along the cochlea’s basilar membrane. Thus, the brain determines a sound’s pitch by recognizing the specific place (on the membrane) that is generating the neural signal. When Nobel laureate-to-be Georg von Békésy (1957) cut holes in the cochleas of guinea pigs and human cadavers and looked inside with a microscope, he discovered that the cochlea vibrated, rather like a shaken bedsheet, in response to sound. High frequencies produced large vibrations near the beginning of the cochlea’s membrane. Low frequencies vibrate more of the membrane, including near the end. But a problem remains: Place theory can explain how we hear high-pitched sounds but not low-pitched sounds. The neural signals generated by low-pitched sounds are not so neatly localized on the basilar membrane.
- **Frequency theory** suggests an alternative: The brain reads pitch by monitoring the frequency of neural impulses traveling up the auditory nerve. The whole basilar membrane vibrates with the incoming sound wave, triggering neural impulses to the brain at the same rate as the sound wave. If the sound wave has a frequency of 100 waves per second, then 100 pulses per second travel up the auditory nerve. But again, a problem remains: An individual neuron cannot fire faster than 1000 times per second. How, then, can we sense sounds with frequencies above 1000 waves per second (roughly the upper third of a piano keyboard)?
- Enter the *volley principle*: Like soldiers who alternate firing so that some can shoot while others reload, neural cells can alternate firing. By firing in rapid succession, they can achieve a *combined frequency* above 1000 waves per second. Thus, place theory best explains how we sense *high pitches*, frequency theory best explains how we sense *low pitches*, and some combination of place and frequency seems to handle the *pitches in the intermediate range*.

place theory in hearing, the theory that links the pitch we hear with the place where the cochlea’s membrane is stimulated.

frequency theory in hearing, the theory that the rate of nerve impulses traveling up the auditory nerve matches the frequency of a tone, thus enabling us to sense its pitch.

Locating Sounds

20-3 How do we locate sounds?

Why don’t we have one big ear—perhaps above our one nose? “All the better to hear you with,” as the wolf said to Red Riding Hood. As the placement of our eyes allows us to sense visual depth, so the placement of our two ears allows us to enjoy stereophonic (“three-dimensional”) hearing.

Two ears are better than one for at least two reasons. If a car to the right honks, your right ear receives a more *intense* sound, and it receives sound slightly *sooner* than your left ear (**FIGURE 20.3**). Because sound travels 750 miles per hour and our ears are but 6 inches apart, the intensity difference and the time lag are extremely small. A just noticeable difference in the direction of two sound sources corresponds to a time difference of just 0.000027 second! Lucky for us, our supersensitive auditory system can detect such minute differences (Brown & Deffenbacher, 1979; Middlebrooks & Green, 1991).

Figure 20.3
How we locate sounds Sound waves strike one ear sooner and more intensely than the other. From this information, our nimble brain computes the sound’s location. As you might therefore expect, people who lose all hearing in one ear often have difficulty locating sounds.

Before You Move On

▶ ASK YOURSELF

If you are a hearing person, imagine that you had been born deaf. Do you think your life would be different?

▶ TEST YOURSELF

What are the basic steps in transforming sound waves into perceived sound?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 20 Review

20-1

What are the characteristics of air pressure waves that we hear as sound, and how does the ear transform sound energy into neural messages?

- Sound waves are bands of compressed and expanded air. Our ears detect these changes in air pressure and transform them into neural impulses, which the brain decodes as sound.
- Sound waves vary in amplitude, which we perceive as differing loudness, and in *frequency*, which we experience as differing *pitch*.
- The outer ear is the visible portion of the ear. The *middle ear* is the chamber between the eardrum and *cochlea*.
- The *inner ear* consists of the cochlea, semicircular canals, and vestibular sacs.
- Through a mechanical chain of events, sound waves traveling through the auditory canal cause tiny vibrations in the eardrum. The bones of the middle ear (the *hammer*, *anvil*, and *stirrup*) amplify the vibrations and relay them to the fluid-filled cochlea. Rippling of the basilar membrane, caused by pressure changes in the cochlear fluid, causes movement of the tiny hair cells, triggering neural messages to be sent (via the thalamus) to the auditory cortex in the brain.
- *Sensorineural hearing loss* (or nerve deafness) results from damage to the cochlea's hair cells or their associated nerves. *Conduction hearing loss* results from damage to the mechanical system that transmits sound waves to the cochlea. *Cochlear implants* can restore hearing for some people.

20-2

What theories help us understand pitch perception?

- *Place theory* explains how we hear high-pitched sounds, and *frequency theory* explains how we hear low-pitched sounds. (A combination of the two theories (the volley principle) explains how we hear pitches in the middle range.)
 - *Place theory* proposes that our brain interprets a particular pitch by decoding the place where a sound wave stimulates the cochlea's basilar membrane.
 - *Frequency theory* proposes that the brain deciphers the frequency of the neural impulses traveling up the auditory nerve to the brain.

20-3

How do we locate sounds?

- Sound waves strike one ear sooner and more intensely than the other. The brain analyzes the minute differences in the sounds received by the two ears and computes the sound's source.

Multiple-Choice Questions

1. What type of hearing loss is due to damage to the mechanism that transmits sound waves to the cochlea?
 - a. Sensorineural
 - b. Window-related
 - c. Conduction
 - d. Cochlear
 - e. Basilar
2. Pitch depends on which of the following?
 - a. Amplitude of a sound wave
 - b. Number of hair cells stimulated
 - c. Strength of nerve impulses traveling up the auditory nerve
 - d. Number of sound waves that reach the ear in a given time
 - e. Decibels of a sound wave
3. Which of the following reflects the notion that pitch is related to the number of impulses traveling up the auditory nerve in a unit of time?
 - a. Place theory
 - b. Frequency theory
 - c. Volley principle
 - d. Sound localization
 - e. Stereophonic hearing
4. The three small bones of the ear are located in the
 - a. cochlea.
 - b. outer ear.
 - c. inner ear.
 - d. middle ear.
 - e. auditory nerve.

Practice FRQs

1. Describe two parts of the ear that transmit sound waves before they reach the hair cells.
2. What roles do the outer, middle, and inner ear play in helping a person hear a song on the radio?

Answer

Students may describe any two of the following:

1 point: The eardrum, a tight membrane separating the middle ear from the outer ear.

1 point: The three bones in the middle ear that transmit sound waves between the eardrum and the cochlea.

1 point: The oval window, the point at which vibrations enter the cochlea.

1 point: The cochlea, where the fluid inside vibrates and the hair cells are stimulated.

(3 points)

Module 21

The Other Senses

Module Learning Objectives

- 21-1** Describe the sense of touch.
- 21-2** Discuss how we best understand and control pain.
- 21-3** Describe the senses of taste and smell.
- 21-4** Explain how we sense our body's position and movement.
- 21-5** Describe how our senses interact.

Although our brain gives seeing and hearing priority in the allocation of cortical tissue, extraordinary happenings occur within our four other senses—our senses of touch, taste, smell, and body position and movement. Sharks and dogs rely on their extraordinary sense of smell, aided by large brain areas devoted to this system. Without our own senses of touch, taste, smell, and body position and movement, we humans would also be seriously handicapped, and our capacities for enjoying the world would be seriously diminished.

Touch

21-1 How do we sense touch?

Although not the first sense to come to mind, touch is vital. Right from the start, touch is essential to our development. Infant rats deprived of their mother's grooming produce less growth hormone and have a lower metabolic rate—a good way to keep alive until the mother returns, but a reaction that stunts growth if prolonged. Infant monkeys allowed to see, hear, and smell—but not touch—their mother become desperately unhappy; those separated by a screen with holes that allow touching are much less miserable. As we will see in Module 46, premature human babies gain weight faster and go home sooner if they are stimulated by hand massage. As lovers, we yearn to touch—to kiss, to stroke, to snuggle. And even strangers, touching only the other's forearms and separated by a curtain, can communicate anger, fear, disgust, love, gratitude, and sympathy at levels well above chance (Hertenstein et al., 2006).

Humorist Dave Barry may be right to jest that your skin “keeps people from seeing the inside of your body, which is repulsive, and it prevents your organs from falling onto the ground.” But skin does much more. Our “sense of touch” is actually a mix of distinct skin senses for pressure, warmth, cold, and pain. Touching various spots on the skin with a soft

“Touch is both the alpha and omega of affection.” -WILLIAM JAMES (1890)

hair, a warm or cool wire, and the point of a pin reveals that some spots are especially sensitive to pressure, others to warmth, others to cold, still others to pain. Other skin sensations are variations of the basic four (*pressure, warmth, cold, and pain*):

- Stroking adjacent pressure spots creates a tickle.
- Repeated gentle stroking of a pain spot creates an itching sensation.
- Touching adjacent cold and pressure spots triggers a sense of wetness, which you can experience by touching dry, cold metal.
- Stimulating nearby cold and warm spots produces the sensation of hot (**FIGURE 21.1**).

Touch sensations involve more than tactile stimulation, however. A self-produced tickle produces less somatosensory cortex activation than does the same tickle from something or someone else (Blakemore et al., 1998). (The brain is wise enough to be most sensitive to unexpected stimulation.)

Pain

21-2 How can we best understand and control pain?

Be thankful for occasional pain. Pain is your body's way of telling you something has gone wrong. Drawing your attention to a burn, a break, or a sprain, pain orders you to change your behavior—"Stay off that turned ankle!" The rare people born without the ability to feel pain may experience severe injury or even die before early adulthood. Without the discomfort that makes us occasionally shift position, their joints fail from excess strain, and without the warnings of pain, the effects of unchecked infections and injuries accumulate (Neese, 1991).

More numerous are those who live with chronic pain, which is rather like an alarm that won't shut off. The suffering of those with persistent or recurring backaches, arthritis, headaches, and cancer-related pain, prompts two questions: What is pain? How might we control it?

Understanding Pain

Our pain experiences vary widely. Women are more pain sensitive than men are (Wickelgren, 2009). Individual pain sensitivity varies, too, depending on genes, physiology, experience, attention, and surrounding culture (Gatchel et al., 2007; Reimann et al., 2010). Thus, feeling pain reflects both bottom-up sensations and top-down processes.

BIOLOGICAL INFLUENCES

There is no one type of stimulus that triggers pain (as light triggers vision). Instead, there are different *nociceptors*—sensory receptors that detect hurtful temperatures, pressure, or chemicals (**FIGURE 21.2** on the next page).

Although no theory of pain explains all available findings, psychologist Ronald Melzack and biologist Patrick Wall's (1965, 1983) classic **gate-control theory** provides a useful model. The spinal cord contains small nerve fibers that conduct most pain signals, and larger fibers that conduct most other sensory signals. Melzack and Wall theorized that the spinal cord contains a neurological "gate." When tissue is injured, the small fibers activate and open the gate, and you feel pain. Large-fiber activity closes the gate, blocking pain signals and preventing them from reaching the brain. Thus, one way to treat chronic pain is to

Figure 21.1
Warm + cold = hot When ice-cold water passes through one coil and comfortably warm water through another, we perceive the combined sensation as burning hot.

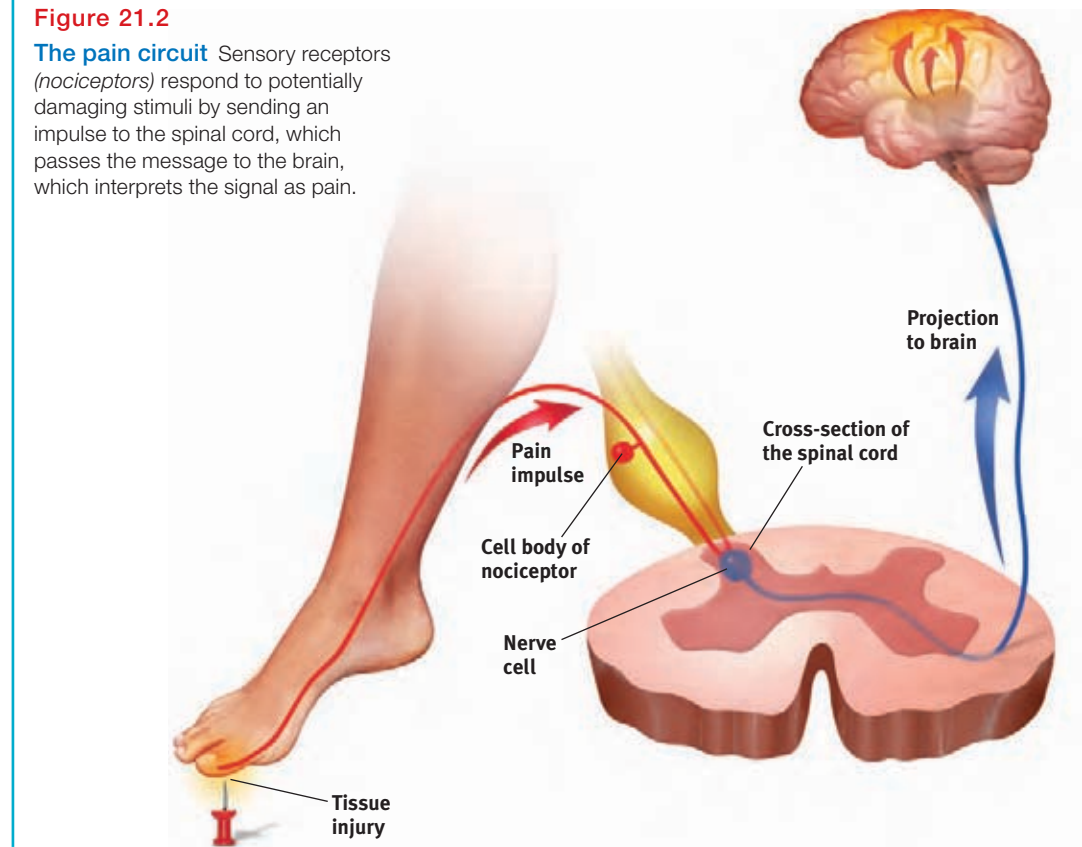

"Pain is a gift" So said a doctor studying 13-year-old Ashlyn Blocker. Ashlyn has a rare genetic mutation that prevents her feeling pain. At birth she didn't cry. As a child, she ran around for two days on a broken ankle. She has put her hands on a hot machine and burned the flesh off. And she has reached into boiling water to retrieve a dropped spoon. "Everyone in my class asks me about it, and I say, 'I can feel pressure, but I can't feel pain.' *Pain!* I cannot feel it!" (Heckert, 2010).

Jeff Riedel/Contour by Getty Images

gate-control theory the theory that the spinal cord contains a neurological "gate" that blocks pain signals or allows them to pass on to the brain. The "gate" is opened by the activity of pain signals traveling up small nerve fibers and is closed by activity in larger fibers or by information coming from the brain.

Figure 21.2

The pain circuit Sensory receptors (*nociceptors*) respond to potentially damaging stimuli by sending an impulse to the spinal cord, which passes the message to the brain, which interprets the signal as pain.

stimulate (by massage, electric stimulation, or acupuncture) “gate-closing” activity in the large neural fibers (Wall, 2000).

But pain is not merely a physical phenomenon of injured nerves sending impulses to a definable brain area—like pulling on a rope to ring a bell. Melzack and Wall noted that brain-to-spinal-cord messages can also close the gate, helping to explain some striking influences on pain. When we are distracted from pain (a psychological influence) and soothed by the release of our naturally painkilling *endorphins* (a biological influence), our experience of pain diminishes. Sports injuries may go unnoticed until the after-game shower. People who carry a gene that boosts the availability of endorphins are less bothered by pain, and their brain is less responsive to pain (Zubieta et al., 2003). Others carry a mutated gene that disrupts pain circuit neurotransmission and experience little pain (Cox et al., 2006). Such discoveries may point the way toward new pain medications that mimic these genetic effects.

The brain can also create pain, as it does in people’s experiences of *phantom limb sensations*, when it misinterprets the spontaneous central nervous system activity that occurs in the absence of normal sensory input. As the dreamer may see with eyes closed, so some 7 in 10 amputees may feel pain or movement in nonexistent limbs (Melzack, 1992, 2005). (An amputee may also try to step off a bed onto a phantom limb or to lift a cup with a phantom hand.) Even those born without a limb sometimes perceive sensations from the absent arm or leg. The brain, Melzack (1998) surmises, comes prepared to anticipate “that it will be getting information from a body that has limbs.”

A similar phenomenon occurs with other senses. People with hearing loss often experience the sound of silence: phantom sounds—a ringing-in-the-ears sensation known as *tinnitus*. Those who lose vision to glaucoma, cataracts, diabetes, or macular degeneration may experience phantom sights—nonthreatening hallucinations (Ramachandran & Blakeslee, 1998). Some with nerve damage have had taste phantoms, such as ice water seeming sickeningly sweet (Goode, 1999). Others have experienced phantom smells, such as nonexistent rotten food. The point to remember: *We feel, see, hear, taste, and smell with our brain*, which can sense even without functioning senses.

PSYCHOLOGICAL INFLUENCES

The psychological effects of distraction are clear in the stories of athletes who, focused on winning, play through the pain. We also seem to edit our *memories* of pain, which often differ from the pain we actually experienced. In experiments, and after medical procedures, people overlook a pain’s duration. Their memory snapshots instead record two factors: their pain’s *peak* moment (which can lead them to recall variable pain, with peaks, as worse [Stone et al., 2005]), and how much pain they felt at the *end*.

In one experiment, researchers asked people to immerse one hand in painfully cold water for 60 seconds, and then the other hand in the same painfully cold water for 60 seconds followed by a slightly less painful 30 seconds more (Kahneman et al., 1993). Which experience would you expect to recall as most painful? Curiously, when asked which trial they would prefer to repeat, most preferred the longer trial, with more net pain—but less pain at the end. Physicians have used this principle with patients undergoing colon exams—lengthening the discomfort by a minute, but lessening its intensity (Kahneman, 1999). Although the extended milder discomfort added to their net pain experience, patients experiencing this taper-down treatment later recalled the exam as less painful than did those whose pain ended abruptly. (If, at the end of a painful root canal, the oral surgeon asks if you’d like to go home or to have a few more minutes of milder discomfort, there’s a case to be made for prolonging your hurt.)

SOCIAL-CULTURAL INFLUENCES

Our perception of pain also varies with our social situation and our cultural traditions. We tend to perceive more pain when others also seem to be experiencing pain (Symbaluk et al., 1997). This may help explain other apparent social aspects of pain, as when pockets of Australian keyboard operators during the mid-1980s suffered outbreaks of severe pain during typing or other repetitive work—without any discernible physical abnormalities (Gawande, 1998). Sometimes the pain in sprain is mainly in the brain—literally. When feeling empathy for another’s pain, a person’s own brain activity may partly mirror that of the other’s brain in pain (Singer et al, 2004).

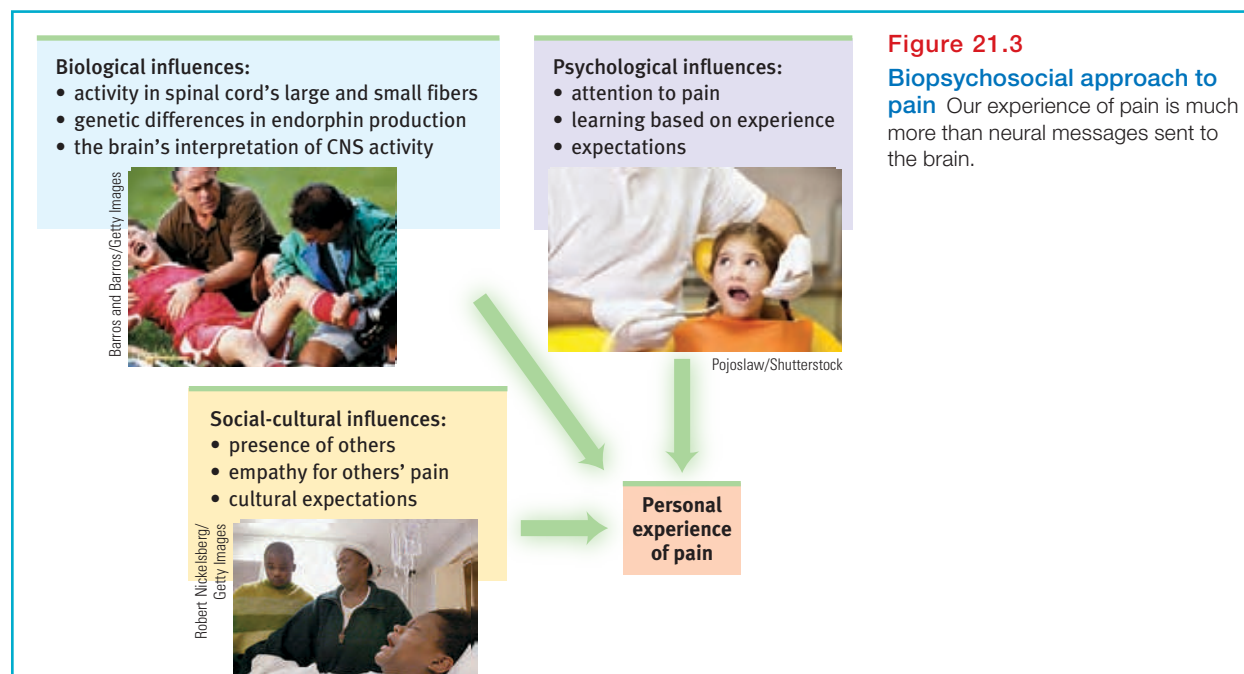

Thus, our perception of pain is a biopsychosocial phenomenon (**FIGURE 21.3**). Viewing pain this way can help us better understand how to cope with pain and treat it.

Playing with pain In a 2012 NFL game, Dallas Cowboys quarterback Tony Romo cracked a rib after colliding with an opposing player. He continued playing through the pain, which reclaimed his attention after the game’s end.

“When belly with bad pains doth swell, It matters naught what else goes well.” -SADI, *THE GULISTAN*, 1258

“Pain is increased by attending to it.” -CHARLES DARWIN, *EXPRESSION OF EMOTIONS IN MAN AND ANIMALS*, 1872

Acupuncture: A jab well done This acupuncturist is attempting to help this woman gain relief from back pain by using needles on points of the patient's hand.

Controlling Pain

If pain is where body meets mind—if it is both a physical and a psychological phenomenon—then it should be treatable both physically and psychologically. Depending on the type of symptoms, pain control clinics select one or more therapies from a list that includes drugs, surgery, acupuncture, electrical stimulation, massage, exercise, hypnosis, relaxation training, and thought distraction.

Even an inert placebo can help, by dampening the central nervous system's attention and responses to painful experiences—mimicking analgesic drugs (Eippert et al., 2009; Wager, 2005). After being injected in the jaw with a stinging saltwater solution, men in one experiment received a placebo said to relieve pain, and they immediately felt better. Being given fake pain-killing chemicals caused the brain to dispense real ones, as indicated by activity in an area that releases natural pain-killing opiates (Scott et al., 2007; Zubieta et al., 2005). "Believing becomes reality," noted one commentator (Thernstrom, 2006), as "the mind unites with the body."

Another experiment pitted two placebos—fake pills and pretend acupuncture—against each other (Kaptchuk et al., 2006). People with persistent arm pain (270 of them) received either sham acupuncture (with trick needles that retracted without puncturing the skin) or blue cornstarch pills that looked like pills often prescribed for strain injury. A fourth of those receiving the nonexistent needle pricks and 31 percent of those receiving the pills complained of side effects, such as painful skin or dry mouth and fatigue. After two months, both groups were reporting less pain, with the fake acupuncture group reporting the greater pain drop.

Distracting people with pleasant images ("Think of a warm, comfortable environment") or drawing their attention away from the painful stimulation ("Count backward by 3s") is an especially effective way to activate pain-inhibiting circuits and to increase pain tolerance (Edwards et al., 2009). A well-trained nurse may distract needle-shy patients by chatting with them and asking them to look away when inserting the needle. For burn victims receiving excruciating wound care, an even more effective distraction comes from immersion in a computer-generated 3-D world, like the snow scene in **FIGURE 21.4**. Functional MRI (fMRI) scans reveal that playing in the virtual reality reduces the brain's pain-related activity (Hoffman, 2004). Because pain is in the brain, diverting the brain's attention may bring relief.

Figure 21.4

Virtual-reality pain control For burn victims undergoing painful skin repair, an escape into virtual reality can powerfully distract attention, thus reducing pain and the brain's response to painful stimulation. The fMRI scans on the right illustrate a lowered pain response when the patient is distracted.

Taste

21-3 How do we experience taste and smell?

Like touch, our sense of taste involves several basic sensations. Taste's sensations were once thought to be sweet, sour, salty, and bitter, with all others stemming from mixtures of these four (McBurney & Gent, 1979). Then, as investigators searched for specialized nerve fibers for the four taste sensations, they encountered a receptor for what we now know is a fifth—the savory meaty taste of *umami*, best experienced as the flavor enhancer monosodium glutamate (MSG), often used in Chinese and Thai food.

Evolutionary psychologists explain that tastes exist for more than our pleasure (see **TABLE 21.1**). Pleasurable tastes attracted our ancestors to energy- or protein-rich foods that enabled their survival. Aversive tastes deterred them from new foods that might be toxic. We see the inheritance of this biological wisdom in today's 2- to 6-year-olds, who are typically fussy eaters, especially when offered new meats or bitter-tasting vegetables, such as spinach and brussels sprouts (Cooke et al., 2003). Meat and plant toxins were both potentially dangerous sources of food poisoning for our ancestors, especially for children. Given repeated small tastes of disliked new foods, children will, however, typically begin to accept them (Wardle et al., 2003). (Module 38 will explore cultural influences on our taste preferences.)

Taste is a chemical sense. Inside each little bump on the top and sides of your tongue are 200 or more taste buds, each containing a pore that catches food chemicals. Into each taste bud pore, 50 to 100 taste receptor cells project antenna-like hairs that sense food molecules. Some receptors respond mostly to sweet-tasting molecules, others to salty-, sour-, umami-, or bitter-tasting ones. It doesn't take much to trigger a response that alerts your brain's temporal lobe. If a stream of water is pumped across your tongue, the addition of a concentrated salty or sweet taste for but one-tenth of a second will get your attention (Kelling & Halpern, 1983). When a friend asks for “just a taste” of your soft drink, you can squeeze off the straw after a mere instant.

Taste receptors reproduce themselves every week or two, so when you burn your tongue with hot pizza, it hardly matters. However, as you grow older, the number of taste buds decreases, as does taste sensitivity (Cowart, 1981). (No wonder adults enjoy strong-tasting foods that children resist.) Smoking and alcohol use accelerate these declines. Those who lose their sense of taste report that food tastes like “straw” and is hard to swallow (Cowart, 2005).

Essential as taste buds are, there's more to taste than meets the tongue. Expectations can influence taste. When told a sausage roll was “vegetarian,” people in one experiment found it decidedly inferior to its identical partner labeled “meat” (Allen et al., 2008). In another experiment, when adults were told that a wine cost \$90 rather than its real \$10 price, they reported it tasting better and a brain area that responds to pleasant experiences showed more activity (Plassmann et al., 2008).

Table 21.1 The Survival Functions of Basic Tastes

Taste	Indicates
<i>Sweet</i>	Energy source
<i>Salty</i>	Sodium essential to physiological processes
<i>Sour</i>	Potentially toxic acid
<i>Bitter</i>	Potential poisons
<i>Umami</i>	Proteins to grow and repair tissue

(Adapted from Cowart, 2005.)

Smell

Life begins with an inhale and ends with an exhale. Between birth and death, you will daily inhale and exhale nearly 20,000 breaths of life-sustaining air, bathing your nostrils in a stream of scent-laden molecules. The resulting experiences of smell (*olfaction*) are strikingly intimate: You inhale something of whatever or whoever it is you smell.

Like taste, smell is a chemical sense. We smell something when molecules of a substance carried in the air reach a tiny cluster of 20 million receptor cells at the top of each

Try This

Impress your friends with your new word for the day: People unable to see are said to experience blindness. People unable to hear experience deafness. People unable to smell experience *anosmia*.

Figure 21.5

The sense of smell If you are to smell a flower, airborne molecules of its fragrance must reach receptors at the top of your nose. Sniffing swirls air up to the receptors, enhancing the aroma. The receptor cells send messages to the brain's olfactory bulb, and then onward to the temporal lobe's primary smell cortex and to the parts of the limbic system involved in memory and emotion.

nasal cavity (**FIGURE 21.5**). These olfactory receptor cells, waving like sea anemones on a reef, respond selectively—to the aroma of a cake baking, to a wisp of smoke, to a friend's fragrance. Instantly, they alert the brain through their axon fibers. Being an old, primitive sense, olfactory neurons bypass the brain's sensory control center, the thalamus.

Research has shown that even nursing infants and their mothers have a literal chemistry to their relationship: They quickly learn to recognize each other's scents (McCarthy, 1986). Aided by smell, a mother fur seal returning to a beach crowded with pups will find her own. Our human sense of smell is less acute than our senses of seeing and hearing. Looking out across a garden, we see its forms and colors in exquisite detail and hear a variety of birds singing, yet we smell little of it without sticking our nose into the blossoms.

Odor molecules come in many shapes and sizes—so many, in fact, that it takes many different receptors to detect them. A large family of genes designs the 350 or so receptor proteins that recognize particular odor molecules (Miller, 2004). Linda Buck and Richard Axel (1991) discovered (in work for which they received a 2004 Nobel Prize) that these receptor proteins are embedded on the surface of nasal cavity neurons. As a key slips into a lock, so odor molecules slip into these receptors. Yet we don't seem to have a distinct receptor for each detectable odor. This suggests that some odors trigger a combination of receptors, in patterns that are interpreted by the olfactory cortex. As the English alphabet's 26 letters can combine to form many words, so odor molecules bind to different receptor arrays, producing the 10,000 odors we can detect (Malnic et al., 1999). It is the combinations of olfactory receptors, which activate different neuron patterns, that allow us to distinguish between the aromas of fresh-brewed and hours-old coffee (Zou et al., 2005).

For humans, the attractiveness of smells depends on learned associations (Herz, 2001). As babies nurse, their preference for the smell of their mother's

Tish1/Shutterstock

breast builds. So, too, with other associations. As good experiences are linked with a particular scent, people come to like that scent, which helps explain why people in the United States tend to like the smell of wintergreen (which they associate with candy and gum) more than do those in Great Britain (where it often is associated with medicine). In another example of odors evoking unpleasant emotions, researchers frustrated Brown University students with a rigged computer game in a scented room (Herz et al., 2004). Later, if exposed to the same odor while working on a verbal task, the students' frustration was rekindled and they gave up sooner than others exposed to a different odor or no odor.

Though it's difficult to recall odors by name, we have a remarkable capacity to recognize long-forgotten odors and their associated memories (Engen, 1987; Schab, 1991). The smell of the sea, the scent of a perfume, or an aroma of a favorite relative's kitchen can bring to mind a happy time. It's a phenomenon the British travel agent chain Lunn Poly understood well. To evoke memories of lounging on sunny, warm beaches, the company once piped the aroma of coconut suntan oil into its shops (Fracasini, 2000).

Our brain's circuitry helps explain an odor's power to evoke feelings and memories (**FIGURE 21.6**). A hotline runs between the brain area receiving information from the nose and the brain's ancient limbic centers associated with memory and emotion. Thus, when put in a foul-smelling room, people expressed harsher judgments of immoral acts (such as lying or keeping a found wallet) and more negative attitudes toward gay men (Inbar et al., 2011; Schnall et al., 2008).

AP Photo/The Charlotte Observer, Layne Bailey

The nose knows Humans have some 20 million olfactory receptors. A bloodhound has 220 million (Herz, 2007).

Figure 21.6

Taste, smell, and memory

Information from the taste buds (yellow arrow) travels to an area between the frontal and temporal lobes of the brain. It registers in an area not far from where the brain receives information from our sense of smell, which interacts with taste. The brain's circuitry for smell (red area) also connects with areas involved in memory storage, which helps explain why a smell can trigger a memory.

Body Position and Movement

21-4 How do we sense our body's position and movement?

Important sensors in your joints, tendons, and muscles enable your **kinesthesia**—your sense of the position and movement of your body parts. By closing your eyes or plugging your ears you can momentarily imagine being without sight or sound. But what would it be like to live without touch or kinesthetic sense—without, therefore, being able to sense the positions of your limbs when you wake during the night? Ian Waterman of Hampshire, England, knows. In 1972, at age 19, Waterman contracted a rare viral infection that destroyed the nerves enabling his sense of light touch and of body position and movement. People with this condition report feeling disembodied, as though their body is dead, not real, not theirs (Sacks, 1985). With prolonged practice, Waterman has learned to walk and eat—by visually focusing on his limbs and directing them accordingly. But if the lights go out, he crumples to the floor (Azar, 1998). Even for the rest of us, vision interacts with kinesthesia. Stand with your right heel in front of your left toes. Easy. Now close your eyes and you will probably wobble.

A companion **vestibular sense** monitors your head's (and thus your body's) position and movement. The biological gyroscopes for this sense of equilibrium are in your inner ear. The *semicircular canals*, which look like a three-dimensional pretzel (Figure 20.1a), and the *vestibular sacs*, which connect the canals with the cochlea, contain fluid that moves when your head rotates or tilts. This movement stimulates hairlike receptors, which send

kinesthesia [kin-ehs-THREE-see-a] the system for sensing the position and movement of individual body parts.

vestibular sense the sense of body movement and position, including the sense of balance.

Bodies in space These high school competitive cheer team members can thank their inner ears for the information that enables their brains to monitor their bodies' position so expertly.

sensory interaction the principle that one sense may influence another, as when the smell of food influences its taste.

messages to the cerebellum at the back of the brain, thus enabling you to sense your body position and to maintain your balance.

If you twirl around and then come to an abrupt halt, neither the fluid in your semicircular canals nor your kinesthetic receptors will immediately return to their neutral state. The dizzy aftereffect fools your brain with the sensation that you're still spinning. This illustrates a principle that underlies perceptual illusions: Mechanisms that normally give us an accurate experience of the world can, under special conditions, fool us. Understanding how we get fooled provides clues to how our perceptual system works.

Sensory Interaction

21-5 How do our senses interact?

Our senses are not totally separate information channels. In interpreting the world, our brain blends their inputs. Consider what happens to your sense of taste if you hold your nose, close your eyes, and have someone feed you various foods. A slice of apple may be indistinguishable from a chunk of raw potato. A piece of steak may taste like cardboard. Without their smells, a cup of cold coffee may be hard to distinguish from a glass of Gatorade. To savor a taste, we normally breathe the aroma through our nose—which is why eating is not much fun when you have a bad cold. Smell can also change our perception of taste: A drink's strawberry odor enhances our perception of its sweetness. Even touch can influence taste. Depending on its texture, a potato chip “tastes” fresh or stale (Smith, 2011). This is **sensory interaction** at work—the principle that one sense may influence another. Smell + texture + taste = flavor.

Vision and hearing may similarly interact. An almost imperceptible flicker of light is more easily visible when accompanied by a short burst of sound (Kayser, 2007). And a sound may be easier to hear with a visual cue. If I (as a person with hearing loss) watch a video with simultaneous captioning, I have no trouble hearing the words I am seeing (and may therefore think I don't need the captioning). If I then turn off the captioning, I suddenly realize I do need it. The eyes guide the ears (**FIGURE 21.7**).

But what do you suppose happens if the eyes and the ears disagree? What if we *see* a speaker saying one syllable while we *hear* another? Surprise: We may perceive a third syllable that blends both inputs. Seeing the mouth movements for *ga* while hearing *ba* we may

perceive *da*. This phenomenon is known as the *McGurk effect*, after its discoverers, psychologist Harry McGurk and his assistant John MacDonald (1976).

Touch also interacts with our other senses. In detecting events, the brain can combine simultaneous touch and visual signals, thanks to neurons projecting from the somatosensory cortex back to the visual cortex (Macaluso et al., 2000). Touch even interacts with hearing. In one experiment, researchers blew a puff of air (such as our mouths produce when saying *pa* and *ta*) on the neck or hands as people heard either these sounds or the more airless sounds *ba* or *da*. To my surprise (and yours?), the people more often misheard

Figure 21.7

Sensory interaction

When a hard-of-hearing listener sees an animated face forming the words being spoken at the other end of a phone line, the words become easier to understand (Knight, 2004). The eyes guide the ears.

Courtesy of Action Hearing Loss

ba or *da* as *pa* or *ta* when played with the faint puff (Gick & Derrick, 2009). Thanks to sensory interaction, they were hearing with their skin.

Our brain even blends our tactile and social judgments:

- After holding a warm drink rather than a cold one, people are more likely to rate someone more warmly, feel closer to them, and behave more generously (IJzerman & Semin, 2009; Williams & Bargh, 2008). Physical warmth promotes social warmth.
- After being given the cold shoulder by others in an experiment, people judge the room as colder than do those treated warmly (Zhong & Leonardelli, 2008). Social exclusion literally feels cold.
- Holding a heavy rather than light clipboard makes job candidates seem more important. Holding rough objects makes social interactions seem more difficult (Ackerman et al., 2010).
- When leaning to the left—by sitting in a left- rather than right-leaning chair, or squeezing a hand-grip with their left hand, or using a mouse with their left hand—people lean more left in their expressed political attitudes (Oppenheimer & Trail, 2010).

These examples of **embodied cognition** illustrate how brain circuits processing our bodily sensations connect with brain circuits responsible for cognition.

So, the senses interact: As we attempt to decipher our world, our brain blends inputs from multiple channels. For many people, an odor, perhaps of mint or chocolate, can evoke a sensation of taste (Stevenson & Tomiczek, 2007). But in a few select individuals, the senses become joined in a phenomenon called *synesthesia*, where one sort of sensation (such as hearing sound) produces another (such as seeing color). Thus, hearing music may activate color-sensitive cortex regions and trigger a sensation of color (Brang et al., 2008; Hubbard et al., 2005). Seeing the number 3 may evoke a taste sensation (Ward, 2003).

* * *

For a summary of our sensory systems, see **TABLE 21.2**. The river of perception is fed by sensation, cognition, and emotion. And that is why we need biological, psychological, and social-cultural levels of analysis.

embodied cognition in psychological science, the influence of bodily sensations, gestures, and other states on cognitive preferences and judgments.

Table 21.2 Summarizing the Senses

Sensory System	Source	Receptors
<i>Vision</i>	Light waves striking the eye	Rods and cones in the retina
<i>Hearing</i>	Sound waves striking the outer ear	Cochlear hair cells in the inner ear
<i>Touch</i>	Pressure, warmth, cold, pain on the skin	Skin receptors detect pressure, warmth, cold, and pain
<i>Taste</i>	Chemical molecules in the mouth	Basic tongue receptors for sweet, sour, salty, bitter, and umami
<i>Smell</i>	Chemical molecules breathed in through the nose	Millions of receptors at top of nasal cavity
<i>Body position—kinesthesia</i>	Any change in position of a body part, interacting with vision	Kinesthetic sensors all over the body
<i>Body movement—vestibular sense</i>	Movement of fluids in the inner ear caused by head/body movement	Hairlike receptors in the semi-circular canals and vestibular sacs

* * *

To feel awe, mystery, and a deep reverence for life, we need look no further than our own perceptual system and its capacity for organizing formless nerve impulses into colorful sights, vivid sounds, and evocative smells. As Shakespeare’s Hamlet recognized, “There are more things in Heaven and Earth, Horatio, than are dreamt of in your philosophy.” Within our ordinary sensory and perceptual experiences lies much that is truly extraordinary—surely much more than has so far been dreamt of in our psychology.

Before You Move On

▶ ASK YOURSELF

Have you ever experienced a feeling that you think could be explained by embodied cognition?

▶ TEST YOURSELF

How does our system for sensing smell differ from our sensory systems for vision, touch, and taste?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 21 Review

21-1 How do we sense touch?

- Our sense of touch is actually several senses—pressure, warmth, cold, and pain—that combine to produce other sensations, such as “hot.”

21-2 How can we best understand and control pain?

- Pain reflects bottom-up sensations (such as input from nociceptors, the sensory receptors that detect hurtful temperatures, pressure, or chemicals) and top-down processes (such as experience, attention, and culture).
- One theory of pain is that a “gate” in the spinal cord either opens to permit pain signals traveling up small nerve fibers to reach the brain, or closes to prevent their passage.
- The biopsychosocial perspective views our perception of pain as the sum of biological, psychological, and social-cultural influences. Pain treatments often combine physical and psychological elements, including placebos and distractions.

21-3 How do we experience taste and smell?

- Taste and smell are chemical senses.
- Taste is a composite of five basic sensations—sweet, sour, salty, bitter, and umami—and of the aromas that interact with information from the taste receptor cells of the taste buds.
- There are no basic sensations for smell. We have some 20 million olfactory receptor cells, with about 350 different receptor proteins.
- Odor molecules trigger combinations of receptors, in patterns that the olfactory cortex interprets. The receptor cells send messages to the brain’s olfactory bulb, then to the temporal lobe, and to parts of the limbic system.

21-4 How do we sense our body’s position and movement?

- Through *kinesthesia*, we sense the position and movement of our body parts.
- We monitor our body’s position and movement, and maintain our balance with our *vestibular sense*.

21-5 How do our senses interact?

- Our senses can influence one another. This *sensory interaction* occurs, for example, when the smell of a favorite food amplifies its taste.
- *Embodied cognition* is the influence of bodily sensations, gestures, and other states on cognitive preferences and judgments.

Multiple-Choice Questions

1. Sensing the position and movement of individual body parts is an example of which sense?
 - a. Kinesthetic
 - b. Vestibular
 - c. Auditory
 - d. Umami
 - e. Olfactory
2. Which of the following is the best example of kinesthesia?
 - a. Awareness of the smell of freshly brewed coffee
 - b. Ability to feel pressure on your arm
 - c. Ability to hear a softly ticking clock
 - d. Ability to calculate where a kicked soccer ball will land from the moment it leaves your foot
 - e. Awareness of the position of your arms when swimming the backstroke
3. Which of the following is the best example of sensory interaction?
 - a. Finding that despite its delicious aroma, a weird-looking meal tastes awful
 - b. Finding that food tastes bland when you have a bad cold
 - c. Finding it difficult to maintain your balance when you have an ear infection
 - d. Finding that the cold pool water doesn't feel so cold after a while
 - e. All of these are examples.
4. Which of the following is most closely associated with hairlike receptors in the semicircular canals?
 - a. Body position
 - b. Smell
 - c. Hearing
 - d. Pain
 - e. Touch

Practice FRQs

1. Describe the receptor cells for taste and smell.

Answer

1 point: Taste: Receptor cells in the tongue detect sweet, sour, salty, bitter, and umami.

1 point: Smell: Olfactory cells line the top of the nasal cavity.

2. Briefly explain the biopsychosocial perspective on pain and pain treatment.

AP[®] Exam Practice Questions

Multiple-Choice Questions

- What is the purpose of the iris?
 - To focus light on the retina
 - To process color
 - To allow light into the eye
 - To enable night vision
 - To detect specific shapes
- Neurons that fire in response to specific edges, lines, angles, and movements are called what?
 - Rods
 - Cones
 - Ganglion cells
 - Feature detectors
 - Bipolar cells

3. Signal detection theory is most closely associated with which perception process?
 - a. Vision
 - b. Sensory adaptation
 - c. Absolute thresholds
 - d. Smell
 - e. Context effects
4. Which of the following represents perceptual constancy?
 - a. We recognize the taste of McDonald's food each time we eat it.
 - b. In photos of people, the people almost always are perceived as figure and everything else as ground.
 - c. We know that the color of a printed page has not changed as it moves from sunlight into shadow.
 - d. From the time they are very young, most people can recognize the smell of a dentist's office.
 - e. The cold water in a lake doesn't seem so cold after you have been swimming in it for a few minutes.
5. Our tendency to see faces in clouds and other ambiguous stimuli is partly based on what perception principle?
 - a. Selective attention
 - b. ESP
 - c. Perceptual set
 - d. Shape constancy
 - e. Bottom-up processing
6. The process by which rods and cones change electromagnetic energy into neural messages is called what?
 - a. Adaptation
 - b. Accommodation
 - c. Parallel processing
 - d. Transduction
 - e. Perceptual setting
7. Which of the following is most likely to influence our memory of a painful event?
 - a. The overall length of the event
 - b. The intensity of pain at the end of the event
 - c. The reason for the pain
 - d. The amount of rest you've had in the 24 hours preceding the event
 - e. The specific part of the body that experiences the pain
8. Frequency theory relates to which element of the hearing process?
 - a. Rate at which the basilar membrane vibrates
 - b. Number of fibers in the auditory nerve
 - c. Point at which the basilar membrane exhibits the most vibration
 - d. Decibel level of a sound
 - e. Number of hair cells in each cochlea
9. Which of the following best represents an absolute threshold?
 - a. A guitar player knows that his D string has just gone out of tune.
 - b. A photographer can tell that the natural light available for a photograph has just faded slightly.
 - c. Your friend amazes you by correctly identifying unlabeled glasses of Coke and Pepsi.
 - d. A cook can just barely taste the salt she has added to her soup.
 - e. Your mom throws out the milk because she says the taste is "off."
10. Which of the following describes a perception process that the Gestalt psychologists would have been interested in?
 - a. Depth perception and how it allows us to survive in the world
 - b. Why we see an object near us as closer rather than larger
 - c. How an organized whole is formed out of its component pieces
 - d. What the smallest units of perception are
 - e. The similarities between shape constancy and size constancy
11. Which perception process are the hammer, anvil, and stirrup involved in?
 - a. Processing intense colors
 - b. Processing information related to our sense of balance
 - c. Supporting a structural frame to hold the eardrum
 - d. Transmitting sound waves to the cochlea
 - e. Holding hair cells that enable hearing
12. Which of the following might result from a disruption of your vestibular sense?
 - a. Inability to detect the position of your arm without looking at it
 - b. Loss of the ability to detect bitter tastes
 - c. Dizziness and a loss of balance
 - d. An inability to detect pain
 - e. Loss of color vision
13. When we go to the movies, we see smooth continuous motion rather than a series of still images because of which process?
 - a. The phi phenomenon
 - b. Perceptual set
 - c. Stroboscopic movement
 - d. Relative motion
 - e. Illusory effect

- 14.** Two monocular depth cues are most responsible for our ability to know that a jet flying overhead is at an elevation of several miles. One cue is relative size. What is the other?
- Relative motion
 - Retinal disparity
 - Interposition
 - Light and shadow
 - Linear perspective
- 15.** Which of the following phrases accurately describes top-down processing?
- The entry-level data captured by our various sensory systems
 - The effect that our experiences and expectations have on perception
 - Our tendency to scan a visual field from top to bottom
 - Our inclination to follow a predetermined set of steps to process sound
 - The fact that information is processed by the higher regions of the brain before it reaches the lower brain

Free-Response Questions

- 1.** While listening to the orchestra as she dances the lead role in *Swan Lake*, a ballerina concludes her performance with a pirouette, spinning around several times before leaping into the arms of her dance partner.

Discuss how the ballerina relied on the following and how each is important.

- Kinesthetic sense
- Vestibular sense
- Semicircular canals
- Hearing

Rubric for Free Response Question 1

1 point: Kinesthesia will allow the ballerina to sense the position of different parts of her body as she dances the role. Thus, she will know that she is to start by facing the audience and, although she has spun around several times, she will always be aware of where the audience is, and where to put her feet and arms in order to accomplish the choreography.

🔗 Page 209

1 point: The vestibular sense enables the dancer to sense her body position and to maintain her balance. 🔗 Pages 209–210

1 point: Semicircular canals near her inner ear help the ballerina maintain her sense of balance. She needs this balance as she leaps and spins, and her training allows her to use her vestibular sense to maintain balance rather than become dizzy. 🔗 Pages 195 and 209

1 point: The ballerina's sense of hearing allows her to perceive the music and to dance to the correct rhythm of each piece of music. 🔗 Pages 194–199

- 2.** Ester is walking to her chemistry class when she notices someone in the distance suddenly duck into a dark doorway. She is suspicious and starts to chase the figure, but misjudges the distance and accidentally runs into the door. She falls down but quickly recovers, and laughs when she discovers that the mystery person is her roommate, who was avoiding Ester, because she had borrowed Ester's favorite sweater without permission and was afraid Ester might be angry.

Use the following terms to explain the perceptual processes involved in this scenario.

- Gate-control theory
- Vestibular sense
- Selective attention
- Signal detection theory
- Binocular cues
- Perceptual set

(6 points)

- 3.** Describe, from the beginning of the process to the end, how your brain is perceiving the words you are reading right now. Use the following terms in your answer.

- Transduction
- Top-down processing
- Retina
- Pupil
- Occipital lobe
- Rods
- Feature detectors

Unit V

States of Consciousness

Modules

22 Understanding Consciousness and Hypnosis

23 Sleep Patterns and Sleep Theories

24 Sleep Deprivation, Sleep Disorders, and Dreams

25 Psychoactive Drugs

Consciousness can be a funny thing. It offers us weird experiences, as when entering sleep or leaving a dream, and sometimes it leaves us wondering who is really in control. After zoning me out with nitrous oxide, my dentist tells me to turn my head to the left. My conscious mind resists: “No way,” I silently say. “You can’t boss me around!” Whereupon my robotic head, ignoring my conscious mind, turns obligingly under the dentist’s control.

During my noontime pickup basketball games, I am sometimes mildly irritated as my body passes the ball while my conscious mind is saying, “No, stop! Sarah is going to intercept!” Alas, my body completes the pass. Other times, as psychologist Daniel Wegner (2002) noted in *The Illusion of Conscious Will*, people believe their consciousness is controlling their actions when it isn’t. In one experiment, two people jointly controlled a computer mouse. Even when their partner (who was actually the experimenter’s accomplice) caused the mouse to stop on a predetermined square, the participants perceived that *they* had caused it to stop there.

Then there are those times when consciousness seems to split. Reading *Green Eggs and Ham* to one of my preschoolers for the umpteenth time, my obliging mouth could say the words while my mind wandered elsewhere. And if someone asks what you’re doing for lunch while you’re texting, it’s not a problem. Your thumbs complete the message as you suggest getting tacos.

What do such experiences reveal? Was my drug-induced dental experience akin to people’s experiences with other *psychoactive drugs* (mood- and perception-altering substances)? Was my automatic obedience to my dentist like people’s

responses to a hypnotist? Does a split in consciousness, as when our minds go elsewhere while reading or texting, explain people's behavior while under hypnosis? And during sleep, when do those weird dream experiences occur, and why? Before considering these questions and more, let's ask a fundamental question: What is *consciousness*?

Module 22

Understanding Consciousness and Hypnosis

Module Learning Objectives

- 22-1** Describe the place of consciousness in psychology's history.
- 22-2** Define *hypnosis*, and describe how a hypnotist can influence a hypnotized subject.
- 22-3** Discuss whether hypnosis is an extension of normal consciousness or an altered state.

Every science has concepts so fundamental they are nearly impossible to define. Biologists agree on what is alive but not on precisely what life is. In physics, *matter* and *energy* elude simple definition. To psychologists, consciousness is similarly a fundamental yet slippery concept.

Defining Consciousness

- 22-1** What is the place of consciousness in psychology's history?

At its beginning, *psychology* was “the description and explanation of states of consciousness” (Ladd, 1887). But during the first half of the twentieth century, the difficulty of scientifically studying consciousness led many psychologists—including those in the emerging school of *behaviorism* (Module 26)—to turn to direct observations of behavior. By the 1960s, psychology had nearly lost consciousness and was defining itself as “the science of behavior.” Consciousness was likened to a car's speedometer: “It doesn't make the car go, it just reflects what's happening” (Seligman, 1991, p. 24).

“Psychology must discard all reference to consciousness.”
—BEHAVIORIST JOHN B. WATSON (1913)

After 1960, mental concepts reemerged. Neuroscience advances related brain activity to sleeping, dreaming, and other mental states. Researchers began studying consciousness

altered by hypnosis and drugs. Psychologists of all persuasions were affirming the importance of *cognition*, or mental processes. Psychology was regaining consciousness.

Most psychologists now define **consciousness** as our awareness of ourselves and our environment. As we saw in Module 13, our conscious awareness is one part of the *dual processing* that goes on in our two-track minds. Although much of our information processing is conscious, much is unconscious and automatic—outside our awareness. Module 16 highlighted our *selective attention*, which directs the spotlight of our awareness, allowing us to assemble information from many sources as we reflect on our past and plan for our future. We are also attentive when we learn a complex concept or behavior. When learning to ride a bike, we focus on obstacles that we have to steer around and on how to use the brakes. With practice, riding a bike becomes semi-automatic, freeing us to focus our attention on other things. As we do so, we experience what the early psychologist William James called a continuous “stream of consciousness,” with each moment flowing into the next. Over time, we flit between different *states of consciousness*, including sleeping, waking, and various altered states (**FIGURE 22.1**).

AP® Exam Tip

Note that our modern-day understanding of the unconscious is very different from Sigmund Freud’s theory of the unconscious (Module 55). Freud believed the unconscious was a hiding place for our most anxiety-provoking ideas and emotions, and that uncovering those hidden thoughts could lead to healing. Now, most psychologists simply view the unconscious track as one that operates without awareness. Make sure you keep these two ideas of the unconscious straight.

Some states occur spontaneously	Daydreaming	Drowsiness	Dreaming
Some are physiologically induced	Hallucinations	Orgasm	Food or oxygen starvation
Some are psychologically induced	Sensory deprivation	Hypnosis	Meditation

Hypnosis

22-2

What is hypnosis, and what powers does a hypnotist have over a hypnotized subject?

Imagine you are about to be hypnotized. The hypnotist invites you to sit back, fix your gaze on a spot high on the wall, and relax. In a quiet voice the hypnotist suggests, “Your eyes are growing tired. . . .Your eyelids are becoming heavy . . . now heavier and heavier. . . .They are beginning to close. . . .You are becoming more deeply relaxed. . . .Your breathing is now deep and regular. . . .Your muscles are becoming more and more relaxed. Your whole body is beginning to feel like lead.”

After a few minutes of this *hypnotic induction*, you may experience **hypnosis**. When the hypnotist suggests, “Your eyelids are shutting so tight that you cannot open them even if you try,” it may indeed seem beyond your control to open your eyelids. Told to forget the number 6, you may be puzzled when you count 11 fingers on your hands. Invited to smell a sensuous perfume that is actually ammonia, you may linger delightedly over its pungent odor. Told that you cannot see a certain object, such as a chair, you may indeed report that it is not there, although you manage to avoid the chair when walking around (illustrating once again that two-track mind of yours).

But is hypnosis really an *altered* state of consciousness? Let’s start with some frequently asked questions.

Frequently Asked Questions About Hypnosis

Hypnotists have no magical mind-control power. Their power resides in the subjects’ openness to suggestion, their ability to focus on certain images or behaviors (Bowers, 1984). But how open to suggestions are we?

Figure 22.1

States of consciousness

In addition to normal, waking awareness, consciousness comes to us in altered states, including daydreaming and meditating.

consciousness our awareness of ourselves and our environment.

hypnosis a social interaction in which one person (the subject) responds to another person’s (the hypnotist’s) suggestions that certain perceptions, feelings, thoughts, or behaviors will spontaneously occur.

AP® Exam Tip

Psychological research corrects the mistaken popular belief that hypnosis or other methods can be used to tap into a pure and complete memory bank. You will learn much more about how memory really works when you get to Unit VII.

“Hypnosis is not a psychological truth serum and to regard it as such has been a source of considerable mischief.” -RESEARCHER KENNETH BOWERS (1987)

FYI

See Module 33 for a more detailed discussion of how people may construct false memories.

“It wasn’t what I expected. But facts are facts, and if one is proved to be wrong, one must just be humble about it and start again.”
-AGATHA CHRISTIE’S MISS MARPLE

posthypnotic suggestion

a suggestion, made during a hypnosis session, to be carried out after the subject is no longer hypnotized; used by some clinicians to help control undesired symptoms and behaviors.

- **Can anyone experience hypnosis?** To some extent, we are all open to suggestion. When people stand upright with their eyes closed and are told that they are swaying back and forth, most will indeed sway a little. In fact, *postural sway* is one of the items assessed on the Stanford Hypnotic Susceptibility Scale. People who respond to such suggestions without hypnosis are the same people who respond with hypnosis (Kirsch & Braffman, 2001).

Highly hypnotizable people—say, the 20 percent who can carry out a suggestion not to smell or react to a bottle of ammonia held under their nose—typically become deeply absorbed in imaginative activities (Barnier & McConkey, 2004; Silva & Kirsch, 1992). Many researchers refer to this as hypnotic ability—the ability to focus attention totally on a task, to become imaginatively absorbed in it, to entertain fanciful possibilities.

- **Can hypnosis enhance recall of forgotten events?** Most people believe (wrongly, as Module 32 will explain) that our experiences are all “in there,” recorded in our brain and available for recall if only we can break through our own defenses (Loftus, 1980). But 60 years of memory research disputes such beliefs. We do not encode everything that occurs around us. We permanently store only some of our experiences, and we may be unable to retrieve some memories we have stored.

“Hypnotically refreshed” memories combine fact with fiction. Since 1980, thousands of people have reported being abducted by UFOs, but most such reports have come from people who are predisposed to believe in aliens, are highly hypnotizable, and have undergone hypnosis (Newman & Baumeister, 1996; Nickell, 1996). Without either person being aware of what is going on, a hypnotist’s hints—“Did you hear loud noises?”—can plant ideas that become the subject’s pseudomemory.

So should testimony obtained under hypnosis be admissible in court? American, Australian, and British courts have agreed it should not. They generally ban testimony from witnesses who have been hypnotized (Druckman & Bjork, 1994; Gibson, 1995; McConkey, 1995).

- **Can hypnosis force people to act against their will?** Researchers have induced hypnotized people to perform an apparently dangerous act: plunging one hand briefly into fuming “acid,” then throwing the “acid” in a researcher’s face (Orne & Evans, 1965). Interviewed a day later, these people emphatically denied their acts and said they would never follow such orders.

Had hypnosis given the hypnotist a special power to control others against their will? To find out, researchers Martin Orne and Frederick Evans unleashed that enemy of so many illusory beliefs—the control group. Orne asked other individuals to *pretend* they were hypnotized. Laboratory assistants, unaware that those in the experiment’s control group had not been hypnotized, treated both groups the same. The result? All the *unhypnotized* participants (perhaps believing that the laboratory context assured safety) performed the same acts as those who were hypnotized.

- **Can hypnosis be therapeutic?** *Hypnotherapists* try to help patients harness their own healing powers (Baker, 1987). **Posthypnotic suggestions** have helped alleviate headaches, asthma, and stress-related skin disorders.

In one statistical digest of 18 studies, the average client whose therapy was supplemented with hypnosis showed greater improvement than 70 percent of other therapy patients (Kirsch et al., 1995, 1996). Hypnosis seemed especially helpful for the treatment of obesity. However, drug, alcohol, and smoking addictions have not responded well to hypnosis (Nash, 2001). In controlled studies, hypnosis speeds the disappearance of warts, but so do the same positive suggestions given without hypnosis (Spanos, 1991, 1996).

- **Can hypnosis relieve pain?** Hypnosis *can* relieve pain (Druckman & Bjork, 1994; Jensen, 2008). When un hypnotized people put their arm in an ice bath, they feel intense pain within 25 seconds. When hypnotized people do the same after being given suggestions to feel no pain, they indeed report feeling little pain. As some dentists know, light hypnosis can reduce fear, thus reducing hypersensitivity to pain.

Hypnosis inhibits pain-related brain activity. In surgical experiments, hypnotized patients have required less medication, recovered sooner, and left the hospital earlier than un hypnotized control patients (Askay & Patterson, 2007; Hammond, 2008; Spiegel, 2007). Nearly 10 percent of us can become so deeply hypnotized that even major surgery can be performed without anesthesia. Half of us can gain at least some pain relief from hypnosis. The surgical use of hypnosis has flourished in Europe, where one Belgian medical team has performed more than 5000 surgeries with a combination of hypnosis, local anesthesia, and a mild sedative (Song, 2006).

Hypnotherapy This therapy aims to help people uncover problem-causing thoughts and feelings, or to change an unwanted behavior.

Explaining the Hypnotized State

22-3 Is hypnosis an extension of normal consciousness or an altered state?

We have seen that hypnosis involves heightened suggestibility. We have also seen that hypnotic procedures do not endow a person with special powers but can sometimes help people overcome stress-related ailments and cope with pain. So, just what *is* hypnosis? Psychologists have proposed two explanations.

HYPNOSIS AS A SOCIAL PHENOMENON

Our attentional spotlight and interpretations powerfully influence our ordinary perceptions. Might hypnotic phenomena reflect such workings of normal consciousness, as well as the power of social influence (Lynn et al., 1990; Spanos & Coe, 1992)? Advocates of the *social influence theory of hypnosis* believe they do.

Does this mean that subjects consciously fake hypnosis? *No*—like actors caught up in their roles, they begin to feel and behave in ways appropriate for “good hypnotic subjects.” The more they like and trust the hypnotist, the more they allow that person to direct their attention and fantasies (Gfeller et al., 1987). “The hypnotist’s ideas become the subject’s thoughts,” explained Theodore Barber (2000), “and the subject’s thoughts produce the hypnotic experiences and behaviors.” Told to scratch their ear later when they hear the word *psychology*, subjects will likely do so—but only if they think the experiment is still under way. If an experimenter eliminates their motivation for acting hypnotized—by stating that hypnosis reveals their “gullibility”—subjects become unresponsive. Such findings support the idea that hypnotic phenomena are an extension of normal social and cognitive processes.

These views illustrate a principle that Module 75 emphasizes: *An authoritative person in a legitimate context can induce people—hypnotized or not—to perform some unlikely acts.* Or as hypnosis researcher Nicholas Spanos (1982) put it, “The overt behaviors of hypnotic subjects are well within normal limits.”

HYPNOSIS AS DIVIDED CONSCIOUSNESS

Other hypnosis researchers believe hypnosis is more than inducing someone to play the role of “good subject.” How, they ask, can we explain why hypnotized subjects sometimes carry out suggested behaviors on cue, even when they believe no one is watching (Perugini et al., 1998)? And why does distinctive brain activity accompany hypnosis (Oakley & Halligan, 2009)? In one

experiment, deeply hypnotized people were asked to imagine a color, and areas of their brain activated as if they were really seeing the color. To the hypnotized person's brain, mere imagination had become a compelling hallucination (Kosslyn et al., 2000). In another experiment, researchers invited hypnotizable and nonhypnotizable people to say the color of letters. This is an easy task, but it slows if, say, green letters form the conflicting word **RED**, a phenomenon known as the *Stroop effect* (Raz et al., 2005). When easily hypnotized people were given a suggestion to focus on the color and to perceive the letters as irrelevant gibberish, they were much less slowed by the word-color conflict. (Brain areas that decode words and detect conflict remained inactive.)

These results would not have surprised famed researcher Ernest Hilgard (1986, 1992), who believed hypnosis involves not only social influence but also a special dual-processing state of **dissociation**—a split between different levels of consciousness. Hilgard viewed hypnotic dissociation as a vivid form of everyday mind splits—similar to doodling while listening to a lecture or typing the end of a sentence while starting a conversation. Hilgard felt that when, for example, hypnotized people lower their arm into an ice bath, as in **FIGURE 22.2**, the hypnosis dissociates the sensation of the pain stimulus (of which the subjects are still aware) from the emotional suffering that defines their experience of pain. The ice water therefore feels cold—very cold—but not painful.

dissociation a split in consciousness, which allows some thoughts and behaviors to occur simultaneously with others.

Figure 22.2

Dissociation or role playing?

A hypnotized woman tested by Ernest Hilgard exhibited no pain when her arm was placed in an ice bath. But asked to press a key if some part of her felt the pain, she did so. To Hilgard, this was evidence of dissociation, or divided consciousness. Proponents of social influence theory, however, maintain that people responding this way are caught up in playing the role of “good subject.”

Divided-consciousness theory:
Hypnosis has caused a split in awareness.

Attention is diverted from a painful ice bath. How?

Courtesy Elizabeth Jecker

Social influence theory:
The subject is so caught up in the hypnotized role that she ignores the cold.

Biological influences:

- distinctive brain activity
- unconscious information processing

Psychological influences:

- focused attention
- expectations
- heightened suggestibility
- dissociation between normal sensations and conscious awareness

Hypnosis

Social-cultural influences:

- presence of an authoritative person in legitimate context
- role playing “good subject”

Figure 22.3

Levels of analysis for hypnosis Using a biopsychosocial approach, researchers explore hypnosis from complementary perspectives.

Another form of dual processing—*selective attention*—may also play a role in hypnotic pain relief. PET scans show that hypnosis reduces brain activity in a region that processes painful stimuli, but not in the sensory cortex, which receives the raw sensory input (Rainville et al., 1997). Hypnosis does not block sensory input, but it may block our attention to those stimuli. This helps explain why an injured athlete, caught up in the competition, may feel little or no pain until the game ends.

Although the divided-consciousness theory of hypnosis is controversial, this much seems clear: There is, without doubt, much more to thinking and acting than we are conscious of. Our information processing, which starts with selective attention, is divided into simultaneous conscious and nonconscious realms. In hypnosis as in life, *much of our behavior occurs on autopilot*. We have two-track minds (**FIGURE 22.3**).

Before You Move On

▶ ASK YOURSELF

You've read about two examples of dissociated consciousness: talking while texting, and thinking about something else while reading a child a bedtime story. Can you think of another example that you have experienced?

▶ TEST YOURSELF

When is the use of hypnosis potentially harmful, and when can hypnosis be used to help?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 22 Review

22-1

What is the place of consciousness in psychology's history?

- After initially claiming consciousness as its area of study in the nineteenth century, psychologists had abandoned it in the first half of the twentieth century, turning instead to the study of observable behavior because they believed consciousness was too difficult to study scientifically.
- Since 1960, under the influence of cognitive psychology and neuroscience, *consciousness* (our awareness of ourselves and our environment) has resumed its place as an important area of research.

22-2

What is hypnosis, and what powers does a hypnotist have over a hypnotized subject?

- *Hypnosis* is a social interaction in which one person suggests to another that certain perceptions, feelings, thoughts, or behaviors will spontaneously occur.
- Hypnosis does not enhance recall of forgotten events (it may even evoke false memories).
- It cannot force people to act against their will, though hypnotized people, like unhypnotized people, may perform unlikely acts.
- *Posthypnotic suggestions* have helped people harness their own healing powers but have not been very effective in treating addiction. Hypnosis can help relieve pain.

22-3

Is hypnosis an extension of normal consciousness or an altered state?

- Many psychologists believe that hypnosis is a form of normal social influence and that hypnotized people act out the role of "good subject" by following directions given by an authoritative person.
- Other psychologists view hypnosis as a *dissociation*—a split between normal sensations and conscious awareness. Selective attention may also contribute by blocking attention to certain stimuli.

Multiple-Choice Questions

1. What do we call awareness of our environment and ourselves?
 - a. Selective attention
 - b. Hypnotism
 - c. Posthypnotic suggestion
 - d. Dissociation
 - e. Consciousness
2. Which of the following is true about daydreaming?
 - a. It occurs spontaneously.
 - b. It is physiologically induced.
 - c. It is psychologically induced.
 - d. It is considered the same as waking awareness.
 - e. It is more like meditation than it is like dreaming.
3. Which of the following states of consciousness occurs when one person suggests to another that certain thoughts or behaviors will spontaneously occur?
 - a. Dreaming
 - b. Hypnosis
 - c. Daydreaming
 - d. Hallucination
 - e. Waking awareness
4. Which of the following is the term most closely associated with the split in consciousness that allows some thoughts and behaviors to occur simultaneously with others?
 - a. Consciousness
 - b. Hypnosis
 - c. Hallucination
 - d. Dissociation
 - e. Meditation

Practice FRQs

1. Identify two states of consciousness that are psychologically induced and two that occur spontaneously.
2. According to the biopsychosocial approach, identify a biological, a psychological, and a social-cultural influence on hypnosis.

Answer

1 point: For any two psychologically induced states: sensory deprivation, hypnosis, or meditation.

1 point: For any two spontaneously occurring states: daydreaming, drowsiness, or dreaming.

(3 points)

Module 23

Sleep Patterns and Sleep Theories

Module Learning Objectives

- 23-1** Describe how our biological rhythms influence our daily functioning.
- 23-2** Describe the biological rhythm of our sleeping and dreaming stages.
- 23-3** Explain how biology and environment interact in our sleep patterns.
- 23-4** Describe sleep's functions.

Catchlight Visual Services/Alamy

Sleep—the irresistible tempter to whom we inevitably succumb. Sleep—the equalizer of teachers and teens. Sleep—sweet, renewing, mysterious sleep. While sleeping, you may feel “dead to the world,” but you are not. Even when you are deeply asleep, your perceptual window is open a crack. You move around on your bed, but you manage not to fall out. The occasional roar of passing vehicles may leave your deep sleep undisturbed, but a cry from a baby’s room quickly interrupts it. So does the sound of your name. Electroencephalograph (EEG) recordings confirm that the brain’s auditory cortex responds to sound stimuli even during sleep (Kutas, 1990). And when you are asleep, as when you are awake, you process most information outside your conscious awareness.

Many of sleep’s mysteries are now being solved as some people sleep, attached to recording devices, while others observe. By recording brain waves and muscle movements, and by observing and occasionally waking sleepers, researchers are glimpsing things that a thousand years of common sense never told us. Perhaps you can anticipate some of their discoveries. Are the following statements true or false?

1. When people dream of performing some activity, their limbs often move in concert with the dream.
2. Older adults sleep more than young adults.
3. Sleepwalkers are acting out their dreams.
4. Sleep experts recommend treating insomnia with an occasional sleeping pill.
5. Some people dream every night; others seldom dream.

All these statements (adapted from Palladino & Carducci, 1983) are *false*. To see why, read on.

Biological Rhythms and Sleep

Like the ocean, life has its rhythmic tides. Over varying periods, our bodies fluctuate, and with them, our minds. Let’s look more closely at two of those biological rhythms—our 24-hour biological clock and our 90-minute sleep cycle.

“I love to sleep. Do you? Isn’t it great? It really is the best of both worlds. You get to be alive and unconscious.” -COMEDIAN RITA RUDNER, 1993

Circadian Rhythm

23-1 How do our biological rhythms influence our daily functioning?

The rhythm of the day parallels the rhythm of life—from our waking at a new day’s birth to our nightly return to what Shakespeare called “death’s counterfeit.” Our bodies roughly synchronize with the 24-hour cycle of day and night by an internal biological clock called the **circadian rhythm** (from the Latin *circa*, “about,” and *diem*, “day”). As morning approaches, body temperature rises, then peaks during the day, dips for a time in early afternoon (when many people take siestas), and begins to drop again in the evening. Thinking is sharpest and memory most accurate when we are at our daily peak in circadian arousal. Try pulling an all-nighter or working an occasional night shift. You’ll feel groggiest in the middle of the night but may gain new energy when your normal wake-up time arrives.

Eric Isselée/Shutterstock

Age and experience can alter our circadian rhythm.

Most teens and young adults are evening-energized “owls,” with performance improving across the day (May & Hasher, 1998). Most older adults are morning-loving “larks,” with performance declining as the day wears on. By mid-evening, when the night has hardly begun for many young adults, retirement homes are typically quiet. At about age 20 (slightly earlier for women), we begin to shift from being owls to being larks (Roenneberg et al., 2004). Women become more morning oriented as they have children and also as they transition to menopause (Leonhard & Randler, 2009; Randler & Bausback, 2010). Morning types tend to do better in school, to take more initiative, and to be less vulnerable to depression (Randler, 2008, 2009; Randler & Frech, 2009).

Peter Chadwick/Science Source

FYI

Dolphins, porpoises, and whales sleep with one side of their brain at a time (Miller et al., 2008).

Sleep Stages

23-2 What is the biological rhythm of our sleeping and dreaming stages?

Sooner or later, sleep overtakes us and consciousness fades as different parts of our brain’s cortex stop communicating (Massimini et al., 2005). Yet the sleeping brain remains active and has its own biological rhythm.

About every 90 minutes, we cycle through four distinct sleep stages. This simple fact apparently was unknown until 8-year-old Armond Aserinsky went to bed one night in 1952. His father, Eugene, a University of Chicago graduate student, needed to test an electroencephalograph he had repaired that day (Aserinsky, 1988; Seligman & Yellen, 1987). Placing electrodes near Armond’s eyes to record the rolling eye movements then believed to occur during sleep, Aserinsky watched the machine go wild, tracing deep zigzags on the graph paper. Could the machine still be broken? As the night proceeded and the activity recurred, Aserinsky realized that the periods of fast, jerky eye movements were accompanied by energetic brain activity. Awakened during one such episode, Armond reported having a dream. Aserinsky had discovered what we now know as **REM sleep** (rapid eye movement sleep).

Similar procedures used with thousands of volunteers showed the cycles were a normal part of sleep (Kleitman, 1960). To appreciate these studies, imagine yourself as a participant. As the hour grows late, you feel sleepy and yawn in response to reduced brain metabolism. (Yawning, which can be socially contagious, stretches your neck muscles and increases your heart rate, which increases your alertness [Moorcroft, 2003].) When you are ready for bed, a

circadian [ser-KAY-dee-an] **rhythm** the biological clock; regular bodily rhythms (for example, of temperature and wakefulness) that occur on a 24-hour cycle.

REM sleep rapid eye movement sleep; a recurring sleep stage during which vivid dreams commonly occur. Also known as *paradoxical sleep*, because the muscles are relaxed (except for minor twitches) but other body systems are active.

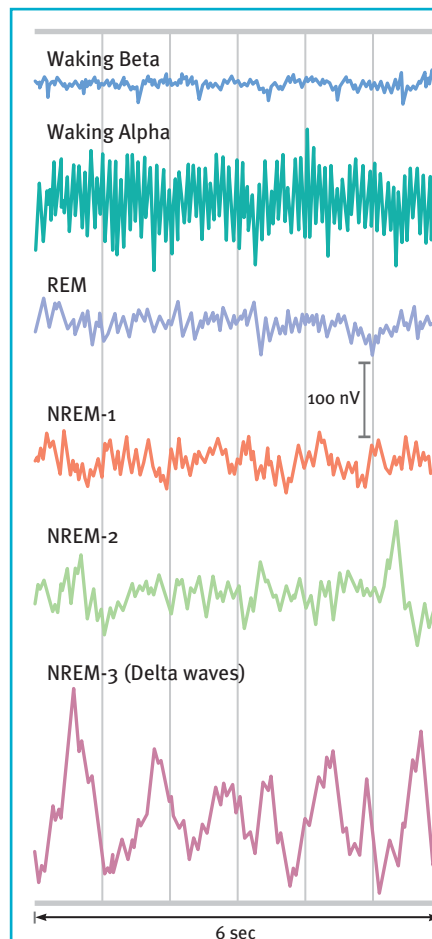

**Figure 23.1**

Measuring sleep activity Sleep researchers measure brain-wave activity, eye movements, and muscle tension by electrodes that pick up weak electrical signals from the brain, eye, and facial muscles. (From Dement, 1978.)

researcher comes in and tapes electrodes to your scalp (to detect your brain waves), on your chin (to detect muscle tension), and just outside the corners of your eyes (to detect eye movements) (**FIGURE 23.1**). Other devices will record your heart rate, respiration rate, and genital arousal.

When you are in bed with your eyes closed, the researcher in the next room sees on the EEG the relatively slow **alpha waves** of your awake but relaxed state (**FIGURE 23.2**). As you adapt to all this equipment, you grow tired and, in an unremembered moment, slip into **sleep** (**FIGURE 23.3**). The transition is marked by the slowed breathing and the irregular brain waves of non-REM stage 1 sleep. Using the new American Academy of Sleep Medicine classification of sleep stages, this is called NREM-1 (Silber et al., 2008).

In one of his 15,000 research participants, William Dement (1999) observed the moment the brain's perceptual window to the outside world slammed shut. Dement asked this sleep-deprived young man, lying on his back with eyelids taped open, to press a button every time a strobe light flashed in his eyes (about every 6 seconds). After a few minutes the young man missed one. Asked why, he said, "Because there was no flash." But there was a flash. He missed it because (as his brain activity revealed) he had fallen asleep for 2 seconds, missing not only the flash 6 inches from his nose but also the awareness of the abrupt moment of entry into sleep.

**Figure 23.2**

Brain waves and sleep stages

The beta waves of an alert, waking state and the regular alpha waves of an awake, relaxed state differ from the slower, larger delta waves of deep NREM-3 sleep. Although the rapid REM sleep waves resemble the near-waking NREM-1 sleep waves, the body is more aroused during REM sleep than during NREM sleep.

Rebecca Spencer, University of Massachusetts, assisted with this figure.

alpha waves the relatively slow brain waves of a relaxed, awake state.

sleep periodic, natural loss of consciousness—as distinct from unconsciousness resulting from a coma, general anesthesia, or hibernation. (Adapted from Dement, 1999.)

**Figure 23.3**

The moment of sleep We seem unaware of the moment we fall into sleep, but someone watching our brain waves could tell. (From Dement, 1999.)

hallucinations false sensory experiences, such as seeing something in the absence of an external visual stimulus.

delta waves the large, slow brain waves associated with deep sleep.

NREM sleep non-rapid eye movement sleep; encompasses all sleep stages except for REM sleep.

“Boy are my eyes tired! I had REM sleep all night long.”

During this brief NREM-1 sleep you may experience fantastic images resembling **hallucinations**—sensory experiences that occur without a sensory stimulus. You may have a sensation of falling (at which moment your body may suddenly jerk) or of floating weightlessly. These *hypnagogic* sensations may later be incorporated into your memories. People who claim to have been abducted by aliens—often shortly after getting into bed—commonly recall being floated off of or pinned down on their beds (Clancy, 2005).

You then relax more deeply and begin about 20 minutes of NREM-2 sleep, with its periodic *sleep spindles*—bursts of rapid, rhythmic brain-wave activity (see Figure 23.2). Although you could still be awakened without too much difficulty, you are now clearly asleep.

Then you transition to the deep sleep of NREM-3. During this slow-wave sleep, which lasts for about 30 minutes, your brain emits large, slow **delta waves** and you are hard to awaken. Ever say to classmates, “That thunder was so loud last night,” only to have them respond, “What thunder?” Those who missed the storm may have been in delta sleep. (It is at the end of the deep, slow-wave NREM-3 sleep that children may wet the bed.)

REM SLEEP

About an hour after you first fall asleep, a strange thing happens. You start to leave behind the stages known as **NREM sleep**. Rather than continuing in deep slumber, you ascend from your initial sleep dive. Returning through NREM-2 (where you spend about half your night), you enter the most intriguing sleep phase—REM sleep (**FIGURE 23.4**). For about 10 minutes, your brain waves become rapid and saw-toothed, more like those of the nearly awake NREM-1 sleep. But unlike NREM-1, during REM sleep your heart rate rises, your breathing becomes rapid and irregular, and every half-minute or so your eyes dart around in momentary bursts of activity behind closed lids.

These eye movements announce the beginning of a dream—often emotional, usually story-like, and richly hallucinatory. Because anyone watching a sleeper’s eyes can notice these REM bursts, it is amazing that science was ignorant of REM sleep until 1952.

Figure 23.4

The stages in a typical night's sleep

People pass through a multistage sleep cycle several times each night, with the periods of deep sleep diminishing and REM sleep periods increasing in duration. As people age, sleep becomes more fragile, with awakenings common among older adults (Kamel et al., 2006; Neubauer, 1999).

AP® Exam Tip

Study this cycle of sleep carefully. One common mistake that students make is to believe that REM sleep comes directly after deep NREM-3 sleep. As you can see, it does not. Generally, NREM-2 follows NREM-3. Then comes REM.

Except during very scary dreams, your genitals become aroused during REM sleep. You have an erection or increased vaginal lubrication, regardless of whether the dream's content is sexual (Karacan et al., 1966). Men's common "morning erection" stems from the night's last REM period, often just before waking.

Your brain's motor cortex is active during REM sleep, but your brainstem blocks its messages. This leaves your muscles relaxed, so much so that, except for an occasional finger, toe, or facial twitch, you are essentially paralyzed. Moreover, you cannot easily be awakened. (This immobility may occasionally linger as you awaken from REM sleep, producing a disturbing experience of *sleep paralysis* [Santomauro & French, 2009].) REM sleep is thus sometimes called *paradoxical sleep*: The body is internally aroused, with waking-like brain activity, yet asleep and externally calm.

The sleep cycle repeats itself about every 90 minutes. As the night wears on, deep NREM-3 sleep grows shorter and disappears. The REM and NREM-2 sleep periods get longer (see Figure 23.4). By morning, we have spent 20 to 25 percent of an average night's sleep—some 100 minutes—in REM sleep. Thirty-seven percent of people report rarely or never having dreams "that you can remember the next morning" (Moore, 2004). Yet even they will, more than 80 percent of the time, recall a dream after being awakened during REM sleep. We spend about 600 hours a year experiencing some 1500 dreams, or more than 100,000 dreams over a typical lifetime—dreams swallowed by the night but not acted out, thanks to REM's protective paralysis.

Uriel Sinai/Getty Images

FYI

People rarely snore during dreams. When REM starts, snoring stops.

FYI

Horses, which spend 92 percent of each day standing and can sleep standing, must lie down for REM sleep (Morrison, 2003).

Safety in numbers? Why would communal sleeping provide added protection for those whose safety depends upon vigilance, such as these soldiers?

ANSWER: With each soldier cycling through the sleep stages independently, it is very likely that at any given time at least one of them will be awake or easily awakened in the event of a threat.

What Affects Our Sleep Patterns?

23-3 How do biology and environment interact in our sleep patterns?

The idea that "everyone needs 8 hours of sleep" is untrue. Newborns often sleep two-thirds of their day, most adults no more than one-third. Still, there is more to our sleep differences than age. Some of us thrive with fewer than 6 hours per night; others regularly rack up 9 hours or more. Such sleep patterns are genetically influenced (Hor & Tafti, 2009). In studies of fraternal and identical twins, only the identical twins had strikingly similar sleep patterns and durations (Webb & Campbell, 1983). Today's researchers are discovering the genes that regulate sleep in humans and animals (Donlea et al., 2009; He et al., 2009).

Sleep patterns are also culturally influenced. In the United States and Canada, adults average 7 to 8 hours per night (Hurst, 2008; National Sleep Foundation, 2010; Robinson & Martin, 2009). (The weeknight sleep of many students and workers falls short of this average [NSF, 2008].) North Americans are nevertheless sleeping less than their counterparts a century ago. Thanks to modern lighting, shift work, and social media and other diversions, those who would have gone to bed at 9:00 P.M. are now up until 11:00 P.M. or later. With sleep, as with waking behavior, biology and environment interact.

Bright morning light tweaks the circadian clock by activating light-sensitive retinal proteins. These proteins control the circadian clock by triggering signals to the brain's **suprachiasmatic nucleus (SCN)**—a pair of grain-of-rice-sized, 10,000-cell clusters in the hypothalamus (Wirz-Justice, 2009). The SCN does its job in part by causing the brain's pineal gland to decrease its production of the sleep-inducing hormone *melatonin* in the morning and to increase it in the evening (**FIGURE 23.5** on the next page).

suprachiasmatic nucleus

(SCN) a pair of cell clusters in the hypothalamus that controls circadian rhythm. In response to light, the SCN causes the pineal gland to adjust melatonin production, thus modifying our feelings of sleepiness.

Figure 23.5

The biological clock Light striking the retina signals the suprachiasmatic nucleus (SCN) to suppress the pineal gland's production of the sleep hormone melatonin. At night, the SCN quiets down, allowing the pineal gland to release melatonin into the bloodstream.

Try This

If our natural circadian rhythm were attuned to a 23-hour cycle, would we instead need to discipline ourselves to stay up later at night and sleep in longer in the morning?

FYI

A circadian disadvantage: One study of a decade's 24,121 Major League Baseball games found that teams who had crossed three time zones before playing a multiday series had nearly a 60 percent chance of losing their first game (Winter et al., 2009).

"Sleep faster, we need the pillows." -YIDDISH PROVERB

Figure 23.6

Animal sleep time Would you rather be a brown bat and sleep 20 hours a day or a giraffe and sleep 2 hours daily (data from NIH, 2010)?

Being bathed in light disrupts our 24-hour biological clock (Czeisler et al., 1999; Dement, 1999). Curiously—given that our ancestors' body clocks were attuned to the rising and setting Sun of the 24-hour day—many of today's young adults adopt something closer to a 25-hour day, by staying up too late to get 8 hours of sleep. For this, we can thank (or blame) Thomas Edison, inventor of the light bulb. This helps explain why, until our later years, we must discipline ourselves to go to bed and force ourselves to get up. Most animals, too, when placed under unnatural constant illumination will exceed a 24-hour day. Artificial light delays sleep.

Sleep often eludes those who stay up late and sleep in on weekends, and then go to bed earlier on Sunday evening in preparation for the new school week (Oren & Terman, 1998). They are like New Yorkers whose biology is on California time. For North Americans who fly to Europe and need to be up when their circadian rhythm cries "SLEEP," bright light (spending the next day outdoors) helps reset the biological clock (Czeisler et al., 1986, 1989; Eastman et al., 1995).

Sleep Theories

23-4 What are sleep's functions?

So, our sleep patterns differ from person to person and from culture to culture. But why do we have this need for sleep?

Psychologists believe sleep may have evolved for five reasons.

1. **Sleep protects.** When darkness shut down the day's hunting, food gathering, and travel, our distant ancestors were better off asleep in a cave, out of harm's way. Those who didn't try to navigate around rocks and cliffs at night were more likely to leave descendants. This fits a broader principle: A species' sleep pattern tends to suit its ecological niche (Siegel, 2009). Animals with the greatest need to graze and the least ability to hide tend to sleep less. (For a sampling of animal sleep times, see **FIGURE 23.6**.)
2. **Sleep helps us recuperate.** It helps restore and repair brain tissue. Bats and other animals with high waking metabolism burn a lot of calories, producing a lot of *free radicals*, molecules that are toxic to neurons. Sleeping a lot gives resting neurons time to repair themselves, while pruning or weakening unused connections (Gilestro et al., 2009; Siegel, 2003; Vyazovskiy et al., 2008). Think of it this way: When consciousness leaves your house, brain construction workers come in for a makeover.

3. **Sleep helps restore and rebuild our fading memories of the day's experiences.** Sleep consolidates our memories—it strengthens and stabilizes neural memory traces (Racsmany et al., 2010; Rasch & Born, 2008). People trained to perform tasks therefore recall them better after a night's sleep, or even after a short nap, than after several hours awake (Stickgold & Ellenbogen, 2008). Among older adults, more sleep leads to better memory of recently learned material (Drummond, 2010). After sleeping well, seniors remember more. And in both humans and rats, neural activity during slow-wave sleep re-enacts and promotes recall of prior novel experiences (Peigneux et al., 2004; Ribeiro et al., 2004). Sleep, it seems, strengthens memories in a way that being awake does not.
4. **Sleep feeds creative thinking.** On occasion, dreams have inspired noteworthy literary, artistic, and scientific achievements, such as the dream that clued chemist August Kekulé to the structure of benzene (Ross, 2006). More commonplace is the boost that a complete night's sleep gives to our thinking and learning. After working on a task, then sleeping on it, people solve problems more insightfully than do those who stay awake (Wagner et al., 2004). They also are better at spotting connections among novel pieces of information (Ellenbogen et al., 2007). To think smart and see connections, it often pays to sleep on it.
5. **Sleep supports growth.** During deep sleep, the pituitary gland releases a growth hormone. This hormone is necessary for muscle development. A regular full night's sleep can also “dramatically improve your athletic ability,” report James Maas and Rebecca Robbins (see Close-up: Sleep and Athletic Performance). As we age, we release less of this hormone and spend less time in deep sleep (Pekkanen, 1982).

Given all the benefits of sleep, it's no wonder that sleep loss hits us so hard.

“Corduroy pillows make headlines.” -ANONYMOUS

Close-up

Sleep and Athletic Performance

Exercise improves sleep. What's not as widely known, report James Maas and Rebecca Robbins (2010), is that sleep improves athletic performance. Well-rested athletes have faster reaction times, more energy, and greater endurance, and teams that build 8 to 10 hours of daily sleep into their training show improved performance. Top violinists also report sleeping 8.5 hours a day on average, and rate practice and sleep as the two most important improvement-fostering activities (Ericsson et al., 1993).

Slow-wave sleep, which occurs mostly in the first half of a night's sleep, produces the human growth hormone necessary for muscle development. REM sleep and NREM-2 sleep, which occur mostly in the final hours of a long night's sleep, help strengthen the neural connections that build enduring memories, including the “muscle memories” learned while practicing tennis or shooting baskets.

The optimal exercise time is late afternoon or early evening, Maas and Robbins advise,

AP Photo/Lionel Cironneau

when the body's natural cooling is most efficient. Early morning workouts are ill-advised, because they increase the risk of injury and rob athletes of valuable sleep. Heavy workouts within three hours of bedtime should also be avoided because the arousal disrupts falling asleep. Precision muscle training, such as shooting free throws, may, however, benefit when followed by sleep.

Maas has been a sleep consultant for college and professional athletes and teams. On Maas' advice, the Orlando Magic cut early morning practices. He also advised one young woman, Sarah Hughes, who felt stymied in her efforts to excel in figure-skating competition. “Cut the early morning practice,” he instructed, as part of the recommended sleep regimen. Soon thereafter, Hughes' performance scores increased, ultimately culminating in her 2002 Olympic gold medal.

Ample sleep supports skill learning and high performance This was the experience of Olympic gold medalist Sarah Hughes.

Before You Move On

▶ ASK YOURSELF

Would you consider yourself a night owl or a morning lark? When do you usually feel most energetic? What time of day works best for you to study?

▶ TEST YOURSELF

What five theories explain our need for sleep?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 23 Review

23-1 How do our biological rhythms influence our daily functioning?

- Our bodies have an internal biological clock, roughly synchronized with the 24-hour cycle of night and day.
- This *circadian rhythm* appears in our daily patterns of body temperature, arousal, sleeping, and waking. Age and experiences can alter these patterns, resetting our biological clock.

23-2 What is the biological rhythm of our sleeping and dreaming stages?

- We cycle through four distinct *sleep* stages about every 90 minutes.
- Leaving the *alpha waves* of the awake, relaxed stage, we descend into the irregular brain waves of non-REM stage 1 sleep (NREM-1), often with the sensation of falling or floating.
- NREM-2 sleep (in which we spend the most time) follows, lasting about 20 minutes, with its characteristic sleep spindles.
- We then enter NREM-3 sleep, lasting about 30 minutes, with large, slow *delta waves*.
- About an hour after falling asleep, we begin periods of REM (*rapid eye movement*) sleep.
- Most dreaming occurs in this REM stage (also known as paradoxical sleep) of internal arousal but outward paralysis.
- During a normal night's sleep, NREM-3 sleep shortens and REM and NREM-2 sleep lengthens.

23-3 How do biology and environment interact in our sleep patterns?

- Biology—our circadian rhythm as well as our age and our body's production of melatonin (influenced by the brain's suprachiasmatic nucleus)—interacts with cultural expectations and individual behaviors to determine our sleeping and waking patterns.

23-4 What are sleep's functions?

- Sleep may have played a protective role in human evolution by keeping people safe during potentially dangerous periods.
- Sleep also helps restore and repair damaged neurons.
- REM and NREM-2 sleep help strengthen neural connections that build enduring memories.
- Sleep promotes creative problem solving the next day.
- During slow-wave sleep, the pituitary gland secretes human growth hormone, which is necessary for muscle development.

Multiple-Choice Questions

- Which of the following represents a circadian rhythm?
 - A burst of growth occurs during puberty.
 - A full Moon occurs about once a month.
 - Body temperature rises each day as morning approaches.
 - When it is summer in the northern hemisphere, it is winter in the southern hemisphere.
 - Pulse rate increases when we exercise.
- In which stage of sleep are you likely to experience hypnagogic sensations of falling?
 - Alpha sleep
 - NREM-1
 - NREM-2
 - NREM-3
 - REM
- What is the role of the suprachiasmatic nucleus (SCN) in sleep?
 - It induces REM sleep approximately every 90 minutes during sleep.
 - It causes the pineal gland to increase the production of melatonin.
 - It causes the pituitary gland to increase the release of human growth hormone.
 - It causes the pituitary gland to decrease the release of human growth hormone.
 - It causes the pineal gland to decrease the production of melatonin.
- Which of the following sleep theories emphasizes sleep's role in restoring and repairing brain tissue?
 - Memory
 - Protection
 - Growth
 - Recuperation
 - Creativity

Practice FRQs

- Sleep serves many functions for us. Briefly explain how sleep can
 - provide protection.
 - promote physical growth.
- Name and briefly describe three stages of sleep when rapid eye movements are not occurring.
(3 points)

Answer

1 point: Sleep kept our ancestors safe from nighttime dangers.

1 point: Sleep promotes the release of pituitary growth hormone.

Module 24

Sleep Deprivation, Sleep Disorders, and Dreams

Module Learning Objectives

- 24-1** Describe the effects of sleep loss, and identify the major sleep disorders.
- 24-2** Describe the most common content of dreams.
- 24-3** Identify proposed explanations for why we dream.

Sleep Deprivation and Sleep Disorders

- 24-1** How does sleep loss affect us, and what are the major sleep disorders?

When our body yearns for sleep but does not get it, we begin to feel terrible. Trying to stay awake, we will eventually lose. It's easy to spot students who have stayed up late to study for a test or finish a term paper: They are often fighting the "nods" (their heads bobbing downward in seconds-long "microsleeps") as they fight to stay awake.

In the tiredness battle, sleep always wins. In 1989, Michael Doucette was named America's Safest Driving Teen. In 1990, while driving home from college, he fell asleep at the wheel and collided with an oncoming car, killing both himself and the other driver. Michael's driving instructor later acknowledged never having mentioned sleep deprivation and drowsy driving (Dement, 1999).

Effects of Sleep Loss

Today, more than ever, our sleep patterns leave us not only sleepy but drained of energy and feelings of well-being. After a succession of 5-hour nights, we accumulate a sleep debt that need not be entirely repaid but cannot be satisfied by one long sleep. "The brain keeps an accurate count of sleep debt for at least two weeks," reported sleep researcher William Dement (1999, p. 64).

Obviously, then, we need sleep. Sleep commands roughly one-third of our lives—some 25 years, on average. But why?

Allowed to sleep unhindered, most adults will sleep at least 9 hours a night (Coren, 1996). With that much sleep, we awake refreshed, sustain better moods, and perform more efficient and accurate work. The U.S. Navy and the National Institutes of Health have demonstrated the benefits of unrestricted sleep in experiments in which volunteers spent 14 hours daily in bed for at least a week. For the first few days, the volunteers averaged 12 hours of sleep a day or more, apparently paying off a sleep debt that averaged 25 to 30 hours.

That accomplished, they then settled back to 7.5 to 9 hours nightly and felt energized and happier (Dement, 1999). In one Gallup survey (Mason, 2005), 63 percent of adults who reported getting the sleep they needed also reported being “very satisfied” with their personal life (as did only 36 percent of those needing more sleep). And when 909 working women reported on their daily moods, the researchers were struck by what mattered little (such as money, so long as the person was not battling poverty), and what mattered a lot: less time pressure at work and a good night’s sleep (Kahneman et al., 2004). Perhaps it’s not surprising, then, that when asked if they had felt well rested on the previous day, 3 in 10 Americans said they had not (Pelham, 2010).

College and university students are especially sleep deprived; 69 percent in one national survey reported “feeling tired” or “having little energy” on several or more days in the last two weeks (AP, 2009). In another survey, 28 percent of high school students acknowledged falling asleep in class at least once a week (Sleep Foundation, 2006). The going needn’t get boring before students start snoring. (To test whether you are one of the many sleep-deprived students, see **TABLE 24.1**.)

Sleep loss is a predictor of depression. Researchers who studied 15,500 young people, 12 to 18 years old, found that those who slept 5 or fewer hours a night had a 71 percent higher risk of depression than their peers who slept 8 hours or more (Gangwisch et al., 2010). This link does not appear to reflect sleep difficulties caused by depression. When children and youth are followed through time, sleep loss predicts depression rather than

MARK RALSTON/AFP/Getty Images

Sleepless and suffering These fatigued, sleep-deprived earthquake rescue workers in China may experience a depressed immune system, impaired concentration, and greater vulnerability to accidents.

FYI

In a 2001 Gallup poll, 61 percent of men, but only 47 percent of women, said they got enough sleep.

Table 24.1

Cornell University psychologist James Maas has reported that most students suffer the consequences of sleeping less than they should. To see if you are in that group, answer the following true-false questions:

True	False	
.....	1. I need an alarm clock in order to wake up at the appropriate time.
.....	2. It's a struggle for me to get out of bed in the morning.
.....	3. Weekday mornings I hit snooze several times to get more sleep.
.....	4. I feel tired, irritable, and stressed out during the week.
.....	5. I have trouble concentrating and remembering.
.....	6. I feel slow with critical thinking, problem solving, and being creative.
.....	7. I often fall asleep watching TV.
.....	8. I often fall asleep in boring meetings or lectures or in warm rooms.
.....	9. I often fall asleep after heavy meals.
.....	10. I often fall asleep while relaxing after dinner.
.....	11. I often fall asleep within five minutes of getting into bed.
.....	12. I often feel drowsy while driving.
.....	13. I often sleep extra hours on weekend mornings.
.....	14. I often need a nap to get through the day.
.....	15. I have dark circles around my eyes.

If you answered “true” to three or more items, you probably are not getting enough sleep. To determine your sleep needs, Maas recommends that you “go to bed 15 minutes earlier than usual every night for the next week—and continue this practice by adding 15 more minutes each week—until you wake without an alarm clock and feel alert all day.” (Sleep Quiz reprinted with permission from James B. Maas, “Sleep to Win!” (Bloomington, IN: AuthorHouse, 2013).)

AP® Exam Tip

Many students try to get by on less and less sleep to try to fit everything in. The irony is that if you stay up too late studying, it can be counterproductive. Sleep deprivation makes it difficult to concentrate and increases the likelihood you will make silly mistakes on tests. The impact on your immune system means you are more likely to get sick. To be the best student you can be, make sleep a priority.

“So shut your eyes
Kiss me goodbye
And sleep
Just sleep.”
—SONG BY MY CHEMICAL ROMANCE

vice versa (Gregory et al., 2009). Moreover, REM sleep’s processing of emotional experiences helps protect against depression (Walker & van der Helm, 2009). After a good night’s sleep, we often do feel better the next day. And that may help to explain why parentally enforced bedtimes predict less depression, and why pushing back school start time leads to improved adolescent sleep, alertness, and mood (Gregory et al., 2009; Owens et al., 2010).

Even when awake, students often function below their peak. And they know it: Four in five teens and three in five 18- to 29-year-olds wish they could get more sleep on weekdays (Mason, 2003, 2005). Yet that teen who staggers glumly out of bed in response to an unwelcome alarm, yawns through morning classes, and feels half-depressed much of the day may be energized at 11:00 P.M. and mindless of the next day’s looming sleepiness (Carskadon, 2002). “Sleep deprivation has consequences—difficulty studying, diminished productivity, tendency to make mistakes, irritability, fatigue,” noted Dement (1999, p. 231). A large sleep debt “makes you stupid.”

It can also make you fatter. Sleep deprivation increases *ghrelin*, a hunger-arousing hormone, and decreases its hunger-suppressing partner, *leptin* (more on these in Module 38). It also increases cortisol, a stress hormone that stimulates the body to make fat. Sure enough, children and adults who sleep less than normal are fatter than those who sleep more (Chen et al., 2008; Knutson et al., 2007; Schoenborn & Adams, 2008). And experimental sleep deprivation of adults increases appetite and eating (Nixon et al., 2008; Patel et al., 2006; Spiegel et al., 2004; Van Cauter et al., 2007). This may help explain the common weight gain among sleep-deprived students (although a review of 11 studies reveals that the mythical college student’s “freshman 15” is, on average, closer to a “first-year 4” [Hull et al., 2007]).

In addition to making us more vulnerable to obesity, sleep deprivation can suppress immune cells that fight off viral infections and cancer (Motivala & Irwin, 2007). One experiment exposed volunteers to a cold virus. Those who had been averaging less than 7 hours sleep a night were 3 times more likely to develop a cold than were those sleeping 8 or more hours a night (Cohen et al., 2009). Sleep’s protective effect may help explain why people who sleep 7 to 8 hours a night tend to outlive those who are chronically sleep deprived, and why older adults who have no difficulty falling or staying asleep tend to live longer than their sleep-deprived agemates (Dement, 1999; Dew et al., 2003). When infections do set in, we typically sleep more, boosting our immune cells.

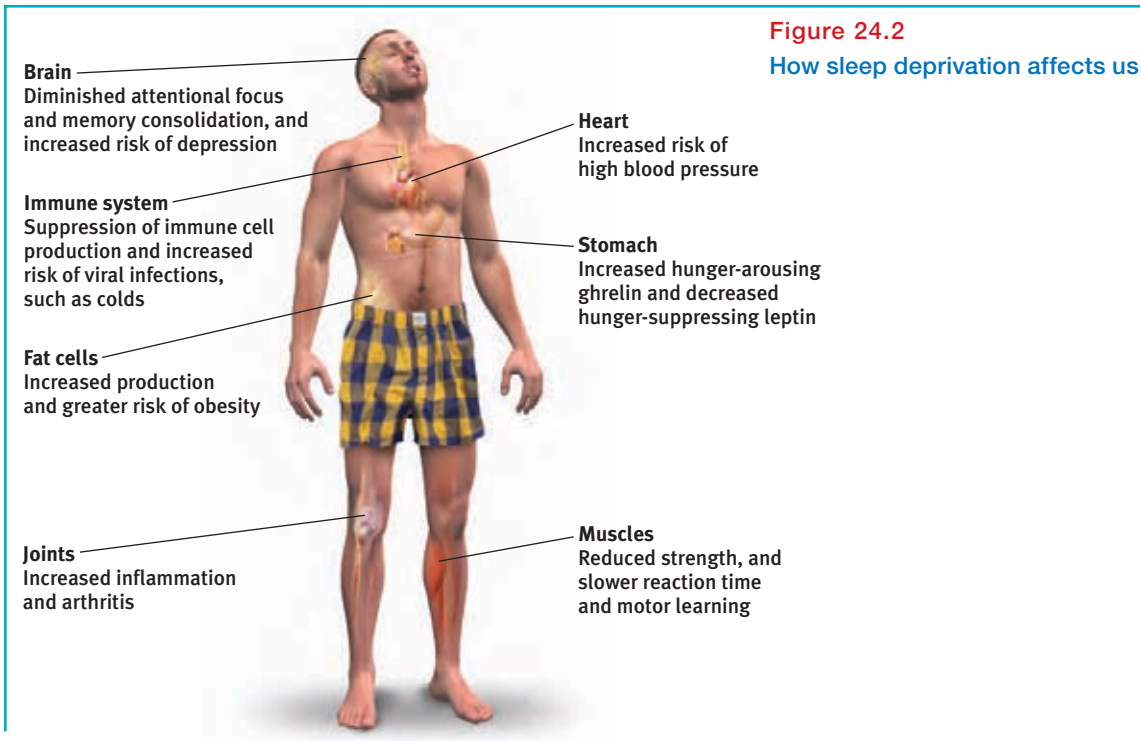

Sleep deprivation slows reactions and increases errors on visual attention tasks similar to those involved in screening airport baggage, performing surgery, and reading X-rays (Lim & Dinges, 2010). Similarly, the result can be devastating for driving, piloting, and equipment operating. Driver fatigue has contributed to an estimated 20 percent of American traffic accidents (Brody, 2002) and to some 30 percent of Australian highway deaths (Maas, 1999). One two-year study examined the driving accident rates of more than 20,000 Virginia 16- to 18-year-olds in two major cities. In one city, the high schools started 75 to 80 minutes later than in the other. The late starters had about 25 percent fewer crashes (Vorona et al., 2011). Consider, too, the timing of four industrial disasters—the 1989 *Exxon Valdez* tanker hitting rocks and spilling millions of gallons of oil on the shores of Alaska; Union Carbide’s 1984 release of toxic gas that killed thousands in Bhopal, India; and the 1979 Three Mile Island and 1986 Chernobyl nuclear accidents. All occurred after midnight, when operators in charge were likely to be drowsiest and unresponsive to signals requiring an alert response. Likewise, the 2013 Asiana Airlines crash landing at San Francisco Airport happened at 3:30 A.M. Korea time, after a 10-hour flight from Seoul. When sleepy frontal lobes confront an unexpected situation, misfortune often results.

Stanley Coren capitalized on what is, for many North Americans, a semi-annual sleep-manipulation experiment—the “spring forward” to “daylight savings” time and “fall backward” to “standard” time. Searching millions of records, Coren found that in both Canada and the United States, accidents increased immediately after the time change that shortens sleep (**FIGURE 24.1**).

**Figure 24.1**

Canadian traffic accidents On the Monday after the spring time change, when people lose one hour of sleep, accidents increased, as compared with the Monday before. In the fall, traffic accidents normally increase because of greater snow, ice, and darkness, but they diminished after the time change. (Adapted from Coren, 1996.)

FIGURE 24.2 summarizes the effects of sleep deprivation. But there is good news! Psychologists have discovered a treatment that strengthens memory, increases concentration, boosts mood, moderates hunger and obesity, fortifies the disease-fighting immune system, and lessens the risk of fatal accidents. Even better news: The treatment feels good, it can be self-administered, the supplies are limitless, and it's available free! If you are a typical high school student, often going to bed near midnight and dragged out of bed six or seven hours later by the dreaded alarm, the treatment is simple: Each night just add 15 minutes to your sleep. Ignore that last text, resist the urge to check in with friends online, and succumb to sleep, "the gentle tyrant."

**Figure 24.2**

How sleep deprivation affects us

"The lion and the lamb shall lie down together, but the lamb will not be very sleepy." -WOODY ALLEN, IN THE MOVIE *LOVE AND DEATH*, 1975

"Sleep is like love or happiness. If you pursue it too ardently it will elude you." -WILSE WEBB, *SLEEP: THE GENTLE TYRANT*, 1992

insomnia recurring problems in falling or staying asleep.

narcolepsy a sleep disorder characterized by uncontrollable sleep attacks. The sufferer may lapse directly into REM sleep, often at inopportune times.

MAJOR SLEEP DISORDERS

No matter what their normal need for sleep, 1 in 10 adults, and 1 in 4 older adults, complain of **insomnia**—not an occasional inability to sleep when anxious or excited, but persistent problems in falling or staying asleep (Irwin et al., 2006).

From middle age on, awakening occasionally during the night becomes the norm, not something to fret over or treat with medication (Vitiello, 2009). Ironically, insomnia is worsened by fretting about one's insomnia. In laboratory studies, insomnia complainers do sleep less than others, but they typically overestimate—by about double—how long it takes them to fall asleep. They also underestimate by nearly half how long they actually have slept. Even if we have been awake only an hour or two, we may *think* we have had very little sleep because it's the waking part we remember.

The most common quick fixes for true insomnia—sleeping pills and alcohol—can aggravate the problem, reducing REM sleep and leaving the person with next-day blahs. Such aids can also lead to *tolerance*—a state in which increasing doses are needed to produce an effect. An ideal sleep aid would mimic the natural chemicals that are abundant during sleep, without side effects. Until scientists can supply this magic pill, sleep experts have offered some tips for getting better quality sleep (**TABLE 24.2**).

Falling asleep is not the problem for people with **narcolepsy** (from *narco*, "numbness," and *lepsy*, "seizure"), who have sudden attacks of overwhelming sleepiness, usually lasting less than 5 minutes. Narcolepsy attacks can occur at the most inopportune times, perhaps just after taking a terrific swing at a softball or when laughing loudly, shouting angrily, or having sex (Dement, 1978, 1999). In severe cases, the person collapses directly into a brief period of REM sleep, with loss of muscular tension. People with narcolepsy—1 in 2000 of us, estimated the Stanford University Center for Narcolepsy (2002)—must therefore live with extra caution. As a traffic menace, "snoozing is second only to boozing," says the American Sleep Disorders Association, and those with narcolepsy are especially at risk (Aldrich, 1989).

Researchers have discovered genes that cause narcolepsy in dogs and humans (Miyagawa et al., 2008; Taheri, 2004). Genes help sculpt the brain, and neuroscientists are searching the brain for narcolepsy-linked abnormalities. One team discovered a relative absence of a hypothalamic neural center that produces *orexin* (also called hypocretin), a neurotransmitter linked to alertness (Taheri et al., 2002; Thannickal et al., 2000). (That discovery has led to the clinical testing of a new sleeping pill that works by blocking orexin's arousing activity.)

Table 24.2 Some Natural Sleep Aids

- Exercise regularly but not in the late evening. (Late afternoon is best.)
- Avoid caffeine after early afternoon, and avoid food and drink near bedtime. The exception would be a glass of milk, which provides raw materials for the manufacture of serotonin, a neurotransmitter that facilitates sleep.
- Relax before bedtime, using dimmer light.
- Sleep on a regular schedule (rise at the same time even after a restless night) and avoid naps.
- Hide the clock face so you aren't tempted to check it repeatedly.
- Reassure yourself that temporary sleep loss causes no great harm.
- Realize that for any stressed organism, being vigilant is natural and adaptive. A personal conflict during the day often means a fitful sleep that night (Åkerstedt et al., 2007; Brissette & Cohen, 2002). And a traumatic stressful event can take a lingering toll on sleep (Babson & Feldner, 2010). Managing your stress levels will enable more restful sleeping. (See Modules 43, 44, and 84 for more on stress.)
- If all else fails, settle for less sleep, either by going to bed later or getting up earlier.

AP Photo/Paul Sakuma. File

Economic recession and stress can rob sleep

A National Sleep Foundation (2009) survey found 27 percent of people reporting sleeplessness related to the economy, their personal finances, and employment, as seems evident in this man looking for work.

Narcolepsy, it is now clear, is a brain disease; it is not just “in your mind.” And this gives hope that narcolepsy might be effectively relieved by a drug that mimics the missing orexin and can sneak through the blood-brain barrier (Fujiki et al., 2003; Siegel, 2000). In the meantime, physicians are prescribing other drugs to relieve narcolepsy’s sleepiness in humans.

Although 1 in 20 of us have **sleep apnea**, it was unknown before modern sleep research. *Apnea* means “with no breath,” and people with this condition intermittently stop breathing during sleep. After an airless minute or so, decreased blood oxygen arouses them and they wake up enough to snort in air for a few seconds, in a process that repeats hundreds of times each night, depriving them of slow-wave sleep. Apnea sufferers don’t recall these episodes the next day. So, despite feeling fatigued and depressed—and hearing their mate’s complaints about their loud “snoring”—many are unaware of their disorder (Peppard et al., 2006).

Sleep apnea is associated with obesity, and as the number of obese Americans has increased, so has this disorder, particularly among overweight men, including some football players (Keller, 2007). Other warning signs are loud snoring, daytime sleepiness and irritability, and (possibly) high blood pressure, which increases the risk of a stroke or heart attack (Dement, 1999). If one doesn’t mind looking a little goofy in the dark (imagine a snorkeler at a slumber party), the treatment—a mask-like device with an air pump that keeps the sleeper’s airway open—can effectively relieve apnea symptoms.

Unlike sleep apnea, **night terrors** target mostly children, who may sit up or walk around, talk incoherently, experience doubled heart and breathing rates, and appear terrified (Hartmann, 1981). They seldom wake up fully during an episode and recall little or nothing the next morning—at most, a fleeting, frightening image. Night terrors are not nightmares (which, like other dreams, typically occur during early morning REM sleep); night terrors usually occur during the first few hours of NREM-3.

Sleepwalking—another NREM-3 sleep disorder—and *sleep talking* are usually childhood disorders, and like narcolepsy, they run in families. (Sleep talking—usually garbled or nonsensical—can occur during any sleep stage [Mahowald & Ettinger, 1990].) Occasional childhood sleepwalking occurs for about one-third of those with a sleepwalking fraternal twin and half of those with a sleepwalking identical twin. The same is true for sleep talking (Hublin et al., 1997, 1998). Sleepwalking is usually harmless. After returning to bed on their own or with the help of a family member, few sleepwalkers recall their trip the next morning. About 20 percent of 3- to 12-year-olds have at least one episode of sleepwalking,

Brian Chase/Shutterstock

sleep apnea a sleep disorder characterized by temporary cessations of breathing during sleep and repeated momentary awakenings.

night terrors a sleep disorder characterized by high arousal and an appearance of being terrified; unlike nightmares, night terrors occur during NREM-3 sleep, within two or three hours of falling asleep, and are seldom remembered.

The Granger Collection, New York

Did Brahms need his own lullabies?

Cranky, overweight, and nap-prone, Johannes Brahms exhibited common symptoms of sleep apnea (Margolis, 2000).

Now I lay me down to sleep

For many with sleep apnea, a continuous positive airway pressure (CPAP) machine makes for sounder sleeping and better quality of life.

usually lasting 2 to 10 minutes; some 5 percent have repeated episodes (Giles et al., 1994). Young children, who have the deepest and longest NREM-3 sleep, are the most likely to experience both night terrors and sleepwalking. As we grow older and deep NREM-3 sleep diminishes, so do night terrors and sleepwalking. After being sleep deprived, we sleep more deeply, which increases any tendency to sleepwalk (Zadra et al., 2008).

A dreamy take on dreamland

The 2010 movie *Inception* creatively played off our interest in finding meaning in our dreams, and in understanding the layers of our consciousness. It further explored the idea of creating false memories through the power of suggestion—an idea we will explore in Module 33.

Photo: Warner Bros. Pictures

Dreams

Now playing at an inner theater near you: the premiere showing of a sleeping person's vivid dream. This never-before-seen mental movie features captivating characters wrapped in a plot so original and unlikely, yet so intricate and so seemingly real, that the viewer later marvels at its creation.

Waking from a troubling dream, wrenched by its emotions, who among us has not wondered

about this weird state of consciousness? How can our brain so creatively, colorfully, and completely construct this alternative world? In the shadowland between our dreaming and waking consciousness, we may even wonder for a moment which is real.

Discovering the link between REM sleep and dreaming opened a new era in dream research. Instead of relying on someone's hazy recall hours or days after having a dream, researchers could catch dreams as they happened. They could awaken people during or within 3 minutes after a REM sleep period and hear a vivid account.

What We Dream

24-2 What do we dream?

Daydreams tend to involve the familiar details of our life—perhaps picturing ourselves explaining to a teacher why a paper will be late, or replaying in our minds personal encounters we relish or regret. **REM dreams**—“hallucinations of the sleeping mind” (Loftus & Ketcham, 1994, p. 67)—are vivid, emotional, and bizarre—so vivid we may confuse them with reality. Awakening from a nightmare, a 4-year-old may be sure there is a bear in the house.

We spend six years of our life in dreams, many of which are anything but sweet. For both women and men, 8 in 10 dreams are marked by at least one negative event or emotion (Domhoff, 2007). Common themes are repeatedly failing in an attempt to do something; of being attacked, pursued, or rejected; or of experiencing misfortune (Hall et al., 1982). Dreams with sexual imagery occur less often than you might think. In one study, only 1 in 10 dreams among young men and 1 in 30 among young women had sexual content (Domhoff, 1996). More commonly, the story line of our dreams incorporates traces of previous days' nonsexual experiences and preoccupations (De Koninck, 2000):

- After suffering a trauma, people commonly report nightmares, which help extinguish daytime fears (Levin & Nielsen, 2007, 2009). One sample of Americans recording their dreams during September 2001 reported an increase in threatening dreams following the 9/11 terrorist attacks (Propper et al., 2007).
- After playing the computer game *Tetris* for 7 hours and then being awakened repeatedly during their first hour of sleep, 3 in 4 people reported experiencing images of the game's falling blocks (Stickgold et al., 2000).
- Compared with city-dwellers, people in hunter-gatherer societies more often dream of animals (Mestel, 1997). Compared with nonmusicians, musicians report twice as many dreams of music (Uga et al., 2006).

dream a sequence of images, emotions, and thoughts passing through a sleeping person's mind. Dreams are notable for their hallucinatory imagery, discontinuities, and incongruities, and for the dreamer's delusional acceptance of the content and later difficulties remembering it.

“I do not believe that I am now dreaming, but I cannot prove that I am not.” -PHILOSOPHER BERTRAND RUSSELL (1872–1970)

FYI

Would you suppose that people dream if blind from birth? Studies in France, Hungary, Egypt, and the United States all found blind people dreaming of using their nonvisual senses—hearing, touching, smelling, tasting (Buquet, 1988; Taha, 1972; Vekassy, 1977).

“For what one has dwelt on by day, these things are seen in visions of the night.” -MENANDER OF ATHENS (342–292 B.C.E.), *THE PRINCIPAL FRAGMENTS*

Our two-track mind is also monitoring our environment while we sleep. Sensory stimuli—a particular odor or a phone’s ringing—may be instantly and ingeniously woven into the dream story. In a classic experiment, researchers lightly sprayed cold water on dreamers’ faces (Dement & Wolpert, 1958). Compared with sleepers who did not get the cold-water treatment, these people were more likely to dream about a waterfall, a leaky roof, or even about being sprayed by someone.

So, could we learn a foreign language by hearing it played while we sleep? If only it were so easy. While sleeping we can learn to associate a sound with a mild electric shock (and to react to the sound accordingly). But we do not remember recorded information played while we are soundly asleep (Eich, 1990; Wyatt & Bootzin, 1994). In fact, anything that happens during the 5 minutes just before we fall asleep is typically lost from memory (Roth et al., 1988). This explains why sleep apnea patients, who repeatedly awaken with a gasp and then immediately fall back to sleep, do not recall the episodes. It also explains why dreams that momentarily awaken us are mostly forgotten by morning. To remember a dream, get up and stay awake for a few minutes.

“Follow your dreams, except for that one where you’re naked at work.” -ATTRIBUTED TO COMEDIAN HENNY YOUNGMAN

Why We Dream

24-3 What are the functions of dreams?

Dream theorists have proposed several explanations of why we dream, including these:

To satisfy our own wishes. In 1900, in his landmark book *The Interpretation of Dreams*, Sigmund Freud offered what he thought was “the most valuable of all the discoveries it has been my good fortune to make.” He proposed that dreams provide a psychic safety valve that discharges otherwise unacceptable feelings. He viewed a dream’s **manifest content** (the apparent and remembered story line) as a censored, symbolic version of its **latent content**, the unconscious drives and wishes that would be threatening if expressed directly. Although most dreams have no overt sexual imagery, Freud nevertheless believed that most adult dreams could be “traced back by analysis to erotic wishes.” Thus, a gun might be a disguised representation of a penis.

Freud considered dreams the key to understanding our inner conflicts. However, his critics say it is time to wake up from Freud’s dream theory, which is a scientific nightmare. Based on the accumulated science, “there is no reason to believe any of Freud’s specific claims about dreams and their purposes,” observed dream researcher William Domhoff (2003). Some contend that even if dreams are symbolic, they could be interpreted any way one wished. Others maintain that dreams hide nothing. A dream about a gun is a dream about a gun. Legend has it that even Freud, who loved to smoke cigars, acknowledged that “sometimes, a cigar is just a cigar.” Freud’s wish-fulfillment theory of dreams has in large part given way to other theories.

To file away memories. The *information-processing* perspective proposes that dreams may help sift, sort, and fix the day’s experiences in our memory. Some studies support this view. When tested the next day after learning a task, those deprived of both slow-wave and REM sleep did not do as well on their new learning as those who slept undisturbed (Stickgold et al., 2000, 2001). People who hear unusual phrases or learn to find hidden visual images before bedtime remember less the next morning if awakened every time they begin REM sleep than they do if awakened during other sleep stages (Empson & Clarke, 1970; Karni & Sagi, 1994).

Brain scans confirm the link between REM sleep and memory. The brain regions that buzz as rats learn to navigate a maze, or as people learn to perform a visual-discrimination

FYI

A popular sleep myth: If you dream you are falling and hit the ground (or if you dream of dying), you die. (Unfortunately, those who could confirm these ideas are not around to do so. Some people, however, have had such dreams and are alive to report them.)

“When people interpret [a dream] as if it were meaningful and then sell those interpretations, it’s quackery.” -SLEEP RESEARCHER J. ALLAN HOBSON (1995)

manifest content according to Freud, the remembered story line of a dream (as distinct from its latent, or hidden, content).

latent content according to Freud, the underlying meaning of a dream (as distinct from its manifest content).

task, buzz again during later REM sleep (Louie & Wilson, 2001; Maquet, 2001). So precise are these activity patterns that scientists can tell where in the maze the rat would be if awake. Others, unpersuaded by these studies, note that memory consolidation may also occur during non-REM sleep (Siegel, 2001; Vertes & Siegel, 2005). This much seems true: A night of solid sleep (and dreaming) has an important place in our lives. To sleep, perchance to remember.

This is important news for students, many of whom, observed researcher Robert Stickgold (2000), suffer from a kind of sleep bulimia—binge-sleeping on the weekend. “If you don’t get good sleep and enough sleep after you learn new stuff, you won’t integrate it effectively into your memories,” he warned. That helps explain why high school students with high grades have averaged 25 minutes more sleep a night than their lower-achieving classmates (Wolfson & Carskadon, 1998).

FYI

Rapid eye movements also stir the liquid behind the cornea; this delivers fresh oxygen to corneal cells, preventing their suffocation.

FYI

Question: Does eating spicy foods cause one to dream more?

Answer: Any food that causes you to awaken more increases your chance of recalling a dream (Moorcroft, 2003).

To develop and preserve neural pathways. Perhaps dreams, or the brain activity associated with REM sleep, serve a *physiological* function, providing the sleeping brain with periodic stimulation. This theory makes developmental sense. As you will see in Unit IX, stimulating experiences preserve and expand the brain’s neural pathways. Infants, whose neural networks are fast developing, spend much of their abundant sleep time in REM sleep (**FIGURE 24.3**).

To make sense of neural static. Other theories propose that dreams erupt from *neural activation* spreading upward from the brainstem (Antrobus, 1991; Hobson, 2003, 2004, 2009). According to one version, dreams are the brain’s attempt to make sense of random neural activity. Much as a neurosurgeon can produce hallucinations by stimulating different parts of a patient’s cortex, so can stimulation originating within the brain. These internal stimuli activate brain areas that process visual images, but not the visual cortex area, which receives raw input from the eyes. As Freud might have expected, PET scans of sleeping people also reveal increased activity in the emotion-related limbic system (in the amygdala) during REM sleep. In contrast, frontal lobe regions responsible for inhibition and logical thinking seem to idle, which may explain why we are less inhibited in our dreams than when awake (Maquet et al., 1996). Add the limbic system’s emotional tone to the brain’s visual bursts and—voilà!—we dream. Damage either the limbic system or the visual centers active during dreaming, and dreaming itself may be impaired (Domhoff, 2003).

Figure 24.3

Sleep across the life span As we age, our sleep patterns change. During our first few months, we spend progressively less time in REM sleep. During our first 20 years, we spend progressively less time asleep. (Adapted from Snyder & Scott, 1972.)

swissmacky/Shutterstock

To reflect cognitive development. Some dream researchers dispute both the Freudian and neural activation theories, preferring instead to see dreams as part of brain maturation and cognitive development (Domhoff, 2010, 2011; Foulkes, 1999). For example, prior to age 9, children’s dreams seem more like a slide show and less like an active story in which the dreamer is an actor. Dreams overlap with waking cognition and feature coherent speech. They simulate reality by drawing on our concepts and knowledge. They engage brain networks that also are active during daydreaming. Unlike the idea that dreams arise from bottom-up brain activation, the cognitive perspective emphasizes our mind’s top-down control of our dream content (Nir & Tononi, 2010).

TABLE 24.2 compares major dream theories. Although today’s sleep researchers debate dreams’ function—and some are skeptical that dreams serve any function—there is one thing they agree on: We need REM sleep. Deprived of it by repeatedly being awakened, people return more and more quickly to the REM stage after falling back to sleep. When finally allowed to sleep undisturbed, they literally sleep like babies—with increased REM sleep, a phenomenon called **REM rebound**. Withdrawing REM-suppressing sleeping medications also increases REM sleep, but with accompanying nightmares.

Most other mammals also experience REM rebound, suggesting that the causes and functions of REM sleep are deeply biological. That REM sleep occurs in mammals—and not in animals such as fish, whose behavior is less influenced by learning—also fits the information-processing theory of dreams.

So does this mean that because dreams serve physiological functions and extend normal cognition, they are psychologically meaningless? Not necessarily. Every psychologically meaningful experience involves an active brain. We are once again reminded of a basic principle: *Biological and psychological explanations of behavior are partners, not competitors.*

REM rebound the tendency for REM sleep to increase following REM sleep deprivation (created by repeated awakenings during REM sleep).

Table 24.2 Dream Theories

Theory	Explanation	Critical Considerations
<i>Freud’s wish-fulfillment</i>	Dreams provide a “psychic safety valve”—expressing otherwise unacceptable feelings; contain manifest (remembered) content and a deeper layer of latent content—a hidden meaning.	Lacks any scientific support; dreams may be interpreted in many different ways.
<i>Information-processing</i>	Dreams help us sort out the day’s events and consolidate our memories.	But why do we sometimes dream about things we have not experienced?
<i>Physiological function</i>	Regular brain stimulation from REM sleep may help develop and preserve neural pathways.	This does not explain why we experience meaningful dreams.
<i>Neural activation</i>	REM sleep triggers neural activity that evokes random visual memories, which our sleeping brain weaves into stories.	The individual’s brain is weaving the stories, which still tells us something about the dreamer.
<i>Cognitive development</i>	Dream content reflects dreamers’ cognitive development—their knowledge and understanding.	Does not address the neuroscience of dreams.

Before You Move On

▶ ASK YOURSELF

In some places, the school day for teenagers runs from 9:00 A.M. to 4:00 P.M. But in the United States, the teen school day often runs from 8:00 A.M. to 3:00 P.M., or even 7:00 A.M. to 2:00 P.M. Early to rise isn't making kids wise, say critics—it's making them sleepy. For optimal alertness and well-being, teens need 8 to 9 hours of sleep a night. So, should early-start schools move to a later start time, even if it requires buying more buses or switching start times with elementary schools? Or is this impractical, and would it do little to remedy the tired-teen problem?

▶ TEST YOURSELF

Are you getting enough sleep? What might you ask yourself to answer this question?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 24 Review

24-1

How does sleep loss affect us, and what are the major sleep disorders?

- Sleep deprivation causes fatigue and irritability, and it impairs concentration, productivity, and memory consolidation. It can also lead to depression, obesity, joint pain, a suppressed immune system, and slowed performance (with greater vulnerability to accidents).
- Sleep disorders include *insomnia* (recurring wakefulness); *narcolepsy* (sudden uncontrollable sleepiness or lapsing into REM sleep); *sleep apnea* (the stopping of breathing while asleep; associated with obesity, especially in men); *night terrors* (high arousal and the appearance of being terrified; NREM-3 disorder found mainly in children); sleepwalking (NREM-3 disorder also found mainly in children); and sleep talking.

24-2

What do we dream?

- We usually *dream* of ordinary events and everyday experiences, most involving some anxiety or misfortune.
- Fewer than 10 percent (and less among women) of dreams have any sexual content.
- Most dreams occur during REM sleep; those that happen during NREM sleep tend to be vague fleeting images.

24-3

What are the functions of dreams?

- There are five major views of the function of dreams.
- Freud's wish-fulfillment: Dreams provide a psychic "safety valve," with *manifest content* (story line) acting as a censored version of *latent content* (underlying meaning that gratifies our unconscious wishes).
- Information-processing: Dreams help us sort out the day's events and consolidate them in memory.
- Physiological function: Regular brain stimulation may help develop and preserve neural pathways in the brain.
- Neural activation: The brain attempts to make sense of neural static by weaving it into a story line.
- Cognitive development: Dreams reflect the dreamer's level of development.
- Most sleep theorists agree that REM sleep and its associated dreams serve an important function, as shown by the *REM rebound* that occurs following REM deprivation in humans and other species.

Multiple-Choice Questions

1. Sleep deprivation can lead to weight gain, reduced muscle strength, suppression of the cells that fight common colds, and most likely which of the following?
 - a. Increased productivity
 - b. Depression
 - c. Decreased mistakes on homework
 - d. Increased feeling of well-being
 - e. Sleep apnea
2. What do we call the sleep disorder that causes you to stop breathing and awaken in order to take a breath?
 - a. Narcolepsy
 - b. Insomnia
 - c. Sleep apnea
 - d. Nightmares
 - e. Night terrors
3. Which of the following dream theories states that dreams help us sort out the day's events and consolidate our memories?
 - a. Information-processing
 - b. Wish-fulfillment
 - c. Physiological function
 - d. Neural activation
 - e. Neural disconnection
4. According to research, which of the following are we most likely to experience after sleep deprivation?
 - a. Night terrors
 - b. Sleep apnea
 - c. Manifest content dreams
 - d. Narcolepsy
 - e. REM rebound

Practice FRQs

1. Identify and briefly describe the three major sleep disorders experienced by adults.

Answer

2 points: Sleep apnea: stops breathing during sleep.

2 points: Narcolepsy: falls asleep suddenly.

2 points: Insomnia: can't fall asleep.

2. Explain the following two theories regarding why we dream. Include a criticism each faces:
 - Freud's theory
 - Neural activation theory

(4 points)

Module 25

Psychoactive Drugs

Module Learning Objectives

- 25-1** Define substance use disorders, and explain the roles of tolerance, withdrawal, and addiction.
- 25-2** Identify the depressants, and describe their effects.
- 25-3** Identify the stimulants, and describe their effects.
- 25-4** Identify the hallucinogens, and describe their effects.

Let's imagine a day in the life of a legal-drug-using business executive. It begins with a wake-up latte. By midday, several cigarettes have calmed frazzled nerves before an appointment at the plastic surgeon's office for wrinkle-smoothing Botox injections. A diet pill before dinner helps stem the appetite, and its stimulating effects can later be partially offset with a glass of wine and two Tylenol PMs. And if performance needs enhancing, there are beta blockers for onstage performers, Viagra for middle-aged men, hormone-delivering "libido patches" for middle-aged women, and Adderall for those hoping to focus their concentration. Before drifting off into REM-depressed sleep, our hypothetical drug user is dismayed by news reports of pill-sharing, pill-popping students.

Tolerance and Addiction

- 25-1** What are substance use disorders, and what role do tolerance, withdrawal, and addiction play in these disorders?

Most of us manage to use some nonprescription drugs in moderation and without disrupting our lives. But some of us develop a self-harming **substance use disorder** (TABLE 25.1). In such cases, the substances being used are **psychoactive drugs**, chemicals that change perceptions and moods. A drug's overall effect depends not only on its biological effects but also on the psychology of the user's expectations, which vary with social and cultural contexts (Ward, 1994). If one culture assumes that a particular drug produces euphoria (or aggression or sexual arousal) and another does not, each culture may find its expectations fulfilled. In Module 81, we'll take a closer look at these interacting forces in the use and potential abuse of particular psychoactive drugs. But here let's consider how our bodies react to the ongoing use of psychoactive drugs.

Why might a person who rarely drinks alcohol get buzzed on one can of beer while a long-term drinker shows few effects until the second six-pack? The answer is **tolerance**. With continued use of alcohol and some other drugs (marijuana is an exception), the user's brain chemistry adapts to offset the drug effect (a process called *neuroadaptation*). To experience the

substance use disorder

continued substance craving and use despite significant life disruption and/or physical risk.

psychoactive drug a chemical substance that alters perceptions and moods.

tolerance the diminishing effect with regular use of the same dose of a drug, requiring the user to take larger and larger doses before experiencing the drug's effect.

Table 25.1 When Is Drug Use a Disorder?

A person may be diagnosed with *substance use disorder* when drug use continues despite significant life disruption. Resulting changes in brain circuits may persist after quitting use of the substance (thus leading to strong cravings when exposed to people and situations that trigger memories of drug use). The severity of substance use disorder varies from *mild* (two to three symptoms) to *moderate* (four to five symptoms) to *severe* (six or more symptoms) (American Psychiatric Association, 2013).

Impaired Control

1. Uses more substance, or for longer, than intended.
2. Tries unsuccessfully to regulate substance use.
3. Spends much time gaining, using, or recovering from substance use.
4. Craves the substance.

Social Impairment

5. Use disrupts obligations at work, school, or home.
6. Continues use despite social problems.
7. Use causes reduced social, recreational, and work activities.

Risky Use

8. Continues use despite hazards.
9. Continues use despite worsening physical or psychological problems.

Drug Action

10. Experiences tolerance (needing more substance for the desired effect).
11. Experiences withdrawal when attempting to end use.

same effect, the user requires larger and larger doses (**FIGURE 25.1**). In chronic alcohol abuse, for example, the person's brain, heart, and liver suffer damage from the excessive amounts of alcohol being "tolerated." Ever-increasing doses of most psychoactive drugs can pose a serious threat to health and may lead to **addiction**: The person craves and uses the substance despite its adverse consequences. (See Thinking Critically About: Addiction on the next page.) The World Health Organization (2008) has reported that, worldwide, 90 million people suffer from such problems related to alcohol and other drugs. Regular users often try to fight their addiction, but abruptly stopping the drug may lead to the undesirable side effects of **withdrawal**.

**Figure 25.1**

Drug tolerance With repeated exposure to a psychoactive drug, the drug's effect lessens. Thus, it takes larger doses to get the desired effect.

FYI

The odds of getting hooked after using various drugs:

Tobacco	32%
Heroin	23%
Alcohol	15%
Marijuana	9%

addiction compulsive craving of drugs or certain behaviors (such as gambling) despite known adverse consequences.

withdrawal the discomfort and distress that follow discontinuing an addictive drug or behavior.

Thinking Critically About

Addiction

In recent years, the concept of addiction has been extended to cover many behaviors formerly considered bad habits or even sins. Psychologists debate whether the concept has been stretched too far, and whether addictions are really as irresistible as commonly believed. For example, “even for a very addictive drug like cocaine, only 15 to 16 percent of people become addicted within 10 years of first use,” observed Terry Robinson and Kent Berridge (2003).

Addictions can be powerful, and many addicts do benefit from therapy or group support. Alcoholics Anonymous has supported millions of people in overcoming their alcohol addiction. But viewing addiction as an uncontrollable disease can undermine people’s self-confidence and their belief that they can change. And that, critics say, would be unfortunate, for many people do voluntarily stop using addictive drugs, without any treatment. Most ex-smokers, for example, have kicked the habit on their own.

The addiction-as-disease-needing-treatment idea has been offered for a host of driven, excessive behaviors—eating, shopping, gambling, work, and sex. However, critics suggest that “addiction” can become an all-purpose excuse when used not as a metaphor (“I’m a science fiction addict”) but as reality. Moreover, they note that labeling a behavior doesn’t explain it. Attributing serial adultery, as in the case of Tiger Woods, to a “sex addiction” does not explain the sexual impulsiveness (Radford, 2010).

Sometimes, though, behaviors such as gambling, video gaming, or online surfing do become compulsive and dysfunctional,

A social networking addiction?

much like abusive drug taking (Gentile, 2009; Griffiths, 2001; Hoelt et al., 2008). Thus, psychiatry’s manual of disorders now includes behavior addictions such as “gambling disorder” and proposes “Internet gaming disorder” for further study (American Psychiatric Association, 2013). Some Internet users, for example, display an apparent inability to resist logging on, and staying on, even when this excessive use impairs their work and relationships (Ko et al., 2005). Stay tuned. Debates over the nature of addiction continue.

David Horsey/Hearst Newspapers

AP® Exam Tip

These three categories—depressants, stimulants, and hallucinogens—are important. There are likely to be questions on the AP® exam that will require you to know how a particular psychoactive drug is classified.

depressants drugs (such as alcohol, barbiturates, and opiates) that reduce neural activity and slow body functions.

Types of Psychoactive Drugs

The three major categories of psychoactive drugs are *depressants*, *stimulants*, and *hallucinogens*. All do their work at the brain’s synapses, inhibiting, stimulating, or mimicking the activity of the brain’s own chemical messengers, the neurotransmitters.

Depressants

25-2 What are depressants, and what are their effects?

Depressants are drugs such as alcohol, barbiturates (tranquilizers), and opiates that calm neural activity and slow body functions.

ALCOHOL

True or false? In small amounts, alcohol is a stimulant. *False*. Low doses of alcohol may, indeed, enliven a drinker, but they do so by acting as a *disinhibitor*—they slow brain activity that controls judgment and inhibitions. Alcohol is an equal-opportunity drug: It increases (disinhibits) helpful tendencies, as when tipsy restaurant patrons leave extravagant tips (Lynn, 1988).

And it increases harmful tendencies, as when sexually aroused men become more disposed to sexual aggression.

Alcohol + sex = the perfect storm. When drinking, both men and women are more disposed to casual sex (Cooper, 2006; Ebel-Lam et al., 2009). *The urges you would feel if sober are the ones you will more likely act upon when intoxicated.*

SLOWED NEURAL PROCESSING Low doses of alcohol relax the drinker by slowing sympathetic nervous system activity. Larger doses cause reactions to slow, speech to slur, and skilled performance to deteriorate. Paired with sleep deprivation, alcohol is a potent sedative. Add these physical effects to lowered inhibitions, and the result can be deadly. Worldwide, several hundred thousand lives are lost each year in alcohol-related accidents and violent crime. As blood-alcohol levels rise and judgment falters, people's qualms about drinking and driving lessen. In experiments, virtually all drinkers who had insisted when sober that they would not drive under the influence later decided to drive home from a bar, even when given a breathalyzer test and told they were intoxicated (Denton & Krebs, 1990; MacDonald et al., 1995). Alcohol can also be life threatening when heavy drinking follows an earlier period of moderate drinking, which depresses the vomiting response. People may poison themselves with an overdose that their bodies would normally throw up.

MEMORY DISRUPTION Alcohol can disrupt memory formation, and heavy drinking can have long-term effects on the brain and cognition. In rats, at a developmental period corresponding to human adolescence, binge drinking contributes to nerve cell death and reduces the birth of new nerve cells. It also impairs the growth of synaptic connections (Crews et al., 2006, 2007). In humans, heavy drinking may lead to blackouts, in which drinkers are unable to recall people they met the night before or what they said or did while intoxicated. These blackouts result partly from the way alcohol suppresses REM sleep, which helps fix the day's experiences into permanent memories.

The prolonged and excessive drinking that characterizes **alcohol use disorder** can shrink the brain (**FIGURE 25.2**). Girls and young women (who have less of a stomach enzyme that digests alcohol) can become addicted to alcohol more quickly than boys and young men do, and they are at risk for lung, brain, and liver damage at lower consumption levels (CASA, 2003; Wuethrich, 2001).

REDUCED SELF-AWARENESS AND SELF-CONTROL In one experiment, those who consumed alcohol (rather than a placebo beverage) were doubly likely to be caught mind-wandering during a reading task, yet were *less* likely to notice that they zoned out (Sayette et al., 2009). Alcohol not only reduces self-awareness, it also produces a sort of "myopia" by focusing attention on an arousing situation (such as a provocation) and distracting attention from normal inhibitions and future consequences (Giancola et al., 2010; Hull et al., 1986; Steele & Josephs, 1990).

Reduced self-awareness may help explain why people who want to suppress their awareness of failures or shortcomings are more likely to drink than are those who feel good about themselves. Losing a business deal, a game, or a romantic partner sometimes elicits a drinking binge.

Ray Ng/TIME & LIFE PICTURES/GETTY IMAGES

Dangerous disinhibition Alcohol consumption leads to feelings of invincibility, which become especially dangerous behind the wheel of a car, such as this one totaled by a teenage drunk driver. This Colorado University Alcohol Awareness Week exhibit prompted many students to post their own anti-drinking pledges (white flags).

Daniel Hammer, NIAAA, NIH, HHS

Figure 25.2
Disordered drinking shrinks the brain MRI scans show brain shrinkage in women with alcohol use disorder (left) compared with women in a control group (right).

alcohol use disorder (popularly known as *alcoholism*). Alcohol use marked by tolerance, withdrawal, and a drive to continue problematic use.

EXPECTANCY EFFECTS As with other drugs, expectations influence behavior. When people *believe* that alcohol affects social behavior in certain ways, and *believe*, rightly or wrongly, that they have been drinking alcohol, they will behave accordingly (Moss & Albery, 2009). In a classic experiment, researchers gave Rutgers University men (who had volunteered for a study on “alcohol and sexual stimulation”) either an alcoholic or a nonalcoholic drink (Abrams & Wilson, 1983). (Both had strong tastes that masked any alcohol.) In each group, half the participants thought they were drinking alcohol and half thought they were not. After watching an erotic movie clip, the men who *thought* they had consumed alcohol were more likely to report having strong sexual fantasies and feeling guilt free. Being able to *attribute* their sexual responses to alcohol released their inhibitions—whether or not they had actually consumed any alcohol. Alcohol’s effect lies partly in that powerful sex organ, the mind.

BARBITURATES

Like alcohol, the **barbiturate** drugs, or *tranquilizers*, depress nervous system activity. Barbiturates such as Nembutal, Seconal, and Amytal are sometimes prescribed to induce sleep or reduce anxiety. In larger doses, they can impair memory and judgment. If combined with alcohol—as sometimes happens when people take a sleeping pill after an evening of heavy drinking—the total depressive effect on body functions can be lethal.

OPIATES

The **opiates**—opium and its derivatives—also depress neural functioning. When using the opiates, which include *heroin*, a user’s pupils constrict, breathing slows, and lethargy sets in as blissful pleasure replaces pain and anxiety. For this short-term pleasure, opiate users may pay a long-term price: a gnawing craving for another fix, a need for progressively larger doses (as tolerance develops), and the extreme discomfort of withdrawal. When repeatedly flooded with an artificial opiate, the brain eventually stops producing *endorphins*, its own opiates. If the artificial opiate is then withdrawn, the brain lacks the normal level of these painkilling neurotransmitters. Those who cannot or choose not to tolerate this state may pay an ultimate price—death by overdose. Opiates include the *narcotics*, such as codeine and morphine, which physicians prescribe for pain relief.

barbiturates drugs that depress central nervous system activity, reducing anxiety but impairing memory and judgment.

opiates opium and its derivatives, such as morphine and heroin; they depress neural activity, temporarily lessening pain and anxiety.

stimulants drugs (such as caffeine, nicotine, and the more powerful amphetamines, cocaine, Ecstasy, and methamphetamine) that excite neural activity and speed up body functions.

amphetamines drugs that stimulate neural activity, causing speeded-up body functions and associated energy and mood changes.

nicotine a stimulating and highly addictive psychoactive drug in tobacco.

Stimulants

25-3 What are stimulants, and what are their effects?

A **stimulant** excites neural activity and speeds up body functions. Pupils dilate, heart and breathing rates increase, and blood sugar levels rise, causing a drop in appetite. Energy and self-confidence also rise.

Stimulants include caffeine, nicotine, the **amphetamines**, cocaine, methamphetamine (“speed”), and Ecstasy (which is also a mild hallucinogen). People use stimulants to feel alert, lose weight, or boost mood or athletic performance. Unfortunately, stimulants can be addictive, as you may know if you are one of the many who use caffeine daily in your coffee, tea, soda, or energy drinks. Cut off from your usual dose, you may crash into fatigue, headaches, irritability, and depression (Silverman et al., 1992). A mild dose of caffeine typically lasts three or four hours, which—if taken in the evening—may be long enough to impair sleep.

NICOTINE

One of the most addictive stimulants is **nicotine**, found in cigarettes and other tobacco products. Imagine that cigarettes were harmless—except, once in every 25,000 packs, an occasional innocent-looking one is filled with dynamite instead of tobacco. Not such a bad

Vasca/Shutterstock

risk of having your head blown off. But with 250 million packs a day consumed worldwide, we could expect more than 10,000 gruesome daily deaths (more than three times the 9/11 fatalities each and every day)—surely enough to have cigarettes banned everywhere.¹

The lost lives from these dynamite-loaded cigarettes approximate those from today's actual cigarettes. A teen-to-the-grave smoker has a 50 percent chance of dying from the habit, and each year, tobacco kills nearly 5.4 million of its 1.3 billion customers worldwide. (Imagine the outrage if terrorists took down an equivalent of 25 loaded jumbo jets today, let alone tomorrow and every day thereafter.) By 2030, annual deaths are expected to increase to 8 million. That means that *1 billion* twenty-first-century people may be killed by tobacco (WHO, 2008). Eliminating smoking would increase life expectancy more than any other preventive measure.

Those addicted to nicotine find it very hard to quit because tobacco products are as powerfully and quickly addictive as heroin and cocaine. Attempts to quit even within the first weeks of smoking often fail (DiFranza, 2008). As with other addictions, smokers develop *tolerance*, and quitting causes nicotine-withdrawal symptoms, including craving, insomnia, anxiety, irritability, and distractibility. Nicotine-deprived smokers trying to focus on a task experience a tripled rate of mind-wandering (Sayette et al., 2010). When not craving a cigarette, they tend to underestimate the power of such cravings (Sayette et al., 2008).

All it takes to relieve this aversive state is a cigarette—a portable nicotine dispenser. Within 7 seconds, a rush of nicotine signals the central nervous system to release a flood of neurotransmitters (**FIGURE 25.3**). Epinephrine and norepinephrine diminish appetite and boost alertness and mental efficiency. Dopamine and opioids calm anxiety and reduce sensitivity to pain (Nowak, 1994; Scott et al., 2004).

¹This analogy, adapted here with world-based numbers, was suggested by mathematician Sam Saunders, as reported by K. C. Cole (1998).

FYI

Smoke a cigarette and nature will charge you 12 minutes—ironically, just about the length of time you spend smoking it (*Discover*, 1996).

Humorist Dave Barry (1995) recalling why he smoked his first cigarette the summer he turned 15: "Arguments against smoking: 'It's a repulsive addiction that slowly but surely turns you into a gasping, gray-skinned, tumor-ridden invalid, hacking up brownish gobs of toxic waste from your one remaining lung.' Arguments for smoking: 'Other teenagers are doing it.' Case closed! Let's light up!"

Figure 25.3

Where there's smoke . . . : The physiological effects of nicotine

Nicotine reaches the brain within 7 seconds, twice as fast as intravenous heroin. Within minutes, the amount in the blood soars.

Nic-A-Teen Virtually nobody starts smoking past the vulnerable teen years. Eager to hook customers whose addiction will give them business for years to come, cigarette companies target teens. Portrayals of smoking by popular actors, such as Robert Pattinson in *Remember Me*, entice teens to imitate.

James Devaney/WireImage

These rewards keep people smoking, even among the 8 in 10 smokers who wish they could stop (Jones, 2007). Each year, fewer than 1 in 7 smokers who want to quit will be able to. Even those who know they are committing slow-motion suicide may be unable to stop (Saad, 2002). Asked “If you had to do it all over again, would you start smoking?” more than 85 percent of adult smokers have answered *No* (Slovic et al., 2002).

Nevertheless, repeated attempts seem to pay off. Half of all Americans who have ever smoked have quit, sometimes aided by a nicotine replacement drug and with encouragement from a counselor or a support group. Success is equally likely whether smokers quit abruptly or gradually (Fiore et al., 2008; Lichtenstein et al., 2010; Lindson et al., 2010). For those who endure, the acute craving and withdrawal symptoms gradually dissipate over the ensuing 6 months (Ward et al., 1997). After a year’s abstinence, only 10 percent will relapse in the next year (Hughes et al., 2010). These nonsmokers may live not only healthier but also happier lives. Smoking correlates with higher rates of depression, chronic disabilities, and divorce (Doherty & Doherty, 1998; Vita et al., 1998). Healthy living seems to add both years to life and life to years.

“Cocaine makes you a new man. And the first thing that new man wants is more cocaine.” -COMEDIAN GEORGE CARLIN (1937–2008)

COCAINE

The recipe for Coca-Cola originally included an extract of the coca plant, creating a **cocaine** tonic for tired elderly people. Between 1896 and 1905, Coke was indeed “the real thing.” But no longer. Cocaine is now snorted, injected, or smoked. It enters the bloodstream quickly, producing a rush of euphoria that depletes the brain’s supply of the neurotransmitters dopamine, serotonin, and norepinephrine (**FIGURE 25.4**). Within the hour, a crash of agitated depression follows as the drug’s effect wears off. Many regular cocaine users chasing this high become addicted. In the lab, cocaine-addicted monkeys have pressed levers more than 12,000 times to gain one cocaine injection (Siegel, 1990).

In situations that trigger aggression, ingesting cocaine may heighten reactions. Caged rats fight when given foot shocks, and they fight even more when given cocaine *and* foot shocks. Likewise, humans who voluntarily ingest high doses of cocaine in laboratory experiments impose higher shock levels on a presumed opponent than do those receiving a placebo (Licata et al., 1993). Cocaine use may also lead to emotional disturbances, suspiciousness, convulsions, cardiac arrest, or respiratory failure.

In national surveys, 3 percent of U.S. high school seniors and 6 percent of British 18- to 24-year-olds reported having tried cocaine during the past year (ACMD, 2009; Johnston et al., 2011). Nearly half had smoked *crack*, a faster-working crystallized form of cocaine that produces a briefer but more intense high, followed by a more intense crash. After several hours, the craving for more wanes, only to return several days later (Gawin, 1991).

Cocaine’s psychological effects depend in part on the dosage and form consumed, but the situation and the user’s expectations and personality also play a role. Given a placebo, cocaine users who *thought* they were taking cocaine often had a cocaine-like experience (Van Dyke & Byck, 1982).

cocaine a powerful and addictive stimulant, derived from the coca plant, producing temporarily increased alertness and euphoria.

methamphetamine a powerfully addictive drug that stimulates the central nervous system, with speeded-up body functions and associated energy and mood changes; over time, appears to reduce baseline dopamine levels.

METHAMPHETAMINE

Methamphetamine is chemically related to its parent drug, *amphetamine* (NIDA, 2002, 2005) but has even greater effects. Methamphetamine triggers the release of the neurotransmitter dopamine, which stimulates brain cells that enhance energy and mood, leading to eight hours or so of heightened energy and euphoria. Its aftereffects may include irritability, insomnia, hypertension, seizures, social isolation, depression, and occasional violent outbursts (Homer et al., 2008). Over time, methamphetamine may reduce baseline dopamine levels, leaving the user with depressed functioning.

ECSTASY

Ecstasy, a street name for **MDMA** (methylenedioxymethamphetamine), is both a stimulant and a mild hallucinogen. As an amphetamine derivative, Ecstasy triggers dopamine release, but its major effect is releasing stored serotonin and blocking its reuptake, thus prolonging serotonin’s feel-good flood (Braun, 2001). Users feel the effect about a half-hour after taking an Ecstasy pill. For three or four hours, they experience high energy, emotional elevation, and (given a social context) connectedness with those around them (“I love everyone”).

During the 1990s, Ecstasy’s popularity soared as a “club drug” taken at nightclubs and all-night raves (Landry, 2002). The drug’s popularity crosses national borders, with an estimated 60 million tablets consumed annually in Britain (ACMD, 2009). There are, however, reasons not to be ecstatic about Ecstasy. One is its dehydrating effect, which—when combined with prolonged dancing—can lead to severe overheating, increased

National Pictures/Topham/The Image Works

AP® Exam Tip

Figure 25.4 is an excellent review of how neurotransmitters work. If there is any part of this that you don’t understand, head back to Module 9 for a complete explanation.

Dramatic drug-induced decline This woman’s methamphetamine addiction led to obvious physical changes. Her decline is evident in these two photos, taken at age 36 (left) and, after four years of addiction, at age 40 (right).

Ecstasy (MDMA) a synthetic stimulant and mild hallucinogen. Produces euphoria and social intimacy, but with short-term health risks and longer-term harm to serotonin-producing neurons and to mood and cognition.

Meth bust As use of the dangerously addictive stimulant methamphetamine has increased, enforcement agencies have increased their efforts to snuff out the labs that produce it.

Bill Greenblatt/UPi Photo Service/Newscom

blood pressure, and death. Another is that long-term, repeated leaching of brain serotonin can damage serotonin-producing neurons, leading to decreased output and increased risk of permanently depressed mood (Croft et al., 2001; McCann et al., 2001; Roiser et al., 2005). Ecstasy also suppresses the disease-fighting immune system, impairs memory, slows thought, and disrupts sleep by interfering with serotonin's control of the circadian clock (Laws & Kokkalis, 2007; Pacifici et al., 2001; Schilt et al., 2007). Ecstasy delights for the night but dispirits the morrow.

Hallucinogens

25-4 What are hallucinogens, and what are their effects?

hallucinogens psychedelic (“mind-manifesting”) drugs, such as LSD, that distort perceptions and evoke sensory images in the absence of sensory input.

LSD a powerful hallucinogenic drug; also known as acid (*lysergic acid diethylamide*).

Hallucinogens distort perceptions and evoke sensory images in the absence of sensory input (which is why these drugs are also called *psychedelics*, meaning “mind-manifesting”). Some, such as LSD and MDMA (Ecstasy), are synthetic. Others, including the mild hallucinogen marijuana, are natural substances.

LSD

Chemist Albert Hofmann created—and on one Friday afternoon in April 1943 accidentally ingested—**LSD** (lysergic acid diethylamide). The result—“an uninterrupted stream of fantastic pictures, extraordinary shapes with intense, kaleidoscopic play of colors”—reminded him of a childhood mystical experience that had left him longing for another glimpse of “a miraculous, powerful, unfathomable reality” (Siegel, 1984; Smith, 2006).

The emotions of an LSD trip vary from euphoria to detachment to panic. The user's current mood and expectations color the emotional experience, but the perceptual distortions and hallucinations have some commonalities. Whether provoked to hallucinate by drugs, loss of oxygen, or extreme sensory deprivation, the brain hallucinates in basically the same way (Siegel, 1982). The experience typically begins with simple geometric forms, such as a lattice, cobweb, or spiral. The next phase consists of more meaningful images; some may be superimposed on a tunnel or funnel, others may be replays of past emotional experiences. As the hallucination peaks, people frequently feel separated from their body and experience dreamlike scenes so real that they may become panic-stricken or harm themselves.

These sensations are strikingly similar to the **near-death experience**, an altered state of consciousness reported by about 15 percent of patients revived from cardiac arrest (Agrillo, 2011; Greyson, 2010). Many describe visions of tunnels (**FIGURE 25.5**), bright lights or beings of light, a replay of old memories, and out-of-body sensations (Siegel, 1980). Given that oxygen deprivation and other insults to the brain are known to produce hallucinations, it is difficult to resist wondering whether a brain under stress manufactures the near-death experience. Following temporal lobe seizures, patients have reported similarly profound mystical experiences. So have solitary sailors and polar explorers while enduring monotony, isolation, and cold (Suedfeld & Mocellin, 1987).

Figure 25.5

Near-death vision or hallucination? Psychologist Ronald Siegel (1977) reported that people under the influence of hallucinogenic drugs often see “a bright light in the center of the field of vision. . . . The location of this point of light create[s] a tunnel-like perspective.” This is very similar to others’ near-death experiences.

MARIJUANA

For 5000 years, hemp has been cultivated for its fiber. The leaves and flowers of this plant, which are sold as marijuana, contain **THC** (delta-9-tetrahydrocannabinol). Whether smoked (getting to the brain in about 7 seconds) or eaten (causing its peak concentration to be reached at a slower, unpredictable rate), THC produces a mix of effects. *Synthetic marijuana* (also called *K2* or *Spice*) mimics THC. Its harmful side effects, which can include agitation and hallucinations, led to its ingredient becoming illegal under the U.S. Synthetic Drug Abuse Prevention Act of 2012.

Marijuana is a difficult drug to classify. It is a mild hallucinogen, amplifying sensitivity to colors, sounds, tastes, and smells. But like alcohol, marijuana relaxes, disinhibits, and may produce a euphoric high. Both alcohol and marijuana impair the motor coordination, perceptual skills, and reaction time necessary for safely operating an automobile or other machine. “THC causes animals to misjudge events,” reported Ronald Siegel (1990, p. 163). “Pigeons wait too long to respond to buzzers or lights that tell them food is available for brief periods; and rats turn the wrong way in mazes.”

Marijuana and alcohol also differ. The body eliminates alcohol within hours. THC and its by-products linger in the body for a week or more, which means that regular users experience less abrupt withdrawal and may achieve a high with smaller amounts of the drug than would be needed by occasional users. This is contrary to the usual path of tolerance, in which repeat users need to take larger doses to feel the same effect.

A user’s experience can vary with the situation. If the person feels anxious or depressed, using marijuana may intensify these feelings. The more often the person uses marijuana, especially during adolescence and in today’s stronger, purified form, the greater the risk of anxiety or depression (Bambico et al., 2010; Hall, 2006; Murray et al., 2007). Daily use bodes a worse outcome than infrequent use.

Marijuana also disrupts memory formation and interferes with immediate recall of information learned only a few minutes before. Such cognitive effects outlast the period of smoking (Messinis et al., 2006). Heavy adult use for over 20 years is associated with a shrinkage of brain areas that process memories and emotions (Yücel et al., 2008). Prenatal exposure through maternal marijuana use impairs brain development (Berghuis et al., 2007; Huizink & Mulder, 2006).

To free up resources to fight crime, some states and countries have passed laws legalizing the possession of small quantities of marijuana. In some cases, legal *medical marijuana* use has been granted to relieve the pain and nausea associated with diseases such

near-death experience an altered state of consciousness reported after a close brush with death (such as by cardiac arrest); often similar to drug-induced hallucinations.

THC the major active ingredient in marijuana; triggers a variety of effects, including mild hallucinations.

as AIDS, glaucoma, and cancer (Munsey, 2010; Watson et al., 2000). In such cases, the Institute of Medicine recommends delivering the THC with medical inhalers. Marijuana smoke, like cigarette smoke, is toxic and can cause cancer, lung damage, and pregnancy complications.

* * *

Despite their differences, the psychoactive drugs summarized in **TABLE 25.2** share a common feature: They trigger negative aftereffects that offset their immediate positive effects and grow stronger with repetition. And this helps explain both tolerance and withdrawal. As the opposing, negative aftereffects grow stronger, it takes larger and larger doses to produce the desired high (*tolerance*), causing the aftereffects to worsen in the drug's absence (*withdrawal*). This in turn creates a need to switch off the withdrawal symptoms by taking yet more of the drug (which may lead to *addiction*).

Table 25.2 A Guide to Selected Psychoactive Drugs

Drug	Type	Pleasurable Effects	Adverse Effects
<i>Alcohol</i>	Depressant	Initial high followed by relaxation and disinhibition	Depression, memory loss, organ damage, impaired reactions
<i>Heroin</i>	Depressant	Rush of euphoria, relief from pain	Depressed physiology, agonizing withdrawal
<i>Caffeine</i>	Stimulant	Increased alertness and wakefulness	Anxiety, restlessness, and insomnia in high doses; uncomfortable withdrawal
<i>Methamphetamine</i>	Stimulant	Euphoria, alertness, energy	Irritability, insomnia, hypertension, seizures
<i>Cocaine</i>	Stimulant	Rush of euphoria, confidence, energy	Cardiovascular stress, suspiciousness, depressive crash
<i>Nicotine</i>	Stimulant	Arousal and relaxation, sense of well-being	Heart disease, cancer
<i>Ecstasy (MDMA)</i>	Stimulant; mild hallucinogen	Emotional elevation, disinhibition	Dehydration, overheating, depressed mood, impaired cognitive and immune functioning
<i>Marijuana</i>	Mild hallucinogen	Enhanced sensation, relief of pain, distortion of time, relaxation	Impaired learning and memory, increased risk of psychological disorders, lung damage from smoke

To learn about the influences on drug use, see Module 81.

Before You Move On

▶ ASK YOURSELF

Do you think people can become addicted not only to psychoactive drugs but also to other repetitive, pleasure-seeking behaviors (such as gambling or “Internet game playing”)?

▶ TEST YOURSELF

Why do tobacco companies try so hard to get customers hooked as teens?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 25 Review

25-1 What are substance use disorders, and what role do tolerance, withdrawal, and addiction play in these disorders?

- Those with a *substance use disorder* may exhibit impaired control, social disruption, risky behavior, and the physical effects of tolerance and withdrawal.
- *Psychoactive drugs* alter perceptions and moods.
- These drugs may produce *tolerance*—requiring larger doses to achieve the desired effect—and *withdrawal*—significant discomfort accompanying efforts to quit.
- *Addiction* is compulsive craving and use of drugs or certain behaviors (such as gambling) despite known adverse consequences.

25-2 What are depressants, and what are their effects?

- *Depressants*, such as alcohol, *barbiturates*, and the *opiates* (which include narcotics), dampen neural activity and slow body functions.
- Alcohol tends to disinhibit, increasing the likelihood that we will act on our impulses, whether harmful or helpful. It also impairs judgment, disrupts memory processes by suppressing REM sleep, and reduces self-awareness and self-control.
- User expectations strongly influence alcohol’s behavioral effects.

25-3 What are stimulants, and what are their effects?

- *Stimulants*—including caffeine, *nicotine*, cocaine, the *amphetamines*, *methamphetamine*, and *Ecstasy*—excite neural activity and speed up body functions, triggering energy and mood changes. All are highly addictive.
- Nicotine’s effects make smoking a difficult habit to kick, yet the percentage of Americans who smoke has been dramatically decreasing.
- Cocaine gives users a fast high, followed within an hour by a crash. Its risks include cardiovascular stress and suspiciousness.
- Use of methamphetamines may permanently reduce dopamine production.
- Ecstasy (MDMA) is a combined stimulant and mild hallucinogen that produces euphoria and feelings of intimacy. Its users risk immune system suppression, permanent damage to mood and memory, and (if taken during physical activity) dehydration and escalating body temperatures.

25-4 What are hallucinogens, and what are their effects?

- *Hallucinogens*—such as *LSD* and marijuana—distort perceptions and evoke *hallucinations*—sensory images in the absence of sensory input. The user’s mood and expectations influence the effects of LSD, but common experiences are hallucinations and emotions varying from euphoria to panic.
- Marijuana’s main ingredient, *THC*, may trigger feelings of disinhibition, euphoria, relaxation, relief from pain, and intense sensitivity to sensory stimuli. It may also increase feelings of depression or anxiety, impair motor coordination and reaction time, disrupt memory formation, and damage lung tissue (because of the inhaled smoke).

Multiple-Choice Questions

- Which of the following represents drug tolerance?
 - Hans has grown to accept the fact that his wife likes to have a beer with her dinner, even though he personally does not approve of the use of alcohol.
 - Jose often wakes up with a headache that lasts until he has his morning cup of coffee.
 - Pierre enjoys the effect of marijuana and is now using the drug several times a week.
 - Jacob had to increase the dosage of his pain medication when the old dosage no longer effectively controlled the pain from his chronic back condition.
 - Chau lost his job and is now homeless as a result of his drug use.
- Which of the following drugs is classified as an opiate?
 - Nicotine
 - Marijuana
 - Heroin
 - Methamphetamine
 - Cocaine
- Which of the following drugs produces effects similar to a near-death experience?
 - Ecstasy
 - Nicotine
 - Barbiturate
 - Methamphetamine
 - LSD
- Which of the following statements is true of alcohol?
 - Alcohol is a stimulant because it produces insomnia.
 - Alcohol is a depressant because it produces bipolar disorder.
 - Alcohol is a stimulant because people do foolish things while under its influence.
 - Alcohol is a depressant because it calms neural activity and slows body function.
 - Alcohol is a stimulant because it increases instances of casual sex.

Practice FRQs

- Name and compare the effects of the two hallucinogens discussed in the text.

Answer

1 point: LSD creates vivid hallucinations and strong emotions.

1 point: Marijuana creates mild hallucinations, enhanced sensory experiences, and impaired judgment.

- Three of the most widely used psychoactive drugs—alcohol, caffeine, and nicotine—are legal for large segments of the population. Name the category that each of these drugs belongs to, and describe one effect of each.

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Sudden sleep attacks at inopportune times are symptomatic of which sleep disorder?
 - Sleep apnea
 - Insomnia
 - Night terrors
 - Sleepwalking
 - Narcolepsy
- Deep sleep occurs in which stage?
 - Hypnagogic
 - REM
 - Alpha
 - NREM-1
 - Delta
- Recurring problems in falling asleep or staying asleep are characteristic of which sleep disorder?
 - Sleep apnea
 - Narcolepsy
 - Insomnia
 - Sleep talking
 - Sleepwalking
- What is the pineal gland's role in sleep?
 - Activating the suprachiasmatic nucleus
 - The production of melatonin
 - The location of hypnagogic images
 - Remembering dreams upon waking
 - Emitting alpha waves

5. What are bursts of rapid, rhythmic brain-wave activity that occur during NREM-2 sleep?
 - a. Hallucinations
 - b. Circadian rhythms
 - c. Alpha waves
 - d. Sleep spindles
 - e. Delta waves
6. Increasing amounts of paradoxical sleep following a period of sleep deprivation is known as what?
 - a. Circadian sleep
 - b. Sleep shifting
 - c. Narcolepsy
 - d. Sleep apnea
 - e. REM rebound
7. Which of these drugs, which acts as both a stimulant and a hallucinogen, can also cause dangerous dehydration?
 - a. LSD
 - b. Ecstasy
 - c. Alcohol
 - d. Cocaine
 - e. Caffeine
8. Recent research most consistently supports the effectiveness of hypnosis in which of the following areas?
 - a. Pain relief
 - b. Recovery of lost memories
 - c. Reduction of sleep deprivation
 - d. Forcing people to act against their will
 - e. Cessation of smoking
9. What are the three major categories of drugs?
 - a. Hallucinogens, depressants, and stimulants
 - b. Stimulants, barbiturates, and hallucinogens
 - c. Amphetamines, barbiturates, and opiates
 - d. MDMA, LSD, and THC
 - e. Alcohol, caffeine, and nicotine
10. Jarod's muscles are relaxed, his body is basically paralyzed, and he is hard to awaken. Which sleep state is Jarod probably experiencing?
 - a. Sleep apnea
 - b. Hypnagogic
 - c. Paradoxical
 - d. Delta
 - e. Sleep deprivation
11. The effects of opiates are similar to the effects of which neurotransmitter?
 - a. Barbiturates
 - b. Endorphins
 - c. Tranquilizers
 - d. Nembutal
 - e. Acetylcholine
12. Slowed reactions, slurred speech, and decreased skill performance are associated with abuse of which drug?
 - a. Nicotine
 - b. Methamphetamine
 - c. Caffeine
 - d. Alcohol
 - e. Ecstasy
13. What term did Ernest Hilgard use to describe a split between different levels of consciousness?
 - a. Hypnagogic imagery
 - b. REM sleep
 - c. Delta waves
 - d. Spindles
 - e. Dissociation
14. Psychologists who study the brain's activity during sleep are most likely to use which of these technologies?
 - a. MRI
 - b. CT scan
 - d. PET scan
 - d. EEG
 - e. EKG
15. What term describes the brain's adaptation to a drug's chemistry, requiring larger and larger doses to experience the same effect?
 - a. Withdrawal
 - b. Tolerance
 - c. Addiction
 - d. Substance use disorder
 - e. Disinhibiting

Free-Response Questions

1. Different biological changes are associated with different states of consciousness. Explain the biological changes (if any) typically associated with the following consciousness-related concepts:
 - Sleep deprivation
 - REM
 - Tolerance
 - Opiates

Rubric for Free Response Question 1

1 point: Sleep deprivation causes a wide range of biological changes in the body, all associated with decreased performance while awake. These biological changes include lack of energy, falling asleep during the day, changes in appetite, suppression of the immune system, decreased focus and attention, and depressed mood. ↻ Pages 234–237

1 point: The REM stage of the sleep cycle is associated with dramatic biological changes. Brain waves and breathing become irregular, heart rate increases, and eyes dart back and forth beneath the eyelids. ↻ Pages 228–229

1 point: After repeated use of some drugs, humans develop tolerance for those substances, meaning that increasing dosages of those drugs are needed to produce the same effect. Tolerance occurs because of biological changes in the brain. The brain's chemistry changes when some psychoactive drugs are repeatedly ingested, interfering with the brain's ability to produce or use some neurotransmitters.

↻ Pages 246–247

1 point: Drugs categorized as opiates cause a range of biological changes in the body. Some of the changes mentioned in the text are: pupil constriction, slower breathing, lethargy, and eventually, painful withdrawal symptoms as the brain loses its ability to produce “natural” endorphins. ↻ Page 250

2. Ernest, a psychology major, is discussing hypnosis with his roommate, Phil. Phil says: “I can’t believe so many people fall for that hypnosis stuff. Hypnosis is just like dreaming. It’s just a different state of consciousness, and a dream can affect someone just like a supposed hypnotic state can.”

Explain how Ernest might use the following terms as he discusses the validity of Phil’s claims.

- Posthypnotic suggestion
- Divided-consciousness theory
- Social influence theory
- Dissociation

(4 points)

3. Consciousness has been defined and studied differently throughout the history of psychology. In your own words, explain how modern psychologists define consciousness, and explain how the following “altered” states of consciousness relate to your definition.

- Hypnosis
- Sleep stages
- Dreams
- Psychoactive drugs

(5 points)

Multiple-choice self-tests and more may be found at www.worthpublishers.com/MyersAP2e

Unit VI

Learning

Modules

- 28** Operant Conditioning's Applications, and Comparison to Classical Conditioning
- 29** Biology, Cognition, and Learning
- 30** Learning by Observation

When a chinook salmon first emerges from its egg in a stream's gravel bed, its genes provide most of the behavioral instructions it needs for life. It knows instinctively how and where to swim, what to eat, and most spectacularly, where to go and when and how to return to its birthplace. Guided by the scent of its home stream, it pursues an upstream odyssey to its ancestral spawning ground and seeks out the best gravel and water flow for breeding. It then mates and, its life mission accomplished, dies.

Unlike salmon, we are not born with a genetic plan for life. Much of what we do we learn from experience. Although we struggle to find the life direction a salmon is born with, our learning gives us more flexibility. We can learn how to build grass huts or snow shelters, submarines or space stations, and thereby adjust to almost any environment. Indeed, nature's most important gift to us may be our *adaptability*—our capacity to learn new behaviors that help us cope with changing circumstances.

Learning breeds hope. What is learnable we can potentially teach—a fact that encourages parents, teachers, coaches, and animal trainers. What has been learned we can potentially change by new learning—an assumption that underlies counseling, psychotherapy, and rehabilitation programs. No matter how unhappy, unsuccessful, or unloving we are, that need not be the end of our story.

No topic is closer to the heart of psychology than *learning*. In earlier units we considered how we learn to think critically, and the learning of visual perceptions and of a drug's expected effect. In later units we will see how learning shapes our thoughts and language, our motivations and emotions, our personalities and attitudes. In Unit VII, we will see how the brain stores and retrieves learning.

Module 26

How We Learn and Classical Conditioning

Module Learning Objectives

- 26-1** Define learning, and identify some basic forms of learning.
- 26-2** Describe the basic components of classical conditioning, and explain behaviorism's view of learning.
- 26-3** Summarize the processes of acquisition, extinction, spontaneous recovery, generalization, and discrimination.
- 26-4** Explain why Pavlov's work remains so important, and describe some applications of his work to human health and well-being.

How Do We Learn?

- 26-1** What is learning, and what are some basic forms of learning?

Psychologists define **learning** as the process of acquiring new and relatively enduring information or behaviors. By learning, we humans are able to adapt to our environments. We learn to expect and prepare for significant events such as food or pain (*classical conditioning*). We typically learn to repeat acts that bring rewards and to avoid acts that bring unwanted results (*operant conditioning*). We learn new behaviors by observing events and by watching others, and through language we learn things we have neither experienced nor observed (*cognitive learning*). But *how* do we learn?

More than 200 years ago, philosophers such as John Locke and David Hume echoed Aristotle's conclusion from 2000 years earlier: We learn by *association*. Our minds naturally

learning the process of acquiring new and relatively enduring information or behaviors.

Try This

Most of us would be unable to name the order of the songs on our favorite album or playlist. Yet, hearing the end of one piece cues (by association) an anticipation of the next. Likewise, when singing your national anthem, you associate the end of each line with the beginning of the next. (Pick a line out of the middle and notice how much harder it is to recall the *previous* line.)

AP® Exam Tip

It's easy to confuse habituation with sensory adaptation, a concept from Unit IV. Recall that sensory adaptation occurs when one of your sensory systems stops registering the presence of an unchanging stimulus—when you go swimming in a cool pool, for example, the water no longer feels cool after you've been in for a few minutes. Habituation, like sensory adaptation, involves a diminished response, but in this case it's a form of learning rather than a function of the sensory system. If you're exposed to the same stimulus over and over, your response decreases. A friend might sneak up and startle you by yelling "Boo!" But you'll probably startle less when he tries it again two minutes later. That's habituation.

habituation an organism's decreasing response to a stimulus with repeated exposure to it.

associative learning learning that certain events occur together. The events may be two stimuli (as in classical conditioning) or a response and its consequences (as in operant conditioning).

stimulus any event or situation that evokes a response.

connect events that occur in sequence. Suppose you see and smell freshly baked bread, eat some, and find it satisfying. The next time you see and smell fresh bread, you will expect that eating it will again be satisfying. So, too, with sounds. If you associate a sound with a frightening consequence, hearing the sound alone may trigger your fear. As one 4-year-old exclaimed after watching a TV character get mugged, "If I had heard that music, I wouldn't have gone around the corner!" (Wells, 1981).

Learned associations often operate subtly. Give people a red pen (associated with error marking) rather than a black pen and, when correcting essays, they will spot more errors and give lower grades (Rutchick et al., 2010). When voting, people are more likely to support taxes to aid education if their assigned voting place is in a school (Berger et al., 2008).

Learned associations also feed our habitual behaviors (Wood & Neal, 2007). As we repeat behaviors in a given context—sleeping in a certain posture in bed, walking certain routes from class to class, eating popcorn in a movie theater—the behaviors become associated with the contexts. Our next experience of the context then evokes our habitual response. How long does it take to form such habits? To find out, one British research team asked 96 university students to choose some healthy behavior (such as running before dinner or eating fruit with lunch), to do it daily for 84 days, and to record whether the behavior felt automatic (something they did without thinking and would find it hard not to do). On average, behaviors became habitual after about 66 days (Lally et al., 2010). (Is there something you'd like to make a routine part of your life? Just do it every day for two months, or a bit longer for exercise, and you likely will find yourself with a new habit.)

Other animals also learn by association. Disturbed by a squirt of water, the sea slug *Aplysia* protectively withdraws its gill. If the squirts continue, as happens naturally in choppy water, the withdrawal response diminishes. We say the slug **habituates**. But if the sea slug repeatedly receives an electric shock just after being squirted, its response to the squirt instead grows stronger. The animal has associated the squirt with the impending shock.

Complex animals can learn to associate their own behavior with its outcomes. An aquarium seal will repeat behaviors, such as slapping and barking, that prompt people to toss it a herring.

By linking two events that occur close together, both animals are exhibiting **associative learning**. The sea slug associates the squirt with an impending shock; the seal associates slapping and barking with a herring treat. Each animal has learned something important to its survival: predicting the immediate future.

This process of learning associations is *conditioning*, and it takes two main forms:

- In *classical conditioning*, we learn to associate two stimuli and thus to anticipate events. (A **stimulus** is any event or situation that evokes a response.) We learn that a flash of lightning signals an impending crack of thunder; when lightning flashes nearby, we start to brace ourselves (**FIGURE 26.1**).
- In *operant conditioning*, we learn to associate a response (our behavior) and its consequence. Thus we (and other animals) learn to repeat acts followed by good results (**FIGURE 26.2**) and avoid acts followed by bad results.

To simplify, we will explore these two types of associative learning separately. Often, though, they occur together, as on one Japanese cattle ranch, where the clever rancher outfitted his herd with electronic pagers, which he calls from his cell phone. After a week of training, the animals learn to associate two stimuli—the beep on their pager and the arrival of food (classical conditioning). But they also learn to associate their hustling to the food trough with the pleasure of eating (operant conditioning).

Classical conditioning

Conditioning is not the only form of learning. Through **cognitive learning** we acquire mental information that guides our behavior. *Observational learning*, one form of cognitive learning, lets us learn from others' experiences. Chimpanzees, for example, sometimes learn behaviors merely by watching others perform them. If one animal sees another solve a puzzle and gain a food reward, the observer may perform the trick more quickly. So, too, in humans: We look and we learn.

Let's look more closely now at classical conditioning.

**Figure 26.2**
Operant conditioning**Before You Move On****▶ ASK YOURSELF**

Can you remember some example from your childhood of learning through classical conditioning—perhaps salivating at the sound or smell of some delicious food cooking in your family kitchen? Can you remember an example of operant conditioning, when you repeated (or decided not to repeat) a behavior because you liked (or hated) its consequences? Can you recall watching someone else perform some act and later repeating or avoiding that act?

▶ TEST YOURSELF

As we develop, we learn cues that lead us to expect and prepare for good and bad events. We learn to repeat behaviors that bring rewards. And we watch others and learn. What do psychologists call these three types of learning?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

cognitive learning the acquisition of mental information, whether by observing events, by watching others, or through language.

classical conditioning a type of learning in which one learns to link two or more stimuli and anticipate events.

behaviorism the view that psychology (1) should be an objective science that (2) studies behavior without reference to mental processes. Most research psychologists today agree with (1) but not with (2).

neutral stimulus (NS) in classical conditioning, a stimulus that elicits no response before conditioning.

Ivan Pavlov “Experimental investigation . . . should lay a solid foundation for a future true science of psychology” (1927).

Classical Conditioning

26-2

What are the basic components of classical conditioning, and what was behaviorism’s view of learning?

For many people, the name Ivan Pavlov (1849–1936) rings a bell. His early twentieth-century experiments—now psychology’s most famous research—are classics, and the phenomenon he explored we justly call **classical conditioning**.

Pavlov’s work laid the foundation for many of psychologist John B. Watson’s ideas. In searching for laws underlying learning, Watson (1913) urged his colleagues to discard reference to inner thoughts, feelings, and motives. The science of psychology should instead study how organisms respond to stimuli in their environments, said Watson: “Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods.” Simply said, psychology should be an objective science based on observable behavior.

This view, which influenced North American psychology during the first half of the twentieth century, Watson called **behaviorism**. Pavlov and Watson shared both a disdain for “mentalist” concepts (such as consciousness) and a belief that the basic laws of learning were the same for all animals—whether dogs or humans. Few researchers today propose that psychology should ignore mental processes, but most now agree that classical conditioning is a basic form of learning by which all organisms adapt to their environment.

Pavlov’s Experiments

Pavlov was driven by a lifelong passion for research. After setting aside his initial plan to follow his father into the Russian Orthodox priesthood, Pavlov received a medical degree at age 33 and spent the next two decades studying the digestive system. This work earned him Russia’s first Nobel Prize in 1904. But his novel experiments on learning, which consumed the last three decades of his life, earned this feisty scientist his place in history.

Pavlov’s new direction came when his creative mind seized on an incidental observation. Without fail, putting food in a dog’s mouth caused the animal to salivate. Moreover, the dog began salivating not only at the taste of the food, but also at the mere sight of the food, or at the food dish, or at the person delivering the food, or even at the sound of that person’s approaching footsteps. At first, Pavlov considered these “psychic secretions” an annoyance—until he realized they pointed to a simple but important form of learning.

Pavlov and his assistants tried to imagine what the dog was thinking and feeling as it drooled in anticipation of the food. This only led them into fruitless debates. So, to explore the phenomenon more objectively, they experimented. To eliminate other possible influences, they isolated the dog in a small room, secured it in a harness, and attached a device to divert its saliva to a measuring instrument (**FIGURE 26.3**). From the next room, they presented food—first by sliding in a food bowl, later by blowing meat powder into the dog’s mouth at a precise moment. They then paired various **neutral stimuli (NS)**—events the dog could see or hear but didn’t associate with food—with food in the dog’s mouth. If a sight or sound regularly signaled the arrival of food, would the dog learn the link? If so, would it begin salivating in anticipation of the food?

PEANUTS

Figure 26.3
Pavlov's device for recording salivation A tube in the dog's cheek collects saliva, which is measured in a cylinder outside the chamber.

The answers proved to be *Yes* and *Yes*. Just before placing food in the dog's mouth to produce salivation, Pavlov sounded a tone. After several pairings of tone and food, the dog, now anticipating the meat powder, began salivating to the tone alone. In later experiments, a buzzer,¹ a light, a touch on the leg, even the sight of a circle set off the drooling. (This procedure works with people, too. When hungry young Londoners viewed abstract figures before smelling peanut butter or vanilla, their brain soon responded in anticipation to the abstract images alone [Gottfried et al., 2003].)

A dog doesn't learn to salivate in response to food in its mouth. Food in the mouth automatically, *unconditionally*, triggers a dog's salivary reflex (**FIGURE 26.4**). Thus, Pavlov called the drooling an **unconditioned response (UR)**. And he called the food an **unconditioned stimulus (US)**.

¹The "buzzer" (English translation) was perhaps Pavlov's supposed bell—a small electric bell (Tully, 2003).

unconditioned response (UR) in classical conditioning, an unlearned, naturally occurring response (such as salivation) to an unconditioned stimulus (US) (such as food in the mouth).

unconditioned stimulus (US) in classical conditioning, a stimulus that unconditionally—naturally and automatically—triggers a response (UR).

Figure 26.4
Pavlov's classic experiment Pavlov presented a neutral stimulus (a tone) just before an unconditioned stimulus (food in mouth). The neutral stimulus then became a conditioned stimulus, producing a conditioned response.

conditioned response (CR)

in classical conditioning, a learned response to a previously neutral (but now conditioned) stimulus (CS).

conditioned stimulus (CS) in classical conditioning, an originally irrelevant stimulus that, after association with an unconditioned stimulus (US), comes to trigger a conditioned response (CR).

acquisition in classical conditioning, the initial stage, when one links a neutral stimulus and an unconditioned stimulus so that the neutral stimulus begins triggering the conditioned response. In operant conditioning, the strengthening of a reinforced response.

higher-order conditioning a procedure in which the conditioned stimulus in one conditioning experience is paired with a new neutral stimulus, creating a second (often weaker) conditioned stimulus. For example, an animal that has learned that a tone predicts food might then learn that a light predicts the tone and begin responding to the light alone. (Also called *second-order conditioning*.)

Salivation in response to the tone, however, is learned. Because it is *conditional* upon the dog's associating the tone and the food, we call this response the **conditioned response (CR)**. The stimulus that used to be neutral (in this case, a previously meaningless tone that now triggers the salivation) is the **conditioned stimulus (CS)**. Distinguishing these two kinds of stimuli and responses is easy: Conditioned = learned; *unconditioned* = *unlearned*.

Let's check your understanding with a second example. An experimenter sounds a tone just before delivering an air puff to your blinking eye. After several repetitions, you blink to the tone alone. What is the NS? The US? The UR? The CS? The CR?²

If Pavlov's demonstration of associative learning was so simple, what did he do for the next three decades? What discoveries did his research factory publish in his 532 papers on salivary conditioning (Windholz, 1997)? He and his associates explored five major conditioning processes: *acquisition*, *extinction*, *spontaneous recovery*, *generalization*, and *discrimination*.

ACQUISITION**26-3**

In classical conditioning, what are the processes of acquisition, extinction, spontaneous recovery, generalization, and discrimination?

To understand the **acquisition**, or initial learning, of the stimulus-response relationship, Pavlov and his associates had to confront the question of timing: How much time should elapse between presenting the NS (the tone, the light, the touch) and the US (the food)? In most cases, not much—half a second usually works well.

What do you suppose would happen if the food (US) appeared before the tone (NS) rather than after? Would conditioning occur? Not likely. With but a few exceptions, conditioning doesn't happen when the NS follows the US. *Remember, classical conditioning is biologically adaptive because it helps humans and other animals prepare for good or bad events.* To Pavlov's dogs, the originally neutral tone became a (CS) after signaling an important biological event—the arrival of food (US). To deer in the forest, the snapping of a twig (CS) may signal a predator's approach (US). If the good or bad event has already occurred, the tone or the sound won't help the animal prepare.

Eric Isselée/Shutterstock

More recent research on male Japanese quail shows how a CS can signal another important biological event (Domjan, 1992, 1994, 2005). Just before presenting an approachable female quail, the researchers turned on a red light. Over time, as the red light continued to herald the female's arrival, the light caused the male quail to become excited. They developed a preference for their cage's red-light district, and when a female appeared, they mated with her more quickly and released more semen and sperm (Matthews et al., 2007). All in all, the

quail's capacity for classical conditioning gives it a reproductive edge.

In humans, too, objects, smells, and sights associated with sexual pleasure can become conditioned stimuli for sexual arousal (Byrne, 1982). Onion breath does not usually produce sexual arousal. But when repeatedly paired with a passionate kiss, it can become a CS and do just that (**FIGURE 26.5**). The larger lesson: *Conditioning helps an animal survive and reproduce—by responding to cues that help it gain food, avoid dangers, locate mates, and produce offspring* (Hollis, 1997).

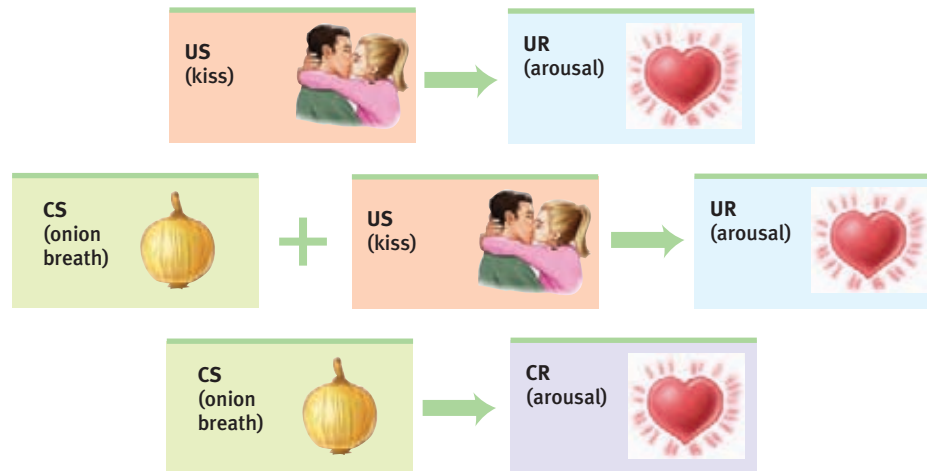

Through **higher-order conditioning**, a new NS can become a new CS. All that's required is for it to become associated with a previously conditioned stimulus. If a tone regularly signals food and produces salivation, then a light that becomes associated with

FYI

Remember:

NS = Neutral Stimulus**US** = Unconditioned Stimulus**UR** = Unconditioned Response**CS** = Conditioned Stimulus**CR** = Conditioned Response

² NS = tone before procedure; US = air puff; UR = blink to air puff; CS = tone after procedure; CR = blink to tone

**Figure 26.5**

An unexpected CS Psychologist Michael Tirrell (1990) recalled: “My first girlfriend loved onions, so I came to associate onion breath with kissing. Before long, onion breath sent tingles up and down my spine. Oh what a feeling!”

the tone may also begin to trigger salivation. Although this higher-order conditioning (also called *second-order conditioning*) tends to be weaker than first-order conditioning, it influences our everyday lives. Imagine that something makes us very afraid (perhaps a guard dog associated with a previous dog bite). If something else, such as the sound of a barking dog, brings to mind that guard dog, the bark alone may make us feel a little afraid.

EXTINCTION AND SPONTANEOUS RECOVERY

What would happen, Pavlov wondered, if after conditioning, the CS occurred repeatedly without the US? If the tone sounded again and again, but no food appeared, would the tone still trigger salivation? The answer was mixed. The dogs salivated less and less, a reaction known as **extinction**, the diminished responding that occurs when the CS (tone) no longer signals an impending US (food). But a different picture emerged when Pavlov allowed several hours to elapse before sounding the tone again. After the delay, the dogs would again begin salivating to the tone (**FIGURE 26.6**). This **spontaneous recovery**—the reappearance of a (weakened) CR after a pause—suggested to Pavlov that extinction was *suppressing* the CR rather than eliminating it.

GENERALIZATION

Pavlov and his students noticed that a dog conditioned to the sound of one tone also responded somewhat to the sound of a new and different tone. Likewise, a dog conditioned to salivate when rubbed would also drool a bit when scratched (Windholz, 1989) or when touched on a different body part (**FIGURE 26.7** on the next page). This tendency to respond likewise to stimuli similar to the CS is called **generalization**.

extinction the diminishing of a conditioned response; occurs in classical conditioning when an unconditioned stimulus (US) does not follow a conditioned stimulus (CS); occurs in operant conditioning when a response is no longer reinforced.

spontaneous recovery the reappearance, after a pause, of an extinguished conditioned response.

generalization the tendency, once a response has been conditioned, for stimuli similar to the conditioned stimulus to elicit similar responses.

AP® Exam Tip

Spontaneous recovery is, in fact, spontaneous. Notice that the extinguished conditioned response returns without any additional pairing with the unconditioned stimulus. It is not a form of acquisition.

**Figure 26.6**

Idealized curve of acquisition, extinction, and spontaneous recovery The rising curve shows that the CR rapidly grows stronger as the NS becomes a CS as it is repeatedly paired with the US (*acquisition*), then weakens as the CS is presented alone (*extinction*). After a pause, the CR reappears (*spontaneous recovery*).

Figure 26.7

Generalization Pavlov demonstrated generalization by attaching miniature vibrators to various parts of a dog's body. After conditioning salivation to stimulation of the thigh, he stimulated other areas. The closer a stimulated spot was to the dog's thigh, the stronger the conditioned response. (From Pavlov, 1927.)

"I don't care if she's a tape dispenser. I love her."

AP® Exam Tip

Generalization and discrimination are introduced in this module, but they don't just apply to classical conditioning. These two concepts will show up in other types of learning as well.

discrimination in classical conditioning, the learned ability to distinguish between a conditioned stimulus and stimuli that do not signal an unconditioned stimulus.

Generalization can be adaptive, as when toddlers taught to fear moving cars also become afraid of moving trucks and motorcycles. And generalized fears can linger. One Argentine writer who underwent torture still recoils with fear when he sees black shoes—his first glimpse of his torturers as they approached his cell. Generalized anxiety reactions have been demonstrated in laboratory studies comparing abused with nonabused children. When an angry face appears on a computer screen, abused children's brain-wave responses are dramatically stronger and longer lasting (Pollak et al., 1998).

Stimuli similar to naturally disgusting objects will, by association, also evoke some disgust, as otherwise desirable fudge does when shaped to resemble dog feces (Rozin et al., 1986). Researchers have also found that we like unfamiliar people more if they look somewhat like someone we've learned to like rather than dislike (Verosky & Todorov, 2010). (They find this by subtly morphing the facial features of someone we've learned to like or dislike onto a novel face.) In each of these human examples, people's emotional reactions to one stimulus have generalized to similar stimuli.

DISCRIMINATION

Pavlov's dogs also learned to respond to the sound of a particular tone and *not* to other tones. This learned ability to *distinguish* between a conditioned stimulus (which predicts the US) and other irrelevant stimuli is called **discrimination**. Being able to recognize differences is adaptive. Slightly different stimuli can be followed by vastly different consequences. Confronted by a guard dog, your heart may race; confronted by a guide dog, it probably will not.

Before You Move On

▶ ASK YOURSELF

How have your emotions or behaviors been classically conditioned?

▶ TEST YOURSELF

In slasher movies, sexually arousing images of women are sometimes paired with violence against women. Based on classical conditioning principles, what might be an effect of this pairing?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Pavlov's Legacy

26-4 Why does Pavlov's work remain so important, and what have been some applications of his work to human health and well-being?

What remains today of Pavlov's ideas? A great deal. Most psychologists now agree that classical conditioning is a basic form of learning. Judged by today's knowledge of the interplay of our biology, psychology, and social-cultural environment, Pavlov's ideas were incomplete. But if we see further than Pavlov did, it is because we stand on his shoulders.

Why does Pavlov's work remain so important? If he had merely taught us that old dogs can learn new tricks, his experiments would long ago have been forgotten. Why should we care that dogs can be conditioned to salivate at the sound of a tone? The importance lies first in this finding: *Many other responses to many other stimuli can be classically conditioned in many other organisms*—in fact, in every species tested, from earthworms to fish to dogs to monkeys to people (Schwartz, 1984). Thus, classical conditioning is one way that virtually all organisms learn to adapt to their environment.

Second, *Pavlov showed us how a process such as learning can be studied objectively*. He was proud that his methods involved virtually no subjective judgments or guesses about what went on in a dog's mind. The salivary response is a behavior measurable in cubic centimeters of saliva. Pavlov's success therefore suggested a scientific model for how the young discipline of psychology might proceed—by isolating the basic building blocks of complex behaviors and studying them with objective laboratory procedures.

APPLICATIONS OF CLASSICAL CONDITIONING

Other units in this text—on consciousness, motivation, emotion, health, psychological disorders, and therapy—show how Pavlov's principles can influence human health and well-being. Two examples:

- Former drug users often feel a craving when they are again in the drug-using context—with people or in places they associate with previous highs. Thus, drug counselors advise addicts to steer clear of people and settings that may trigger these cravings (Siegel, 2005).
- Classical conditioning even works on the body's disease-fighting immune system. When a particular taste accompanies a drug that influences immune responses, the taste by itself may come to produce an immune response (Ader & Cohen, 1985).

Pavlov's work also provided a basis for Watson's (1913) idea that human emotions and behaviors, though biologically influenced, are mainly a bundle of conditioned responses. Working with an 11-month-old, Watson and Rosalie Rayner (1920; Harris, 1979) showed how specific fears might be conditioned. Like most infants, "Little Albert" feared loud noises but not white rats. Watson and Rayner presented a white rat and, as Little Albert reached to touch it, struck a hammer against a steel bar just behind his head. After seven repeats of seeing the rat and hearing the frightening noise, Albert burst into tears at the mere sight of the rat. Five days later, he had generalized this startled fear reaction to the sight of a rabbit, a dog, and a sealskin coat, but not to dissimilar objects, such as toys.

For years, people wondered what became of Little Albert. Not until 2009 did some psychologist-sleuths identify him as Douglas Merritte, the son of a campus hospital wet nurse who received \$1 for her tot's participation. Sadly, Albert died at age 6, apparently having suffered all his short life from congenital hydrocephalus, complicated later by meningitis. This brain damage probably influenced his behavior during Watson and Rayner's experiment (Beck et al., 2009, 2010; Fridlund et al., 2012a,b). People also wondered what became of Watson. After losing his Johns Hopkins professorship over an affair with Rayner (whom he later married), he joined an advertising agency as the company's resident psychologist. There he used his knowledge of associative learning to conceive many successful advertising campaigns, including one for Maxwell House that helped make the "coffee break" an American custom (Hunt, 1993).

John B. Watson Watson (1924) admitted to "going beyond my facts" when offering his famous boast: "Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchant-chief, and, yes, even beggarman and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors."

Little Albert In Watson and Rayner's experiments, "Little Albert" learned to fear a white rat after repeatedly experiencing a loud noise as the rat was presented. In this experiment, what was the US? The UR? The NS? The CS? The CR?

ANSWERS: The US was the loud noise; the UR was the fear response; the NS was the rat before it was paired with the noise; the CS was the rat after pairing; the CR was fear.

Both images Archives of the History of American Psychology, The University of Akron

The treatment of Little Albert would be unacceptable by today's ethical standards. Also, some psychologists, noting that the infant's fear wasn't learned quickly, had difficulty repeating Watson and Rayner's findings with other children. Nevertheless, Little Albert's learned fears led many psychologists to wonder whether each of us might be a walking repository of conditioned emotions. If so, might extinction procedures or even new conditioning help us change our unwanted responses to emotion-arousing stimuli? One patient, who for 30 years had feared going into an elevator alone, did just that. Following his therapist's advice, he forced himself to enter 20 elevators a day. Within 10 days, his fear had nearly vanished (Ellis & Becker, 1982). With support from AirTran, comedian-writer Mark Malkoff likewise extinguished his fear of flying. He lived on an airplane for 30 days, taking 135 flights that had him in the air 14 hours a day (NPR, 2009). After a week and a half, his fears had faded and he began playing games with fellow passengers. (His favorite antic was the "toilet paper experiment": He'd put one end of a roll in the toilet, unroll the rest down the aisle, and flush. The entire roll would be sucked down in three seconds.) In Units XII and XIII we will see more examples of how psychologists use behavioral techniques to treat emotional disorders and promote personal growth.

Module 26 Review

26-1 What is learning, and what are some basic forms of learning?

- *Learning* is the process of acquiring new and relatively enduring information or behaviors.
- In *associative learning*, we learn that certain events occur together.
- In classical conditioning, we learn to associate two or more stimuli (a *stimulus* is any event or situation that evokes a response).
- In operant conditioning, we learn to associate a response and its consequences.
- Through *cognitive learning*, we acquire mental information that guides our behavior. For example, in observational learning, we learn new behaviors by observing events and watching others.

26-2 What are the basic components of classical conditioning, and what was behaviorism's view of learning?

- *Classical conditioning* is a type of learning in which an organism comes to associate stimuli.
- In classical conditioning, an *NS* is a stimulus that elicits no response before conditioning.
- A *UR* is an event that occurs naturally (such as salivation), in response to some stimulus.
- A *US* is something that naturally and automatically (without learning) triggers the unlearned response (as food in the mouth triggers salivation).
- A *CS* is a previously neutral stimulus (such as a tone) that, after association with a *US* (such as food) comes to trigger a *CR*.
- A *CR* is the learned response (salivating) to the originally neutral (but now conditioned) stimulus.
- Ivan Pavlov's work on classical conditioning laid the foundation for *behaviorism*, the view that psychology should be an objective science that studies behavior without reference to mental processes.
- The behaviorists believed that the basic laws of learning are the same for all species, including humans.

26-3 In classical conditioning, what are the processes of acquisition, extinction, spontaneous recovery, generalization, and discrimination?

- In classical conditioning, *acquisition* is associating an *NS* with the *US* so that the *NS* begins triggering the *CR*.
- Acquisition occurs most readily when the *NS* is presented just before (ideally, about a half-second before) a *US*, preparing the organism for the upcoming event. This finding supports the view that classical conditioning is biologically adaptive. Through *higher-order conditioning*, a new *NS* can become a new *CS*.
- *Extinction* is diminished responding when the *CS* no longer signals an impending *US*.
- *Spontaneous recovery* is the appearance of a formerly extinguished response, following a rest period.
- *Generalization* is the tendency to respond to stimuli that are similar to a *CS*.
- *Discrimination* is the learned ability to distinguish between a *CS* and other irrelevant stimuli.

26-4 Why does Pavlov's work remain so important, and what have been some applications of his work to human health and well-being?

- Pavlov taught us that significant psychological phenomena can be studied objectively, and that classical conditioning is a basic form of learning that applies to all species.
- Classical conditioning techniques are used to improve human health and well-being in many areas, including therapy for those recovering from drug addiction and for those overcoming fears. The body's immune system may also respond to classical conditioning.

Multiple-Choice Questions

- Which of the following is best defined as a relatively permanent change in behavior due to experience?
 - Acquisition
 - Stimulus
 - Learning
 - Habituation
 - Response
- Lynn is teaching learning. Every time she claps her hands, Charlie turns off the light. When Randy claps in approval of Lynn's presentation, Charlie does not turn the light off. What concept has Charlie demonstrated?
 - Habituation
 - Discrimination
 - Spontaneous recovery
 - Extinction
 - Habituation
- Classical conditioning is the type of learning in which a person links two or more stimuli and
 - forgets about them.
 - lays them out in sequence.
 - shuts down.
 - anticipates events.
 - receives a reward.
- In classical conditioning, the unconditioned stimulus
 - naturally triggers a response.
 - is a naturally occurring response.
 - is initially irrelevant, and then comes to trigger a response.
 - objectively studies psychology.
 - is Pavlovian.
- Students are accustomed to a bell ringing to indicate the end of a class period. The principal decides to substitute popular music for the bell to indicate the end of each class period. Students quickly respond to the music in the same way they did to the bell. What principle does this illustrate?
 - Acquisition
 - Habituation
 - Generalization
 - Functional fixedness
 - Stimulus
- The work of Ivan Pavlov and John Watson fits best into which of psychology's perspectives?
 - Humanism
 - Gestalt psychology
 - Trait theory
 - Behaviorism
 - Neuropsychology

Practice FRQs

- Carter's goldfish has been classically conditioned to swim to the top of the fish tank every time the light is turned on. This happened because Carter always turns on the light in the room just before feeding the fish. Identify what each of the following would be in this example, making sure you explain why you know your identification is correct.
 - Conditioned response (CR)
 - Conditioned stimulus (CS)
 - Unconditioned stimulus (US)
- A researcher paired the sound of a whistle with an air puff to the eye to classically condition Ashley to blink when the whistle alone was sounded. Explain how the researcher could demonstrate the following:
 - Generalization
 - Extinction
 - Spontaneous recovery

(3 points)

Answer

1 point: The goldfish swimming to the top of the tank when the light is turned on is the CR because the fish has learned to behave in this way.

1 point: The light is the CS because the goldfish has learned to respond to this stimulus. The light was initially an NS.

1 point: The food is the US because this stimulus will naturally cause the fish to swim to the top of the tank.

Module 27

Operant Conditioning

Module Learning Objectives

- 27-1** Describe operant conditioning, and explain how operant behavior is reinforced and shaped.
- 27-2** Discuss the differences between positive and negative reinforcement, and identify the basic types of reinforcers.
- 27-3** Explain how the different reinforcement schedules affect behavior.
- 27-4** Discuss how punishment and negative reinforcement differ, and explain how punishment affects behavior.
- 27-5** Describe the controversy over Skinner's views of human behavior.

Operant Conditioning

- 27-1** What is operant conditioning, and how is operant behavior reinforced and shaped?

It's one thing to classically condition a dog to salivate at the sound of a tone, or a child to fear moving cars. To teach an elephant to walk on its hind legs or a child to say *please*, we turn to operant conditioning.

Classical conditioning and operant conditioning are both forms of associative learning, yet their difference is straightforward:

- *Classical conditioning* forms associations between stimuli (a CS and the US it signals). It also involves *respondent behavior*—actions that are automatic responses to a stimulus (such as salivating in response to meat powder and later in response to a tone).
- In **operant conditioning**, organisms associate their own actions with consequences. Actions followed by reinforcers increase; those followed by punishers often decrease. Behavior that *operates* on the environment to *produce* rewarding or punishing stimuli is called *operant behavior*.

Skinner's Experiments

B. F. Skinner (1904–1990) was a college English major and an aspiring writer who, seeking a new direction, entered psychology graduate school. He went on to become modern behaviorism's most influential and controversial figure. Skinner's work elaborated on what psychologist Edward L. Thorndike (1874–1949) called the **law of effect**: Rewarded

AP® Exam Tip

Don't be fooled by the fact that classical conditioning is presented before operant conditioning. Classical conditioning was understood before operant conditioning, but operant conditioning has a larger impact on our day-to-day lives.

operant conditioning a type of learning in which behavior is strengthened if followed by a reinforcer or diminished if followed by a punisher.

law of effect Thorndike's principle that behaviors followed by favorable consequences become more likely, and that behaviors followed by unfavorable consequences become less likely.

Figure 27.1**Cat in a puzzle box**

Thorndike used a fish reward to entice cats to find their way out of a puzzle box (right) through a series of maneuvers. The cats' performance tended to improve with successive trials (left), illustrating Thorndike's *law of effect*. (Adapted from Thorndike, 1898.)

behavior is likely to recur (**FIGURE 27.1**). Using Thorndike's law of effect as a starting point, Skinner developed a behavioral technology that revealed principles of *behavior control*. These principles also enabled him to teach pigeons such unpigeon-like behaviors as walking in a figure 8, playing Ping-Pong, and keeping a missile on course by pecking at a screen target.

Figure 27.2

A Skinner box Inside the box, the rat presses a bar for a food reward. Outside, a measuring device (not shown here) records the animal's accumulated responses.

For his pioneering studies, Skinner designed an **operant chamber**, popularly known as a *Skinner box* (**FIGURE 27.2**). The box has a bar (a lever) that an animal presses—or a key (a disc) the animal pecks—to release a reward of food or water. It also has a device that records these responses. This design creates a stage on which rats and others animals act out Skinner's concept of **reinforcement**: any event that strengthens (increases the frequency of) a preceding response. What is reinforcing depends on the animal and the conditions. For people, it may be praise, attention, or a paycheck. For hungry and thirsty rats, food and water work well. Skinner's experiments have done far more than teach us how to pull habits out of a rat. They have explored the precise conditions that foster efficient and enduring learning.

operant chamber in operant conditioning research, a chamber (also known as a *Skinner box*) containing a bar or key that an animal can manipulate to obtain a food or water reinforcer; attached devices record the animal's rate of bar pressing or key pecking.

reinforcement in operant conditioning, any event that *strengthens* the behavior it follows.

shaping an operant conditioning procedure in which reinforcers guide behavior toward closer and closer approximations of the desired behavior.

Shaping Behavior

Imagine that you wanted to condition a hungry rat to press a bar. Like Skinner, you could tease out this action with **shaping**, gradually guiding the rat's actions toward the desired behavior. First, you would watch how the animal naturally behaves, so that you could build on its existing behaviors. You might give the rat a bit of food each time it approaches the bar. Once the rat is approaching regularly, you would give the food only when it moves close to the bar, then closer still. Finally, you would require it to touch the bar to get food. With this method of *successive approximations*, you reward responses that are ever-closer to the final desired behavior, and you ignore all other responses. By making rewards contingent on desired behaviors, researchers and animal trainers gradually shape complex behaviors.

Shaping can also help us understand what nonverbal organisms perceive. Can a dog distinguish red and green? Can a baby hear the difference between lower- and higher-pitched tones? If we can shape them to respond to one stimulus and not to another, then we know they can perceive the difference. Such experiments have even shown that some animals can form concepts. When experimenters reinforced pigeons for pecking after

Reuters/CORBIS

Reinforcers vary with circumstances What is reinforcing (a heat lamp) to one animal (a cold meerkat) may not be to another (an overheated child). What is reinforcing in one situation (a cold snap at the Taronga Zoo in Sydney) may not be in another (a sweltering summer day).

seeing a human face, but not after seeing other images, the pigeon's behavior showed that it could recognize human faces (Herrnstein & Loveland, 1964). In this experiment, the human face was a **discriminative stimulus**. Like a green traffic light, discriminative stimuli signal that a response will be reinforced. After being trained to discriminate among classes of events or objects—flowers, people, cars, chairs—pigeons can usually identify the category in which a new pictured object belongs (Bhatt et al., 1988; Wasserman, 1993). They have even been trained to discriminate between the music of Bach and Stravinsky (Porter & Neuringer, 1984).

In everyday life, we continually reinforce and shape others' behavior, said Skinner, though we may not mean to do so. Isaac's whining, for example, annoys his dad, but look how he typically responds:

Isaac: Could you take me to the mall?

Father: (*Ignores Isaac and stays focused on his phone*)

Isaac: Dad, I need to go to the mall.

Father: (*distracted*) Uh, yeah, just a minute.

Isaac: DAAAD! The mall!!

Father: Show some manners! Okay, where are my keys. . .

Isaac's whining is reinforced, because he gets something desirable—his dad's attention. Dad's response is reinforced because it gets rid of something aversive—Isaac's whining.

Or consider a teacher who pastes gold stars on a wall chart beside the names of children scoring 100 percent on spelling tests. As everyone can then see, some children consistently do perfect work. The others, who take the same test and may have worked harder than the academic all-stars, get no rewards. The teacher would be better advised to apply the principles of operant conditioning—to reinforce all spellers for gradual improvements (successive approximations toward perfect spelling of words they find challenging).

Types of Reinforcers

27-2

How do positive and negative reinforcement differ, and what are the basic types of reinforcers?

Up to now, we've mainly been discussing **positive reinforcement**, which strengthens a response by *presenting* a typically pleasurable stimulus after a response. But, as we saw in the whining Isaac story, there are *two* basic kinds of reinforcement (**TABLE 27.1** on the next page).

discriminative stimulus

in operant conditioning, a stimulus that elicits a response after association with reinforcement (in contrast to related stimuli not associated with reinforcement).

positive reinforcement

increasing behaviors by presenting positive reinforcers. A positive reinforcer is any stimulus that, when *presented* after a response, strengthens the response.

Shaping a dog to play the piano

Using a method of successive approximations, with a food reward for each small step—hopping up on the piano bench, putting her paws on the keys, actually making sounds—this dog was taught to “play” the piano, and now does so frequently!

Antonia Brune, Valentine Photography

Table 27.1 Ways to Increase Behavior

Operant Conditioning Term	Description	Examples
Positive reinforcement	Add a desirable stimulus	Pet a dog that comes when you call it; pay the person who paints your house
Negative reinforcement	Remove an aversive stimulus	Take painkillers to end pain; fasten seat belt to end loud beeping

Negative reinforcement *strengthens* a response by *reducing or removing* something negative. Isaac’s whining was *positively* reinforced, because Isaac got something desirable—his father’s attention. His dad’s response to the whining (taking Isaac to the mall) was negatively reinforced, because it ended an aversive event—Isaac’s whining. Similarly, taking aspirin may relieve your headache, and pushing the snooze button will silence your annoying alarm. These welcome results provide negative reinforcement and increase the odds that you will repeat these behaviors. For drug addicts, the negative reinforcement of ending withdrawal pangs can be a compelling reason to resume using (Baker et al., 2004). Note that *negative reinforcement is not punishment*. (Some friendly advice: Repeat the last five words in your mind.) Rather, negative reinforcement *removes* a punishing (aversive) event. Think of negative reinforcement as something that provides relief—from that whining teenager, bad headache, or annoying alarm.

Sometimes negative and positive reinforcement coincide. Imagine a worried student who, after goofing off and getting a bad test grade, studies harder for the next test. This increased effort may be *negatively* reinforced by reduced anxiety, and *positively* reinforced by a better grade. Whether it works by reducing something aversive, or by giving something desirable, *reinforcement is any consequence that strengthens behavior*.

HI AND LOIS

negative reinforcement

increasing behaviors by stopping or reducing negative stimuli. A negative reinforcer is any stimulus that, when *removed* after a response, strengthens the response. (Note: Negative reinforcement is not punishment.)

primary reinforcer an innately reinforcing stimulus, such as one that satisfies a biological need.

conditioned reinforcer a stimulus that gains its reinforcing power through its association with a primary reinforcer; also known as a *secondary reinforcer*.

PRIMARY AND CONDITIONED REINFORCERS

Getting food when hungry or having a painful headache go away is innately satisfying. These **primary reinforcers** are unlearned. **Conditioned reinforcers**, also called *secondary reinforcers*, get their power through learned association with primary reinforcers. If a rat in a Skinner box learns that a light reliably signals a food delivery, the rat will work to turn on the light. The light has become a conditioned reinforcer. Our lives are filled with conditioned reinforcers—money, good grades, a pleasant tone of voice—each of which has been linked with more basic rewards.

IMMEDIATE AND DELAYED REINFORCERS

Let’s return to the imaginary shaping experiment in which you were conditioning a rat to press a bar. Before performing this “wanted” behavior, the hungry rat will engage in a sequence of “unwanted” behaviors—scratching, sniffing, and moving around. If you present

food immediately after any one of these behaviors, the rat will likely repeat that rewarded behavior. But what if the rat presses the bar while you are distracted, and you delay giving the reinforcer? If the delay lasts longer than about 30 seconds, the rat will not learn to press the bar. You will have reinforced other incidental behaviors—more sniffing and moving—that intervened after the bar press.

Unlike rats, humans do respond to delayed reinforcers: the paycheck at the end of the week, the good grade at the end of the term, the trophy at the end of the season. Indeed, to function effectively we must learn to delay gratification. In laboratory testing, some 4-year-olds show this ability. In choosing a candy, they prefer having a big one tomorrow to munching on a small one right now. Learning to control our impulses in order to achieve more valued rewards is a big step toward maturity (Logue, 1998a,b). No wonder children who make such choices have tended to become socially competent and high-achieving adults (Mischel et al., 1989).

To our detriment, small but immediate consequences (the enjoyment of late-night videos or texting, for example) are sometimes more alluring than big but delayed consequences (feeling alert tomorrow). For many teens, the immediate gratification of risky, unprotected sex in passionate moments prevails over the delayed gratifications of safe sex or saved sex. And for many people, the immediate rewards of today's gas-guzzling vehicles, air travel, and air conditioning prevail over the bigger future consequences of global climate change, rising seas, and extreme weather.

“Oh, not bad. The light comes on, I press the bar, they write me a check. How about you?”

Reinforcement Schedules

27-3 How do different reinforcement schedules affect behavior?

In most of our examples, the desired response has been reinforced every time it occurs. But **reinforcement schedules** vary. With **continuous reinforcement**, learning occurs rapidly, which makes this the best choice for mastering a behavior. But extinction also occurs rapidly. When reinforcement stops—when we stop delivering food after the rat presses the bar—the behavior soon stops. If a normally dependable candy machine fails to deliver a chocolate bar twice in a row, we stop putting money into it (although a week later we may exhibit spontaneous recovery by trying again).

Real life rarely provides continuous reinforcement. Salespeople do not make a sale with every pitch. But they persist because their efforts are occasionally rewarded. This persistence is typical with **partial (intermittent) reinforcement** schedules, in which responses are sometimes reinforced, sometimes not. Learning is slower to appear, but *resistance to extinction* is greater than with continuous reinforcement. Imagine a pigeon that has learned to peck a key to obtain food. If you gradually phase out the food delivery until it occurs only rarely, in no predictable pattern, the pigeon may peck 150,000 times without a reward (Skinner, 1953). Gambling machines and lottery tickets reward gamblers in much the same way—occasionally and unpredictably. And like pigeons, slot players keep trying, time and time again. With intermittent reinforcement, hope springs eternal.

Lesson for child caregivers: Partial reinforcement also works with children. *Occasionally* giving in to children's tantrums for the sake of peace and quiet intermittently reinforces the tantrums. This is the very best procedure for making a behavior persist.

Skinner (1961) and his collaborators compared four schedules of partial reinforcement. Some are rigidly fixed, some unpredictably variable.

Fixed-ratio schedules reinforce behavior after a set number of responses. Coffee shops may reward us with a free drink after every 10 purchased. In the laboratory, rats may be reinforced on a fixed ratio of, say, one food pellet for every 30 responses. Once conditioned, animals will pause only briefly after a reinforcer before returning to a high rate of responding (**FIGURE 27.3** on the next page).

reinforcement schedule

a pattern that defines how often a desired response will be reinforced.

continuous reinforcement

reinforcing the desired response every time it occurs.

partial (intermittent)

reinforcement reinforcing a response only part of the time; results in slower acquisition of a response but much greater resistance to extinction than does continuous reinforcement.

fixed-ratio schedule in operant conditioning, a reinforcement schedule that reinforces a response only after a specified number of responses.

“The charm of fishing is that it is the pursuit of what is elusive but attainable, a perpetual series of occasions for hope.” -SCOTTISH AUTHOR JOHN BUCHAN (1875–1940)

Figure 27.3**Intermittent reinforcement schedules**

Skinner's laboratory pigeons produced these response patterns to each of four reinforcement schedules. (Reinforcers are indicated by diagonal marks.) For people, as for pigeons, reinforcement linked to number of responses (a *ratio schedule*) produces a higher response rate than reinforcement linked to amount of time elapsed (an *interval schedule*). But the predictability of the reward also matters. An unpredictable (*variable*) schedule produces more consistent responding than does a predictable (*fixed*) schedule.

Vitaly Titov & Maria Sidelnikova/Shutterstock

**AP® Exam Tip**

The word “interval” in schedules of reinforcement means that an interval of time must pass before reinforcement. There is nothing the learner can do to shorten the interval. The word “ratio” refers to the ratio of responses to reinforcements. If the learner responds with greater frequency, there will be more reinforcements.

Variable-ratio schedules provide reinforcers after a seemingly unpredictable number of responses. This is what slot-machine players and fly-casting anglers experience—unpredictable reinforcement—and what makes gambling and fly fishing so hard to extinguish even when both are getting nothing for something. Because reinforcers increase as the number of responses increases, variable-ratio schedules produce high rates of responding.

Fixed-interval schedules reinforce the first response after a fixed time period. Animals on this type of schedule tend to respond more frequently as the anticipated time for reward draws near. People check more frequently for the mail as the delivery time approaches. A hungry child jiggles the Jell-O more often to see if it has set. Pigeons peck keys more rapidly as the time for reinforcement draws nearer. This produces a choppy stop-start pattern rather than a steady rate of response (see Figure 27.3).

Variable-interval schedules reinforce the first response after *varying* time intervals. Like the longed-for responses that finally reward persistence in rechecking e-mail or Facebook, variable-interval schedules tend to produce slow, steady responding. This makes sense, because there is no knowing when the waiting will be over (**TABLE 27.2**).

In general, response rates are higher when reinforcement is linked to the number of responses (a ratio schedule) rather than to time (an interval schedule). But responding is more consistent when reinforcement is unpredictable (a variable schedule) than when it is predictable (a fixed schedule). Animal behaviors differ, yet Skinner (1956) contended

variable-ratio schedule

in operant conditioning, a reinforcement schedule that reinforces a response after an unpredictable number of responses.

fixed-interval schedule

in operant conditioning, a reinforcement schedule that reinforces a response only after a specified time has elapsed.

variable-interval schedule

in operant conditioning, a reinforcement schedule that reinforces a response at unpredictable time intervals.

Table 27.2 Schedules of Reinforcement

	Fixed	Variable
<i>Ratio</i>	<i>Every so many:</i> reinforcement after every <i>n</i> th behavior, such as buy 10 coffees, get 1 free, or pay per product unit produced	<i>After an unpredictable number:</i> reinforcement after a random number of behaviors, as when playing slot machines or fly casting
<i>Interval</i>	<i>Every so often:</i> reinforcement for behavior after a fixed time, such as Tuesday discount prices	<i>Unpredictably often:</i> reinforcement for behavior after a random amount of time, as in checking for a Facebook response

that the reinforcement principles of operant conditioning are universal. It matters little, he said, what response, what reinforcer, or what species you use. The effect of a given reinforcement schedule is pretty much the same: “Pigeon, rat, monkey, which is which? It doesn’t matter. . . . Behavior shows astonishingly similar properties.”

Punishment

27-4 How does punishment differ from negative reinforcement, and how does punishment affect behavior?

Reinforcement increases a behavior; **punishment** does the opposite. A *punisher* is any consequence that *decreases* the frequency of a preceding behavior (**TABLE 27.3**). Swift and sure punishers can powerfully restrain unwanted behavior. The rat that is shocked after touching a forbidden object and the child who is burned by touching a hot stove will learn not to repeat those behaviors. A dog that has learned to come running at the sound of an electric can opener will stop coming if its owner runs the machine to attract the dog and banish it to the basement.

Table 27.3 Ways to Decrease Behavior

Type of Punisher	Description	Examples
<i>Positive punishment</i>	Administer an aversive stimulus	Spray water on a barking dog; give a traffic ticket for speeding
<i>Negative punishment</i>	Withdraw a rewarding stimulus	Take away a teen’s driving privileges; revoke a library card for nonpayment of fines

Criminal behavior, much of it impulsive, is also influenced more by swift and sure punishers than by the threat of severe sentences (Darley & Alter, 2011). Thus, when Arizona introduced an exceptionally harsh sentence for first-time drunk drivers, the drunk-driving rate changed very little. But when Kansas City police started patrolling a high crime area to increase the sureness and swiftness of punishment, that city’s crime rate dropped dramatically.

How should we interpret the punishment studies in relation to parenting practices? Many psychologists and supporters of nonviolent parenting note four major drawbacks of physical punishment (Gershoff, 2002; Marshall, 2002).

1. *Punished behavior is suppressed, not forgotten. This temporary state may (negatively) reinforce parents’ punishing behavior.* The child swears, the parent swats, the parent hears no more swearing and feels the punishment successfully stopped the behavior. No wonder spanking is a hit with so many U.S. parents of 3- and 4-year-olds—more than 9 in 10 of whom acknowledged spanking their children (Kazdin & Benjet, 2003).
2. *Punishment teaches discrimination among situations.* In operant conditioning, *discrimination* occurs when an organism learns that certain responses, but not others, will be reinforced. Did the punishment effectively end the child’s swearing? Or did the child simply learn that it’s not okay to swear around the house, though okay elsewhere?
3. *Punishment can teach fear.* In operant conditioning, *generalization* occurs when an organism’s response to similar stimuli is also reinforced. A punished child may associate fear not only with the undesirable behavior but also with the person who delivered the punishment or the place it occurred. Thus, children may learn to fear a punishing teacher and try to avoid school, or may become more anxious (Gershoff et al., 2010). For such reasons, most European countries and most U.S. states now ban

Try This

Telemarketers are reinforced by which schedule? People checking the oven to see if the cookies are done are on which schedule? Airline frequent-flyer programs that offer a free flight after every 25,000 miles of travel use which reinforcement schedule?

ANSWERS: Telemarketers are reinforced on a variable-ratio schedule (after varying numbers of rings). Cookie checkers are reinforced on a fixed-interval schedule. Frequent-flyer programs use a fixed-ratio schedule.

AP® Exam Tip

Remember that *any kind of reinforcement* (positive, negative, primary, conditioned, immediate, delayed, continuous, or partial) encourages the behavior. *Any kind of punishment* discourages the behavior. Positive and negative do not refer to values—it’s not that positive reinforcement (or punishment) is the good kind and negative is the bad. Think of positive and negative mathematically; a stimulus is added with positive reinforcement (or punishment) and a stimulus is subtracted with negative reinforcement (or punishment).

punishment an event that tends to decrease the behavior that it follows.

David Strickler/The Image Works

Children see, children do?

Children who often experience physical punishment tend to display more aggression.

B. F. Skinner “I am sometimes asked, ‘Do you think of yourself as you think of the organisms you study?’ The answer is yes. So far as I know, my behavior at any given moment has been nothing more than the product of my genetic endowment, my personal history, and the current setting” (1983).

hitting children in schools and child-care institutions (www.stophitting.com). Thirty-three countries, including those in Scandinavia, further outlaw hitting by parents, providing children the same legal protection given to spouses.

4. *Physical punishment may increase aggression by modeling aggression as a way to cope with problems.* Studies find that spanked children are at increased risk for aggression (and depression and low self-esteem). We know, for example, that many aggressive delinquents and abusive parents come from abusive families (Straus & Gelles, 1980; Straus et al., 1997).

Some researchers note a problem. Well, *yes*, they say, physically punished children may be more aggressive, for the same reason that people who have undergone psychotherapy are more likely to suffer depression—because they had preexisting problems that triggered the treatments (Larzelere, 2000, 2004). Which is the chicken and which is the egg? Correlations don’t hand us an answer.

If one adjusts for preexisting antisocial behavior, then an occasional single swat or two to misbehaving 2- to 6-year-olds looks more effective (Baumrind et al., 2002; Larzelere & Kuhn, 2005). That is especially so if two other conditions are met:

1. The swat is used only as a backup when milder disciplinary tactics, such as a time-out (removing them from reinforcing surroundings), fail.
2. The swat is combined with a generous dose of reasoning and reinforcing.

Other researchers remain unconvinced. After controlling for prior misbehavior, they report that more frequent spankings of young children predict future aggressiveness (Grogan-Kaylor, 2004; Taylor et al., 2010).

Parents of delinquent youths are often unaware of how to achieve desirable behaviors without screaming at or hitting their children (Patterson et al., 1982). Training programs can help transform dire threats (“Apologize right now or I’m taking that cell phone away!”) into positive incentives (“You’re welcome to have your phone back when you apologize.”). Stop and think about it. Aren’t many threats of punishment just as forceful, and perhaps more effective, when rephrased positively? Thus, “If you don’t get your homework done, I’m not giving you money for a movie!” would better be phrased as . . .

In classrooms, too, teachers can give feedback on papers by saying, “No, but try this . . .” and “Yes, that’s it!” Such responses reduce unwanted behavior while reinforcing more desirable alternatives. Remember: *Punishment tells you what not to do; reinforcement tells you what to do.*

What punishment often teaches, said Skinner, is how to avoid it. Most psychologists now favor an emphasis on reinforcement.

Skinner’s Legacy

27-5 Why did Skinner’s ideas provoke controversy?

B. F. Skinner stirred a hornet’s nest with his outspoken beliefs. He repeatedly insisted that external influences (not internal thoughts and feelings) shape behavior. And he urged people to use operant principles to influence others’ behavior at school, work, and home. Knowing that behavior is shaped by its results, he said we should use rewards to evoke more desirable behavior.

Skinner’s critics objected, saying that he dehumanized people by neglecting their personal freedom and by seeking to control their actions. Skinner’s reply: External consequences already haphazardly control people’s behavior. Why not administer those consequences toward human betterment? Wouldn’t reinforcers be more humane than the punishments used in homes, schools, and prisons? And if it is humbling to think that our history has shaped us, doesn’t this very idea also give us hope that we can shape our future?

Before You Move On

▶ ASK YOURSELF

Does your social media behavior (such as checking for new messages) make sense now that you've learned about the different kinds of reinforcement schedules?

▶ TEST YOURSELF

Fill in the three blanks below with one of the following terms: negative reinforcement (NR), positive punishment (PP), and negative punishment (NP). The first answer, positive reinforcement (PR) is provided for you.

Type of Stimulus	Give It	Take It Away
Desired (for example, a teen's use of the car):	1. PR	2.
Undesired/aversive (for example, an insult):	3.	4.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 27 Review

27-1

What is operant conditioning, and how is operant behavior reinforced and shaped?

- In *operant conditioning*, behaviors followed by reinforcers increase; those followed by punishers often decrease.
- Expanding on Edward Thorndike's *law of effect*, B. F. Skinner and others found that the behavior of rats or pigeons placed in an *operant chamber* (Skinner box) can be *shaped* by using reinforcers to guide closer and closer approximations of the desired behavior.

27-2

How do positive and negative reinforcement differ, and what are the basic types of reinforcers?

- *Reinforcement* is any consequence that strengthens behavior. *Positive reinforcement* adds a desirable stimulus to increase the frequency of a behavior. *Negative reinforcement* removes an aversive stimulus to increase the frequency of a behavior.
- *Primary reinforcers* (such as receiving food when hungry or having nausea end during an illness) are innately satisfying—no learning is required.
- *Conditioned* (or secondary) *reinforcers* (such as cash) are satisfying because we have learned to associate them with more basic rewards (such as the food or medicine we buy with them).
- Immediate reinforcers (such as a purchased treat) offer immediate payback; delayed reinforcers (such as a weekly paycheck) require the ability to delay gratification.

27-3 How do different reinforcement schedules affect behavior?

- A *reinforcement schedule* defines how often a response will be reinforced.
- In *continuous reinforcement* (reinforcing desired responses every time they occur), learning is rapid, but so is extinction if rewards cease. In *partial (intermittent) reinforcement* (reinforcing responses only sometimes), initial learning is slower, but the behavior is much more resistant to extinction.
- *Fixed-ratio schedules* reinforce behaviors after a set number of responses; *variable-ratio schedules*, after an unpredictable number.
- *Fixed-interval schedules* reinforce behaviors after set time periods; *variable-interval schedules*, after unpredictable time periods.

27-4 How does punishment differ from negative reinforcement, and how does punishment affect behavior?

- *Punishment* administers an undesirable consequence (such as spanking) or withdraws something desirable (such as taking away a favorite toy) in an attempt to decrease the frequency of a behavior (a child's disobedience).
- Negative reinforcement (taking an aspirin) removes an aversive stimulus (a headache). This desired consequence (freedom from pain) increases the likelihood that the behavior (taking aspirin to end pain) will be repeated.
- Punishment can have undesirable side effects, such as suppressing rather than changing unwanted behaviors; teaching aggression; creating fear; encouraging discrimination (so that the undesirable behavior appears when the punisher is not present); and fostering depression and low self-esteem.

27-5 Why did Skinner's ideas provoke controversy?

- Critics of Skinner's principles believed the approach dehumanized people by neglecting their personal freedom and seeking to control their actions. Skinner replied that people's actions are already controlled by external consequences, and that reinforcement is more humane than punishment as a means for controlling behavior.

Multiple-Choice Questions

1. What do we call the kind of learning in which behavior is strengthened if followed by a reinforcer?
 - a. Operant conditioning
 - b. Respondent behavior
 - c. Classical conditioning
 - d. Shaping
 - e. Punishment
2. Which of the following best describes a discriminative stimulus?
 - a. Something that elicits a response after association with a reinforcer
 - b. An innately reinforcing stimulus
 - c. Something that when removed increases the likelihood of the behavior
 - d. An event that decreases the behavior it follows
 - e. An amplified stimulus feeding back information to responses
3. Thorndike's principle that behaviors followed by favorable consequences become more likely is known as what?
 - a. Law of effect
 - b. Operant conditioning
 - c. Shaping
 - d. Respondent behavior
 - e. Discrimination
4. All of the following are examples of primary reinforcers except a
 - a. rat's food reward in a Skinner box.
 - b. cold drink on a hot day.
 - c. high score on an exam for which a student studied diligently.
 - d. hug from a loved one.
 - e. large meal following an extended time without food.

Practice FRQs

1. Mom is frustrated because 3-year-old Maya has started to spit frequently. She has decided to temporarily put away one of Maya's toys every time she spits. Mom is going to continue this until Maya has stopped spitting.
 - Explain whether Mom's plan uses reinforcement or punishment.
 - Explain whether Mom's plan is a positive or negative form of reinforcement or punishment.
2. A business owner is considering different compensation plans for her sales force. Identify what schedule of reinforcement is reflected in each of the following plans, making sure you explain why each answer is correct:
 - The owner will pay a \$1,500 bonus each time a hundred units are sold.
 - The owner will have a lottery each month. Each salesperson will get one lottery ticket for every one hundred units sold. The salesperson with the winning ticket will get \$5,000.
 - The owner will pay each salesperson a monthly salary that does not depend on units sold.

Answer

1 point: The plan uses punishment, because it is designed to reduce the frequency of spitting.

1 point: This is negative punishment because toys are being taken away from Maya.

Module 28

Operant Conditioning's Applications, and Comparison to Classical Conditioning

Module Learning Objectives

28-1

Identify some ways to apply operant conditioning principles at school, in sports, at work, at home, and for self-improvement.

28-2

Identify the characteristics that distinguish operant conditioning from classical conditioning.

Applications of Operant Conditioning

FYI

In later units we will see how psychologists apply operant conditioning principles to help people moderate high blood pressure or gain social skills.

28-1

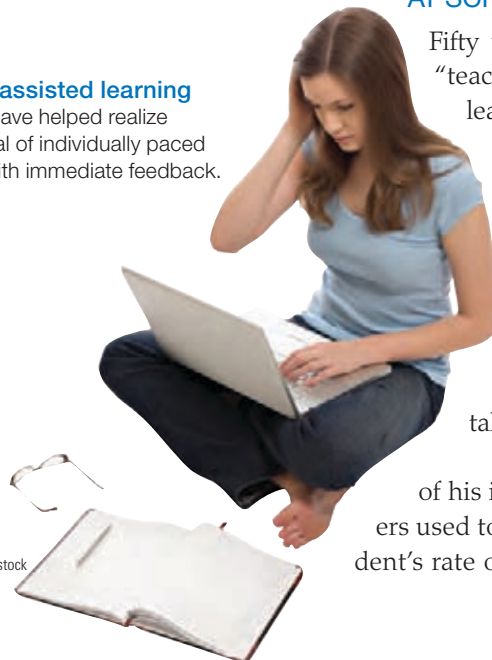

How might Skinner's operant conditioning principles be applied at school, in sports, at work, at home, and for self-improvement?

Would you like to apply operant conditioning principles to your own life—to be a healthier person, a more successful student, or a high-achieving athlete? Reinforcement technologies are at work in schools, sports, workplaces, and homes, and these principles can support our self-improvement as well (Flora, 2004).

AT SCHOOL

Computer-assisted learning

Computers have helped realize Skinner's goal of individually paced instruction with immediate feedback.

Christopher Halloran/Shutterstock

Fifty years ago, Skinner envisioned a day when “teaching machines and textbooks” would shape learning in small steps, immediately reinforcing correct responses. He believed that such machines and texts would revolutionize education and free teachers to focus on each student's special needs. “Good instruction demands two things,” Skinner said. “Students must be told immediately whether what they do is right or wrong and, when right, they must be directed to the step to be taken next.”

Skinner might be pleased to know that many of his ideals for education are now possible. Teachers used to find it difficult to pace material to each student's rate of learning, and to provide prompt feedback.

Electronic adaptive quizzing does both. Students move through quizzes at their own pace, according to their own level of understanding. And they get immediate feedback on their efforts.

IN SPORTS

The key to shaping behavior in athletic performance, as elsewhere, is first reinforcing small successes and then gradually increasing the challenge. Golf students can learn putting by starting with very short putts, and then, as they build mastery, eventually stepping back farther and farther. Novice batters can begin with half swings at an oversized ball pitched from 10 feet away, giving them the immediate pleasure of smacking the ball. As the hitters' confidence builds with their success and they achieve mastery at each level, the pitcher gradually moves back—to 15, then 22, 30, and 40.5 feet—and eventually introduces a standard baseball. Compared with children taught by conventional methods, those trained by this behavioral method have shown faster skill improvement (Simek & O'Brien, 1981, 1988).

In sports as in the laboratory, the accidental timing of rewards can produce *superstitious behaviors*. If a Skinner box food dispenser gives a pellet of food every 15 minutes, whatever the animal happened to be doing just before the food arrives (perhaps scratching itself) is more likely to be repeated and reinforced, which occasionally can produce a persistent superstitious behavior. Likewise, if a baseball or softball player gets a hit after tapping the plate with the bat, he or she may be more likely to do so again. Over time the player may experience partial reinforcement for what becomes a superstitious behavior.

AT WORK

Knowing that reinforcers influence productivity, many organizations have invited employees to share the risks and rewards of company ownership. Others focus on reinforcing a job well done. Rewards are most likely to increase productivity if the desired performance has been well defined and is achievable. The message for managers? *Reward specific, achievable behaviors, not vaguely defined "merit."*

Operant conditioning also reminds us that reinforcement should be *immediate*. IBM legend Thomas Watson understood. When he observed an achievement, he wrote the employee a check on the spot (Peters & Waterman, 1982). But rewards need not be material or lavish. An effective manager may simply walk the floor and sincerely affirm people for good work, or write notes of appreciation for a completed project. As Skinner said, "How much richer would the whole world be if the reinforcers in daily life were more effectively contingent on productive work?"

AT HOME

As we have seen, parents can learn from operant conditioning practices. Parent-training researchers remind us that by saying, "Get ready for bed" but caving in to protests or defiance, parents reinforce such whining and arguing (Wierson & Forehand, 1994). Exasperated, they may then yell or gesture menacingly. When the child, now frightened, obeys, that reinforces the parents' angry behavior. Over time, a destructive parent-child relationship develops.

AP® Exam Tip

Notice how useful operant conditioning is. People with an understanding of the principles of operant conditioning possess a tremendous tool for changing behavior. If you don't like the way your friends, teachers, coaches, or parents behave, pay attention to the uses of operant conditioning!

© The New Yorker Collection, 2001, Mick Stevens from cartoonbank.com. All Rights Reserved.

*"I wrote another five hundred words.
Can I have another cookie?"*

To disrupt this cycle, parents should remember that basic rule of shaping: *Notice people doing something right and affirm them for it.* Give children attention and other reinforcers when they are behaving *well*. Target a specific behavior, reward it, and watch it increase. When children misbehave or are defiant, don't yell at them or hit them. Simply explain the misbehavior and give them a time-out.

FOR SELF-IMPROVEMENT

Finally, we can use operant conditioning in our own lives (see Close-up:

Training Our Partners). To build up your *self-control*, you need to reinforce your own desired behaviors (perhaps to exercise more often) and extinguish the undesired ones (to stop texting while studying, for example). Psychologists suggest taking these steps:

1. *State your goal in measurable terms, and announce it.* You might, for example, aim to boost your study time by an hour a day and share that goal with some close friends.
2. *Monitor how often you engage in your desired behavior.* You might log your current study time, noting under what conditions you do and don't study. (When I began writing textbooks, I logged how I spent my time each day and was amazed to discover how much time I was wasting.)
3. *Reinforce the desired behavior.* To increase your study time, give yourself a reward (a snack or some activity you enjoy) only after you finish your extra hour of study. Agree with your friends that you will join them for weekend activities only if you have met your realistic weekly studying goal.

Close-up

Training Our Partners

For a book I was writing about a school for exotic animal trainers, I started commuting from Maine to California, where I spent my days watching students do the seemingly impossible: teaching hyenas to pirouette on command, cougars to offer their paws for a nail clipping, and baboons to skateboard.

I listened, rapt, as professional trainers explained how they taught dolphins to flip and elephants to paint. Eventually it hit me that the same techniques might work on that stubborn but lovable species, the American husband.

The central lesson I learned from exotic animal trainers is that I should reward behavior I like and ignore behavior I don't. After all, you don't get a sea lion to balance a ball on the end of its nose by nagging. The same goes for the American husband.

Back in Maine, I began thanking Scott if he threw one dirty shirt into the hamper. If he threw in two, I'd kiss him. Meanwhile, I would step over any soiled clothes on the floor without one sharp word, though I did sometimes kick them

under the bed. But as he basked in my appreciation, the piles became smaller.

I was using what trainers call "approximations," rewarding the small steps toward learning a whole new behavior. . . . Once I started thinking this way, I couldn't stop. At the school in California, I'd be scribbling notes on how to walk an emu or have a wolf accept you as a pack member, but I'd be thinking, "I can't wait to try this on Scott. . . ."

After two years of exotic animal training, my marriage is far smoother, my husband much easier to love. I used to take his faults personally; his dirty clothes on the floor were an affront, a symbol of how he didn't care enough about me. But thinking of my husband as an exotic species gave me the distance I needed to consider our differences more objectively.

Excerpted with permission from Sutherland, A., (2006, June 25). What Shamu taught me about a happy marriage, *New York Times*.

By Amy Sutherland

4. *Reduce the rewards gradually.* As your new behaviors become more habitual, give yourself a mental pat on the back instead of a cookie.

In addition, we can literally learn from ourselves. There is some evidence that when we have feedback about our bodily responses, we can sometimes change those responses. (See Close-up: Biofeedback.)

Close-up

Biofeedback

Knowing the damaging effects of stress, could we train people to counteract stress, bringing their heart rate and blood pressure under conscious control? When a few psychologists started experimenting with this idea, many of their colleagues thought them foolish. After all, these functions are controlled by the autonomic (“involuntary”) nervous system. Then, in the late 1960s, experiments by respected psychologists made the skeptics wonder. Neal Miller, for one, found that rats could modify their heartbeat if given pleasurable brain stimulation when their heartbeat increased or decreased. Later research revealed that some paralyzed humans could also learn to control their blood pressure (Miller & Brucker, 1979).

Miller was experimenting with **biofeedback**, a system of recording, amplifying, and feeding back information about

subtle physiological responses. Biofeedback instruments mirror the results of a person’s own efforts, thereby allowing the person to learn techniques for controlling a particular physiological response (**FIGURE 28.1**). After a decade of study, however, researchers decided the initial claims for biofeedback were overblown and oversold (Miller, 1985). A 1995 National Institutes of Health panel declared that biofeedback works best on tension headaches.

biofeedback a system for electronically recording, amplifying, and feeding back information regarding a subtle physiological state, such as blood pressure or muscle tension.

Figure 28.1 Biofeedback systems Biofeedback systems—such as this one, which records tension in the forehead muscle of a headache sufferer—allow people to monitor their subtle physiological responses. As this man relaxes his forehead muscle, the pointer on the display screen (or a tone) may go lower.

Contrasting Classical and Operant Conditioning

28-2 How does operant conditioning differ from classical conditioning?

Both classical and operant conditioning are forms of *associative learning*. Both involve *acquisition*, *extinction*, *spontaneous recovery*, *generalization*, and *discrimination*. But these two forms of learning also differ. Through classical (Pavlovian) conditioning, we associate different stimuli we do not control, and we respond automatically (**respondent behaviors**) (**TABLE 28.1** on the next page). Through operant conditioning, we associate our own behaviors that act on our environment to produce rewarding or punishing stimuli (**operant behaviors**) with their consequences.

As we will see next, our biology and cognitive processes influence both classical and operant conditioning.

respondent behavior behavior that occurs as an automatic response to some stimulus.

operant behavior behavior that operates on the environment, producing consequences.

“O! This learning, what a thing it is.” -WILLIAM SHAKESPEARE, *THE TAMING OF THE SHREW*, 1597

Table 28.1 Comparison of Classical and Operant Conditioning

	Classical Conditioning	Operant Conditioning
<i>Basic idea</i>	Organism associates events.	Organism associates behavior and resulting events.
<i>Response</i>	Involuntary, automatic.	Voluntary, operates on environment.
<i>Acquisition</i>	Associating events; NS is paired with US and becomes CS.	Associating response with a consequence (reinforcer or punisher).
<i>Extinction</i>	CR decreases when CS is repeatedly presented alone.	Responding decreases when reinforcement stops.
<i>Spontaneous recovery</i>	The reappearance, after a rest period, of an extinguished CR.	The reappearance, after a rest period, of an extinguished response.
<i>Generalization</i>	The tendency to respond to stimuli similar to the CS.	Organism's response to similar stimuli is also reinforced.
<i>Discrimination</i>	The learned ability to distinguish between a CS and other stimuli that do not signal a US.	Organism learns that certain responses, but not others, will be reinforced.

Before You Move On

▶ ASK YOURSELF

Can you recall a time when a teacher, coach, family member, or employer helped you learn something by shaping your behavior in little steps until you achieved your goal?

▶ TEST YOURSELF

Salivating in response to a tone paired with food is a(n) _____ behavior; pressing a bar to obtain food is a(n) _____ behavior.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 28 Review

28-1

How might Skinner's operant conditioning principles be applied at school, in sports, at work, at home, and for self-improvement?

- At school, teachers can use shaping techniques to guide students' behaviors, and they can use electronic adaptive quizzing to provide immediate feedback.
- In sports, coaches can build players' skills and self-confidence by rewarding small improvements.
- At work, managers can boost productivity and morale by rewarding well-defined and achievable behaviors.
- At home, parents can reward desired behaviors but not undesirable ones.
- We can shape our own behaviors by stating our goals, monitoring the frequency of desired behaviors, reinforcing desired behaviors, and gradually reducing rewards as behaviors become habitual.

28-2

How does operant conditioning differ from classical conditioning?

- In operant conditioning, an organism learns associations between its own behavior and resulting events; this form of conditioning involves *operant behavior* (behavior that operates on the environment, producing rewarding or punishing consequences).
- In classical conditioning, the organism forms associations between stimuli—events it does not control; this form of conditioning involves *respondent behavior* (automatic responses to some stimulus).

Multiple-Choice Questions

1. What do we call it when the CR decreases as the CS is repeatedly presented alone?
 - a. Generalization
 - b. Discrimination
 - c. Spontaneous recovery
 - d. Extinction
 - e. Acquisition
2. The basic idea behind classical conditioning is that the organism
 - a. associates events.
 - b. associates behavior and resulting events.
 - c. voluntarily operates on the environment.
 - d. associates response with a consequence.
 - e. quits responding when reward stops.
3. What do we call the reappearance, after a rest period, of an extinguished response?
 - a. Acquisition
 - b. Spontaneous recovery
 - c. Discrimination
 - d. Operant conditioning
 - e. Classical conditioning
4. What do we call behavior that occurs as an automatic response to some stimulus?
 - a. Respondent behavior
 - b. Operant behavior
 - c. Extinguished behavior
 - d. Biofeedback conditioning
 - e. Skinnerian conditioning
5. Superstitious behavior can be produced by
 - a. careful manipulation of a classical conditioning experiment.
 - b. the accidental timing of rewards.
 - c. possession of a large number of traditionally lucky items.
 - d. cognitive awareness of superstitious behavior in others.
 - e. the change in a reinforcement schedule from ratio to interval.

Practice FRQs

1. Explain two differences between classical and operant conditioning.

Answer

Any two differences described in Table 28.1 can be used to answer. Examples include:

1 point: Classical conditioning involves involuntary responses, but operant conditioning involves voluntary responses.

1 point: In classical conditioning, the learner associates two events (a conditioned stimulus with an unconditioned stimulus). In operant conditioning, the learner associates a behavior with a consequence.

2. Raud is planning to use operant conditioning to help him reach his self-improvement goal of running in his community's 10-kilometer race in July. Explain four things Raud should include in his self-improvement plan.

(4 points)

Module 29

Biology, Cognition, and Learning

Module Learning Objectives

- 29-1** Explain how biological constraints affect classical and operant conditioning.
- 29-2** Explain how cognitive processes affect classical and operant conditioning.
- 29-3** Identify the two ways that people learn to cope with personal problems.
- 29-4** Describe how a perceived lack of control can affect people's behavior and health.

AP® Exam Tip

In the middle of the twentieth century, behaviorism was the dominant perspective in psychology, with little attention paid to the influence of biology and cognition in learning. Now we know better. As you read through this module, notice how important biological and cognitive factors are for understanding learning.

From drooling dogs, running rats, and pecking pigeons we have learned much about the basic processes of learning. But conditioning principles don't tell us the whole story. Today's learning theorists recognize that learning is the product of the interaction of biological, psychological, and social-cultural influences (**FIGURE 29.1**).

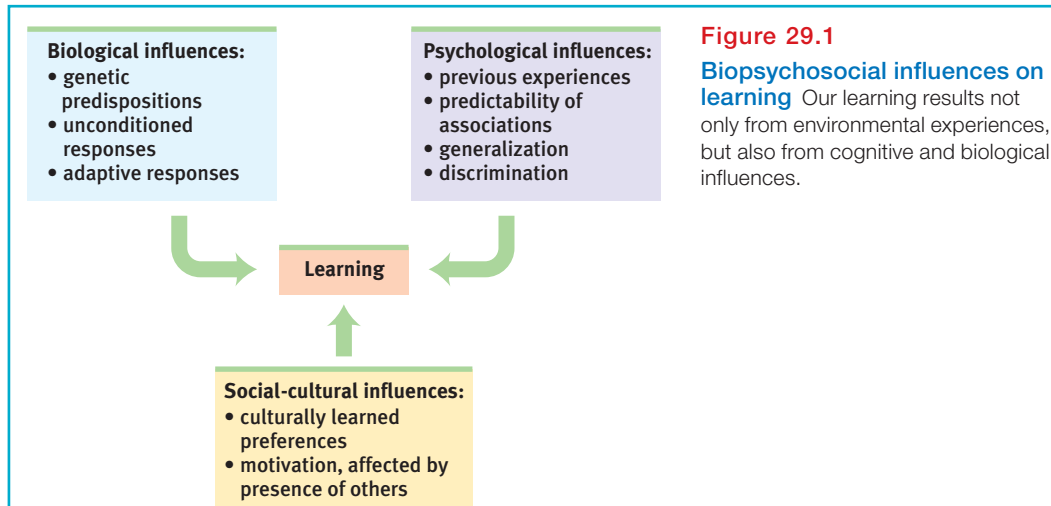

Biological Constraints on Conditioning

- 29-1** How do biological constraints affect classical and operant conditioning?

Ever since Charles Darwin, scientists have assumed that all animals share a common evolutionary history and thus share commonalities in their makeup and functioning. Pavlov and Watson, for example, believed the basic laws of learning were essentially similar in all animals. So it should make little difference whether one studied pigeons or people. Moreover, it seemed that any natural response could be conditioned to any neutral stimulus.

Limits on Classical Conditioning

In 1956, learning researcher Gregory Kimble proclaimed, "Just about any activity of which the organism is capable can be conditioned and . . . these responses can be conditioned to any stimulus that the organism can perceive" (p. 195). Twenty-five years later, he humbly acknowledged that "half a thousand" scientific reports had proven him wrong (Kimble, 1981). More than the early behaviorists realized, an animal's capacity for conditioning is constrained by its biology. Each species' predispositions prepare it to learn the associations that enhance its survival. Environments are not the whole story.

**Figure 29.1**

Biopsychosocial influences on learning Our learning results not only from environmental experiences, but also from cognitive and biological influences.

John Garcia As the laboring son of California farmworkers, Garcia attended school only in the off-season during his early childhood years. After entering junior college in his late twenties, and earning his Ph.D. in his late forties, he received the American Psychological Association's Distinguished Scientific Contribution Award "for his highly original, pioneering research in conditioning and learning." He was also elected to the National Academy of Sciences.

John Garcia was among those who challenged the prevailing idea that all associations can be learned equally well. While researching the effects of radiation on laboratory animals, Garcia and Robert Koelling (1966) noticed that rats began to avoid drinking water from the plastic bottles in radiation chambers. Could classical conditioning be the culprit? Might the rats have linked the plastic-tasting water (a CS) to the sickness (UR) triggered by the radiation (US)?

To test their hunch, Garcia and Koelling exposed the rats to a particular taste, sight, or sound (CS) and later also to radiation or drugs (US) that led to nausea and vomiting (UR). Two startling findings emerged: First, even if sickened as late as several hours after tasting a particular novel flavor, the rats thereafter avoided that flavor. This appeared to violate the notion that for conditioning to occur, the US must immediately follow the CS.

Second, the sickened rats developed aversions to tastes but not to sights or sounds. This contradicted the behaviorists' idea that any perceivable stimulus could serve as a CS. But it made adaptive sense. For rats, the easiest way to identify tainted food is to taste it; if sickened after sampling a new food, they thereafter avoid it. This response, called *taste aversion*, makes it difficult to eradicate a population of "bait-shy" rats by poisoning.

Humans, too, seem biologically prepared to learn some associations rather than others. If you become violently ill four hours after eating contaminated seafood, you will probably develop an aversion to the taste of seafood but usually not to the sight of the associated restaurant, its plates, the people you were with, or the music you heard there. (In contrast, birds, which hunt by sight, appear biologically primed to develop aversions to the *sight* of tainted food [Nicolaus et al., 1983].)

Garcia's early findings on taste aversion were met with an onslaught of criticism. As the German philosopher Arthur Schopenhauer (1788–1860) once said, important ideas are first ridiculed, then attacked, and finally taken for granted. Leading journals refused to publish Garcia's work: The findings are impossible, said some critics. But, as often happens in science, Garcia and Koelling's taste-aversion research is now basic textbook material.

BSIP SA / Alamy

Taste aversion If you became violently ill after eating oysters, you probably would have a hard time eating them again. Their smell and taste would have become a CS for nausea. This learning occurs readily because our biology prepares us to learn taste aversions to toxic foods.

It is also a good example of experiments that begin with the discomfort of some laboratory animals and end by enhancing the welfare of many others. In one conditioned taste-aversion study, coyotes and wolves were tempted into eating sheep carcasses laced with a sickening poison. Thereafter, they developed an aversion to sheep meat; two wolves later penned with a live sheep seemed actually to fear it (Gustavson et al., 1974, 1976). These studies not only saved the sheep from their predators, but also saved the sheep-shunning coyotes and wolves from angry ranchers and farmers who had wanted to destroy them. Similar applications have prevented baboons from raiding African gardens, raccoons from attacking chickens, and ravens and crows from feeding on crane eggs. In all these cases, research helped preserve both the prey and their predators, who occupy an important ecological niche (Dingfelder, 2010; Garcia & Gustavson, 1997).

Such research supports Darwin's principle that natural selection favors traits that aid survival. Our ancestors who readily learned taste aversions were unlikely to eat the same toxic food again and were more likely to survive and leave descendants. Nausea, like anxiety, pain, and other bad feelings, serves a good purpose. Like a low-oil warning on a car dashboard, each alerts the body to a threat (Neese, 1991).

And remember those Japanese quail that were conditioned to get excited by a red light that signaled a receptive female's arrival? Michael Domjan and his colleagues (2004) report that such conditioning is even speedier, stronger, and more durable when the CS is *ecologically relevant*—something similar to stimuli associated with sexual activity in the natural environment, such as the stuffed head of a female quail. In the real world, observes Domjan (2005), conditioned stimuli have a natural association with the unconditioned stimuli they predict.

The tendency to learn behaviors favored by natural selection may help explain why we humans seem to be naturally disposed to learn associations between the color red and sexuality. Female primates display red when nearing ovulation. In human females, enhanced bloodflow produces the red blush of flirtation and sexual excitation. Does the frequent pairing of red and sex—with Valentine's hearts, red-light districts, and red lipstick—naturally enhance men's attraction to women? Experiments (**FIGURE 29.2**) suggest that, without men's awareness, it does (Elliot & Niesta, 2008). In follow-up studies, men who viewed a supposed female conversation partner in a red rather than green shirt chose to sit closer to where they expected her to sit and to ask her more intimate questions (Kayser et al., 2010).

And it's not just men: Women tend to perceive men as more attractive when seen on a red background or in red clothing (Elliot et al., 2010).

"All animals are on a voyage through time, navigating toward futures that promote their survival and away from futures that threaten it. Pleasure and pain are the stars by which they steer." -PSYCHOLOGISTS DANIEL T. GILBERT AND TIMOTHY D. WILSON, "PROSPECTION: EXPERIENCING THE FUTURE," 2007

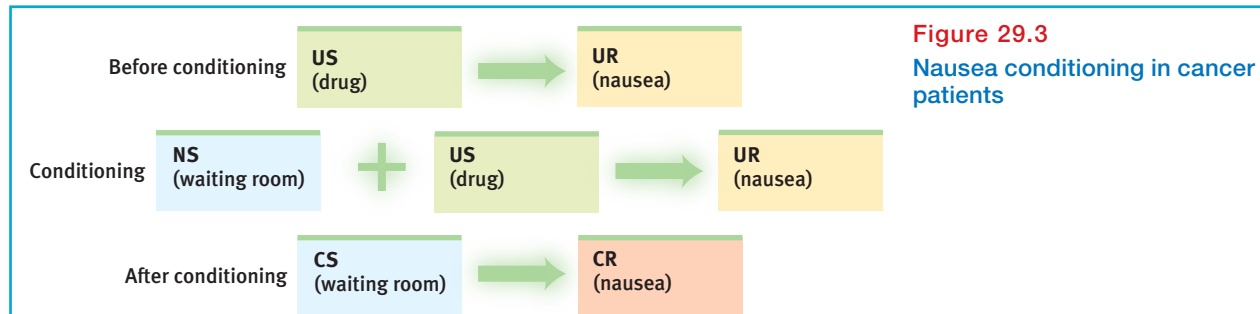

Animal taste aversion As an alternative to killing wolves and coyotes that preyed on sheep, some ranchers have sickened the animals with lamb laced with a drug.

Figure 29.2

Romantic red In a series of experiments that controlled for other factors (such as the brightness of the image), men found women more attractive and sexually desirable when framed in red (Elliot & Niesta, 2008).

Both images Kathryn Brownson, Hope College

A genetic predisposition to associate a CS with a US that follows predictably and immediately is adaptive: Causes often immediately precede effects. Often, but not always, as we saw in the taste-aversion findings. At such times, our predispositions can trick us. When chemotherapy triggers nausea and vomiting more than an hour following treatment, cancer patients may over time develop classically conditioned nausea (and sometimes anxiety) to the sights, sounds, and smells associated with the clinic (**FIGURE 29.3**) (Hall, 1997). Merely returning to the clinic's waiting room or seeing the nurses can provoke these conditioned feelings (Burish & Carey, 1986; Davey, 1992). Under normal circumstances, such revulsion to sickening stimuli would be adaptive.

"Once bitten, twice shy." -G. F. NORTHALL, *FOLK-PHRASES*, 1894

Limits on Operant Conditioning

As with classical conditioning, nature sets limits on each species' capacity for operant conditioning. Mark Twain (1835–1910) said it well: "Never try to teach a pig to sing. It wastes your time and annoys the pig."

We most easily learn and retain behaviors that reflect our biological predispositions. Thus, using food as a reinforcer, you could easily condition a hamster to dig or to rear up, because these are among the animal's natural food-searching behaviors. But you won't be so successful if you use food as a reinforcer to shape face washing and other hamster behaviors that aren't normally associated with food or hunger (Shettleworth, 1973). Similarly, you could easily teach pigeons to flap their wings to avoid being shocked, and to peck to obtain food: Fleeing with their wings and eating with their beaks are natural pigeon behaviors. However, pigeons would have a hard time learning to peck to avoid a shock, or to flap their wings to obtain food (Foree & LoLordo, 1973). The principle: *Biological constraints predispose organisms to learn associations that are naturally adaptive.*

In the early 1940s, University of Minnesota graduate students Marian Breland and Keller Breland witnessed the power of operant conditioning (1961; Bailey & Gillaspay, 2005). Their mentor was B. F. Skinner. Impressed with his results, they began training dogs, cats, chickens, parakeets, turkeys, pigs, ducks, and hamsters. The rest is history. The company they formed spent the next half-century training more than 15,000 animals from 140 species for movies, traveling shows, amusement parks, corporations, and the government. And along the way, the Brelands themselves mentored others, including Sea World's first director of training.

In their early training days, the Brelands presumed that operant principles would work on almost any response an animal could make. But along the way, they too learned about biological constraints. In one act, pigs trained to pick up large wooden "dollars" and deposit them in a piggy bank began to drift back

Natural athletes Animals can most easily learn and retain behaviors that draw on their biological predispositions, such as horses' inborn ability to move around obstacles with speed and agility.

FYI

For more information on animal behavior, see books by (I am not making this up) Robin Fox and Lionel Tiger.

to their natural ways. They dropped the coin, pushed it with their snouts as pigs are prone to do, picked it up again, and then repeated the sequence—delaying their food reinforcer. This *instinctive drift* occurred as the animals reverted to their biologically predisposed patterns.

Cognition's Influence on Conditioning

29-2

How do cognitive processes affect classical and operant conditioning?

Cognitive Processes and Classical Conditioning

In their dismissal of “mentalistic” concepts such as consciousness, Pavlov and Watson underestimated the importance not only of biological constraints on an organism’s learning capacity, but also the effects of cognitive processes (thoughts, perceptions, expectations). The early behaviorists believed that rats’ and dogs’ learned behaviors could be reduced to mindless mechanisms, so there was no need to consider cognition. But Robert Rescorla and Allan Wagner (1972) showed that an animal can learn the *predictability* of an event. If a shock always is preceded by a tone, and then may also be preceded by a light that accompanies the tone, a rat will react with fear to the tone but not to the light. Although the light is always followed by the shock, it adds no new information; the tone is a better predictor. The more predictable the association, the stronger the conditioned response. It’s as if the animal learns an *expectancy*, an awareness of how likely it is that the US will occur.

Associations can influence attitudes (Hofmann et al., 2010). When British children viewed novel cartoon characters alongside either ice cream (*Yum!*) or brussels sprouts (*Yuck!*), they came to like best the ice-cream-associated characters (Field, 2006). Other researchers have classically conditioned adults’ attitudes, using little-known Pokémon characters (Olson & Fazio, 2001). The participants, playing the role of a security guard monitoring a video screen, viewed a stream of words, images, and Pokémon characters. Their task, they were told, was to respond to one target Pokémon character by pressing a button. Unnoticed by the participants, when two other Pokémon characters appeared on the screen, one was consistently associated with various positive words and images (such as *awesome* or a hot fudge sundae); the other appeared with negative words and images (such as *awful* or a cockroach). Without any conscious memory for the pairings, the participants formed more gut-level liking for the characters associated with the positive stimuli.

Follow-up studies indicate that conditioned likes and dislikes are even stronger when people notice and are aware of the associations they have learned (Shanks, 2010). Cognition matters.

Such experiments help explain why classical conditioning treatments that ignore cognition often have limited success. For example, people receiving therapy for alcohol use disorder may be given alcohol spiked with a nauseating drug. Will they then associate alcohol with sickness? If classical conditioning were merely a matter of “stamping in” stimulus associations, we might hope so, and to some extent this does occur (as we will see in Module 71). However, one’s awareness that the nausea is induced by the drug, not the alcohol, often weakens the association between drinking alcohol and feeling sick. So, even in classical conditioning, it is (especially with humans) not simply the CS-US association but also the thought that counts.

Cognitive Processes and Operant Conditioning

B. F. Skinner acknowledged the biological underpinnings of behavior and the existence of private thought processes. Nevertheless, many psychologists criticized him for discounting the importance of these influences.

“All brains are, in essence, anticipation machines.” -DANIEL C. DENNETT, *CONSCIOUSNESS EXPLAINED*, 1991

A mere eight days before dying of leukemia in 1990, Skinner stood before the American Psychological Association convention. In this final address, he again resisted the growing belief that cognitive processes (thoughts, perceptions, expectations) have a necessary place in the science of psychology and even in our understanding of conditioning. He viewed “cognitive science” as a throwback to early twentieth-century introspectionism. For Skinner, thoughts and emotions were behaviors that follow the same laws as other behaviors.

Nevertheless, the evidence of cognitive processes cannot be ignored. For example, animals on a fixed-interval reinforcement schedule respond more and more frequently as the time approaches when a response will produce a reinforcer. Although a strict behaviorist would object to talk of “expectations,” the animals behave as if they expected that repeating the response would soon produce the reward.

LATENT LEARNING

Evidence of cognitive processes has also come from studying rats in mazes, including classic studies by Edward Chase Tolman (1886–1959) and C. H. Honzik that were done in Skinner’s youth. Rats exploring a maze, given no obvious rewards, seem to develop a **cognitive map**, a mental representation of the maze, much like your mental map of your school. This map, and the rats’ learning, is not demonstrated until the experimenter places food in the maze’s goal box, which motivates the rats to run the maze at least as quickly and efficiently as other rats that were previously reinforced with food for this result (Tolman & Honzik, 1930).

Like people sightseeing in a new town, the exploring rats seemingly experienced **latent learning** during their earlier tours. That learning became apparent only when there was some incentive to demonstrate it. Children, too, may learn from watching a parent but demonstrate the learning only much later, as needed. The point to remember: *There is more to learning than associating a response with a consequence; there is also cognition.* In Unit VII we will encounter more striking evidence of cognitive abilities in solving problems and in using language.

INSIGHT LEARNING

Some learning occurs after little or no systematic interaction with our environment. For example, we may puzzle over a problem, and suddenly, the pieces fall together as we perceive the solution in a sudden flash of **insight**—an abrupt, true-seeming, and often satisfying solution (Topolinski & Reber, 2010). Ten-year-old Johnny Appleton’s insight solved a problem that had stumped construction workers: how to rescue a young robin that had fallen into a narrow 30-inch-deep hole in a cement-block wall. Johnny’s solution: Slowly pour in sand, giving the bird enough time to keep its feet on top of the constantly rising pile (Ruchlis, 1990).

INTRINSIC MOTIVATION

The cognitive perspective has also shown us the limits of rewards: Promising people a reward for a task they already enjoy can backfire. Excessive rewards can destroy **intrinsic motivation**—the desire to perform a behavior effectively for its own sake. In experiments, children have been promised a payoff for playing with an interesting puzzle or toy. Later, they played with the toy *less* than other unpaid children did (Deci et al., 1999; Tang & Hall, 1995). Likewise, rewarding children with toys or candy for reading diminishes the time they spend reading (Marinak & Gambrell, 2008). It is as if they think, “If I have to be bribed into doing this, it must not be worth doing for its own sake.” This overuse of bribes—leading people to see their actions as externally controlled rather than internally appealing—has been called *overjustification*.

Pure love If this girl were suddenly told that she must look after her baby cousin from now on, she might lose some of the joy that her intrinsic motivation to care for him has provided.

extrinsic motivation a desire to perform a behavior to receive promised rewards or avoid threatened punishment.

To sense the difference between intrinsic motivation and **extrinsic motivation** (behaving in certain ways to gain external rewards or avoid threatened punishment), think about your experience in this course. Are you feeling pressured to finish this reading before a deadline? Worried about your grade? Eager for college credit by doing well on the AP® Exam? If *Yes*, then you are extrinsically motivated (as, to some extent, almost all students must be). Are you also finding the material interesting? Does learning it make you feel more competent? If there were no grade at stake, might you be curious enough to want to learn the material for its own sake? If *Yes*, intrinsic motivation also fuels your efforts.

Youth sports coaches who aim to promote enduring interest in an activity, not just to pressure players into winning, should focus on the intrinsic joy of playing and of reaching one's potential (Deci & Ryan, 1985, 2009). Giving people choices also enhances their intrinsic motivation (Patall et al., 2008). Nevertheless, rewards used to signal a job well done (rather than to bribe or control someone) can be effective (Boggiano et al., 1985). "Most improved player" awards, for example, can boost feelings of competence and increase enjoyment of a sport. Rightly administered, rewards can raise performance and spark creativity (Eisenberger & Aselage, 2009; Henderlong & Lepper, 2002). And extrinsic rewards (such as the college scholarships and jobs that often follow good grades) are here to stay. **TABLE 29.1** compares the biological and cognitive influences on classical and operant conditioning.

Table 29.1 Biological and Cognitive Influences on Conditioning

	Classical Conditioning	Operant Conditioning
<i>Biological predispositions</i>	Natural predispositions constrain what stimuli and responses can easily be associated.	Organisms best learn behaviors similar to their natural behaviors; unnatural behaviors instinctively drift back toward natural ones.
<i>Cognitive processes</i>	Organisms develop expectation that CS signals the arrival of US.	Organisms develop expectation that a response will be reinforced or punished; they also exhibit latent learning, without reinforcement.

Learning and Personal Control

29-3 In what two ways do people learn to cope with personal problems?

copng alleviating stress using emotional, cognitive, or behavioral methods.

problem-focused coping attempting to alleviate stress directly—by changing the stressor or the way we interact with that stressor.

emotion-focused coping attempting to alleviate stress by avoiding or ignoring a stressor and attending to emotional needs related to one's stress reaction.

Problems in life are unavoidable. This fact gives us a clear message: We need to learn to **cope** with the problems in our lives by alleviating the *stress* they cause with emotional, cognitive, or behavioral methods.

Some problems, called stressors, we address directly, with **problem-focused coping**. If our impatience leads to a family fight, we may go directly to that family member to work things out. We tend to use problem-focused strategies when we feel a sense of control over a situation and think we can change the circumstances, or at least change ourselves to deal with the circumstances more capably.

We turn to **emotion-focused coping** when we cannot—or *believe* we cannot—change a situation. If, despite our best efforts, we cannot get along with that family member, we may search for stress relief by reaching out to friends for support and comfort. Emotion-focused strategies can be adaptive, as when we exercise or keep busy with hobbies to avoid thinking about an old addiction. Emotion-focused strategies can be maladaptive, however, as when

Huntstock, Inc./Alamy

Emotion-focused coping

Reaching out to friends can help us attend to our emotional needs in stressful situations.

students worried about not keeping up with the reading in class go out to party to get it off their mind. Sometimes a problem-focused strategy (catching up with the reading) more effectively reduces stress and promotes long-term health and satisfaction.

When challenged, some of us tend to respond with cool problem-focused coping, others with emotion-focused coping (Connor-Smith & Flachsbart, 2007). Our feelings of personal control, our explanatory style, and our supportive connections all influence our ability to cope. So, how might learning influence whether we cope successfully?

Learned Helplessness

29-4 How does a perceived lack of control affect people's behavior and health?

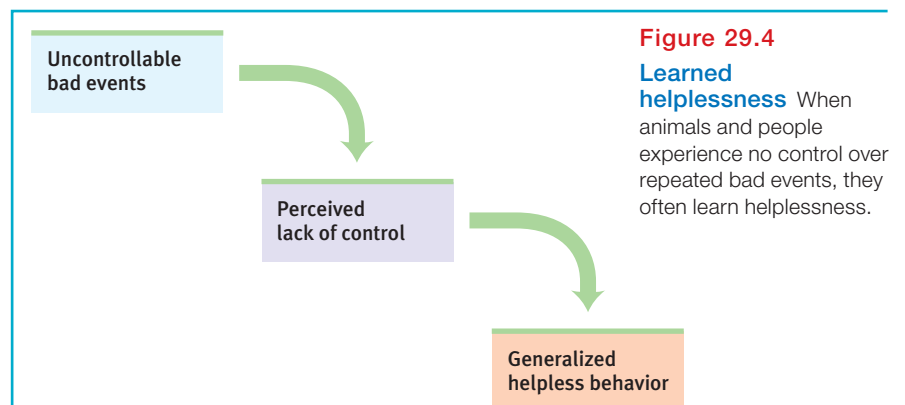

Picture the scene: Two rats receive simultaneous shocks. One can turn a wheel to stop the shocks. The helpless rat, but not the wheel turner, becomes more susceptible to ulcers and lowered immunity to disease (Laudenslager & Reite, 1984). In humans, too, uncontrollable threats trigger the strongest stress responses (Dickerson & Kemeny, 2004).

Feeling helpless and oppressed may lead to a state of passive resignation called **learned helplessness** (FIGURE 29.4). Researcher Martin Seligman (1975, 1991) discovered this in some long-ago experiments in which dogs were strapped in a harness and given repeated shocks, with no opportunity to avoid them. Later, when placed in another situation where they *could* escape the punishment by simply leaping a hurdle, the dogs cowered as if without hope. In contrast, animals able to escape the first shocks learned personal control and easily escaped the shocks in the new situation.

Humans can also learn helplessness. When repeatedly faced with traumatic events over which they have no control, people come to feel helpless, hopeless, and depressed.

Perceiving a loss of control, we become more vulnerable to stress and ill health. A famous study of elderly nursing home residents with little perceived control over their activities found that they declined faster and died sooner than those given more control (Rodin, 1986). Workers able to adjust office furnishings and control interruptions and distractions in their work environment have experienced

learned helplessness the hopelessness and passive resignation an animal or human learns when unable to avoid repeated aversive events.

Happy to have control After working on the building—alongside Habitat for Humanity volunteers—for several months, this family is finally experiencing the joy of having their own new home.

less stress (O’Neill, 1993). Such findings may help explain why British civil service workers at the executive grades have tended to outlive those at clerical or laboring grades, and why Finnish workers with low job stress have been less than half as likely to die of strokes or heart disease as those with a demanding job and little control. The more control workers have, the longer they live (Bosma et al., 1997, 1998; Kivimaki et al., 2002; Marmot et al., 1997).

Increasing self-control—allowing prisoners to move chairs and control room lights and the TV, having workers participate in decision making, offering nursing home patients choices about their environment—noticeably improves health and morale (Humphrey et al., 2007; Wang et al., 2010). In the case of the nursing home patients, 93 percent of those encouraged to exert more control became more alert, active, and happy (Rodin, 1986). As researcher Ellen Langer (1983, p. 291) concluded, “Perceived control is basic to human functioning.”

Control may also help explain a well-established link between economic status and longevity (Jokela et al., 2009). In one study of 843 grave markers in an old graveyard in Glasgow, Scotland, those with the costliest, highest pillars (indicating the most affluence) tended to have lived the longest (Carroll et al., 1994). Likewise, those living in Scottish regions with the least overcrowding and unemployment have the greatest longevity. There and elsewhere, high economic status predicts a lower risk of heart and respiratory diseases (Sapolsky, 2005). Wealthy predicts healthy among children, too (Chen, 2004). With higher economic status come reduced risks of low birth weight, infant mortality, smoking, and violence. Even among other primates, individuals at the bottom of the social pecking order have been more likely than their higher-status companions to become sick when exposed to a cold-like virus (Cohen et al., 1997). But high status also entails stress: High-status baboons and monkeys who frequently have to physically defend their dominant position show high stress levels (Sapolsky, 2005).

Why does perceived loss of control predict health problems? Because losing control provokes an outpouring of stress hormones. When rats cannot control shock or when primates or humans feel unable to control their environment, stress hormone levels rise, blood pressure increases, and immune responses drop (Rodin, 1986; Sapolsky, 2005). Captive animals therefore experience more stress and are more vulnerable to disease than are wild animals (Roberts, 1988). Human studies have confirmed that crowding in high-density neighborhoods, prisons, and college and university dorms is another source of diminished feelings of control—and of elevated levels of stress hormones and blood pressure (Fleming et al., 1987; Ostfeld et al., 1987).

INTERNAL VERSUS EXTERNAL LOCUS OF CONTROL

If experiencing a loss of control can be stressful and unhealthy, do people who generally feel in control of their lives enjoy better health? Consider your own feelings of control. Do you believe that your life is beyond your control? That getting a decent summer job depends mainly on being in the right place at the right time? Or do you more strongly believe that what happens to you is your own doing? That being a success is a matter of hard work? Did your parents influence your feelings of control? Did your culture?

Hundreds of studies have compared people who differ in their perceptions of control. On one side are those who have what psychologist Julian Rotter called an **external locus of control**—the perception that chance or outside forces determine their fate. On the other are those who perceive an **internal locus of control**, who believe that they control their own destiny. In study after study, “internals” have achieved more in school and work,

external locus of control

the perception that chance or outside forces beyond our personal control determine our fate.

internal locus of control

the perception that you control your own fate.

acted more independently, enjoyed better health, and felt less depressed than did “externals” (Lefcourt, 1982; Ng et al., 2006). Moreover, they were better at delaying gratification and coping with various stressors, including marital problems (Miller & Monge, 1986). One study followed 7551 British people for two decades. Those who expressed a more internal locus of control at age 10 exhibited less obesity, hypertension, and distress at age 30 (Gale et al., 2008). Other studies have found that people who believe in free will, or that willpower is controllable, learn better, perform better at work, and are more helpful (Job et al., 2010; Stillman et al., 2010).

Compared with their parents’ generation, more Americans now endorse an external locus of control (Twenge et al., 2004). This shift may help explain an associated increase in rates of depression and other psychological disorders in the new generation (Twenge et al., 2010).

DEPLETING AND STRENGTHENING SELF-CONTROL

Self-control is the ability to control impulses and delay short-term gratification for longer-term rewards. In studies, this ability has predicted good adjustment, better grades, and social success (Tangney et al., 2004). Students who planned their day’s activities and then lived out their day as planned were also at low risk for depression (Nezlek, 2001).

Self-control often fluctuates. Like a muscle, self-control temporarily weakens after an exertion, replenishes with rest, and becomes stronger with exercise (Baumeister & Exline, 2000; Hagger et al., 2010; Vohs & Baumeister, 2011). Exercising willpower temporarily depletes the mental energy needed for self-control on other tasks (Gaillott & Baumeister, 2007). In one experiment, hungry people who had resisted the temptation to eat chocolate chip cookies abandoned a tedious task sooner than those who had not resisted the cookies. And after expending willpower on laboratory tasks, such as stifling prejudice or saying the color of words (for example, “red” even if the red-colored word was *green*), people were less restrained in their aggressive responses to provocation and in their sexuality (DeWall et al., 2007; Gaillot & Baumeister, 2007).

self-control the ability to control impulses and delay short-term gratification for greater long-term rewards.

AP Photo/Marty Lederhandler

Extreme self-control Our ability to exert self-control increases with practice, and some of us have practiced more than others! Magician David Blaine (above) endured standing in a block of ice (in which a small space had been carved out for him) for nearly 62 hours for a stunt in New York’s Times Square. A number of performing artists make their living as very convincing human statues, as does this actress (left) performing on The Royal Mile in Edinburgh, Scotland.

Researchers have found that exercising willpower depletes the blood sugar and neural activity associated with mental focus (Inzlicht & Gutsell, 2007). What, then, might be the effect of deliberately boosting people's blood sugar when self-control is depleted? Giving energy-boosting sugar (in a naturally rather than an artificially sweetened lemonade) had a sweet effect: It strengthened people's effortful thinking and reduced their financial impulsiveness (Masicampo & Baumeister, 2008; Wang & Dvorak, 2010). Even dogs can experience both self-control depletion on the one hand and rejuvenation with sugar on the other (Miller et al., 2010).

In the long run, self-control requires attention and energy. With physical exercise and time-managed study programs, people have strengthened their self-control, as seen in both their performance on laboratory tasks and their improved self-management of eating, drinking, smoking, and household chores (Oaten & Cheng, 2006a,b). *The bottom line:* We can grow our willpower muscles—our capacity for self-regulation. But doing so requires some (dare I say it?) willpower.

Before You Move On

▶ ASK YOURSELF

How are you intrinsically motivated? What are some extrinsic motivators in your life?

▶ TEST YOURSELF

When faced with a situation over which you feel you have no sense of control, is it most effective to use emotion- or problem-focused coping? Why?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 29 Review

29-1

How do biological constraints affect classical and operant conditioning?

- Classical conditioning principles, we now know, are constrained by biological predispositions, so that learning some associations is easier than learning others.
- Learning is adaptive: Each species learns behaviors that aid its survival.
- Biological constraints also place limits on operant conditioning. Training that attempts to override biological constraints will probably not endure because animals will revert to predisposed patterns.
- In operant conditioning, *cognitive mapping* and *latent learning* research demonstrate the importance of cognitive processes in learning.
- Other research shows that excessive rewards (driving *extrinsic motivation*) can undermine *intrinsic motivation*.

29-2

How do cognitive processes affect classical and operant conditioning?

- In classical conditioning, animals may learn when to expect a US and may be aware of the link between stimuli and responses.

29-3

In what two ways do people learn to cope with personal problems?

- We use *problem-focused coping* to change the stressor or the way we interact with it.
- We use *emotion-focused coping* to avoid or ignore stressors and attend to emotional needs related to stress reactions.

29-4**How does a perceived lack of control affect people's behavior and health?**

- Being unable to avoid repeated aversive events can lead to *learned helplessness*.
- People who perceive an *internal locus of control* achieve more, enjoy better health, and are happier than those who perceive an *external locus of control*.
- *Self-control* requires attention and energy, but it predicts good adjustment, better grades, and social success.
- A perceived lack of control provokes an outpouring of hormones that put people's health at risk.

Multiple-Choice Questions

1. What do we call a desire to perform a behavior in order to receive promised rewards or to avoid threatened punishment?
 - a. Latent learning
 - b. Extrinsic motivation
 - c. Intrinsic motivation
 - d. Insight learning
 - e. Emotion-focused coping
2. Which ability is a good predictor of good adjustment, better grades, and social success?
 - a. Self-control
 - b. Locus of control
 - c. Problem-focused coping
 - d. Learned helplessness
 - e. Emotion-focused coping
3. Elephants appear to have the capacity to remember large-scale spaces over long periods. Which of the following best identifies this capacity?

a. Latent learning	d. Intrinsic motivation
b. Insight	e. Extrinsic motivation
c. Cognitive maps	
4. The perception that we control our own fate is also called what?
 - a. Self-control
 - b. Learned helplessness
 - c. Internal locus of control
 - d. External locus of control
 - e. Emotion-focused coping
5. A woman had been pondering a problem for days and was about to give up when, suddenly, the solution came to her. Her experience can be best described as what?
 - a. Cognitive mapping
 - b. Insight
 - c. Operant conditioning
 - d. Classical conditioning
 - e. Unconscious associative learning

Practice FRQs

1. Provide two specific examples of how biology can influence classical conditioning.

Answer

Any two examples from the module can be used to answer. Possibilities include:

1 point: Garcia's research showed that rats are more likely to develop a classically conditioned aversion to tastes than to sights or sounds.

1 point: Humans are biologically predisposed to form associations between the color red and sexuality.

2. Describe how each of the following can show the impact of cognition on operant conditioning.

- Latent learning
- Insight learning
- Intrinsic motivation

(3 points)

Module 30

Learning by Observation

Module Learning Objectives

- 30-1** Describe the process of observational learning, and explain how some scientists believe it is enabled by mirror neurons.
- 30-2** Discuss the impact of prosocial modeling and of antisocial modeling.

©J/Jamie Grill/Getty Images

30-1 What is observational learning, and how do some scientists believe it is enabled by mirror neurons?

observational learning learning by observing others. Also called *social learning*.

modeling the process of observing and imitating a specific behavior.

AP® Exam Tip

Bandura's Bobo doll experiment is one of the most famous in psychology. It shows up frequently on the AP® exam.

Albert Bandura “The Bobo doll follows me wherever I go. The photographs are published in every introductory psychology text and virtually every undergraduate takes introductory psychology. I recently checked into a Washington hotel. The clerk at the desk asked, ‘Aren’t you the psychologist who did the Bobo doll experiment?’ I answered, ‘I am afraid that will be my legacy.’ He replied, ‘That deserves an upgrade. I will put you in a suite in the quiet part of the hotel!’” (2005).

Cognition is certainly a factor in **observational learning** (also called *social learning*) in which higher animals, especially humans, learn without direct experience, by watching and imitating others. A child who sees his sister burn her fingers on a hot stove learns not to touch it. We learn our native languages and various other specific behaviors by observing and imitating others, a process called **modeling**.

Picture this scene from an experiment by Albert Bandura, the pioneering researcher of observational learning (Bandura et al., 1961): A preschool child works on a drawing. An adult in another part of the room is building with Tinkertoys. As the child watches, the adult gets up and for nearly 10 minutes pounds, kicks, and throws around the room a large inflated Bobo doll, yelling, “Sock him in the nose. . . . Hit him down. . . . Kick him.”

The child is then taken to another room filled with appealing toys. Soon the experimenter returns and tells the child she has decided to save these good toys “for the other children.” She takes the now-frustrated child to a third room containing a few toys, including a Bobo doll. Left alone, what does the child do?

Compared with children not exposed to the adult model, those who viewed the model’s actions were more likely to lash out at the doll. Observing the aggressive outburst apparently lowered their inhibitions. But *something more* was also at work, for the children imitated the very acts they had observed and used the very words they had heard (**FIGURE 30.1**).

That “something more,” Bandura suggests, was this: By watching a model, we experience *vicarious reinforcement* or *vicarious punishment*, and we learn to anticipate a behavior’s consequences in situations like those we are observing. We are especially likely to learn from people we perceive

Courtesy of Albert Bandura, Stanford University

Figure 30.1

as similar to ourselves, as successful, or as admirable. Functional MRI scans show that when people observe someone winning a reward (and especially when it's someone likable and similar to themselves) their own brain reward systems activate, much as if they themselves had won the reward (Mobbs et al., 2009). When we identify with someone, we experience their outcomes vicariously. Lord Chesterfield (1694–1773) had the idea: “We are, in truth, more than half what we are by imitation.”

Mirrors and Imitation in the Brain

On a 1991 hot summer day in Parma, Italy, a lab monkey awaited its researchers' return from lunch. The researchers had implanted wires next to its motor cortex, in a frontal lobe brain region that enabled the monkey to plan and enact movements. The monitoring device would alert the researchers to activity in that region of the monkey's brain. When the monkey moved a peanut into its mouth, for example, the device would buzz. That day, as one of the researchers reentered the lab, ice cream cone in hand, the monkey stared at him. As the researcher raised the cone to lick it, the monkey's monitor buzzed—as if the motionless monkey had itself moved (Blakeslee, 2006; Iacoboni, 2008, 2009).

The same buzzing had been heard earlier, when the monkey watched humans or other monkeys move peanuts to their mouths. The flabbergasted researchers had, they believed, stumbled onto a previously unknown type of neuron (Rizzolatti et al., 2002, 2006). These presumed **mirror neurons** may provide a neural basis for everyday imitation and observational learning. When a monkey grasps, holds, or tears something, these neurons fire. And they likewise fire when the monkey observes another doing so. When one monkey sees, its neurons mirror what another monkey does.

Imitation is widespread in other species. In one experiment, a monkey watching another selecting certain pictures to gain treats learned to imitate the order of choices (**FIGURE 30.2** on the next page). In other research, rhesus macaque monkeys rarely made up quickly after a fight—unless they grew up with forgiving older macaques. Then, more often than not, their fights, too, were quickly followed by reconciliation (de Waal & Johanowicz, 1993). Rats, pigeons, crows, and gorillas all observe others and learn (Byrne et al., 2011; Dugatkin, 2002).

mirror neurons frontal lobe neurons that some scientists believe fire when performing certain actions or when observing another doing so. The brain's mirroring of another's action may enable imitation and empathy.

Mirror neurons at work?

“Your back is killing me!”

Monkey B's screen

As Module 85 describes, chimpanzees observe and imitate all sorts of novel foraging and tool use behaviors, which are then transmitted from generation to generation within their local culture (Hopper et al., 2008; Whiten et al., 2007).

In humans, imitation is pervasive. Our catchphrases, fashions, ceremonies, foods, traditions, morals, and fads all spread by one person copying another. Imitation shapes even very young humans' behavior (Bates & Byrne, 2010). Shortly after birth, a baby may imitate an adult who sticks out his tongue. By 8 to 16 months, infants imitate various novel gestures (Jones, 2007). By age 12 months (**FIGURE 30.3**), they look where an adult is looking (Meltzoff et al., 2009). And by age 14 months, children imitate acts modeled on TV (Meltzoff, 1988; Meltzoff & Moore, 1989, 1997). Even as 2½-year-olds, when many of their mental abilities are near those of adult chimpanzees, young humans surpass chimps at social tasks such as imitating another's solution to a problem (Herrmann et al., 2007). Children see, children do.

So strong is the human predisposition to learn from watching adults that 2- to 5-year-old children *overimitate*. Whether living in urban Australia or rural Africa, they copy even irrelevant adult actions. Before reaching for a toy in a plastic jar, they will first stroke the jar with a feather if that's what they have observed (Lyons et al., 2007). Or, imitating an adult, they will wave a stick over a box and then use the stick to push on a knob that opens the box—when all they needed to do to open the box was to push on the knob (Nielsen & Tomaselli, 2010).

Humans, like monkeys, have brains that support empathy and imitation. Researchers cannot insert experimental electrodes in human brains, but they can use fMRI scans to see brain activity associated with performing and with observing actions. So, is the human

"Children need models more than they need critics." -JOSEPH JOUBERT, *PENSÉES*, 1842

Figure 30.3

Imitation This 12-month-old infant sees an adult look left, and immediately follows her gaze. (From Meltzoff et al., 2009.)

Meltzoff, A. N., Kuhl, P. K., Movellan, J., & Sejnowski, T. J. (2009). Foundations for a new science of learning. *Science*, 325, 294-298.

capacity to simulate another's action and to share in another's experience due to specialized mirror neurons? Or is it due to distributed brain networks? That issue is currently being debated (Gallese et al. 2011; Iacoboni, 2008, 2009; Mukamel et al., 2010). Regardless, children's brains enable their empathy and their ability to infer another's mental state, an ability known as *theory of mind*.

The brain's response to observing others makes emotions contagious. Through its neurological echo, our brain simulates and vicariously experiences what we observe. So real are these mental instant replays that we may misremember an action we have observed as an action we have performed (Lindner et al., 2010). But through these reenactments, we grasp others' states of mind. Observing others' postures, faces, voices, and writing styles, we unconsciously synchronize our own to theirs—which helps us feel what they are feeling (Bernieri et al., 1994; Ireland & Pennebaker, 2010). We find ourselves yawning when they yawn, laughing when they laugh.

When observing movie characters smoking, smokers' brains spontaneously simulate smoking, which helps explain their cravings (Wagner et al., 2011). Seeing a loved one's pain, our faces mirror the other's emotion. But as **FIGURE 30.4** shows, so do our brains. In this fMRI scan, the pain imagined by an empathic romantic partner has triggered some of the same brain activity experienced by the loved one actually having the pain (Singer et al., 2004). Even reading fiction may trigger such activity, as we mentally simulate (and vicariously experience) the experiences described (Mar & Oatley, 2008; Speer et al., 2009). The bottom line: *Brain activity underlies our intensely social nature.*

Figure 30.4
Experienced and imagined pain in the brain Brain activity related to actual pain (left) is mirrored in the brain of an observing loved one (right). Empathy in the brain shows up in emotional brain areas, but not in the somatosensory cortex, which receives the physical pain input.

Applications of Observational Learning

30-2 What is the impact of prosocial modeling and of antisocial modeling?

So the big news from Bandura's studies and the mirror-neuron research is that we look, we mentally imitate, and we learn. Models—in our family or neighborhood, or on TV—may have effects, good or bad.

Prosocial Effects

The good news is that **prosocial** (positive, helpful) models can have prosocial effects. Many business organizations effectively use *behavior modeling* to help new employees learn communications, sales, and customer service skills (Taylor et al., 2005). Trainees gain these skills faster when they are able to observe the skills being modeled effectively by experienced workers (or actors simulating them).

prosocial behavior positive, constructive, helpful behavior. The opposite of antisocial behavior.

A model caregiver

This girl is learning orphan-nursing skills, as well as compassion from her mentor in this Humane Society program. As the sixteenth-century proverb states, “Example is better than precept.”

Zumapress/Newscom

People who exemplify nonviolent, helpful behavior can also prompt similar behavior in others. India’s Mahatma Gandhi and America’s Martin Luther King, Jr., both drew on the power of modeling, making nonviolent action a powerful force for social change in both countries. Parents are also powerful models. European Christians who risked their lives to rescue Jews from the Nazis usually had a close relationship with at least one parent who modeled a strong moral or humanitarian concern; this was also true for U.S. civil rights activists in the 1960s (Lon-

don, 1970; Oliner & Oliner, 1988). The observational learning of morality begins early. Socially responsive toddlers who readily imitate their parents tend to become preschoolers with a strong internalized conscience (Forman et al., 2004).

Models are most effective when their actions and words are consistent. Sometimes, however, models say one thing and do another. To encourage children to read, read to them and surround them with books and people who read. To increase the odds that your children will practice your religion, worship and attend religious activities with them. Many parents seem to operate according to the principle “Do as I say, not as I do.” Experiments suggest that children learn to do both (Rice & Grusec, 1975; Rushton, 1975). Exposed to a hypocrite, they tend to imitate the hypocrisy—by doing what the model did and saying what the model said.

Antisocial Effects

The bad news is that observational learning may have *antisocial effects*. This helps us understand why abusive parents might have aggressive children, and why many men who beat their wives had wife-battering fathers (Stith et al., 2000). Critics note that being aggressive could be passed along by parents’ genes. But with monkeys we know it can be environmental. In study after study, young monkeys separated from their mothers and subjected to high levels of aggression grew up to be aggressive themselves (Chamove, 1980). The lessons we learn as children are not easily replaced as adults, and they are sometimes visited on future generations.

TV shows and Internet videos are a powerful source of observational learning. While watching TV and videos, children may “learn” that bullying is an effective way to control others, that free and easy sex brings pleasure without later misery or disease, or that men should be tough and women gentle. And they have ample time to learn such lessons. During their first 18 years, most children in developed countries spend more time watching TV shows than they spend in school. The average teen watches TV shows more than 4 hours a day; the average adult, 3 hours (Robinson & Martin, 2009; Strasburger et al., 2010).

TV-show viewers are learning about life from a rather peculiar storyteller, one that reflects the culture’s mythology but not its reality. Between 1998 and 2006, prime-time violence reportedly increased 75 percent (PTC, 2007). If we include cable programming and video rentals, the violence numbers escalate. An analysis of more than 3000 network and cable programs aired during one closely studied year revealed that nearly 6 in 10 featured violence, that 74 percent of the violence went unpunished, that 58 percent did not show the victims’ pain, that nearly half the incidents involved “justified” violence, and that nearly half involved an attractive perpetrator. These conditions define the recipe for the *violence-viewing effect* described in many studies (Donnerstein, 1998, 2011). To read more about this effect, see Thinking Critically About: Does Viewing Media Violence Trigger Violent Behavior?

FYI

Screen time’s greatest effect may stem from what it displaces. Children and adults who spend several hours a day in front of a screen spend that many fewer hours in other pursuits—talking, studying, playing, reading, or socializing face-to-face with friends. What would you have done with your extra time if you had spent even half as many hours in front of a screen, and how might you therefore be different?

“The problem with television is that the people must sit and keep their eyes glued to a screen: The average American family hasn’t time for it. Therefore the showmen are convinced that . . . television will *never* be a serious competitor of [radio] broadcasting.”

—NEW YORK TIMES, 1939

Thinking Critically About

Does Viewing Media Violence Trigger Violent Behavior?

Was the judge who, in 1993, tried two British 10-year-olds for the murder of a 2-year-old right to suspect that the pair had been influenced by “violent video films”? Were the American media right to wonder if Adam Lanza, the 2012 mass killer of young children and their teachers at Connecticut’s Sandy Hook Elementary School, was influenced by his playing of the violent video games found stockpiled in his home? To understand whether violence viewing leads to violent behavior, researchers have done some 600 correlational and experimental studies (Anderson & Gentile, 2008; Comstock, 2008; Murray, 2008).

Correlational studies do support this link:

- In the United States and Canada, homicide rates doubled between 1957 and 1974, just when TV was introduced and spreading. Moreover, census regions with later dates for TV service also had homicide rates that jumped later.
- White South Africans were first introduced to TV in 1975. A similar near-doubling of the homicide rate began after 1975 (Centerwall, 1989).
- Elementary schoolchildren with heavy exposure to media violence (via TV, videos, and video games) tend to get into more fights (**FIGURE 30.5**). As teens, they are at greater risk for violent behavior (Boxer et al., 2009).

But as we know from Unit II, correlation need not mean causation. So these studies do not prove that viewing violence causes aggression (Freedman, 1988; McGuire, 1986). Maybe aggressive children prefer violent programs. Maybe abused or neglected children are both more aggressive and more often left in front of the TV or computer. Maybe violent programs simply reflect, rather than affect, violent trends.

To pin down causation, psychologists experimented. They randomly assigned some viewers to observe violence and others to watch entertaining nonviolence. Does viewing cruelty prepare

people, when irritated, to react more cruelly? To some extent, it does. This is especially so when an attractive person commits seemingly justified, realistic violence that goes unpunished and causes no visible pain or harm (Donnerstein, 1998, 2011).

The violence-viewing effect seems to stem from at least two factors. One is *imitation* (Geen & Thomas, 1986). Children as young as 14 months will imitate acts they observe on TV (Meltzoff & Moore, 1989, 1997). As they watch, their brains simulate the behavior, and after this inner rehearsal they become more likely to act it out. Thus, in one experiment, violent play increased sevenfold immediately after children viewed *Power Rangers* episodes (Boyatzis et al., 1995). As happened in the Bobo doll experiment, children often precisely imitated the models’ violent acts—in this case, flying karate kicks.

Prolonged exposure to violence also *desensitizes* viewers. They become more indifferent to it when later viewing a brawl, whether on TV or in real life (Fanti et al., 2009; Rule & Ferguson, 1986). Adult males who spent three evenings watching sexually violent movies became progressively less bothered by the rapes and slashings. Compared with those in a control group, the film watchers later expressed less sympathy for domestic violence victims, and they rated the victims’ injuries as less severe (Mullin & Linz, 1995). Likewise, moviegoers were less likely to help an injured woman pick up her crutches if they had just watched a violent rather than a nonviolent movie (Bushman & Anderson, 2009).

Drawing on such findings, the American Academy of Pediatrics (2009) has advised pediatricians that “media violence can contribute to aggressive behavior, desensitization to violence, nightmares, and fear of being harmed.” Indeed, an evil psychologist could hardly imagine a better way to make people indifferent to brutality than to expose them to a graded series of scenes, from fights to killings to the mutilations in slasher movies (Donnerstein et al., 1987). Watching cruelty fosters indifference.

Stanislav Sohnisev/Getty Images

Figure 30.5 Heavy exposure to media violence predicts future aggressive behavior Researchers studied more than 400 third- to fifth-graders. After controlling for existing differences in hostility and aggression, the researchers reported increased aggression in those heavily exposed to violent TV, videos, and video games (Gentile et al., 2004).

* * *

Our knowledge of learning principles comes from the work of hundreds of investigators. This unit has focused on the ideas of a few pioneers—Ivan Pavlov, John Watson, B. F. Skinner, and Albert Bandura. They illustrate the impact that can result from single-minded devotion to a few well-defined problems and ideas. These researchers defined the issues and impressed on us the importance of learning. As their legacy demonstrates, intellectual history is often made by people who risk going to extremes in pushing ideas to their limits (Simonton, 2000).

Before You Move On

▶ ASK YOURSELF

Who has been a significant role model for you? For whom are you a model?

▶ TEST YOURSELF

Jason's parents and older friends all smoke, but they advise him not to. Juan's parents and friends don't smoke, but they say nothing to deter him from doing so. Will Jason or Juan be more likely to start smoking?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 30 Review

30-1

What is observational learning, and how do some scientists believe it is enabled by mirror neurons?

- In *observational learning*, as we observe and imitate others we learn to anticipate a behavior's consequences, because we experience vicarious reinforcement or vicarious punishment.
- Our brain's frontal lobes have a demonstrated ability to mirror the activity of another's brain. The same areas fire when we perform certain actions (such as responding to pain or moving our mouth to form words), as when we observe someone else performing those actions.

30-2

What is the impact of prosocial modeling and of antisocial modeling?

- Children tend to imitate what a model does and says, whether the behavior being *modeled* is *prosocial* (positive, constructive, and helpful) or antisocial.
- If a model's actions and words are inconsistent, children may imitate the hypocrisy they observe.

Multiple-Choice Questions

1. Bandura's famous Bobo doll experiment is most closely associated with which of the following?
 - a. Latent learning
 - b. Classical conditioning
 - c. Operant conditioning
 - d. Cognitive maps
 - e. Observational learning
2. Which of the following processes is the best term for explaining how we learn languages?
 - a. Biofeedback
 - b. Discrimination
 - c. Modeling
 - d. Insight
 - e. Creativity

- 3.** Which of the following is the most likely consequence of the brain's tendency to vicariously experience something we observe?
- Actual physical injury
 - The risk of misremembering our own actions
 - Interference with associative learning
 - The elimination of classically conditioned responses to stimuli
 - A confusion between reinforcers and rewards in an operant conditioning setting
- 4.** When is prosocial modeling most effective?
- When the model acts in a way consistent with the prosocial lesson
 - When the model verbally emphasizes the prosocial lesson but acts as she chooses
 - When the model is predisposed to the prosocial conduct
 - When the observer has a close personal relationship with the model
 - When the model is well-known
- 5.** Which of the following is the best synonym for social learning?
- Observational learning
 - Modeling
 - Mirror neuron imitation
 - Prosocial model
 - Imitation

Practice FRQs

- 1.** Explain how Bandura's Bobo doll experiment illustrates each of the following:
- Modeling
 - Mirror neurons
- 2.** A young boy is left at home with his older brother while their parents drop off the family car for repairs. While the parents are out, the older brother prepares lunch for the young boy. Then the older brother takes the younger brother outside where he entertains him by building several fires with small twigs. Explain how the older brother's conduct is:
- Prosocial modeling
 - Antisocial modeling

Answer

1 point: Modeling can be described as the behavior of the child as he or she imitates the adult.

1 point: Mirror neurons on the child's brain presumably would fire the same way when watching the adult or when imitating the adult's behavior.

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Which of the following most accurately describes an impact of punishment?
 - Punishment is a good way to increase a behavior, as long as it is not used too frequently.
 - Punishment may create problems in the short term but rarely produces long-term side effects.
 - Punishment can be effective at stopping specific behaviors quickly.
 - Punishment typically results in an increase of a behavior that caused the removal of an aversive stimulus.
 - Punishment should never be used (in the opinion of most psychologists), because the damage it causes can never be repaired.

2. Which of the following is an application of shaping?
 - a. A mother who wants her daughter to hit a baseball first praises her for holding a bat, then for swinging it, and then for hitting the ball.
 - b. A pigeon pecks a disk 25 times for an opportunity to receive a food reinforcement.
 - c. A rat presses a bar when a green light is on but not when a red light is on.
 - d. A rat gradually stops pressing a bar when it no longer receives a food reinforcement.
 - e. A gambler continues to play a slot machine, even though he has won nothing on his last 20 plays, and he has lost a significant amount of money.
3. What is one of the principal functions of mirror neurons?
 - a. To allow an organism to replace an unconditioned response with a conditioned response
 - b. To help produce intrinsic motivation in some children
 - c. To be the mechanism by which the brain accomplishes observational learning
 - d. To produce the neural associations that are the basis of both classical and operant conditioning
 - e. To explain why modeling prosocial behavior is more effective than modeling negative behavior
4. Which of the following illustrates generalization?
 - a. A rabbit that has been conditioned to blink to a tone also blinks when a similar tone is sounded.
 - b. A dog salivates to a tone but not to a buzzer.
 - c. A light is turned on repeatedly until a rat stops flexing its paw when it's turned on.
 - d. A pigeon whose disk-pecking response has been extinguished is placed in a Skinner box three hours later and begins pecking the disk again.
 - e. A child is startled when the doorbell rings.
5. What did Albert Bandura's Bobo doll experiments demonstrate?
 - a. Children are likely to imitate the behavior of adults.
 - b. There may be a negative correlation between televised violence and aggressive behavior.
 - c. Children are more likely to copy what adults say than what adults do.
 - d. Allowing children to watch too much television is detrimental to their development.
 - e. Observational learning can explain the development of fears in children.
6. What did Robert Rescorla and Allan Wagner's experiments establish?
 - a. That the acquisition of a CR depends on pairing the CS and the US
 - b. That different species respond differently to classical conditioning situations
 - c. The current belief that classical conditioning is really a form of operant conditioning
 - d. That mirror neurons form the biological basis of classical conditioning
 - e. The importance of cognitive factors in classical conditioning
7. What does Edward Thorndike's law of effect state?
 - a. The difference between positive and negative reinforcement
 - b. That behavior maintained by partial reinforcement is more resistant to extinction than behavior maintained by continuous reinforcement
 - c. How shaping can be used to establish operant conditioning
 - d. That rewarded behavior is more likely to happen again
 - e. The limited effectiveness of punishment
8. Which of the following processes would produce the acquisition of a conditioned response?
 - a. Repeatedly present an unconditioned response
 - b. Administer the conditioned stimulus without the unconditioned stimulus
 - c. Make sure that the conditioned stimulus comes at least one minute before the unconditioned stimulus
 - d. Pair a neutral stimulus with an unconditioned stimulus several times
 - e. Present the conditioned stimulus until it starts to produce an unconditioned response
9. Which of the following would help determine what stimuli an organism can distinguish between?
 - a. Negative reinforcement
 - b. A variable-ratio schedule of reinforcement
 - c. A fixed-ratio schedule of reinforcement
 - d. Extinction
 - e. A discriminative stimulus
10. A student studies diligently to avoid the bad feelings associated with a previously low grade on a test. In this case, the studying behavior is being strengthened because of what kind of reinforcement?
 - a. Positive reinforcement
 - b. Negative reinforcement
 - c. Delayed reinforcement
 - d. Primary reinforcement
 - e. Conditioned reinforcement

- 11.** Taste aversion studies lead researchers to which of the following conclusions?
- Taste is the most fundamental of the senses.
 - There are genetic predispositions involved in taste learning.
 - Animals must evaluate a situation cognitively before taste aversion develops.
 - Taste aversion is a universal survival mechanism.
 - An unconditioned stimulus must occur within seconds of a CS for conditioning to occur.
- 12.** Mary checks her phone every 30 minutes for incoming text messages. Her behavior is being maintained by what kind of reinforcement schedule?
- Fixed-interval
 - Variable-interval
 - Variable-ratio
 - Fixed-ratio
 - Continuous
- 13.** A dog is trained to salivate when it hears a tone associated with food. Then the tone is sounded repeatedly without an unconditioned stimulus until the dog stops salivating. Later, when the tone sounds again, the dog salivates again. This is a description of what part of the conditioning process?
- Spontaneous recovery
 - Extinction
 - Generalization
 - Discrimination
 - Acquisition
- 14.** Latent learning is evidence for which of these conclusions?
- Punishment is an ineffective means of controlling behavior.
 - Negative reinforcement should be avoided when possible.
 - Cognition plays an important role in operant conditioning.
 - Conditioned reinforcers are more effective than primary reinforcers.
 - Shaping is usually not necessary for operant conditioning.
- 15.** Classical and operant conditioning are based on the principles of which psychological perspective?
- Cognitive
 - Biological
 - Behaviorist
 - Evolutionary
 - Humanist

Free-Response Questions

- 1.** Briefly explain how the concepts below could be used to help a child stop throwing temper tantrums.
- Extinction (operant conditioning)
 - Positive reinforcement
 - Modeling
 - Negative reinforcement
 - Shaping
 - Extinction (classical conditioning)

Rubric for Free Response Question 1

1 point: Extinction (operant conditioning) The child might be throwing a temper tantrum because that behavior is being reinforced (for example, it gains the child desired attention from a parent). Extinction could be used to stop the temper tantrum by removing the reinforcement. Without the reinforcement, eventually the behavior (tantrums) should decrease. [↻](#) Pages 279, 290

1 point: Positive reinforcement A positive reinforcement (such as reading a favorite book) could be used to encourage a behavior other than temper tantrums. The child could be given the positive reinforcement after a “prosocial” behavior, such as sharing a toy with a friend instead of throwing a tantrum. [↻](#) Page 277

1 point: Modeling The child might learn to avoid temper tantrums through modeling or observational learning. A parent or other adult could show positive behaviors when disappointed, and the child might imitate this behavior. [↻](#) Page 304

1 point: Negative reinforcement Negative reinforcement occurs when a stimulus is removed, and this removal reinforces a behavior. In this situation, a parent or adult could sit the child on a “time-out” seat as soon as the temper tantrum begins. The child could leave the time out seat as soon as she or he stops crying. The removal of the aversive stimulus of the time out seat could reinforce not crying, and help to stop the temper tantrums. [↻](#) Page 278

1 point: Shaping A parent or other adult could gradually shape the child's negative behavior toward desired behaviors by rewarding successive approximations. For example, a child could first be rewarded for crying more quietly during a tantrum, then for stopping yelling, then for avoiding the tantrum completely.  Page 276

1 point: Extinction (classical conditioning) In the context of classical conditioning, a behavior becomes extinct because a neutral stimulus is repeatedly presented without the unconditioned stimulus. For example, a child might have been classically conditioned to throw a tantrum whenever the child's brother is present, because the brother always pinches the child. The tantrums could be made extinct by convincing the brother to stop the pinching. The conditioned stimulus (the brother) is presented to the child without the unconditioned stimulus (the pinching). After repeated pairings, the conditioned response of the tantrum should become extinct.  Pages 269, 290

Multiple-choice self-tests and more may be found at www.worthpublishers.com/MyersAP2e

2. Martin is a sixth-grade teacher who feels he is not able to connect with some of his students. Several of them have had academic problems in the past and although Martin feels that they can do the work, he believes that these students have given up. Explain how Martin could use each of these concepts to learn how best to help his students succeed.

- External locus of control
- Self-control
- Learned helplessness
- Intrinsic motivation

(4 points)

3. Researchers investigating conditioning throughout the history of psychology reached very different conclusions about how humans learn behaviors. Explain how these theorists might explain this example of behavior and response: A child cries when she sees a large pile of peas on her dinner plate.

- Edward Thorndike
- B. F. Skinner
- Ivan Pavlov
- Albert Bandura

(4 points)

Unit VII

Cognition

Modules

- 31** Studying and Building Memories
- 32** Memory Storage and Retrieval
- 33** Forgetting, Memory Construction, and Memory Improvement
- 34** Thinking, Concepts, and Creativity
- 35** Solving Problems and Making Decisions
- 36** Thinking and Language

I revised this unit's first three modules after collaborating with Janie Wilson, Professor of Psychology at Georgia Southern University and Vice President for Programming of the Society for the Teaching of Psychology.

Throughout history, we humans have both bemoaned our foolishness and celebrated our wisdom. The poet T. S. Eliot was struck by “the hollow men . . . Head-piece filled with straw.” But Shakespeare’s Hamlet extolled the human species as “noble in reason! . . . infinite in faculties! . . . in apprehension how like a god!” In the preceding units, we have likewise marveled at both our abilities and our errors.

Elsewhere in this text, we study the human brain—three pounds of wet tissue the size of a small cabbage, yet containing circuitry more complex than the planet’s telephone networks. We appreciate the amazing abilities of newborns. We marvel at our sensory system, translating visual stimuli into nerve impulses, distributing them for parallel processing, and reassembling them into colorful perceptions. Little wonder that our species has had the collective genius to invent the camera, the car, and the computer; to unlock the atom and crack the genetic code; to travel out to space and into our brain’s depths.

Yet we have also seen that our species is kin to the other animals, influenced by the same principles that produce learning in rats and pigeons. We have noted that

we not-so-wise humans are easily deceived by perceptual illusions, pseudopsychic claims, and false memories.

In this unit, we encounter further instances of these two images of the human condition—the rational and the irrational. We will ponder our memory’s enormous capacity, and the ease with which our two-track mind processes information, with and without our awareness. We will consider how we use and misuse the information we receive, perceive, store, and retrieve. We will look at our gift for language and consider how and why it develops. And we will reflect on how deserving we are of our species name, *Homo sapiens*—wise human.

Module 31

Studying and Building Memories

Module Learning Objectives

- 31-1** Define *memory*.
- 31-2** Explain how psychologists describe the human memory system.
- 31-3** Distinguish between explicit and implicit memories.
- 31-4** Identify the information we process automatically.
- 31-5** Explain how sensory memory works.
- 31-6** Describe the capacity of our short-term and working memory.
- 31-7** Describe the effortful processing strategies that help us remember new information.
- 31-8** Describe the levels of processing and their effect on encoding.

Be thankful for memory. We take it for granted, except when it malfunctions. But it is our memory that accounts for time and defines our life. It is our memory that enables us to recognize family, speak our language, find our way home, and locate food and water. It is our memory that enables us to enjoy an experience and then mentally replay and enjoy it again. And it is our memory that occasionally pits us against those whose offenses we cannot forget.

AP® Exam Tip

The next three modules deal with memory. Not only is this a significant topic on the AP® exam, it is also one of the most practical topics in psychology, especially if you're a student! Some of your preconceptions about memory may be accurate and some may not. As you read, think about how you can apply what you're learning in order to be a better student.

memory the persistence of learning over time through the encoding, storage, and retrieval of information.

In large part, we are what we remember. Without memory—our storehouse of accumulated learning—there would be no savoring of past joys, no guilt or anger over painful recollections. We would instead live in an enduring present, each moment fresh. But each person would be a stranger, every language foreign, every task—dressing, eating, biking—a new challenge. You would even be a stranger to yourself, lacking that continuous sense of self that extends from your distant past to your momentary present.

Studying Memory

31-1 What is memory?

To a psychologist, **memory** is learning that has persisted over time; it is information that has been acquired, stored, and can be retrieved.

Research on memory's extremes has helped us understand how memory works. At age 92, my father suffered a small stroke that had but one peculiar effect. He was as mobile as before. His genial personality was intact. He knew us and enjoyed poring over family photo albums and reminiscing about his past. But he had lost most of his ability to lay down new memories of conversations and everyday episodes. He could not tell me what day of the week it was, or what he'd had for lunch. Told repeatedly of his brother-in-law's death, he was surprised and saddened each time he heard the news.

At the other extreme are people who would be gold medal winners in a memory Olympics. Russian journalist Shereshevskii, or S, had merely to listen while other reporters scribbled notes (Luria, 1968). You and I could parrot back a string of about 7—maybe even 9—digits. S could repeat up to 70, if they were read about 3 seconds apart in an otherwise silent room. Moreover, he could recall digits or words backward as easily as forward. His accuracy was unerring, even when recalling a list as much as 15 years later. “Yes, yes,” he might recall. “This was a series you gave me once when we were in your apartment. . . . You were sitting at the table and I in the rocking chair. . . . You were wearing a gray suit. . . .”

Amazing? Yes, but consider your own impressive memory. You remember countless voices, sounds, and songs; tastes, smells, and textures; faces, places, and happenings. Imagine viewing more than 2500 slides of faces and places for 10 seconds each. Later, you see 280 of these slides, paired with others you've never seen. Actual participants in this experiment recognized 90 percent of the slides they had viewed in the first round (Haber, 1970). In a follow-up experiment, people exposed to 2800 images for only 3 seconds each spotted the repeats with 82 percent accuracy (Konkle et al., 2010).

Or imagine yourself looking at a picture fragment, such as the one in **FIGURE 31.1**. Also imagine that you had seen the complete picture for a couple of seconds 17 years earlier. This, too, was a real experiment, and participants who had previously seen the complete drawings were more likely to identify the objects than were members of a control group (Mitchell, 2006). Moreover, the picture memory reappeared even for those who did not consciously recall participating in the long-ago experiment!

How do we accomplish such memory feats? How does our brain pluck information out of the world around us and tuck that information away for later use? How can we remember things we have not thought about for years, yet forget the name of someone we met a minute ago? How are memories stored in our brains? Why will you be likely, later in this module, to misrecall this sentence: “*The angry rioter threw the rock at the window*”? In this and the next two modules, we'll consider these fascinating questions and more, including tips on how we can improve our own memories.

© The New Yorker Collection, 1987, Warren Miller from cartoonbank.com. All Rights Reserved.

Figure 31.1

What is this? People who had, 17 years earlier, seen the complete image (in Figure 31.4 when you turn the page) were more likely to recognize this fragment, even if they had forgotten the earlier experience (Mitchell, 2006).

Memory Models

31-2 How do psychologists describe the human memory system?

Architects make miniature house models to help clients imagine their future homes. Similarly, psychologists create memory models to help us think about how our brain forms and retrieves memories. *Information-processing models* are analogies that compare human memory to a computer's operations. Thus, to remember any event, we must

- *get information into our brain*, a process called **encoding**.
- *retain that information*, a process called **storage**.
- *later get the information back out*, a process called **retrieval**.

Like all analogies, computer models have their limits. Our memories are less literal and more fragile than a computer's. Moreover, most computers process information sequentially, even while alternating between tasks. Our dual-track brain processes many things simultaneously (some of them unconsciously) by means of **parallel processing**. As you enter the lunchroom, you simultaneously—in parallel—process information about the people you see, the sounds of voices, and the smell of the food.

To focus on this complex, simultaneous processing, one information-processing model, *connectionism*, views memories as products of interconnected neural networks. Specific memories arise from particular activation patterns within these networks. Every time you learn something new, your brain's neural connections change, forming and strengthening pathways that allow you to interact with and learn from your constantly changing environment.

To explain our memory-forming process, Richard Atkinson and Richard Shiffrin (1968) proposed another model, with three stages:

1. We first record to-be-remembered information as a fleeting **sensory memory**.
2. From there, we process information into **short-term memory**, where we encode it through *rehearsal*.
3. Finally, information moves into **long-term memory** for later retrieval.

Other psychologists have updated this model (**FIGURE 31.2**) to include important newer concepts, including *working memory* and *automatic processing*.

WORKING MEMORY

Alan Baddeley and others (Baddeley, 2001, 2002; Engle, 2002) challenged Atkinson and Shiffrin's view of short-term memory as a small, brief storage space for recent thoughts and experiences. Research shows that this stage is not just a temporary shelf for holding incoming information. It's an active desktop where your brain processes information, making sense of new input and linking it with long-term memories. Whether we hear *eye-scream* as "ice cream" or "I scream" will depend on how the context and our experience guide us in interpreting and encoding the sounds.

encoding the processing of information into the memory system—for example, by extracting meaning.

storage the process of retaining encoded information over time.

retrieval the process of getting information out of memory storage.

parallel processing the processing of many aspects of a problem simultaneously; the brain's natural mode of information processing for many functions. Contrasts with the step-by-step (serial) processing of most computers and of conscious problem solving.

sensory memory the immediate, very brief recording of sensory information in the memory system.

short-term memory activated memory that holds a few items briefly, such as the seven digits of a phone number while dialing, before the information is stored or forgotten.

long-term memory the relatively permanent and limitless storehouse of the memory system. Includes knowledge, skills, and experiences.

AP® Exam Tip

You will see several versions of Figure 31.2 as you work your way through Modules 31, 32, and 33. Pay attention! This model may look confusing now, but will make more and more sense as its components are described in more detail.

Figure 31.2

A modified three-stage processing model of memory Atkinson and Shiffrin's classic three-step model helps us to think about how memories are processed, but today's researchers recognize other ways long-term memories form. For example, some information slips into long-term memory via a "back door," without our consciously attending to it (*automatic processing*). And so much active processing occurs in the short-term memory stage that many now prefer the term *working memory*.

Figure 31.3

Working memory Alan Baddeley's (2002) model of working memory, simplified here, includes *visual* and *auditory rehearsal* of new information. A hypothetical *central executive* (manager) focuses attention and pulls information from long-term memory to help make sense of new information.

To emphasize the active processing that takes place in this middle stage, psychologists use the term **working memory**. Right now, you are using your working memory to link the information you're reading with your previously stored information (Cowan, 2010; Kail & Hall, 2001).

The pages you are reading may enter working memory through vision. You might also repeat the information using auditory rehearsal. As you integrate these memory inputs with your existing long-term memory, your attention is focused. Baddeley (2002) suggested a *central executive* handles this focused processing (**FIGURE 31.3**).

Without focused attention, information often fades. In one experiment, people read and typed new information they would later need, such as "An ostrich's eye is bigger than its brain." If they knew the information would be available online, they invested less energy in remembering, and they remembered the trivia less well (Sparrow et al., 2011). Sometimes Google replaces rehearsal.

**Figure 31.4**

Now you know People who had seen this complete image were, 17 years later, more likely to recognize the fragment in Figure 31.1.

working memory a newer understanding of short-term memory that focuses on conscious, active processing of incoming auditory and visual-spatial information, and of information retrieved from long-term memory.

explicit memory memory of facts and experiences that one can consciously know and "declare." (Also called *declarative memory*.)

effortful processing encoding that requires attention and conscious effort.

automatic processing unconscious encoding of incidental information, such as space, time, and frequency, and of well-learned information, such as word meanings.

implicit memory retention independent of conscious recollection. (Also called *nondeclarative memory*.)

Before You Move On

▶ ASK YOURSELF

How have you used the three parts of your memory system (encoding, storage, and retrieval) in learning something new today?

▶ TEST YOURSELF

Memory includes (in alphabetical order) long-term memory, sensory memory, and working/short-term memory. What's the correct order of these three memory stages?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Building Memories: Encoding

Dual-Track Memory: Effortful Versus Automatic Processing

31-3 How do explicit and implicit memories differ?

As we have seen throughout this text, our mind operates on two tracks:

- Atkinson and Shiffrin's model focused on how we process our **explicit memories**—the facts and experiences we can consciously know and declare (thus, also called *declarative memories*). We encode explicit memories through conscious, **effortful processing**.
- Behind the scenes, outside the Atkinson-Shiffrin stages, other information skips the conscious encoding track and barges directly into storage. This **automatic processing**, which happens without our awareness, produces **implicit memories** (also called *nondeclarative memories*).

Automatic Processing and Implicit Memories

31-4 What information do we automatically process?

Our implicit memories include *procedural* memory for automatic skills (such as how to ride a bike) and classically conditioned *associations* among stimuli. Visiting your dentist, you may, thanks to a conditioned association linking the dentist's office with the painful drill, find yourself with sweaty palms. You didn't plan to feel that way when you got to the dentist's office; it happened *automatically*.

Without conscious effort you also automatically process information about

- *space*. While studying, you often encode the place on a page or in your notebook where certain material appears; later, when you want to retrieve information about automatic processing, for example, you may visualize the location of that information on this page.
- *time*. While going about your day, you unintentionally note the sequence of its events. Later, realizing you've left your backpack somewhere, the event sequence your brain automatically encoded will enable you to retrace your steps.
- *frequency*. You effortlessly keep track of how many times things happen, as when you suddenly realize, *This is the third time I've run into her today*.

Our two-track mind engages in impressively efficient information processing. As one track automatically tucks away many routine details, the other track is free to focus on conscious, effortful processing. This reinforces an important principle introduced in Module 18's description of parallel processing: Mental feats such as vision, thinking, and memory may seem to be single abilities, but they are not. Rather, we split information into different components for separate and simultaneous processing.

Effortful Processing and Explicit Memories

Automatic processing happens so effortlessly that it is difficult to shut off. When you see words in your native language, perhaps on the side of a delivery truck, you can't help but read them and register their meaning. *Learning* to read wasn't automatic. You may recall working hard to pick out letters and connect them to certain sounds. But with experience and practice, your reading became automatic. Imagine now learning to read reversed sentences like this:

.citamotua emoceb nac gnissecorp luftroffeE

At first, this requires effort, but after enough practice, you would also perform this task much more automatically. We develop many skills in this way. We learn to drive, to text, to speak a new language with effort, but then these tasks become automatic.

SENSORY MEMORY

31-5 How does sensory memory work?

Sensory memory (recall Figure 31.2) feeds our active working memory, recording momentary images of scenes or echoes of sounds. How much of this page could you sense and recall with less exposure than a lightning flash? In one experiment (Sperling, 1960), people viewed three rows of three letters each, for only one-twentieth of a second (**FIGURE 31.5**). After the nine letters disappeared, they could recall only about half of them.

Was it because they had insufficient time to glimpse them? *No*. The researcher, George Sperling, cleverly demonstrated that people actually *could* see and recall all the letters, but only momentarily. Rather than ask them to recall all nine letters at

Figure 31.5

Total recall—briefly When George Sperling flashed a group of letters similar to this for one-twentieth of a second, people could recall only about half the letters. But when signaled to recall a particular row immediately after the letters had disappeared, they could do so with near-perfect accuracy.

K	Z	R
Q	B	T
S	G	N

iconic memory a momentary sensory memory of visual stimuli; a photographic or picture-image memory lasting no more than a few tenths of a second.

echoic memory a momentary sensory memory of auditory stimuli; if attention is elsewhere, sounds and words can still be recalled within 3 or 4 seconds.

FYI

The Magical Number Seven has become psychology's contribution to an intriguing list of magic sevens—the Seven Wonders of the Ancient World, the seven seas, the seven deadly sins, the seven primary colors, the seven musical scale notes, the seven days of the week—seven magical sevens.

once, he sounded a high, medium, or low tone immediately *after* flashing the nine letters. This tone directed participants to report only the letters of the top, middle, or bottom row, respectively. Now they rarely missed a letter, showing that all nine letters were momentarily available for recall.

Sperling's experiment demonstrated **iconic memory**, a fleeting sensory memory of visual stimuli. For a few tenths of a second, our eyes register a photographic or picture-image memory of a scene, and we can recall any part of it in amazing detail. But if Sperling delayed the tone signal by more than half a second, the image faded and participants again recalled only about half the letters. Our visual screen clears quickly, as new images are superimposed over old ones.

We also have an impeccable, though fleeting, memory for auditory stimuli, called **echoic memory** (Cowan, 1988; Lu et al., 1992). Picture yourself in class, as your attention veers to thoughts of the weekend. If your mildly irked teacher tests you by asking, "What did I just say?" you can recover the last few words from your mind's echo chamber. Auditory echoes tend to linger for 3 or 4 seconds.

CAPACITY OF SHORT-TERM AND WORKING MEMORY

31-6 What is the capacity of our short-term and working memory?

George Miller (1956) proposed that short-term memory can retain about seven information bits (give or take two). Other researchers have confirmed that we can, if nothing distracts us, recall about seven digits, or about six letters or five words (Baddeley et al., 1975). How quickly do our short-term memories disappear? To find out, researchers asked people to remember three-consonant groups, such as *CHJ* (Peterson & Peterson, 1959). To prevent rehearsal, the researchers asked them, for example, to start at 100 and count aloud backward by threes. After 3 seconds, people recalled the letters only about half the time; after 12 seconds, they seldom recalled them at all (**FIGURE 31.6**). Without the active processing that we now understand to be a part of our working memory, short-term memories have a limited life.

Working-memory capacity varies, depending on age and other factors. Compared with children and older adults, young adults have more working-memory capacity, so they can use their mental workspace more efficiently. This means their ability to multitask is relatively greater. But whatever our age, we do better and more efficient work when focused, without distractions, on one task at a time. "One of the most stubborn, persistent phenomenon of the mind," notes cognitive psychologist Daniel Willingham (2010), "is that when you do two things at once, you don't do either one as well as when you do them one at a time." *The bottom line:* It's probably a bad idea to try to watch TV, text your friends, and write a psychology paper all at the same time!

Working-memory capacity varies, depending on age and other factors. Compared with children and older adults, young adults have more working-memory capacity, so they can use their mental workspace more efficiently. This means their ability to multitask is relatively greater. But whatever our age, we do better and more efficient work when focused, without distractions, on one task at a time. "One of the most stubborn, persistent phenomenon of the mind," notes cognitive psychologist Daniel Willingham (2010), "is that when you do two things at once, you don't do either one as well as when you do them one at a time." *The bottom line:* It's probably a bad idea to try to watch TV, text your friends, and write a psychology paper all at the same time!

Figure 31.6

Short-term memory decay

Unless rehearsed, verbal information may be quickly forgotten. (From Peterson & Peterson, 1959; see also Brown, 1958.)

EFFORTFUL PROCESSING STRATEGIES

31-7 What are some effortful processing strategies that can help us remember new information?

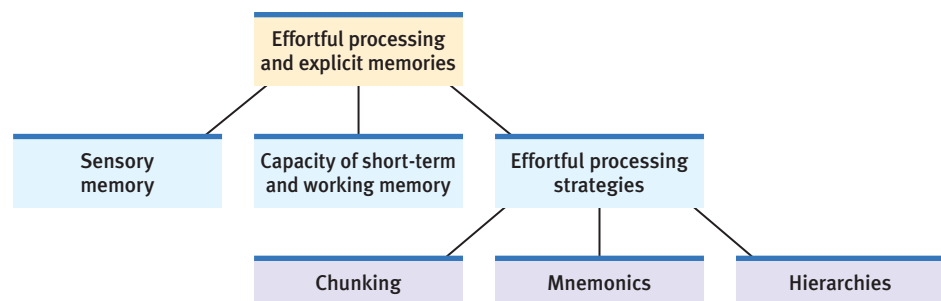

Research shows that several effortful processing strategies can boost our ability to form new memories. Later, when we try to retrieve a memory, these strategies can make the difference between success and failure.

HIERARCHIES When people develop expertise in an area, they process information not only in chunks but also in *hierarchies* composed of a few broad concepts divided and subdivided into narrower concepts and facts. This section, for example, aims to help you organize some of the memory concepts we have been discussing (**FIGURE 31.9**).

Organizing knowledge in hierarchies helps us retrieve information efficiently, as Gordon Bower and his colleagues (1969) demonstrated by presenting words either randomly or grouped into categories. When the words were organized into categories, recall was two to three times better. Such results show the benefits of organizing what you study—of giving special attention to the module objectives, headings, and Ask Yourself and Test Yourself questions. Taking class and text notes in outline format—a type of hierarchical organization—may also prove helpful.

Figure 31.9

Hierarchies aid retrieval When we organize words or concepts into hierarchical groups, as illustrated here with some of the concepts from this section, we remember them better than when we see them presented randomly.

“The mind is slow in unlearning what it has been long in learning.”
 —ROMAN PHILOSOPHER SENECA
 (4 B.C.E.–65 C.E.)

AP® Exam Tip

It’s not the studying you do in May that will determine your success on the AP® exam; it’s the studying you do now. It’s a good idea to take a little time each week to quickly review material from earlier in the course. When was the last time you looked at information from the previous units?

spacing effect the tendency for distributed study or practice to yield better long-term retention than is achieved through massed study or practice.

testing effect enhanced memory after retrieving, rather than simply rereading, information. Also sometimes referred to as a *retrieval practice effect* or *test-enhanced learning*.

shallow processing encoding on a basic level based on the structure or appearance of words.

DISTRIBUTED PRACTICE

We retain information (such as classmates’ names) better when our encoding is distributed over time. More than 300 experiments over the last century have consistently revealed the benefits of this **spacing effect** (Cepeda et al., 2006). *Massed practice* (cramming) can produce speedy short-term learning and a feeling of confidence. But to paraphrase pioneer memory researcher Hermann Ebbinghaus (1885), those who learn quickly also forget quickly. *Distributed practice* produces better long-term recall. After you’ve studied long enough to master the material, further study at that time becomes inefficient (Rohrer & Pashler, 2007). Better to spend that extra reviewing time later—a day later if you need to remember something 10 days hence, or a month later if you need to remember something 6 months hence (Cepeda et al., 2008).

Spreading your learning over several months, rather than over a shorter term, can help you retain information for a lifetime. In a 9-year experiment, Harry Bahrick and three of his family members (1993) practiced foreign language word translations for a given number of times, at intervals ranging from 14 to 56 days. Their consistent finding: The longer the space between practice sessions, the better their retention up to 5 years later.

One effective way to distribute practice is *repeated self-testing*, a phenomenon that researchers Henry Roediger and Jeffrey Karpicke (2006) have called the **testing effect**. In this text, for example, the testing questions interspersed throughout and at the end of each module and unit offer such opportunities. Better to practice retrieval (as any exam will demand) than merely to reread material (which may lull you into a false sense of mastery).

The point to remember: Spaced study and self-assessment beat cramming and rereading. Practice may not make perfect, but smart practice—occasional rehearsal with self-testing—makes for lasting memories.

LEVELS OF PROCESSING

31-8 What are the levels of processing, and how do they affect encoding?

Memory researchers have discovered that we process verbal information at different levels, and that depth of processing affects our long-term retention. **Shallow processing** encodes on a very basic level, such as a word’s letters or, at a more intermediate level, a word’s sound.

Making things memorable

For suggestions on how to apply the *testing effect* to your own learning, watch this 5-minute YouTube animation: tinyurl.com/HowToRemember.

Deep processing encodes *semantically*, based on the meaning of the words. The deeper (more meaningful) the processing, the better our retention.

In one classic experiment, researchers Fergus Craik and Endel Tulving (1975) flashed words at people. Then they asked the viewers a question that would elicit different levels of processing. To experience the task yourself, rapidly answer the following sample questions:

deep processing encoding semantically, based on the meaning of the words; tends to yield the best retention.

Sample Questions to Elicit Processing	Word Flashed	Yes	No
1. Is the word in capital letters?	CHAIR	_____	_____
2. Does the word rhyme with train?	brain	_____	_____
3. Would the word fit in this sentence? The girl put the _____ on the table.	doll	_____	_____

Which type of processing would best prepare you to recognize the words at a later time? In Craik and Tulving's experiment, the deeper, semantic processing triggered by the third question yielded a much better memory than did the shallower processing elicited by the second question or the very shallow processing elicited by question 1 (which was especially ineffective).

MAKING MATERIAL PERSONALLY MEANINGFUL

If new information is not meaningful or related to our experience, we have trouble processing it. Put yourself in the place of the students whom John Bransford and Marcia Johnson (1972) asked to remember the following recorded passage:

The procedure is actually quite simple. First you arrange things into different groups. Of course, one pile may be sufficient depending on how much there is to do. . . . After the procedure is completed one arranges the materials into different groups again. Then they can be put into their appropriate places. Eventually they will be used once more and the whole cycle will then have to be repeated. However, that is part of life.

When the students heard the paragraph you have just read, without a meaningful context, they remembered little of it. When told the paragraph described washing clothes (something meaningful to them), they remembered much more of it—as you probably could now after rereading it.

AP[®] Exam Tip

Are you often pressed for time? The most effective way to cut down on the amount of time you need to spend studying is to increase the meaningfulness of the material. If you can relate the material to your own life—and that's pretty easy when you're studying psychology—it takes less time to master it.

Try This

Here is another sentence I will ask you about later (in Module 33):
“The fish attacked the swimmer.”

Can you repeat the sentence about the rioter that I gave you at this module’s beginning? (“The angry rioter threw . . .”) Perhaps, like those in an experiment by William Brewer (1977), you recalled the sentence by the meaning you encoded when you read it (for example, “The angry rioter threw the rock *through* the window”) and not as it was written (“The angry rioter threw the rock *at* the window”). Referring to such mental mismatches, researchers have likened our minds to theater directors who, given a raw script, imagine the finished stage production (Bower & Morrow, 1990). Asked later what we heard or read, we recall not the literal text but *what we encoded*. Thus, studying for a test, you may remember your class notes rather than the class itself.

We can avoid some of these mismatches by rephrasing what we see and hear into meaningful terms. From his experiments on himself, German philosopher Hermann Ebbinghaus (1850–1909) estimated that, compared with learning nonsense material, learning meaningful material required one-tenth the effort. As memory researcher Wayne Wickelgren (1977, p. 346) noted, “The time you spend thinking about material you are reading and relating it to previously stored material is about the most useful thing you can do in learning any new subject matter.”

Psychologist-actor team Helga Noice and Tony Noice (2006) have described how actors inject meaning into the daunting task of learning “all those lines.” They do it by first coming to understand the flow of meaning: “One actor divided a half-page of dialogue into three [intentions]: ‘to flatter,’ ‘to draw him out,’ and ‘to allay his fears.’” With this meaningful sequence in mind, the actor more easily remembered the lines.

We have especially good recall for information we can meaningfully relate to ourselves. Asked how well certain adjectives describe someone else, we often forget them; asked how well the adjectives describe us, we remember the words well. This tendency, called the *self-reference effect*, is especially strong in members of individualist Western cultures (Symons & Johnson, 1997; Wagar & Cohen, 2003). Information deemed “relevant to me” is processed more deeply and remains more accessible. Knowing this, you can profit from taking time to find personal meaning in what you are studying.

The point to remember: The amount remembered depends both on the time spent learning and on your making it meaningful for deep processing.

Before You Move On

▶ ASK YOURSELF

Can you think of three ways to employ the principles in this section to improve your own learning and retention of important ideas?

▶ TEST YOURSELF

What would be the most effective strategy to learn and retain a list of names of key historical figures for a week? For a year?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 31 Review

31-1 What is memory?

- *Memory* is learning that has persisted over time, through the storage and retrieval of information.

31-2 How do psychologists describe the human memory system?

- Psychologists use memory models to think and communicate about memory.
- Information-processing models involve three processes: *encoding*, *storage*, and *retrieval*.
- The connectionism information-processing model views memories as products of interconnected neural networks.
- The three processing stages in the Atkinson-Shiffrin model are *sensory memory*, *short-term memory*, and *long-term memory*. More recent research has updated this model to include two important concepts: (1) *working memory*, to stress the active processing occurring in the second memory stage; and (2) automatic processing, to address the processing of information outside of conscious awareness.

31-3 How do explicit and implicit memories differ?

- Through *parallel processing*, the human brain processes many things simultaneously, on dual tracks.
- *Explicit* (declarative) *memories*—our conscious memories of facts and experiences—form through *effortful processing*, which requires conscious effort and attention.
- *Implicit* (nondeclarative) *memories*—of skills and classically conditioned associations—happen without our awareness, through *automatic processing*.

31-4 What information do we automatically process?

- In addition to skills and classically conditioned associations, we automatically process incidental information about space, time, and frequency.

31-5 How does sensory memory work?

- Sensory memory feeds some information into working memory for active processing there.
- An *iconic memory* is a very brief (a few tenths of a second) sensory memory of visual stimuli; an *echoic memory* is a three- or four-second sensory memory of auditory stimuli.

31-6 What is the capacity of our short-term and working memory?

- Short-term memory capacity is about seven items, plus or minus two, but this information disappears from memory quickly without rehearsal.
- Working memory capacity varies, depending on age, intelligence level, and other factors.

31-7 What are some effortful processing strategies that can help us remember new information?

- Effective effortful processing strategies include *chunking*, *mnemonics*, hierarchies, and distributed practice sessions.
- The *testing effect* is the finding that consciously retrieving, rather than simply rereading, information enhances memory.

31-8 What are the levels of processing, and how do they affect encoding?

- Depth of processing affects long-term retention.
 - In *shallow processing*, we encode words based on their structure or appearance.
 - Retention is best when we use *deep processing*, encoding words based on their meaning.
- We also more easily remember material that is personally meaningful—the self-reference effect.

Multiple-Choice Questions

1. Caitlin, a fifth grader, is asked to remember her second-grade teacher's name. What measure of retention will Caitlin use to answer this question?
 - a. Storage
 - b. Recognition
 - c. Relearning
 - d. Recall
 - e. Encoding
2. Working memory is most active during which portion of the information-processing model?
 - a. Short-term memory
 - b. Sensory memory
 - c. Retrieval
 - d. Encoding
 - e. Long-term memory
3. Your memory of which of the following is an example of implicit memory?
 - a. What you had for breakfast yesterday
 - b. The need to spend some time reviewing tomorrow for an upcoming psychology quiz
 - c. Which way to turn the car key to start the engine
 - d. That George Washington was the first President
 - e. How exciting it was to get the best birthday present ever
4. Which of the following is the most accurate description of the capacity of short-term and working memory?
 - a. Lasts for about 2 days in most circumstances
 - b. Lasts for less than half a minute unless you rehearse the information
 - c. Is thought to be unlimited—there is always room for more information
 - d. Can handle about a half dozen items for each of the tasks you are working on at any time
 - e. Can handle about a half dozen items total
5. Which of the following is most likely to lead to semantic encoding of a list of words?
 - a. Thinking about how the words relate to your own life
 - b. Practicing the words for a single extended period
 - c. Breaking up the practice into several relatively short sessions
 - d. Noticing where in a sentence the words appear
 - e. Focusing on the number of vowels and consonants in the words

Practice FRQs

1. To remember something, we must get information into our brain, retain the information, and later get the information back out. Making sure you use the terms for these three steps of the process, explain how this system would apply if you needed to learn the name of a new student who just enrolled in your school today.
2. Last evening, Carlos' mom told him he needed to buy milk today. So, he hopped on his bicycle this morning and headed to the corner store to pick up a gallon. Explain how both implicit and explicit memories were involved in Carlos' errand.

(4 points)

Answer

1 point: Encoding is the process of getting the new student's name into your brain.

1 point: Storage is keeping that name in your memory.

1 point: Retrieval is the process of using that name when greeting the new student later.

Module 32

Memory Storage and Retrieval

Module Learning Objectives

- 32-1** Describe the capacity and location of our long-term memories.
- 32-2** Describe the roles of the frontal lobes and hippocampus in memory processing.
- 32-3** Describe the roles of the cerebellum and basal ganglia in our memory processing.
- 32-4** Discuss how emotions affect our memory processing.
- 32-5** Explain how changes at the synapse level affect our memory processing.
- 32-6** Explain how memory is measured.
- 32-7** Describe how external cues, internal emotions, and order of appearance influence memory retrieval.

Memory Storage

- 32-1** What is the capacity of long-term memory? Are our long-term memories processed and stored in specific locations?

In Arthur Conan Doyle's *A Study in Scarlet*, Sherlock Holmes offers a popular theory of memory capacity:

I consider that a man's brain originally is like a little empty attic, and you have to stock it with such furniture as you choose. . . . It is a mistake to think that that little room has elastic walls and can distend to any extent. Depend upon it, there comes a time when for every addition of knowledge you forget something that you knew before.

Contrary to Holmes' "memory model," our capacity for storing long-term memories is essentially limitless. Our brains are not like attics, which once filled can store more items only if we discard old ones.

Retaining Information in the Brain

I marveled at my aging mother-in-law, a retired pianist and organist. At age 88, her blind eyes could no longer read music. But let her sit at a keyboard and she would flawlessly play any of hundreds of hymns, including ones she had not thought of for 20 years. Where did her brain store those thousands of sequenced notes?

"Our memories are flexible and superimposable, a panoramic blackboard with an endless supply of chalk and erasers."
-ELIZABETH LOFTUS AND KATHERINE KETCHAM, *THE MYTH OF REPPRESSED MEMORY*, 1994

For a time, some surgeons and memory researchers marveled at patients' seeming vivid memories triggered by brain stimulation during surgery. Did this prove that our whole past, not just well-practiced music, is "in there," in complete detail, just waiting to be relived? On closer analysis, the seeming flashbacks appeared to have been invented, not relived (Loftus & Loftus, 1980). In a further demonstration that memories do not reside in single, specific spots, psychologist Karl Lashley (1950) trained rats to find their way out of a maze, then surgically removed pieces of their brain's cortex and retested their memory. No matter which small brain section he removed, the rats retained at least a partial memory of how to navigate the maze.

The point to remember: Despite the brain's vast storage capacity, we do not store information as libraries store their books, in discrete, precise locations. Instead, many parts of the brain interact as we encode, store, and retrieve the information that forms our memories.

EXPLICIT-MEMORY SYSTEM: THE FRONTAL LOBES AND HIPPOCAMPUS

32-2 What roles do the frontal lobes and hippocampus play in memory processing?

As with perception, language, emotion, and much more, memory requires brain networks. The network that processes and stores your explicit memories for facts and episodes includes your frontal lobes and hippocampus. When you summon up a mental encore of a past experience, many brain regions send input to your frontal lobes for working memory processing (Fink et al., 1996; Gabrieli et al., 1996; Markowitsch, 1995). The left and right frontal lobes process different types of memories. Recalling a password and holding it in working memory, for example, would activate the left frontal lobe. Calling up a visual party scene would more likely activate the right frontal lobe.

Cognitive neuroscientists have found that the **hippocampus**, a temporal-lobe neural center located in the limbic system, is the brain's equivalent of a "save" button for explicit memories (**FIGURE 32.1**). Brain scans, such as PET scans of people recalling words, and autopsies of people who had *amnesia* (memory loss) have revealed that new explicit memories of names, images, and events are laid down via the hippocampus (Squire, 1992).

Damage to this structure therefore disrupts recall of explicit memories. Chickadees and other birds can store food in hundreds of places and return to these unmarked caches months later—but not if their hippocampus has been removed (Kamil & Cheng, 2001; Sherry & Vaccarino, 1989). With left-hippocampus damage, people have trouble remembering verbal information, but they have no trouble recalling visual designs and locations. With right-hippocampus damage, the problem is reversed (Schacter, 1996).

Subregions of the hippocampus also serve different functions. One part is active as people learn to associate names with faces (Zeineh et al., 2003). Another part is active as memory champions engage in spatial mnemonics (Maguire et al., 2003b). The rear area, which processes spatial memory, grows bigger the longer a London cabbie has navigated the maze of streets (Maguire et al., 2003a).

Memories are not permanently stored in the hippocampus. Instead, this structure seems to act as a loading dock where the brain registers and temporarily holds the elements of a remembered episode—its smell, feel, sound, and location. Then, like older files shifted to a basement storeroom, memories migrate for storage elsewhere.

Sleep supports memory consolidation. During deep sleep, the hippocampus processes memories for later retrieval. After a training experience, the greater

hippocampus a neural center located in the limbic system; helps process explicit memories for storage.

Figure 32.1

The hippocampus Explicit memories for facts and episodes are processed in the hippocampus and fed to other brain regions for storage.

the hippocampus activity during sleep, the better the next day's memory will be (Peigneux et al., 2004). Researchers have watched the hippocampus and brain cortex displaying simultaneous activity rhythms during sleep, as if they were having a dialogue (Euston et al., 2007; Mehta, 2007). They suspect that the brain is replaying the day's experiences as it transfers them to the cortex for long-term storage. Cortex areas surrounding the hippocampus support the processing and storing of explicit memories (Squire & Zola-Morgan, 1991).

IMPLICIT-MEMORY SYSTEM: THE CEREBELLUM AND BASAL GANGLIA

32-3 What roles do the cerebellum and basal ganglia play in our memory processing?

Your hippocampus and frontal lobes are processing sites for your *explicit* memories. But you could lose those areas and still, thanks to automatic processing, lay down *implicit* memories for skills and conditioned associations. Joseph LeDoux (1996) recounted the story of a brain-damaged patient whose amnesia left her unable to recognize her physician as, each day, he shook her hand and introduced himself. One day, she yanked her hand back, for the physician had pricked her with a tack in his palm. The next time he returned to introduce himself she refused to shake his hand but couldn't explain why. Having been *classically conditioned*, she just wouldn't do it.

The *cerebellum* plays a key role in forming and storing the implicit memories created by classical conditioning. With a damaged cerebellum, people cannot develop certain conditioned reflexes, such as associating a tone with an impending puff of air—and thus do not blink in anticipation of the puff (Daum & Schugens, 1996; Green & Woodruff-Pak, 2000). When researchers surgically disrupted the function of different pathways in the cerebellum of rabbits, the rabbits became unable to learn a conditioned eyeblink response (Krupa et al., 1993; Steinmetz, 1999). Implicit memory formation needs the cerebellum (**FIGURE 32.2**).

The *basal ganglia*, deep brain structures involved in motor movement, facilitate formation of our procedural memories for skills (Mishkin, 1982; Mishkin et al., 1997). The basal ganglia receive input from the cortex but do not return the favor of sending information back to the cortex for conscious awareness of procedural learning. If you have learned how to ride a bike, thank your basal ganglia.

Our implicit memory system, enabled partly by the cerebellum and basal ganglia, helps explain why the reactions and skills we learned during infancy reach far into our future. Yet as adults, our conscious memory of our first three years is blank, an experience called *infantile amnesia*. In one study, events children experienced and discussed with their mothers at age 3 were 60 percent remembered at age 7 but only 34 percent remembered at age 9 (Bauer et al., 2007). Two influences contribute to infantile amnesia: First, we index much of our explicit memory using words that nonspeaking children have not learned. Second, the hippocampus is one of the last brain structures to mature.

The Amygdala, Emotions, and Memory

32-4 How do emotions affect our memory processing?

Our emotions trigger stress hormones that influence memory formation. When we are excited or stressed, these hormones make more glucose energy available to fuel brain activity, signaling the brain that something important has happened. Moreover, stress hormones provoke the *amygdala* (two limbic system, emotion-processing clusters) to initiate a memory

Hippocampus hero
Among animals, one contender for champion memorist would be a mere birdbrain—the Clark's Nutcracker—which during winter and spring can locate up to 6000 caches of pine seed it had previously buried (Shettleworth, 1993).

trace in the frontal lobes and basal ganglia and to boost activity in the brain's memory-forming areas (Buchanan, 2007; Kensinger, 2007) (**FIGURE 32.3**). The result? Emotional arousal can sear certain events into the brain, while disrupting memory for neutral events around the same time (Birnbaum et al., 2004; Brewin et al., 2007).

Emotions often persist without our conscious awareness of what caused them. In one ingenious experiment, patients with hippocampal damage (which left them unable to form new explicit memories) watched a sad film and later a happy film. After the viewing, they did not consciously recall the films, but the sad or happy emotion persisted (Feinstein et al., 2010).

Significantly stressful events can form almost indelible (unforgettable) memories. After traumatic experiences—a school shooting, a house fire, a rape—vivid recollections of the horrific event may intrude again and again. It is as if they were burned in: “Stronger emotional experiences make for stronger, more reliable memories,” noted James McGaugh (1994, 2003). This makes adaptive sense. Memory serves to predict the future and to alert us to potential dangers. Conversely, weaker emotions mean weaker memories. People given a drug that blocked the effects of stress hormones later had more trouble remembering the details of an upsetting story (Cahill, 1994).

Emotion-triggered hormonal changes help explain why we long remember exciting or shocking events, such as our first kiss or our whereabouts when learning of a loved one's death. In a 2006 Pew survey, 95 percent of American adults said they could recall exactly where they were or what they were doing when they first heard the news of the 9/11 terrorist attacks. This perceived clarity of memories of surprising, significant events leads some psychologists to call them **flashbulb memories**. It's as if the brain commands, “Capture this!”

The people who experienced a 1989 San Francisco earthquake did just that. A year and a half later, they had perfect recall of where they had been and what they were doing (verified by their recorded thoughts within a day or two of the quake). Others' memories for the circumstances under which they merely *heard* about the quake were more prone to errors (Neisser et al., 1991; Palmer et al., 1991).

Our flashbulb memories are noteworthy for their vividness and the confidence with which we recall them. But as we relive, rehearse, and discuss them, these memories may come to err, as misinformation seeps in (Conway et al., 2009; Talarico & Rubin, 2003, 2007).

Synaptic Changes

32-5 How do changes at the synapse level affect our memory processing?

As you read this module and think and learn about memory characteristics and processes, your brain is changing. Given increased activity in particular pathways, neural interconnections are forming and strengthening.

The quest to understand the physical basis of memory—how information becomes embedded in brain matter—has sparked study of the synaptic meeting places where neurons communicate with one another via their neurotransmitter messengers.

Eric Kandel and James Schwartz (1982) observed synaptic changes during learning in the sending neurons of the California sea slug, *Aplysia*, a simple animal with a mere 20,000 or so unusually large and accessible nerve cells. Module 26 noted how the sea slug can be classically conditioned (with electric shock) to reflexively withdraw its gills when squirted with water, much as a shell-shocked soldier jumps at the sound of a snapping twig. By observing the slug's neural connections before and after conditioning,

Art Directors & TRIP/Alamy

Aplysia The California sea slug, which neuroscientist Eric Kandel studied for 45 years, has increased our understanding of the neural basis of learning.

Kandel and Schwartz pinpointed changes. When learning occurs, the slug releases more of the neurotransmitter *serotonin* into certain synapses. Those synapses then become more efficient at transmitting signals.

In experiments with people, rapidly stimulating certain memory-circuit connections has increased their sensitivity for hours or even weeks to come. The sending neuron now needs less prompting to release its neurotransmitter, and more connections exist between neurons (**FIGURE 32.4**). This increased efficiency of potential neural firing, called **long-term potentiation (LTP)**, provides a neural basis for learning and remembering associations (Lynch, 2002; Whitlock et al., 2006). Several lines of evidence confirm that LTP is a physical basis for memory:

- Drugs that block LTP interfere with learning (Lynch & Staubli, 1991).
- Mutant mice engineered to lack an enzyme needed for LTP couldn't learn their way out of a maze (Silva et al., 1992).
- Rats given a drug that enhanced LTP learned a maze with half the usual number of mistakes (Service, 1994).
- Injecting rats with a chemical that blocked the preservation of LTP erased recent learning (Pastalkova et al., 2006).

After long-term potentiation has occurred, passing an electric current through the brain won't disrupt old memories. But the current will wipe out very recent memories. Such is the experience both of laboratory animals and of severely depressed people given *electroconvulsive therapy* (see Module 73). A blow to the head can do the same. Football players and boxers momentarily knocked unconscious typically have no memory of events just before the knockout (Yarnell & Lynch, 1970). Their working memory had no time to consolidate the information into long-term memory before the lights went out.

Some memory-biology explorers have helped found companies that are competing to develop memory-altering drugs. The target market for memory-boosting drugs includes millions of people with Alzheimer's disease, millions more with *mild neurocognitive disorder* that often becomes Alzheimer's, and countless millions who would love to turn back the clock on age-related memory decline. From expanding memories perhaps will come bulging profits.

In your lifetime, will you have access to safe and legal drugs that boost your fading memory without nasty side effects and without cluttering your mind with trivia best forgotten? That question has yet to be answered. But in the meantime, one safe and free memory enhancer is already available for high schoolers everywhere: effective study techniques followed by adequate *sleep!* (You'll find study tips in Module 2 and at the end of this module, and sleep coverage in Modules 23 and 24.)

"The biology of the mind will be as scientifically important to this [new] century as the biology of the gene [was] to the twentieth century." -ERIC KANDEL, ACCEPTANCE REMARKS FOR HIS 2000 NOBEL PRIZE

long-term potentiation (LTP)

an increase in a cell's firing potential after brief, rapid stimulation. Believed to be a neural basis for learning and memory.

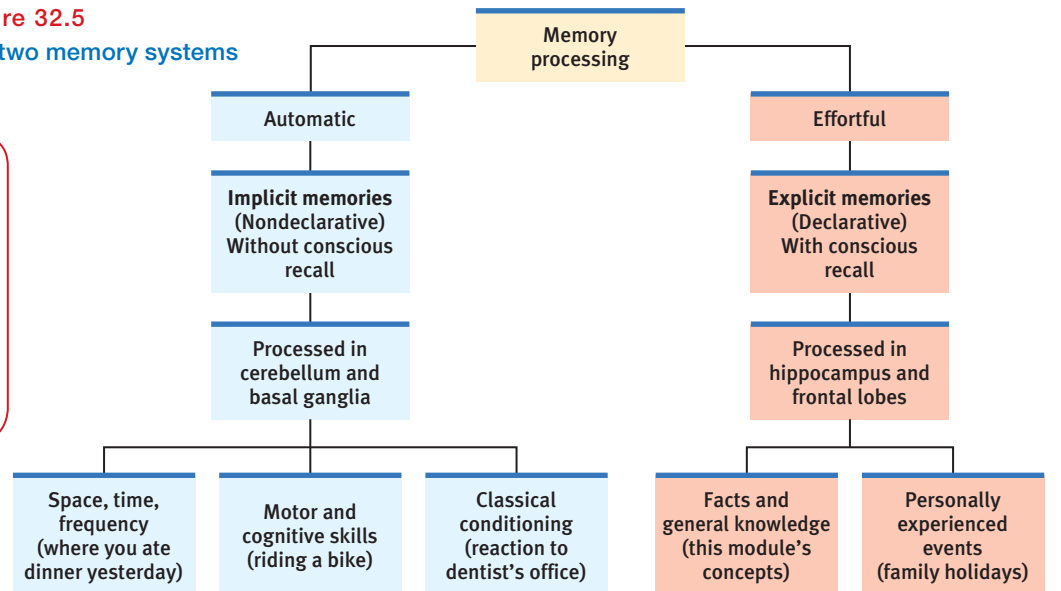

Figure 32.4

Doubled receptor sites Electron microscope image (a) shows just one receptor site (gray) reaching toward a sending neuron before long-term potentiation. Image (b) shows that, after LTP, the receptor sites have doubled. This means that the receiving neuron has increased sensitivity for detecting the presence of the neurotransmitter molecules that may be released by the sending neuron. (From Toni et al., 1999.)

FIGURE 32.5 summarizes the brain's two-track memory processing and storage system for implicit (automatic) and explicit (effortful) memories.

Figure 32.5
Our two memory systems

AP® Exam Tip

Figure 32.5 is an excellent summary. Why don't you review it for a few minutes and then see how much of it you can reproduce on a piece of paper? That will give you a good assessment of which parts of the memory process you know and which parts you still need to work on.

Before You Move On

▶ ASK YOURSELF

Can you name an instance in which stress has helped you remember something, and another instance in which stress has interfered with remembering something?

▶ TEST YOURSELF

Your friend tells you that her father experienced brain damage in an accident. She wonders if psychology can explain why he can still play checkers very well but has a hard time holding a sensible conversation. What can you tell her?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Retrieval: Getting Information Out

After the magic of brain encoding and storage, we still have the daunting task of retrieving the information. What triggers retrieval? How do psychologists study this phenomenon?

Measuring Retention

32-6 How is memory measured?

To a psychologist, evidence of memory includes these three *measures of retention*:

- **recall**—retrieving information that is not currently in your conscious awareness but that was learned at an earlier time. A fill-in-the-blank question tests your recall.
- **recognition**—identifying items previously learned. A multiple-choice question tests your recognition.
- **relearning**—learning something more quickly when you learn it a second or later time. When you study for a final exam or engage a language used in early childhood, you will relearn the material more easily than you did initially.

recall a measure of memory in which the person must retrieve information learned earlier, as on a fill-in-the-blank test.

recognition a measure of memory in which the person need only identify items previously learned, as on a multiple-choice test.

relearning a measure of memory that assesses the amount of time saved when learning material again.

Long after you cannot recall most of the people in your high school graduating class, you may still be able to recognize their yearbook pictures from a photographic lineup and pick their names from a list of names. In one experiment, people who had graduated 25 years earlier could not *recall* many of their old classmates, but they could *recognize* 90 percent of their pictures and names (Bahrick et al., 1975). If you are like most students, you, too, could probably recognize more names of Snow White's Seven Dwarfs than you could recall (Miserandino, 1991).

Our recognition memory is impressively quick and vast. "Is your friend wearing a new or old outfit?" "Old." "Is this 5-second movie clip from a film you've ever seen?" "Yes." "Have you ever seen this person before—this minor variation on the same old human features (two eyes, one nose, and so on)?" "No." Before the mouth can form our answer to any of millions of such questions, the mind knows, and knows that it knows.

Our speed at *relearning* also reveals memory. Hermann Ebbinghaus showed this more than a century ago, in his learning experiments, using nonsense syllables. He randomly selected a sample of syllables, practiced them, and tested himself. To get a feel for his experiments, rapidly read aloud, eight times over, the following list (from Baddeley, 1982), then look away and try to recall the items:

JIH, BAZ, FUB, YOX, SUJ, XIR, DAX, LEQ, VUM, PID, KEL, WAV,
TUV, ZOF, GEK, HIW.

The day after learning such a list, Ebbinghaus could recall few of the syllables. But they weren't entirely forgotten. As **FIGURE 32.6** portrays, the more frequently he repeated the list aloud on day 1, the fewer repetitions he required to *relearn* the list on day 2. Additional rehearsal (*overlearning*) of verbal information increases retention, especially when practice is distributed over time. For students, this means that it is important to continue to rehearse course material even after you know it.

The point to remember: Tests of recognition and of time spent relearning demonstrate that *we remember more than we can recall*.

Retrieval Cues

32-7 How do external cues, internal emotions, and order of appearance influence memory retrieval?

Imagine a spider suspended in the middle of her web, held up by the many strands extending outward from her in all directions to different points. If you were to trace a pathway to the spider, you would first need to create a path from one of these anchor points and then follow the strand down into the web.

The process of retrieving a memory follows a similar principle, because memories are held in storage by a web of associations, each piece of information interconnected with others. When you encode into memory a target piece of information, such as the name of the person sitting next to you in class, you associate with it other bits of information about your surroundings, mood, seating position, and so on. These bits can serve as *retrieval cues* that you can later use to access the information. The more retrieval cues you have, the better your chances of finding a route to the suspended memory.

PRIMING

The best retrieval cues come from associations we form at the time we encode a memory—smells, tastes, and sights that can evoke our memory of the associated person or event. To call up visual cues when trying to recall something, we may mentally place ourselves in the

Remembering things past Even if Taylor Swift and Leonardo DiCaprio had not become famous, their high school classmates would most likely still recognize their high school photos.

Time in minutes
taken to relearn
list on day 2

Figure 32.6

Ebbinghaus' retention curve

Ebbinghaus found that the more times he practiced a list of nonsense syllables on day 1, the fewer repetitions he required to relearn it on day 2. Speed of relearning is one measure of memory retention. (From Baddeley, 1982.)

"Memory is not like a container that gradually fills up; it is more like a tree growing hooks onto which memories are hung." -PETER RUSSELL, *THE BRAIN BOOK*, 1979

priming the activation, often unconsciously, of particular associations in memory.

original context. After losing his sight, British scholar John Hull (1990, p. 174) described his difficulty recalling such details:

I knew I had been somewhere, and had done particular things with certain people, but where? I could not put the conversations . . . into a context. There was no background, no features against which to identify the place. Normally, the memories of people you have spoken to during the day are stored in frames which include the background.

Often our associations are activated without our awareness. The philosopher-psychologist William James referred to this process, which we call **priming**, as the “wakening of associations.” Seeing or hearing the word *rabbit* primes associations with *hare*, even though we may not recall having seen or heard *rabbit* (**FIGURE 32.7**).

Priming is often “memoryless memory”—invisible memory, without your conscious awareness. If, walking down a hallway, you see a poster of a missing child, you may then unconsciously be primed to interpret an ambiguous adult-child interaction as a possible kidnapping (James, 1986). Although you no longer have the poster in mind, it predisposes your interpretation.

Priming can influence behaviors as well. In one study, participants primed with money-related words were less likely to help another person when asked (Vohs et al., 2006). In such cases, money may prime our materialism and self-interest rather than the social norms that encourage us to help (Ariely, 2009).

Seeing or hearing the word *rabbit*

Activates concept

Primes spelling the spoken word *hair/hare* as *h-a-r-e*

Figure 32.7

Priming—awakening associations

After seeing or hearing *rabbit*, we are later more likely to spell the spoken word as *h-a-r-e*. The spreading of associations unconsciously activates related associations. This phenomenon is called priming. (Adapted from Bower, 1986.)

CONTEXT-DEPENDENT MEMORY

Putting yourself back in the context where you experienced something can prime your memory retrieval. As **FIGURE 32.8** illustrates, when scuba divers listened to a word list in two different settings (either 10 feet underwater or sitting on the beach), they recalled more words if retested in the same place (Godden & Baddeley, 1975).

You may have experienced similar context effects. Consider this scenario: While taking notes from this book, you realize you need to sharpen your pencil. You get up and walk into another room, but then you cannot remember why. After returning to your desk it hits you: “I wanted to sharpen this pencil!” What happens to create this frustrating experience?

Olga Khorooshunova/Shutterstock

Figure 32.8

The effects of context on memory

In this experiment, words heard underwater were best recalled underwater. Words heard on land were best recalled on land. (Adapted from Godden & Baddeley, 1975.)

Percentage of words recalled

In one context (desk, reading psychology), you realize your pencil needs sharpening. When you go to the other room and are in a different context, you have few cues to lead you back to that thought. When you are once again at your desk, you are back in the context in which you encoded the thought (“*This pencil is dull*”).

In several experiments, one researcher found that a familiar context could activate memories even in 3-month-olds (Rovee-Collier, 1993). After infants learned that kicking a crib mobile would make it move (via a connecting ribbon from the ankle), the infants kicked more when tested again in the same crib with the same bumper than when in a different context.

STATE-DEPENDENT MEMORY

Closely related to context-dependent memory is *state-dependent memory*. What we learn in one state—be it drunk or sober—may be more easily recalled when we are again in that state. What people learn when drunk they don’t recall well in *any* state (alcohol disrupts storage). But they recall it slightly better when again drunk. Someone who hides money when drunk may forget the location until drunk again.

Our mood states provide an example of memory’s state dependence. Emotions that accompany good or bad events become retrieval cues (Fiedler et al., 2001). Thus, our memories are somewhat **mood congruent**. If you’ve had a bad evening—your date never showed, your Chicago Cubs hat disappeared, your TV went out 10 minutes before the end of a show—your gloomy mood may facilitate recalling other bad times. Being depressed sours memories by priming negative associations, which we then use to explain our current mood. In many experiments, people put in a buoyant mood—whether under hypnosis or just by the day’s events (a World Cup soccer victory for German participants in one study)—have recalled the world through rose-colored glasses (DeSteno et al., 2000; Forgas et al., 1984; Schwarz et al., 1987). They judged themselves competent and effective, other people benevolent, happy events more likely.

Knowing this mood-memory connection, we should not be surprised that in some studies *currently* depressed people have recalled their parents as rejecting, punitive, and guilt promoting, whereas *formerly* depressed people’s recollections more closely resembled the more positive descriptions given by those who never suffered depression (Lewinsohn & Rosenbaum, 1987; Lewis, 1992). Similarly, adolescents’ ratings of parental warmth in one week gave little clue to how they would rate their parents six weeks later (Bornstein et al., 1991). When teens were down, their parents seemed inhuman; as their mood brightened, their parents morphed from devils into angels. In a good or bad mood, we persist in attributing to reality our own changing judgments, memories, and interpretations. In a bad mood, we may read someone’s look as a glare and feel even worse. In a good mood, we may encode the same look as interest and feel even better. Passions exaggerate.

This retrieval effect helps explain why our moods persist. When happy, we recall happy events and therefore see the world as a happy place, which helps prolong our good mood. When depressed, we recall sad events, which darkens our interpretations of current events. For those of us with a predisposition to depression, this process can help maintain a vicious, dark cycle.

SERIAL POSITION EFFECT

Another memory-retrieval quirk, the **serial position effect**, can leave us wondering why we have large holes in our memory of a list of recent events. Imagine it’s your first day in a new job, and your manager is introducing co-workers. As you meet each person, you silently repeat everyone’s name, starting from the beginning. As the last person smiles and turns away, you feel confident you’ll be able to greet your new co-workers by name the next day.

Don’t count on it. Because you have spent more time rehearsing the earlier names than the later ones, those are the names you’ll probably recall more easily the next day.

Try This

Ask a friend two rapid-fire questions: (a) How do you pronounce the word spelled by the letters s-h-o-p? (b) What do you do when you come to a green light? If your friend answers “stop” to the second question, you have demonstrated priming.

“I can’t remember what we’re arguing about, either. Let’s keep yelling, and maybe it will come back to us.”

© The New Yorker Collection, 2005. David Sipress from cartoonbank.com. All Rights Reserved.

“When a feeling was there, they felt as if it would never go; when it was gone, they felt as if it had never been; when it returned, they felt as if it had never gone.”
—GEORGE MACDONALD, *WHAT’S MINE’S MINE*, 1886

mood-congruent memory the tendency to recall experiences that are consistent with one’s current good or bad mood.

serial position effect our tendency to recall best the last (a *recency effect*) and first items (a *primacy effect*) in a list.

Figure 32.9

The serial position effect Immediately after the royal newlyweds, William and Kate, made their way through the receiving line of special guests, they would probably have recalled the names of the last few people best. But later they may have been able to recall the first few people best.

Ian West/WPA Pool/Getty Images

In experiments, when people view a list of items (words, names, dates, even odors) and immediately try to recall them in any order, they fall prey to the serial position effect (Reed, 2000). They briefly recall the last items especially quickly and well (*a recency effect*), perhaps because those last items are still in working memory. But after a delay, when they have shifted their attention away from the last items, their recall is best for the first items (*a primacy effect*; see **FIGURE 32.9**).

Before You Move On

▶ ASK YOURSELF

What sort of mood have you been in lately? How has your mood colored your memories, perceptions, and expectations?

▶ TEST YOURSELF

You have just watched a movie that includes a chocolate factory. After the chocolate factory is out of mind, you nevertheless feel a strange urge for a chocolate bar. How do you explain this in terms of priming?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 32 Review

32-1

What is the capacity of long-term memory? Are our long-term memories processed and stored in specific locations?

- Our long-term memory capacity is essentially unlimited.
- Memories are not stored intact in the brain in single spots. Many parts of the brain interact as we form and retrieve memories.

32-2

What are the roles of the frontal lobes and hippocampus in memory processing?

- The frontal lobes and *hippocampus* are parts of the brain network dedicated to explicit memory formation.
 - Many brain regions send information to the frontal lobes for processing.
 - The hippocampus, with the help of surrounding areas of cortex, registers and temporarily holds elements of explicit memories before moving them to other brain regions for long-term storage.

32-3 What roles do the cerebellum and basal ganglia play in our memory processing?

- The cerebellum and basal ganglia are parts of the brain network dedicated to implicit memory formation.
 - The cerebellum is important for storing classically conditioned memories.
 - The basal ganglia are involved in motor movement and help form procedural memories for skills.
- Many reactions and skills learned during our first three years continue into our adult lives, but we cannot consciously remember learning these associations and skills, a phenomenon psychologists call “infantile amnesia.”

32-4 How do emotions affect our memory processing?

- Emotional arousal causes an outpouring of stress hormones, which lead to activity in the brain’s memory-forming areas. Significantly stressful events can trigger very clear *flashbulb memories*.

32-5 How do changes at the synapse level affect our memory processing?

- *Long-term potentiation (LTP)* appears to be the neural basis for learning and memory. In LTP, neurons become more efficient at releasing and sensing the presence of neurotransmitters, and more connections develop between neurons.

32-6 How is memory measured?

- Evidence of memory may be seen in an ability to *recall* information, *recognize* it, or *relearn* it more easily on a later attempt.

32-7 How do external cues, internal emotions, and order of appearance influence memory retrieval?

- External cues activate associations that help us retrieve memories; this process may occur without our awareness, as it does in *priming*.
- Returning to the same physical context or emotional state (*mood congruency*) in which we formed a memory can help us retrieve it.
- The *serial position effect* accounts for our tendency to recall best the last items (which may still be in working memory) and the first items (which we’ve spent more time rehearsing) in a list.

Multiple-Choice Questions

1. What two parts of the brain are most involved in explicit memory?
 - a. Frontal lobes and basal ganglia
 - b. Amygdala and hippocampus
 - c. Amygdala and cerebellum
 - d. Cerebellum and basal ganglia
 - e. Frontal lobes and hippocampus
2. Which of the following statements most accurately reflects the relationship between emotions and memory?
 - a. Emotion blocks memory, and it is generally true that we are unable to recall highly emotional events.
 - b. Excitement tends to increase the chance that an event will be remembered, but stress decreases the chance that an event will be remembered.
 - c. Stress tends to increase the chance that an event will be remembered, but excitement decreases the chance that an event will be remembered.
 - d. The effect of emotion on memory depends on the interpretation of the event in the frontal lobes.
 - e. Emotion enhances memory because it is important for our survival to remember events that make us emotional.

3. Which of the following is an example of flashbulb memory?
- Barry remembers an especially bright sunrise because he was by the ocean and the sunlight reflected off the water.
 - Robert remembers that correlation does not prove a cause–effect relationship because his teacher emphasized this fact over and over again.
 - Anna remembers when her father returned from an overseas military deployment because the day was very emotional for her.
 - Kris has stronger memories of her second grade teacher than she does of her third grade teacher because her second grade teacher has the same name as her neighbor.
 - Anton remembers a moment from his last homecoming dance because a strobe light seemed to freeze the scene in his imagination.
4. Juan returns to his grandparent’s house after a 10-year absence. The flood of memories about his childhood visits is best explained by which of the following?
- Recall
 - Priming
 - Explicit memory
 - The serial position effect
 - Flashbulb memory
5. Which of the following is an example of the primacy effect?
- Remembering the most important assignment you have to complete for school tomorrow
 - Remembering the skills you learned early in life, such as walking
 - Remembering the last thing your English teacher talked about in class yesterday, but nothing from earlier in the class period
 - Remembering the names of the first two co-workers you met on the first day of your new job
 - Remembering that your clocks must be moved ahead one hour when daylight savings time begins in the spring

Practice FRQs

1. Consider an explicit memory, such as a memory of what happened in your science class yesterday.
Explain the process that allows memory to occur at the synaptic level.
Explain the role of two parts of the brain in your memory of the class.
2. You have a friend, Rachel, who cannot remember where she left a check she had received from a relative for her birthday. She remembers having drunk several cups of tea the morning she received the check, and she remembers taking it to her bedroom. Explain how Rachel can take advantage of context-dependent memory and state-dependent memory to remember where in her bedroom she left the check.

Answer

1 point: Long-term potentiation (LTP) increases the cells’ firing potential at the synapse.

1 point: The hippocampus gives the command to “save” a memory.

1 point: The frontal lobes allow you to process the memory information.

(2 points)

Module 33

Forgetting, Memory Construction, and Memory Improvement

Module Learning Objectives

- 33-1** Explain why we forget.
- 33-2** Explain how misinformation, imagination, and source amnesia influence our memory construction, and describe how we decide whether a memory is real or false.
- 33-3** Describe the reliability of young children’s eyewitness descriptions, and discuss the controversy related to claims of repressed and recovered memories.
- 33-4** Describe how you can use memory research findings to do better in this and other courses.

Forgetting

33-1 Why do we forget?

Amid all the applause for memory—all the efforts to understand it, all the books on how to improve it—have any voices been heard in praise of forgetting? William James (1890, p. 680) was such a voice: “If we remembered everything, we should on most occasions be as ill off as if we remembered nothing.” To discard the clutter of useless or out-of-date information—last year’s locker combination, a friend’s old phone number, restaurant orders already cooked and served—is surely a blessing. The Russian memory whiz S, whom we met at the beginning of Module 31, was haunted by his junk heap of memories. They dominated his consciousness. He had difficulty thinking abstractly—generalizing, organizing, evaluating. After reading a story, he could recite it but would struggle to summarize its gist.

A more recent case of a life overtaken by memory is “A. J.,” whose experience has been studied and verified by a University of California at Irvine research team (Parker et al., 2006). A. J., who has identified herself as Jill Price, compares her memory with “a running movie that never stops. It’s like a split screen. I’ll be talking to someone and seeing something else. . . . Whenever I see a date flash on the television (or anywhere for that matter) I automatically go back to that day and remember where I was, what I was doing, what day it fell on, and on and on and on and on. It is nonstop, uncontrollable, and totally exhausting.” A good memory is helpful, but so is the ability to forget. If a memory-enhancing pill becomes available, it had better not be *too* effective.

“Amnesia seeps into the crevices of our brains, and amnesia heals.”
 —JOYCE CAROL OATES, “WORDS FAIL, MEMORY BLURS, LIFE WINS,” 2001

More often, however, our unpredictable memory dismays and frustrates us. Memories are quirky. My own memory can easily call up such episodes as that wonderful first kiss with the woman I love, or trivial facts like the air mileage from London to Detroit. Then it abandons me when I discover I have failed to encode, store, or retrieve a student's name, or where I left my sunglasses.

Forgetting and the Two-Track Mind

English novelist and critic C. S. Lewis described the forgetting that plagues us all. We are

bombarded every second by sensations, emotions, thoughts . . . nine-tenths of which [we] must simply ignore. The past [is] a roaring cataract of billions upon billions of such moments: Any one of them too complex to grasp in its entirety, and the aggregate beyond all imagination. . . . At every tick of the clock, in every inhabited part of the world, an unimaginable richness and variety of 'history' falls off the world into total oblivion.

For some, memory loss is severe and permanent. Consider Henry Molaison (known as "H. M.," 1926–2008). For 55 years after having brain surgery to stop severe seizures, Molaison was unable to form new conscious memories. He was, as before his surgery, intelligent and did daily crossword puzzles. Yet, reported neuroscientist Suzanne Corkin (2005), "I've known H. M. since 1962, and he still doesn't know who I am." For about 20 seconds during a conversation he could keep something in mind. When distracted, he would lose what was just said or what had just occurred. Thus, he never could name the current president of the United States (Ogden, 2012).

Molaison suffered from **anterograde amnesia**—he could recall his past, but he could not form new memories. (Those who cannot recall their past—the old information stored in long-term memory—suffer from **retrograde amnesia**.)

Neurologist Oliver Sacks (1985, pp. 26–27) described another patient, Jimmie, who had anterograde amnesia resulting from brain damage. Jimmie had no memories—thus, no sense of elapsed time—beyond his injury in 1945.

When Jimmie gave his age as 19, Sacks set a mirror before him: "Look in the mirror and tell me what you see. Is that a 19-year-old looking out from the mirror?"

Jimmie turned ashen, gripped the chair, cursed, then became frantic: "What's going on? What's happened to me? Is this a nightmare? Am I crazy? Is this a joke?" When his attention was diverted to some children playing baseball, his panic ended, the dreadful mirror forgotten.

Sacks showed Jimmie a photo from *National Geographic*. "What is this?" he asked.

"It's the Moon," Jimmie replied.

"No, it's not," Sacks answered. "It's a picture of the Earth taken from the Moon."

"Doc, you're kidding? Someone would've had to get a camera up there!"

"Naturally."

"Hell! You're joking—how the hell would you do that?" Jimmie's wonder was that of a bright young man from nearly 70 years ago reacting with amazement to his travel back to the future.

Careful testing of these unique people reveals something even stranger: Although incapable of recalling new facts or anything they have done recently, Molaison, Jimmie, and others with similar conditions can learn nonverbal tasks. Shown hard-to-find figures in pictures (in the *Where's Waldo?* series), they can quickly spot them again later. They can find their way to the bathroom, though without being able to tell you where it is. They can learn to read mirror-image writing or do a jigsaw puzzle, and they have even been taught complicated job skills (Schacter, 1992, 1996; Xu & Corkin, 2001). They can be classically conditioned. However, *they do all these things with no awareness of having learned them.*

Molaison and Jimmie lost their ability to form new explicit memories, but their automatic processing ability remained intact. Like Alzheimer's patients,

FYI

Cellist Yo-Yo Ma forgot his 266-year-old, \$2.5 million cello in a New York taxi. (He later recovered it.)

AP® Exam Tip

Retrograde amnesia acts backward in time, just like when you choose a "retro" look for a party and wear clothes from an earlier time.

anterograde amnesia an inability to form new memories.

retrograde amnesia an inability to retrieve information from one's past.

"Waiter, I'd like to order, unless I've eaten, in which case bring me the check."

whose *explicit* memories for new people and events are lost, they can form new *implicit* memories (Lustig & Buckner, 2004). They can learn *how* to do something, but they will have no conscious recall of learning their new skill. Such sad cases confirm that we have two distinct memory systems, controlled by different parts of the brain.

For most of us, forgetting is a less drastic process. Let's consider some of the reasons we forget.

Encoding Failure

Much of what we sense we never notice, and what we fail to encode, we will never remember (**FIGURE 33.1**). Age can affect encoding efficiency. The brain areas that jump into action when young adults encode new information are less responsive in older adults. This slower encoding helps explain age-related memory decline (Grady et al., 1995).

But no matter how young we are, we selectively attend to few of the myriad sights and sounds continually bombarding us. When texting during class, students may fail to encode details that their more attentive classmates are encoding for next week's test. Without effort, many potential memories never form.

Studying a famous brain Jacopo Annese and other scientists at the University of California, San Diego's Brain Observatory are preserving Henry Molaison's brain for the benefit of future generations. Their careful work will result in a freely available online brain atlas.

Figure 33.1
Forgetting as encoding failure We cannot remember what we have not encoded.

Storage Decay

Even after encoding something well, we sometimes later forget it. To study the durability of stored memories, Hermann Ebbinghaus (1885) learned more lists of nonsense syllables and measured how much he retained when relearning each list, from 20 minutes to 30 days later. The result, confirmed by later experiments, was his famous forgetting curve: *The course of forgetting is initially rapid, then levels off with time* (**FIGURE 33.2**; Wixted & Ebbesen, 1991).

Figure 33.2
Ebbinghaus' forgetting curve After learning lists of nonsense syllables, such as YOX and JIH, Ebbinghaus studied how much he retained up to 30 days later. He found that memory for novel information fades quickly, then levels out. (Adapted from Ebbinghaus, 1885.)

Figure 33.3

The forgetting curve for Spanish learned in school

Compared with people just completing a Spanish course, those 3 years out of the course remembered much less. Compared with the 3-year group, however, those who studied Spanish even longer ago did not forget much more. (Adapted from Bahrick, 1984.)

Bill Aron/Photo Edit

Harry Bahrick (1984) found a similar forgetting curve for Spanish vocabulary learned in school. Compared with those just completing a high school or college Spanish course, people 3 years out of school had forgotten much of what they had learned (**FIGURE 33.3**). However, what people remembered then, they still remembered 25 and more years later. Their forgetting had leveled off.

One explanation for these forgetting curves is a gradual fading of the physical memory trace. Cognitive neuroscientists are getting closer to solving the mystery of the physical storage of memory and are increasing our understanding of how memory storage could decay. Like books you can't find in your high school library, memories may be inaccessible for many reasons. Some were never acquired (not encoded). Others were discarded (stored memories decay). And others are out of reach because we can't retrieve them.

Retrieval Failure

Often, forgetting is not memories faded but memories unretrieved. We store in long-term memory what's important to us or what we've rehearsed. But sometimes important events defy our attempts to access them (**FIGURE 33.4**). How frustrating when a name lies poised on the tip of our tongue, just beyond reach. Given retrieval cues ("It begins with an M"), we may easily retrieve the elusive memory. Retrieval problems contribute to the occasional memory failures of older adults, who more frequently are frustrated by tip-of-the-tongue forgetting (Abrams, 2008).

Do you recall the gist of the sentence I asked you to remember in Module 32's discussion of making information personally meaningful? If not, does the word *shark* serve as a retrieval cue? Experiments show that *shark* (likely what you visualized) more readily retrieves

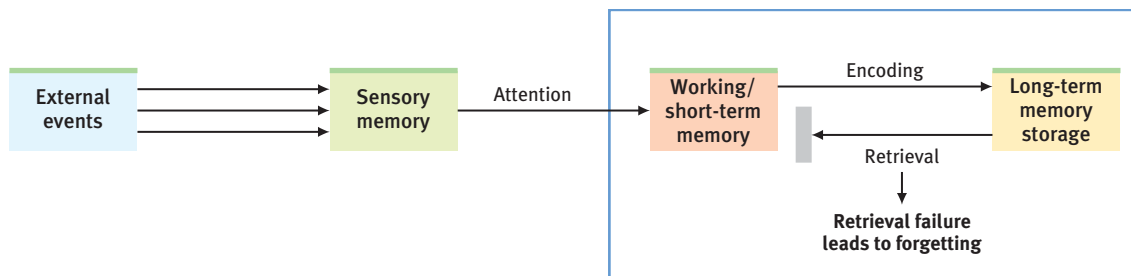

FYI

Deaf persons fluent in sign language experience a parallel "tip of the fingers" phenomenon (Thompson et al., 2005).

Figure 33.4

Retrieval failure

Sometimes even stored information cannot be accessed, which leads to forgetting.

the image you stored than does the sentence’s actual word, *fish* (Anderson et al., 1976). (The sentence was “*The fish attacked the swimmer.*”)

But retrieval problems occasionally stem from interference and, perhaps, from motivated forgetting.

INTERFERENCE

As you collect more and more information, your mental attic never fills, but it surely gets cluttered. Sometimes the clutter interferes, as new learning and old collide. **Proactive** (*forward-acting*) **interference** occurs when prior learning disrupts your recall of new information. Your well-rehearsed Facebook password may interfere with your retrieval of your newly learned copy machine code.

Retroactive (*backward-acting*) **interference** occurs when new learning disrupts recall of old information. If someone sings new lyrics to the tune of an old song, you may have trouble remembering the original words. It is rather like a second stone tossed in a pond, disrupting the waves rippling out from the first.

Information presented in the hour before sleep is protected from retroactive interference because the opportunity for interfering events is minimized (Diekelmann & Born, 2010; Nesca & Koulack, 1994). Researchers John Jenkins and Karl Dallenbach (1924) first discovered this in a now-classic experiment. Day after day, two people each learned some nonsense syllables, then tried to recall them after up to 8 hours of being awake or asleep at night. As **FIGURE 33.5** shows, forgetting occurred more rapidly after being awake and involved with other activities. The investigators surmised that “forgetting is not so much a matter of the decay of old impressions and associations as it is a matter of interference, inhibition, or obliteration of the old by the new” (1924, p. 612).

The hour before sleep is a good time to commit information to memory (Scullin & McDaniel, 2010), though information presented in the *seconds* just before sleep is seldom remembered (Wyatt & Bootzin, 1994). If you’re considering learning *while* sleeping, forget it. We have little memory for information played aloud in the room during sleep, although the ears do register it (Wood et al., 1992).

Old and new learning do not always compete with each other, of course. Previously learned information (Latin) often facilitates our learning of new information (French). This phenomenon is called *positive transfer*.

proactive interference the disruptive effect of prior learning on the recall of new information.

retroactive interference the disruptive effect of new learning on the recall of old information.

AP® Exam Tip

Here’s the prefix “retro” again and it means exactly the same thing with interference that it did for amnesia. In both cases, they’re exerting an influence back in time.

Figure 33.5
Retroactive interference More forgetting occurred when a person stayed awake and experienced other new material. (From Jenkins & Dallenbach, 1924.)

MOTIVATED FORGETTING

To remember our past is often to revise it. Years ago, the huge cookie jar in our kitchen was jammed with freshly baked chocolate chip cookies. Still more were cooling across racks on the counter. Twenty-four hours later, not a crumb was left. Who had taken them?

Fuse/Thinkstock

During that time, my wife, three children, and I were the only people in the house. So while memories were still fresh, I conducted a little memory test. Andy admitted wolfing down as many as 20. Peter thought he had eaten 15. Laura guessed she had stuffed her then-6-year-old body with 15 cookies. My wife, Carol, recalled eating 6, and I remembered consuming 15 and taking 18 more to the office. We sheepishly accepted responsibility for 89 cookies. Still, we had not come close; there had been 160.

Why do our memories fail us? This happens in part because, as Carol Tavris and Elliot Aronson have pointed out, memory is an “unreliable, self-serving historian” (2007, p. 6). Consider one study, in which researchers told some participants about the benefits of frequent toothbrushing. Those individuals then recalled (more than others did) having frequently brushed their teeth in the preceding 2 weeks (Ross et al., 1981).

FIGURE 33.6 reminds us that as we process information, we filter, alter, or lose much of it. So why were my family and I so far off in our estimates of the cookies we had eaten? Was it an *encoding* problem? (Did we just not notice what we had eaten?) Was it a storage problem? (Might our memories of cookies, like Ebbinghaus’ memory of nonsense syllables, have melted away almost as fast as the cookies themselves?) Or was the information still intact but not *retrievable* because it would be embarrassing to remember?¹

Sigmund Freud might have argued that our memory systems self-censored this information. He proposed that we **repress** painful or unacceptable memories to protect

¹ One of my cookie-scarfing sons, on reading this in his father’s textbook years later, confessed he had fibbed “a little.”

repression in psychoanalytic theory, the basic defense mechanism that banishes from consciousness anxiety-arousing thoughts, feelings, and memories.

AP® Exam Tip

There are many references to Sigmund Freud in the text. Most of your knowledge of Freud probably came from popular culture, and it often conflicts with the discoveries of modern researchers. The AP® exam may test your understanding of researchers’ views of Freud.

“Someday we’ll look back at this time in our lives and be unable to remember it.”

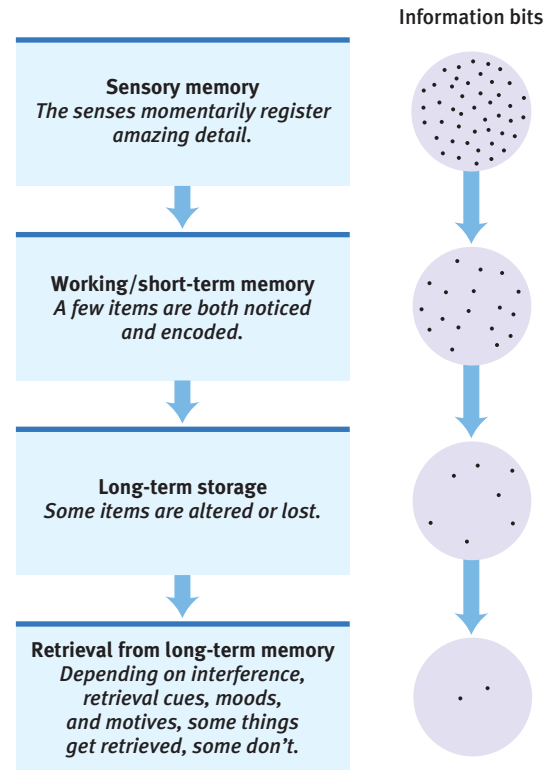

Figure 33.6
When do we forget? Forgetting can occur at any memory stage. As we process information, we filter, alter, or lose much of it.

our self-concept and to minimize anxiety. But the repressed memory lingers, he believed, and can be retrieved by some later cue or during therapy. Repression was central to Freud's psychoanalytic theory (more on that in Module 55) and was a popular idea in mid-twentieth-century psychology and beyond. In one study, 9 in 10 university students agreed that "memories for painful experiences are sometimes pushed into unconsciousness" (Brown et al., 1996). Some therapists assume it. Today, however, increasing numbers of memory researchers think repression rarely, if ever, occurs. People succeed in forgetting unwanted neutral information (yesterday's parking place), but it's harder to forget emotional events (Payne & Corrigan, 2007). Thus, we may have intrusive memories of the very traumatic experiences we would most like to forget.

Before You Move On

▶ ASK YOURSELF

Most people, especially as they grow older, wish for a better memory. Is that true of you? Or do you more often wish you could better discard old memories?

▶ TEST YOURSELF

Can you offer examples of proactive and retroactive interference?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Memory Construction Errors

33-2

How do misinformation, imagination, and source amnesia influence our memory construction? How do we decide whether a memory is real or false?

Memory is not precise. Like scientists who infer a dinosaur's appearance from its remains, we infer our past from stored information plus what we later imagined, expected, saw, and heard. We don't just retrieve memories, we reweave them, noted Daniel Gilbert (2006, p. 79): "Information acquired after an event alters memory of the event." We often construct our memories as we encode them, and every time we "replay" a memory, we replace the original with a slightly modified version (Hardt et al., 2010). (Memory researchers call this *reconsolidation*.) So, in a sense, said Joseph LeDoux (2009), "your memory is only as good as your last memory. The fewer times you use it, the more pristine it is." This means that, to some degree, "all memory is false" (Bernstein & Loftus, 2009b). Let's examine some of the ways we rewrite our past.

Misinformation and Imagination Effects

In more than 200 experiments, involving more than 20,000 people, Elizabeth Loftus has shown how eyewitnesses reconstruct their memories after a crime or an accident. In one experiment, two groups of people watched a film of a traffic accident and then answered questions about what they had seen (Loftus & Palmer, 1974). Those asked, "About how fast were the cars going when they *smashed* into each other?" gave higher speed estimates than those asked, "About how fast were the cars going when they *hit* each other?" A week later, when asked whether they recalled seeing any broken glass, people who had heard *smashed* were more than twice as likely to report seeing glass fragments (**FIGURE 33.7** on the next page). In fact, the film showed no broken glass.

In many follow-up experiments around the world, others have witnessed an event, received or not received misleading information about it, and then taken a memory test. The repeated result is a **misinformation effect**: Exposed to misleading information, we tend to

AP® Exam Tip

Read this entire section particularly carefully. Many people harbor misconceptions about how memory works, and a lot of the misconceptions are dealt with in the next few pages. Memory does *not* function like a video recorder!

misinformation effect

incorporating misleading information into one's memory of an event.

"Memory is insubstantial. Things keep replacing it. Your batch of snapshots will both fix and ruin your memory. . . . You can't remember anything from your trip except the wretched collection of snapshots." -ANNIE DILLARD, "TO FASHION A TEXT," 1988

Figure 33.7

Memory construction In this experiment, people viewed a film of a car accident (left). Those who later were asked a leading question recalled a more serious accident than they had witnessed. (From Loftus & Palmer, 1974.)

misremember. A yield sign becomes a stop sign, hammers become screwdrivers, Coke cans become peanut cans, breakfast cereal becomes eggs, and a clean-shaven man morphs into a man with a mustache (Loftus et al., 1992). So powerful is the misinformation effect that it can influence later attitudes and behaviors (Bernstein & Loftus, 2009).

Just hearing a vivid retelling of an event can implant false memories. One experiment falsely suggested to some Dutch university students that, as children, they became ill after eating spoiled egg salad (Geraerts et al., 2008). After absorbing that suggestion, a significant minority were less likely to eat egg-salad sandwiches, both immediately and 4 months later.

Even repeatedly *imagining* nonexistent actions and events can create false memories. American and British university students were asked to imagine certain childhood events, such as breaking a window with their hand or having a skin sample removed from a finger. One in four of them later recalled the imagined event as something that had really happened (Garry et al., 1996; Mazzoni & Memon, 2003).

Digitally altered photos have also produced this *imagination inflation*. In experiments, researchers have altered photos from a family album to show some family members taking a hot-air balloon ride. After viewing these photos (rather than photos showing just the balloon), children reported more false memories and indicated high confidence in those memories. When interviewed several days later, they reported even richer details of their false memories (Strange et al., 2008; Wade et al., 2002).

In British and Canadian university surveys, nearly one-fourth of students have reported autobiographical memories that they later realized were not accurate (Mazzoni et al., 2010).

DOONESBURY

I empathize. For decades, my cherished earliest memory was of my parents getting off the bus and walking to our house, bringing my baby brother home from the hospital. When, in middle age, I shared that memory with my father, he assured me they did *not* bring their newborn home on the Seattle Transit System. The human mind, it seems, comes with built-in Photoshopping software.

Source Amnesia

Among the frailest parts of a memory is its source. We may recognize someone but have no idea where we have seen the person. We may dream an event and later be unsure whether it really happened. We may misrecall how we learned about something (Henkel et al., 2000). Psychologists are not immune to the process. Famed child psychologist Jean Piaget was startled as an adult to learn that a vivid, detailed memory from his childhood—a nursemaid’s thwarting his kidnapping—was utterly false. He apparently constructed the memory from repeatedly hearing the story (which his nursemaid, after undergoing a religious conversion, later confessed had never happened). In attributing his “memory” to his own experiences, rather than to his nursemaid’s stories, Piaget exhibited **source amnesia** (also called *source misattribution*). Misattribution is at the heart of many false memories. Authors and songwriters sometimes suffer from it. They think an idea came from their own creative imagination, when in fact they are unintentionally plagiarizing something they earlier read or heard.

Debra Poole and Stephen Lindsay (1995, 2001, 2002) demonstrated source amnesia among preschoolers. They had the children interact with “Mr. Science,” who engaged them in activities such as blowing up a balloon with baking soda and vinegar. Three months later, on three successive days, their parents read them a story describing some things the children had experienced with Mr. Science and some they had not. When a new interviewer asked what Mr. Science had done with them—“Did Mr. Science have a machine with ropes to pull?”—4 in 10 children spontaneously recalled him doing things that had happened only in the story.

Source amnesia also helps explain **déjà vu** (French for “already seen”). Two-thirds of us have experienced this fleeting, eerie sense that “I’ve been in this exact situation before.” It happens most commonly to well-educated, imaginative young adults, especially when tired or stressed (Brown, 2003, 2004; McAneny, 1996). Some wonder, “How could I recognize a situation I’m experiencing for the first time?” Others may think of reincarnation (“I must have experienced this in a previous life”) or precognition (“I viewed this scene in my mind before experiencing it”).

The key to déjà vu seems to be familiarity with a stimulus without a clear idea of where we encountered it before (Cleary, 2008). Normally, we experience a feeling of *familiarity* (thanks to temporal lobe processing) before we consciously remember details (thanks to hippocampus and frontal lobe processing). When these functions (and brain regions) are out of sync, we may experience a feeling of familiarity without conscious recall. Our amazing brains try to make sense of such an improbable situation, and we get an eerie feeling that we’re reliving some earlier part of our life. After all, the situation is familiar, even though we have no idea why. Our source amnesia forces us to do our best to make sense of an odd moment.

Discerning True and False Memories

Because the misinformation effect and source amnesia happen outside our awareness, it is nearly impossible to sift suggested ideas out of the larger pool of real memories (Schooler et al., 1986). Perhaps you can recall describing a childhood experience to a friend and filling in memory gaps with reasonable guesses and assumptions. We all do it, and after more retellings, those guessed details—now absorbed into our memories—may feel as real as if we had actually experienced them (Roediger et al., 1993). Much as perceptual illusions may seem like real perceptions, unreal memories feel like real memories.

“It isn’t so astonishing, the number of things I can remember, as the number of things I can remember that aren’t so.” -MARK TWAIN (1835–1910)

Try This

In the discussion of mnemonics in Module 31, I gave you six words and told you I would quiz you about them later. How many of these words can you now recall? Of these, how many are high-imagery words? How many are low-imagery? (You can check your list against the six inverted words below.)

Bicycle, void, cigarette, inherent, fire, process

“Do you ever get that strange feeling of *vujà dé*? Not *déjà vu*; *vujà dé*. It’s the distinct sense that, somehow, something just happened that has never happened before. Nothing seems familiar. And then suddenly the feeling is gone. *Vujà dé*.” -COMEDIAN GEORGE CARLIN (1937–2008), IN *FUNNY TIMES*, DECEMBER 2001

source amnesia attributing to the wrong source an event we have experienced, heard about, read about, or imagined. (Also called *source misattribution*.) Source amnesia, along with the misinformation effect, is at the heart of many false memories.

déjà vu that eerie sense that “I’ve experienced this before.” Cues from the current situation may unconsciously trigger retrieval of an earlier experience.

False memories can be very persistent. Imagine that I were to read aloud a list of words such as *candy*, *sugar*, *honey*, and *taste*. Later, I ask you to recognize the presented words from a larger list. If you are at all like the people tested by Henry Roediger and Kathleen McDermott (1995), you would err three out of four times—by falsely remembering a nonpresented similar word, such as *sweet*. We more easily remember the gist than the words themselves.

Memory construction helps explain why 79 percent of 200 convicts exonerated by later DNA testing had been misjudged based on faulty eyewitness identification (Garrett, 2008). It explains why “hypnotically refreshed” memories of crimes so easily incorporate errors, some of which originate with the hypnotist’s leading questions (“*Did you hear loud noises?*”). It explains why dating partners who fell in love have overestimated their first impressions of one another (“*It was love at first sight*”), while those who broke up underestimated their earlier liking (“*We never really clicked*”) (McFarland & Ross, 1987). How people feel today tends to be how they recall they have always felt (Mazzoni & Vannucci, 2007; and recall from Module 4 our tendency to *hindsight bias*). As George Vaillant (1977, p. 197) noted after following adult lives through time, “It is all too common for caterpillars to become butterflies and then to maintain that in their youth they had been little butterflies. Maturation makes liars of us all.”

Children’s Eyewitness Recall

33-3

How reliable are young children’s eyewitness descriptions, and why are reports of repressed and recovered memories so hotly debated?

If memories can be sincere, yet sincerely wrong, might children’s recollections of sexual abuse be prone to error? “It would be truly awful to ever lose sight of the enormity of child abuse,” observed Stephen Ceci (1993). Yet Ceci and Maggie Bruck’s (1993, 1995) studies of children’s memories have made them aware of how easily children’s memories can be molded. For example, they asked 3-year-olds to show on anatomically correct dolls where a pediatrician had touched them. Of the children who had not received genital examinations, 55 percent pointed to either genital or anal areas.

In other experiments, the researchers studied the effect of suggestive interviewing techniques (Bruck & Ceci, 1999, 2004). In one study, children chose a card from a deck of possible happenings, and an adult then read the card to them. For example, “Think real hard, and tell me if this ever happened to you. Can you remember going to the hospital with a mousetrap on your finger?” In interviews, the same adult repeatedly asked children to think about several real and fictitious events. After 10 weeks of this, a new adult asked the same question. The stunning result: 58 percent of preschoolers produced false (often vivid) stories regarding one or more events they had never experienced (Ceci et al., 1994). Here’s one of those stories:

My brother Colin was trying to get Blowtorch [an action figure] from me, and I wouldn’t let him take it from me, so he pushed me into the wood pile where the mousetrap was. And then my finger got caught in it. And then we went to the hospital, and my mommy, daddy, and Colin drove me there, to the hospital in our van, because it was far away. And the doctor put a bandage on this finger.

Given such detailed stories, professional psychologists who specialize in interviewing children could not reliably separate the real memories from the false ones. Nor could the children themselves. The above child, reminded that his parents had told him several times that the mousetrap incident never happened—that he had imagined it—protested, “But it really did happen. I remember it!” In another experiment, preschoolers merely overheard an erroneous remark that a magician’s missing rabbit had gotten loose in their classroom. Later, when the children were suggestively questioned, 78 percent of them recalled actually seeing the rabbit (Principe et al., 2006). “[The] research leads me to worry about the possibility of false allegations. It is not a tribute to one’s scientific integrity to walk down the middle of the road if the data are more to one side,” said Ceci (1993).

Does this mean that children can never be accurate eyewitnesses? *No*. When questioned about their experiences in neutral words they understood, children often accurately recalled what happened and who did it (Goodman, 2006; Howe, 1997; Pipe, 1996). And when interviewers used less suggestive, more effective techniques, even 4- to 5-year-old children produced more accurate recall (Holliday & Albon, 2004; Pipe et al., 2004). Children were especially accurate when they had not talked with involved adults prior to the interview and when their disclosure was made in a first interview with a neutral person who asked nonleading questions.

Repressed or Constructed Memories of Abuse?

The research on source amnesia and the misinformation effect raises concerns about therapist-guided “recovered” memories. There are two tragedies related to adult recollections of child abuse. One happens when people don’t believe abuse survivors who tell their secret. The other happens when innocent people are falsely accused.

Some well-intentioned therapists have reasoned with patients that “people who’ve been abused often have your symptoms, so you probably were abused. Let’s see if, aided by hypnosis or drugs, or helped to dig back and visualize your trauma, you can recover it.” Patients exposed to such techniques may then form an image of a threatening person. With further visualization, the image grows more vivid. The patient ends up stunned, angry, and ready to confront or sue the remembered abuser. The accused person (often a parent or relative) is equally stunned and devastated, and vigorously denies the accusation.

Critics are not questioning most therapists’ professionalism. Nor are they questioning the accusers’ sincerity; even if false, their memories are heartfelt. Critics’ charges are specifically directed against clinicians who use “memory work” techniques, such as “guided imagery,” hypnosis, and dream analysis to recover memories. “Thousands of families were cruelly ripped apart,” with “previously loving adult daughters” suddenly accusing fathers (Gardner, 2006). Irate clinicians have countered that those who argue that recovered memories of abuse never happen are adding to abused people’s trauma and playing into the hands of child molesters.

In an effort to find a sensible common ground that might resolve psychology’s “memory war,” professional organizations (the American Medical, American Psychological, and American Psychiatric Associations; the Australian Psychological Society; the British Psychological Society; and the Canadian Psychiatric Association) have convened study panels and issued public statements. Those committed to protecting abused children and those committed to protecting wrongly accused adults have agreed on the following:

- **Sexual abuse happens.** And it happens more often than we once supposed. Although sexual abuse can leave its victims at risk for problems ranging from sexual dysfunction to depression (Freyd et al., 2007), there is no characteristic “survivor syndrome”—no group of symptoms that lets us spot victims of sexual abuse (Kendall-Tackett et al., 1993).
- **Injustice happens.** Some innocent people have been falsely convicted. And some guilty people have evaded responsibility by casting doubt on their truth-telling accusers.
- **Forgetting happens.** Many of those actually abused were either very young when abused or may not have understood the meaning of their experience—circumstances under which forgetting is common. Forgetting isolated past events, both negative and positive, is an ordinary part of everyday life.
- **Recovered memories are commonplace.** Cued by a remark or an experience, we all recover memories of long-forgotten events, both pleasant and unpleasant. What many psychologists debate is twofold: Does the unconscious mind sometimes *forcibly repress* painful experiences? If so, can these experiences be retrieved by certain therapist-aided techniques? (Memories that surface naturally are more likely to be verified [Geraerts et al., 2007].)

“When memories are ‘recovered’ after long periods of amnesia, particularly when extraordinary means were used to secure the recovery of memory, there is a high probability that the memories are false.” -ROYAL COLLEGE OF PSYCHIATRISTS WORKING GROUP ON REPORTED RECOVERED MEMORIES OF CHILD SEXUAL ABUSE (BRANDON ET AL., 1998)

- **Memories of things happening before age 3 are unreliable.** We cannot reliably recall happenings from our first three years. As noted earlier, this infantile amnesia happens because our brain pathways have not yet developed enough to form the kinds of memories we will form later in life. Most psychologists—including most clinical and counseling psychologists—therefore doubt “recovered” memories of abuse during infancy (Gore-Felton et al., 2000; Knapp & VandeCreek, 2000). The older a child was when suffering sexual abuse, and the more severe the abuse, the more likely it is to be remembered (Goodman et al., 2003).
- **Memories “recovered” under hypnosis or the influence of drugs are especially unreliable.** Under hypnosis, people will incorporate all kinds of suggestions into their memories, even memories of “past lives.”
- **Memories, whether real or false, can be emotionally upsetting.** Both the accuser and the accused may suffer when what was born of mere suggestion becomes, like an actual trauma, a stinging memory that drives bodily stress (McNally, 2003, 2007). Some people knocked unconscious in unremembered accidents know this all too well. They have later developed stress disorders after being haunted by memories they constructed from photos, news reports, and friends’ accounts (Bryant, 2001).

So, does *repression* of threatening memories ever occur? Or is this concept—the cornerstone of Freud’s theory and of so much popular psychology—misleading? In Modules 55 and 56, we will return to this hotly debated issue. For now, this much appears certain: The most common response to a traumatic experience (witnessing a loved one’s murder, being terrorized by a hijacker or a rapist, losing everything in a natural disaster) is not banishment of the experience into the unconscious. Rather, such experiences are typically etched on the mind as vivid, persistent, haunting memories (Porter & Peace, 2007). As Robert Kraft (2002) said of the experience of those trapped in the Nazi death camps, “Horror sears memory, leaving . . . the consuming memories of atrocity.”

Before You Move On

▶ ASK YOURSELF

Could you be an impartial jury member in a trial of a parent accused of sexual abuse based on a recovered memory, or of a therapist being sued for creating a false memory of abuse? Why or why not?

▶ TEST YOURSELF

How would source amnesia affect us if we were to remember all of our waking experiences as well as all of our dreams?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Improving Memory

33-4

How can you use memory research findings to do better in this and other courses?

Biology’s findings benefit medicine. Botany’s findings benefit agriculture. So, too, can psychology’s research on memory benefit education. Here, for easy reference, is a summary of some research-based suggestions that could help you remember information when you need it. The SQ3R (Survey, Question, Read, Retrieve, Review) study technique introduced in Module 2 incorporates several of these strategies:

Rehearse repeatedly. To master material, use distributed (spaced) practice. To learn a concept, give yourself many separate study sessions. Take advantage of life’s little intervals—riding a bus, walking to lunch, waiting for class to start. New memories are weak; exercise them and they will strengthen. To memorize specific facts or figures, Thomas Landauer (2001) has advised, “rehearse the name or number you are trying to memorize, wait a few seconds, rehearse again, wait a little longer, rehearse again, then wait longer still and rehearse yet again. The waits should be as long as possible without losing the information.” Reading complex material with minimal rehearsal yields little retention. Rehearsal and critical reflection help more. It pays to study actively.

Make the material meaningful. You can build a network of retrieval cues by taking text and class notes in your own words. Apply the concepts to your own life. Form images. Understand and organize information. Relate the material to what you already know or have experienced. As William James (1890) suggested, “Knit each new thing on to some acquisition already there.” Restate concepts in your own words. Mindlessly repeating someone else’s words won’t supply many retrieval cues. On an exam, you may find yourself stuck when a question uses phrasing different from the words you memorized.

Activate retrieval cues. Mentally re-create the situation and the mood in which your original learning occurred. Jog your memory by allowing one thought to cue the next.

Use mnemonic devices. Associate items with peg words. Make up a story that incorporates vivid images of the items. Chunk information into acronyms. Create rhythmic rhymes (“*i before e, except after c*”).

Minimize interference. Study before sleep. Do not schedule back-to-back study times for topics that are likely to interfere with each other, such as Spanish and French.

Sleep more. During sleep, the brain reorganizes and consolidates information for long-term memory. Sleep deprivation disrupts this process.

Test your own knowledge, both to rehearse it and to find out what you don’t yet know. Don’t be lulled into overconfidence by your ability to recognize information. Test your recall using the Test Yourself items found throughout each unit, and the numbered Learning Objective Questions at the end of each module. Outline sections. Define the terms and concepts listed at each unit’s end before turning back to their definitions. Try the Multiple-Choice and Practice FRQ questions at the end of each module, and take the AP® Exam Practice Questions at the end of each unit.

©Image Source/Corbis

Thinking and memory Actively thinking as we read, by rehearsing and relating ideas, and by making the material personally meaningful, yields the best retention.

Before You Move On

▶ ASK YOURSELF

Which of the study and memory strategies suggested in this section will work best for you?

▶ TEST YOURSELF

What are the recommended memory strategies you just read about? (One advised rehearsing to-be-remembered material. What were the others?)

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 33 Review

33-1 Why do we forget?

- *Anterograde amnesia* is an inability to form new memories.
- *Retrograde amnesia* is an inability to retrieve old memories.
- Normal forgetting happens because we have never encoded information; because the physical trace has decayed; or because we cannot retrieve what we have encoded and stored.
- Retrieval problems may result from *proactive* (forward-acting) *interference*, as prior learning interferes with recall of new information, or from *retroactive* (backward-acting) *interference*, as new learning disrupts recall of old information.
- Some believe that motivated forgetting occurs, but researchers have found little evidence of *repression*.

33-2 How do misinformation, imagination, and source amnesia influence our memory construction? How do we decide whether a memory is real or false?

- In experiments demonstrating the *misinformation effect*, people have formed false memories, by incorporating misleading details, either after receiving wrong information after an event, or after repeatedly *imagining* and rehearsing something that never happened.
- When we reassemble a memory during retrieval, we may attribute it to the wrong source (*source amnesia*). Source amnesia may help explain *déjà vu*.
- False memories feel like real memories and can be persistent but are usually limited to the gist of the event.

33-3 How reliable are young children's eyewitness descriptions, and why are reports of repressed and recovered memories so hotly debated?

- Children are susceptible to the misinformation effect, but if questioned in neutral words they understand, they can accurately recall events and people involved in them.
- The debate (between memory researchers and some well-meaning therapists) focuses on whether most memories of early childhood abuse are repressed and can be recovered during therapy using "memory work" techniques using leading questions or hypnosis.
- Psychologists now agree that (1) sexual abuse happens; (2) injustice happens; (3) forgetting happens; (4) recovered memories are commonplace; (5) memories of things that happened before age 3 are unreliable; (6) memories "recovered" under hypnosis or the influence of drugs are especially unreliable; and (7) memories, whether real or false, can be emotionally upsetting.

33-4 How can you use memory research findings to do better in this and other courses?

- Memory research findings suggest the following strategies for improving memory: Study repeatedly, make material meaningful, activate retrieval cues, use mnemonic devices, minimize interference, sleep more, and test yourself to be sure you can retrieve, as well as recognize, material.

Multiple-Choice Questions

- Which of the following is an example of anterograde amnesia?
 - Halle has no memories of the first 10 years of her life.
 - William has lost his memory of the 2 weeks before he had surgery to remove a benign brain tumor.
 - Louis can remember his past, but has not been able to form new long-term memories since experiencing a brain infection 4 years ago.
 - Maddie can't remember the details of when she was mugged downtown 6 months ago.
 - Kalund struggles in school because he consistently misremembers what his teachers said in class.
- Muhammad has been in his school cafeteria hundreds of times. It is a large room, and there are nine free-standing pillars that support the roof. One day, to illustrate the nature of forgetting, Muhammad's teacher asks him how many pillars there are in the cafeteria. Muhammad has difficulty answering the question, but finally replies that he thinks there are six pillars. What memory concept does this example illustrate?
 - Storage decay
 - Retrograde amnesia
 - Proactive interference
 - Retroactive interference
 - Encoding failure

- 3.** What does Hermann Ebbinghaus' forgetting curve show about the nature of storage decay?
- The rate of forgetting increases as time goes on.
 - The rate of forgetting decreases as time goes on.
 - The rate of forgetting does not change as time goes on.
 - The rate of forgetting varies according to the motivation of the learner.
 - The rate of forgetting varies according to the emotional state of the learner.
- 4.** Which of the following is an example of proactive interference?
- You can't recall your locker combination from sixth grade because your current locker combination interferes.
 - You can't recall your new cell phone number because your old number interferes.
 - You can't recall what you studied in first period because what you studied in fourth period interferes.
 - You can't recall what you studied on Monday because what you studied on Tuesday interferes.
 - You can't recall who won the state swim meet last year because the winner of this year's meet interferes.
- 5.** The text discusses therapist-guided "recovered" memories. Which of the following statements represents an appropriate conclusion about this issue?
- Therapists who use hypnosis are likely to help their patients retrieve repressed memories.
 - Statistics indicate that childhood sexual abuse rarely occurs; therefore, recovered memories of such abuse must be false.
 - Memories are only rarely recovered; once you are unable to retrieve a memory you will probably never be able to retrieve it.
 - One indicator of whether a recovered memory is true is the patient's emotional response; only true recovered memories are emotionally upsetting.
 - Since the brain is not sufficiently mature to store accurate memories of events before the age of 3, memories from the first 3 years of life are not reliable.

Practice FRQs

- 1.** Tasnia feels like she encodes material well, but still forgets the material on test day. Explain how her forgetting might be related to problems with each of the following:
- Storage
 - Retrieval
- 2.** Your younger sister has asked you for help because she feels she cannot remember class material well enough to get good grades on her tests. Provide three specific pieces of advice that she should consider, making sure that your advice is based on psychological science.

(3 points)

Answer

1 point: Forgetting may be related to the decay of stored material.

1 point: Forgetting may be related to interference during retrieval (or motivated forgetting).

Module 34

Thinking, Concepts, and Creativity

Module Learning Objectives

34-1 Define *cognition*, and describe the functions of concepts.

34-2 Identify the factors associated with creativity, and describe ways of promoting creativity.

cognition all the mental activities associated with thinking, knowing, remembering, and communicating.

concept a mental grouping of similar objects, events, ideas, or people.

prototype a mental image or best example of a category. Matching new items to a prototype provides a quick and easy method for sorting items into categories (as when comparing feathered creatures to a prototypical bird, such as a robin).

© The New Yorker Collection, 1977. Jeff Kaufman from cartoonbank.com. All Rights Reserved.

"Attention, everyone! I'd like to introduce the newest member of our family."

In some ways, we humans are, as we will see, dim-witted. We fear the wrong things. We allow the day's hot or cold weather to color our judgments of global climate change. We tend to be overconfident in our judgments and to persevere in clinging to discredited beliefs. Yet we also display remarkable mental powers. Our intelligence, creativity, and language mark us as "little less than the angels."

Thinking and Concepts

34-1 What is cognition, and what are the functions of concepts?

Let's begin our study of **cognition**—the mental activities associated with thinking, knowing, remembering, and communicating information—by appreciating our human smarts.

Consider, for example, our ability to form **concepts**—mental groupings of similar objects, events, ideas, and people. The concept *chair* includes many items—a baby's high chair, a reclining chair, a dentist's chair—all of which are for sitting. Concepts simplify our thinking. Imagine life without them. We would need a different name for every person, event, object, and idea. We could not ask a child to "throw the ball" because there would be no concept of *throw* or *ball*. Instead of saying, "They were angry," we would have to describe expressions, intensities, and words. Concepts such as *ball* and *anger* give us much information with little cognitive effort.

We often form our concepts by developing **prototypes**—a mental image or best example of a category (Rosch, 1978). People more quickly agree that "a robin is a bird" than that "a penguin is a bird." For most of us, the robin is the birdier bird; it more closely resembles our bird prototype. And the more closely something matches our prototype of a concept—bird or car—the more readily we recognize it as an example of the concept.

Once we place an item in a category, our memory of it later shifts toward the category prototype, as it did for Belgian students who viewed ethnically blended faces. For example, when viewing a blended face in which 70 percent of the features were Caucasian and 30 percent were Asian, the students categorized the

Courtesy Everett Collection

face as Caucasian. Later, as their memory shifted toward the Caucasian prototype, they were more likely to remember an 80 percent Caucasian face than the 70 percent Caucasian they had actually seen (Corneille et al., 2004). Likewise, if shown a 70 percent Asian face, they later remembered a more prototypically Asian face. So, too, with gender: People who viewed 70 percent male faces categorized them as male (no surprise there) and then later misremembered them as even more prototypically male (Huart et al., 2005).

Move away from our prototypes, and category boundaries may blur. Is a tomato a fruit? Is a 17-year-old female a girl or a woman? Is a whale a fish or a mammal? Because a whale fails to match our “mammal” prototype, we are slower to recognize it as a mammal. Similarly, when symptoms don’t fit one of our disease prototypes, we are slow to perceive an illness (Bishop, 1991). People whose heart attack symptoms (shortness of breath, exhaustion, a dull weight in the chest) don’t match their heart attack prototype (sharp chest pain) may not seek help. And when behaviors don’t fit our discrimination prototypes—of White against Black, male against female, young against old—we often fail to notice prejudice. People more easily detect male prejudice against females than female against males or female against females (Inman & Baron, 1996; Marti et al., 2000). Concepts speed and guide our thinking. But they don’t always make us wise.

© Oleksiy Maksymenko/agefotostock

Toying with our prototypes It takes a bit longer to conceptualize a Smart Car as an actual car, because it looks more like a toy than our mental prototype for car.

Creativity

34-2 What is creativity, and what fosters it?

Pierre de Fermat, a seventeenth-century mischievous genius, challenged mathematicians of his day to match his solutions to various number theory problems. His most famous challenge—*Fermat’s last theorem*—baffled the greatest mathematical minds, even after a \$2 million prize (in today’s dollars) was offered in 1908 to whoever first created a proof.

Princeton mathematician Andrew Wiles had pondered the problem for more than 30 years and had come to the brink of a solution. One morning, out of the blue, the final “incredible revelation” struck him. “It was so indescribably beautiful; it was so simple and so elegant. I couldn’t understand how I’d missed it. . . . It was the most important moment of my working life” (Singh, 1997, p. 25).

Wiles’ incredible moment illustrates **creativity**—the ability to produce ideas that are both novel and valuable (Hennessey & Amabile, 2010). Studies suggest that a certain level of aptitude—a score above 120 on a standard intelligence test—supports creativity. Those who score exceptionally high in quantitative aptitude as 13-year-olds are more likely to obtain graduate science and math degrees and create published or patented work (Park et al., 2008; Robertson et al., 2010). Intelligence matters. Yet, there is more to creativity than what intelligence tests reveal. Indeed, the two kinds of thinking engage different brain areas. Intelligence tests, which typically demand a single correct answer, require **convergent thinking**. Injury to the left parietal lobe damages this ability. Creativity tests (*How many uses can you think of for a brick?*) require **divergent thinking**. Injury to certain areas of the frontal lobes can leave reading, writing, and arithmetic skills intact but destroy imagination (Kolb & Whishaw, 2006).

Although there is no agreed-upon creativity measure—there is no Creativity Quotient (CQ) corresponding to an Intelligence Quotient (IQ) score—Robert Sternberg and his colleagues have identified five components of creativity (Sternberg, 1988, 2003; Sternberg & Lubart, 1991, 1992):

1. **Expertise**—a well-developed base of knowledge—furnishes the ideas, images, and phrases we use as mental building blocks. “Chance favors only the prepared mind,” observed Louis Pasteur. The more blocks we have, the more chances we have to combine them in novel ways. Wiles’ well-developed base of knowledge put the needed theorems and methods at his disposal.

FYI

After picking up a Nobel Prize in Stockholm, physicist Richard Feynman stopped in Queens, New York, to look at his high school record. “My grades were not as good as I remembered,” he reported, “and my IQ was [a good, though unexceptional] 124” (Faber, 1987).

creativity the ability to produce novel and valuable ideas.

convergent thinking narrows the available problem solutions to determine the single best solution.

divergent thinking expands the number of possible problem solutions (creative thinking that diverges in different directions).

2. **Imaginative thinking skills** provide the ability to see things in novel ways, to recognize patterns, and to make connections. Having mastered a problem's basic elements, we redefine or explore it in a new way. Copernicus first developed expertise regarding the solar system and its planets, and then creatively defined the system as revolving around the Sun, not the Earth. Wiles' imaginative solution combined two partial solutions.
3. **A venturesome personality** seeks new experiences, tolerates ambiguity and risk, and perseveres in overcoming obstacles. Wiles risked much of his time in pursuit of his dream and persevered in near-isolation from the mathematics community partly to stay focused and avoid distraction.
4. **Intrinsic motivation** is being driven more by interest, satisfaction, and challenge than by external pressures (Amabile & Hennessey, 1992). Creative people focus less on extrinsic motivators—meeting deadlines, impressing people, or making money—than on the pleasure and stimulation of the work itself. Asked how he solved such difficult scientific problems, Isaac Newton reportedly answered, "By thinking about them all the time." Wiles concurred: "I was so obsessed by this problem that . . . I was thinking about it all the time—[from] when I woke up in the morning to when I went to sleep at night" (Singh & Riber, 1997).
5. **A creative environment** sparks, supports, and refines creative ideas. After studying the careers of 2026 prominent scientists and inventors, Dean Keith Simonton (1992) noted that the most eminent were mentored, challenged, and supported by their colleagues. Many had the emotional intelligence needed to network effectively with peers. Even Wiles stood on the shoulders of others and wrestled his problem with the collaboration of a former student. Creativity-fostering environments support innovation, team-building, and communication (Hülshleger et al., 2009). They also support contemplation. After Jonas Salk solved a problem that led to the polio vaccine while in a monastery, he designed the Salk Institute to provide contemplative spaces where scientists could work without interruption (Sternberg, 2006). Google has estimated that nearly half its product innovations have been sparked during the 20 percent of employee time reserved for unstructured creative thinking (Mayer, 2006).

Imaginative thinking Cartoonists often display creativity as they see things in new ways or make unusual connections.

"For the love of God, is there a doctor in the house?"

For those seeking to boost the creative process, research offers some ideas:

- *Develop your expertise.* Ask yourself what you care about and most enjoy. Follow your passion and become an expert at something.
- *Allow time for incubation.* Given sufficient knowledge available for novel connections, a period of inattention to a problem (“sleeping on it”) allows for unconscious processing to form associations (Zhong et al., 2008). So think hard on a problem, then set it aside and come back to it later.
- *Set aside time for the mind to roam freely.* Take time away from attention-absorbing television, social networking, and video gaming. Jog, go for a long walk, or meditate.
- *Experience other cultures and ways of thinking.* Living abroad sets the creative juices flowing. Even after controlling for other variables, students who have spent time abroad are more adept at working out creative solutions to problems (Leung et al., 2008; Maddux et al., 2009, 2010). Multicultural experiences expose us to multiple perspectives and facilitate flexible thinking.

A creative environment

Before You Move On

▶ ASK YOURSELF

Imagine patiently waiting your turn at a store, and then having some late-arriving adults served before you. The clerk also checks inside your bag as you leave the store. What is a prototype, and what sort of “teenager” prototype does the clerk seem to have in mind?

▶ TEST YOURSELF

According to Robert Sternberg, what are the five components of creativity?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 34 Review

34-1

What is cognition, and what are the functions of concepts?

- *Cognition* refers to all the mental activities associated with thinking, knowing, remembering, and communicating.
- We use *concepts*, mental groupings of similar objects, events, ideas, or people, to simplify and order the world around us.
- We form most concepts around *prototypes*, or best examples of a category.

34-2

What is creativity, and what fosters it?

- *Creativity*, the ability to produce novel and valuable ideas, correlates somewhat with intelligence, but beyond an intelligence test score of 120, that correlation dwindles.
- Sternberg has proposed that creativity has five components: expertise, imaginative thinking skills; a venturesome personality; intrinsic motivation; and a creative environment that sparks, supports, and refines creative ideas.

Multiple-Choice Questions

1. Which of the following is the best term for mental activities associated with remembering, thinking, and knowing?
 - a. Cognition
 - b. Concepts
 - c. Prototypes
 - d. Convergent thinking
 - e. Divergent thinking
2. Which of the following is the best phrase for the narrowing of available problem solutions with the goal of determining the best solution?
 - a. Allowing for incubation
 - b. Divergent thinking
 - c. Developing expertise
 - d. Convergent thinking
 - e. Experiencing other cultures
3. Producing valuable and novel ideas best defines which of the following?
 - a. Prototyping
 - b. Cognition
 - c. Intrinsic motivation
 - d. Venturesome personality
 - e. Creativity

Practice FRQs

1. Compare the notions of concept and prototype.
2. Identify and explain four of the five components of creativity mentioned in this module.

Answer

1 point: A concept is a mental grouping of similar objects, events, ideas, and people.

1 point: A prototype is a mental image or best example of a category.

(4 points)

Module 35

Solving Problems and Making Decisions

Module Learning Objectives

- 35-1** Describe the cognitive strategies that assist our problem solving, and identify the obstacles that hinder it.
- 35-2** Explain what is meant by intuition, and describe how the representativeness and availability heuristics, overconfidence, belief perseverance, and framing influence our decisions and judgments.
- 35-3** Describe how smart thinkers use intuition.

Problem Solving: Strategies and Obstacles

- 35-1** What cognitive strategies assist our problem solving, and what obstacles hinder it?

One tribute to our rationality is our problem-solving skill. What's the best route around this traffic jam? How should we handle a friend's criticism? How can we get in the house without our keys?

Some problems we solve through *trial and error*. Thomas Edison tried thousands of light bulb filaments before stumbling upon one that worked. For other problems, we use **algorithms**, step-by-step procedures that guarantee a solution. But step-by-step algorithms can be laborious and exasperating. To find a word using the 10 letters in *SPLOYOCHYG*, for example, you could try each letter in each of the 10 positions—907,200 permutations in all. Rather than give you a computing brain the size of a beach ball, nature resorts to **heuristics**, simpler thinking strategies. Thus, you might reduce the number of options in the *SPLOYOCHYG* example by grouping letters that often appear together (*CH* and *GY*) and excluding rare letter combinations (such as two *Y*'s together). By using heuristics and then applying trial and error, you may hit on the answer. Have you guessed it?¹

Sometimes, no problem-solving strategy seems to be at work at all, and we arrive at a solution to a problem with **insight**. Teams of researchers have identified brain activity associated with sudden flashes of insight (Kounios & Beeman, 2009; Sandkühler & Bhat-tacharya, 2008). They gave people a problem: Think of a word that will form a compound word or phrase with each of three other words in a set (such as *pine*, *crab*, and *sauce*), and press a button to sound a bell when you know the answer. (If you need a hint: The word is a fruit.²) EEGs or fMRIs (functional MRIs) revealed the problem solver's brain activity.

¹ Answer to SPLOYOCHYG anagram: PSYCHOLOGY.

² The word is apple: pineapple, crabapple, applesauce.

AP® Exam Tip

There are several sample problems for you to enjoy in this section. It can be very interesting to ask several of your friends to try to solve them, too. Have them talk through the problem out loud and you will gain some understanding of the processes they are using.

algorithm a methodical, logical rule or procedure that guarantees solving a particular problem. Contrasts with the usually speedier—but also more error-prone—use of *heuristics*.

heuristic a simple thinking strategy that often allows us to make judgments and solve problems efficiently; usually speedier but also more error-prone than *algorithms*.

insight a sudden realization of a problem's solution; contrasts with strategy-based solutions.

Heuristic searching To search for hot cocoa mix, you could search every supermarket aisle (an algorithm), or check the breakfast, beverage, and baking supplies sections (heuristics). The heuristics approach is often speedier, but an algorithmic search guarantees you will find it eventually.

Fancy Collection/SuperStock

From Mark Jung-Beeman, Northwestern University and John Kounios, Drexel University

Figure 35.1

The Aha! moment A burst of right temporal lobe activity accompanied insight solutions to word problems (Jung-Beeman et al., 2004). The red dots designate EEG electrodes. The light gray lines show the distribution of high-frequency activity accompanying insight. The insight-related activity is centered in the right temporal lobe (yellow area).

In the first experiment, about half the solutions were by a sudden Aha! insight. Before the Aha! moment, the problem solvers' frontal lobes (which are involved in focusing attention) were active, and there was a burst of activity in the right temporal lobe, just above the ear (**FIGURE 35.1**).

We are also not the only creatures to display insight, as psychologist Wolfgang Köhler (1925) demonstrated in an experiment with Sultan, a chimpanzee. Köhler placed a piece of fruit and a long stick outside Sultan's cage. Inside the cage, he placed a short stick, which Sultan grabbed, using it to try to reach the fruit. After several failed attempts, he dropped the stick and seemed to survey the situation. Then suddenly, as if thinking "Aha!" Sultan jumped up and seized the short stick again. This time, he used it to pull in the longer stick—which he then used to reach the fruit. What is more, apes will even exhibit foresight, by storing a tool they can use to retrieve food the next day (Mulcahy & Call, 2006).

Insight strikes suddenly, with no prior sense of "getting warmer" or feeling close to a solution (Knoblich & Oellinger, 2006; Metcalfe, 1986). When the answer pops into mind (*apple!*), we feel a happy sense of satisfaction. The joy of a joke may similarly lie in our sudden comprehension of an unexpected ending or a double meaning: "You don't need a parachute to skydive. You only need a parachute to skydive twice."

Inventive as we are, other cognitive tendencies may lead us astray. For example, we more eagerly seek out and favor evidence verifying our ideas than evidence refuting them (Klayman & Ha, 1987; Skov & Sherman, 1986). Peter Wason (1960) demonstrated this tendency, known as **confirmation bias**, by giving British university students the three-number sequence 2-4-6 and asking them to guess the rule he had used to devise the series. (The rule was simple: any three ascending numbers.) Before submitting answers, students generated their own three-number sets and Wason told them whether their sets conformed to his rule. Once *certain* they had the rule, they could announce it. The result? Seldom right but never in doubt. Most students formed a wrong idea ("*Maybe it's counting by twos*") and then searched only for confirming evidence (by testing 6-8-10, 100-102-104, and so forth).

"Ordinary people," said Wason (1981), "evade facts, become inconsistent, or systematically defend themselves against the threat of new information relevant to the issue." Thus, once people form a belief—that vaccines cause autism spectrum disorder, that President Barack Obama is a Kenyan-born Muslim, that gun control does (or does not) save lives—they prefer belief-confirming information. The results can be momentous. The U.S. war against Iraq was launched on the belief that Saddam Hussein possessed weapons of mass destruction (WMD) that posed an immediate threat. When that assumption turned out to be false, the bipartisan U.S. Senate Select Committee on Intelligence (2004) identified confirmation bias as partly to blame: Administration analysts "had a tendency to accept information which supported [their presumptions] . . . more readily than information which contradicted" them. Sources denying such weapons were deemed "either lying or

confirmation bias a tendency to search for information that supports our preconceptions and to ignore or distort contradictory evidence.

"The human understanding, when any proposition has been once laid down . . . forces everything else to add fresh support and confirmation." -FRANCIS BACON, *NOVUM ORGANUM*, 1620

not knowledgeable about Iraq’s problems,” while those sources who reported ongoing WMD activities were seen as “having provided valuable information.”

Once we incorrectly represent a problem, it’s hard to restructure how we approach it. If the solution to the matchstick problem in **FIGURE 35.2** eludes you, you may be experiencing *fixation*—an inability to see a problem from a fresh perspective. (For the solution, turn the page to see **FIGURE 35.3**.)

A prime example of fixation is **mental set**, our tendency to approach a problem with the mind-set of what has worked for us previously. Indeed, solutions that worked in the past often do work on new problems. Consider:

Given the sequence *O-T-T-F-?-?-?*, what are the final three letters?

Most people have difficulty recognizing that the three final letters are *F(ive)*, *S(ix)*, and *S(even)*. But solving this problem may make the next one easier:

Given the sequence *J-F-M-A-?-?-?*, what are the final three letters? (If you don’t get this one, ask yourself what month it is.)

As a perceptual set predisposes what we perceive, a mental set predisposes how we think; sometimes this can be an obstacle to problem solving, as when our mental set from our past experiences with matchsticks predisposes us to arrange them in two dimensions.

Forming Good and Bad Decisions and Judgments

35-2 What is intuition, and how can the representativeness and availability heuristics, overconfidence, belief perseverance, and framing influence our decisions and judgments?

When making each day’s hundreds of judgments and decisions (*Is it worth the bother to take a jacket? Can I trust this person? Should I shoot the basketball or pass to the player who’s hot?*), we seldom take the time and effort to reason systematically. We just follow our **intuition**, our fast, automatic, unreasoned feelings and thoughts. After interviewing policy makers in government, business, and education, social psychologist Irving Janis (1986) concluded that they “often do not use a reflective problem-solving approach. How do they usually arrive at their decisions? If you ask, they are likely to tell you . . . they do it mostly by *the seat of their pants*.”

When we need to act quickly, the mental shortcuts we call *heuristics* enable snap judgments. Thanks to our mind’s automatic information processing, intuitive judgments are instantaneous and usually effective. However, research by cognitive psychologists Amos Tversky and Daniel Kahneman (1974) on the *representativeness* and *availability heuristics* showed how these generally helpful shortcuts can lead even the smartest people into dumb decisions.³

³ Tversky and Kahneman’s joint work on decision making received a 2002 Nobel Prize; sadly, only Kahneman was alive to receive the honor.

“In creating these problems, we didn’t set out to fool people. All our problems fooled us, too.” Amos Tversky (1985)

“Intuitive thinking [is] fine most of the time. . . . But sometimes that habit of mind gets us in trouble.” Daniel Kahneman (2005)

Figure 35.2
The matchstick problem How would you arrange six matches to form four equilateral triangles?

B. Veley

“The problem is I can’t tell the difference between a deeply wise, intuitive nudge from the Universe and one of my own bone-headed ideas!”

“Kahneman and his colleagues and students have changed the way we think about the way people think.” -AMERICAN PSYCHOLOGICAL ASSOCIATION PRESIDENT, SHARON BREHM, 2007

mental set a tendency to approach a problem in one particular way, often a way that has been successful in the past.

intuition an effortless, immediate, automatic feeling or thought, as contrasted with explicit, conscious reasoning.

Figure 35.3

Solution to the matchstick

problem To solve this problem, you must view it from a new perspective, breaking the fixation of limiting solutions to two dimensions.

The Representativeness Heuristic

To judge the likelihood of things in terms of how well they represent particular prototypes is to use the **representativeness heuristic**. To illustrate, consider:

A stranger tells you about a person who is short, slim, and likes to read poetry, and then asks you to guess whether this person is more likely to be a professor of classics at an Ivy League university or a truck driver (adapted from Nisbett & Ross, 1980). Which would be the better guess?

Did you answer “professor”? Many people do, because the description seems more *representative* of Ivy League scholars than of truck drivers. The representativeness heuristic enabled you to make a snap judgment. But it also led you to ignore other relevant information. When I help people think through this question, the conversation goes something like this:

Question: First, let’s figure out how many professors fit the description. How many Ivy League universities do you suppose there are?

Answer: Oh, about 10, I suppose.

Question: How many classics professors would you guess there are at each?

Answer: Maybe 4.

Question: Okay, that’s 40 Ivy League classics professors. What fraction of these are short and slim?

Answer: Let’s say half.

Question: And, of these 20, how many like to read poetry?

Answer: I’d say half—10 professors.

Question: Okay, now let’s figure how many truck drivers fit the description. How many truck drivers do you suppose there are?

Answer: Maybe 400,000.

Question: What fraction are short and slim?

Answer: Not many—perhaps 1 in 8.

Question: Of these 50,000, what percentage like to read poetry?

Answer: Truck drivers who like poetry? Maybe 1 in 100—oh, oh, I get it— that leaves 500 short, slim, poetry-reading truck drivers.

Comment: Yup. So, even if we accept your stereotype that the description is more representative of classics professors than of truck drivers, the odds are 50 to 1 that this person is a truck driver.

The representativeness heuristic influences many of our daily decisions. To judge the likelihood of something, we intuitively compare it with our mental representation of that category—of, say, what truck drivers are like. If the two match, that fact usually overrides other considerations of statistics or logic.

The Availability Heuristic

The **availability heuristic** operates when we estimate the likelihood of events based on how mentally available they are. Casinos entice us to gamble by signaling even small wins with bells and lights—making them vividly memorable—while keeping big losses soundlessly invisible.

The availability heuristic can lead us astray in our judgments of other people, too. Anything that makes information “pop” into mind—its vividness, recency, or distinctiveness—can make it seem commonplace. If someone from a particular ethnic or religious group commits a terrorist act, as happened on September 11, 2001, when Islamic extremists killed

representativeness heuristic

judging the likelihood of things in terms of how well they seem to represent, or match, particular prototypes; may lead us to ignore other relevant information.

availability heuristic

estimating the likelihood of events based on their availability in memory; if instances come readily to mind (perhaps because of their vividness), we presume such events are common.

nearly 3000 people in the United States in coordinated terrorist attacks, our readily available memory of the dramatic event may shape our impression of the whole group.

Even during that horrific year, terrorist acts claimed comparatively few lives. Yet when the statistical reality of greater dangers (see **FIGURE 35.4**) was pitted against a single vivid case, the memorable case won, as emotion-laden images of terror exacerbated our fears (Sunstein, 2007).

We often fear the wrong things. We fear flying because we play in our heads some air disaster. We fear letting our children walk to school because we play in our heads tapes of abducted and brutalized children. We fear swimming in ocean waters because we replay *Jaws* in our heads. Even just passing by a person who sneezes and coughs heightens our perceptions of various health risks (Lee et al., 2010). And so, thanks to these readily available images, we come to fear extremely rare events. (Turn the page to see Thinking Critically About: The Fear Factor—Why We Fear the Wrong Things.)

Meanwhile, the lack of comparably available images of global climate change—which some scientists regard as a future “Armageddon in slow motion”—has left most people little concerned (Pew, 2007). The vividness of a recent local cold day reduces their concern about long-term global warming and overwhelms less memorable scientific data (Li et al., 2011). Dramatic outcomes make us gasp; probabilities we hardly grasp. As of 2013, some 60 nations—including Canada, many in Europe, and the United States—have, however, sought to harness the positive power of vivid, memorable images by putting eye-catching warnings and graphic photos on cigarette packages (Riordan, 2013). This campaign may work, where others have failed. As psychologist Paul Slovic (2007) points out, we reason emotionally and neglect probabilities. We overfeel and underthink. In one experiment, donations to a starving 7-year-old child were greater when her image was *not* accompanied by statistical information about the millions of needy African children like her (Small et al., 2007). “If I look at the mass, I will never act,” Mother Teresa reportedly said. “If I look at the one, I will.” “The more who die, the less we care,” noted Slovic (2010).

Overconfidence

Sometimes our judgments and decisions go awry simply because we are more confident than correct. Across various tasks, people overestimate their performance (Metcalfe, 1998). If 60 percent of people correctly answer a factual question, such as “Is absinthe a liqueur or a precious stone?” they will typically average 75 percent confidence (Fischhoff et al., 1977). (It’s a licorice-flavored liqueur.) This tendency to overestimate the accuracy of our knowledge and judgments is **overconfidence**.

It was an overconfident BP that, before its exploded drilling platform spewed oil into the Gulf of Mexico, downplayed safety concerns, and then downplayed the spill’s magnitude (Mohr et al., 2010; Urbina, 2010). It is overconfidence that drives stockbrokers and investment managers to market their ability to outperform stock market averages, despite overwhelming evidence to the contrary (Malkiel, 2004). A purchase of stock X, recommended by a broker who judges this to be the time to buy, is usually balanced by a sale made by someone who judges this to be the time to sell. Despite their confidence, buyer and seller cannot both be right.

History is full of leaders who were more confident than correct. And classrooms are full of overconfident students who expect to finish assignments and write papers ahead of schedule (Buehler et al., 1994). In fact, the projects generally take about twice the number of days predicted.

Figure 35.4
Risk of death from various causes in the United States, 2001 (Data assembled from various government sources by Randall Marshall et al., 2007.)

overconfidence the tendency to be more confident than correct—to overestimate the accuracy of our beliefs and judgments.

“Don’t believe everything you think.” -BUMPER STICKER

Thinking Critically About

The Fear Factor—Why We Fear the Wrong Things

After the 9/11 attacks, many people feared flying more than driving. In a 2006 Gallup survey, only 40 percent of Americans reported being “not afraid at all” to fly. Yet from 2005 to 2007 Americans were—mile for mile—170 times more likely to die in an automobile or pickup truck crash than on a scheduled flight (National Safety Council, 2010). In 2009 alone, 33,808 Americans were killed in motor vehicle accidents—that’s 650 dead people each week. Meanwhile, in 2009 (as in 2007 and 2008) zero died from airline accidents on scheduled flights.

In a late 2001 essay, I calculated that if—because of 9/11—we flew 20 percent less and instead drove half those unflown miles, about 800 more people would die in the year after 9/11 (Myers, 2001). German psychologist Gerd Gigerenzer (2004, 2006) later checked this estimate against actual accident data. (Why didn’t I think of that?) U.S. traffic deaths did indeed increase significantly in the last three months of 2001 (**FIGURE 35.5**). By the end of 2002, Gigerenzer estimated, 1600 Americans had “lost their lives on the road by trying to avoid the risk of flying.” Despite our greater fear of flying, flying’s greatest danger is, for most people, the drive to the airport.

Why do we fear the wrong things? Why do we judge terrorism to be a greater risk than accidents? Psychologists have identified four influences that feed fear and cause us to ignore higher risks.

1. *We fear what our ancestral history has prepared us to fear.* Human emotions were road tested in the Stone Age. Our old brain prepares us to fear yesterday’s risks: snakes, lizards, and spiders (which combined now kill a tiny fraction of the number killed by modern-day threats, such as cars and cigarettes). Yesterday’s risks also prepare us to fear confinement and heights, and therefore flying.
2. *We fear what we cannot control.* Driving we control; flying we do not.
3. *We fear what is immediate.* The dangers of flying are mostly telescoped into the moments of takeoff and landing. The dangers of driving are diffused across many moments to come, each trivially dangerous.
4. *Thanks to the availability heuristic, we fear what is most readily available in memory.* Powerful, vivid images, like that of United Flight 175 slicing into the World Trade Center, feed our judgments of risk. Thousands of safe car trips have extinguished our anxieties about driving. Similarly, we remember (and fear) widespread disasters (hurricanes, tornadoes, earthquakes) that kill people dramatically, in bunches. But we fear too little the less dramatic threats that claim lives quietly, one by one, continuing into the distant future. Bill Gates has noted that each year a half-million children worldwide die from rotavirus. This is the equivalent of four 747s full of children *every day*, and we hear nothing of it (Glass, 2004).

Figure 35.5

Scared onto deadly highways Images of 9/11 etched a sharper image in American minds than did the millions of fatality-free flights on U.S. airlines during 2002 and after. Dramatic events are readily available to memory, and they shape our perceptions of risk. In the three months after 9/11, those faulty perceptions led more Americans to travel, and some to die, by car. (Adapted from Gigerenzer, 2004.)

Thinking Critically About *(continued)*

Dramatic deaths in bunches breed concern and fear

The memorable Haitian earthquake that killed some 250,000 people stirred an outpouring of justified concern. Meanwhile, according to the World Health Organization, a silent earthquake of poverty-related malaria was killing about that many people, mostly in Africa, every four months.

Ian Berry/Magnum Photos

The news, and our own memorable experiences, can make us disproportionately fearful of infinitesimal risks. As one risk analyst explained, “If it’s in the news, don’t worry about

it. The very definition of *news* is ‘something that hardly ever happens’” (Schneier, 2007). Despite people’s fear of dying in a terrorist attack on an airplane, the last decade produced one terrorist attempt for every 10.4 million flights—less than one-twentieth the chance of any one of us being struck by lightning (Silver, 2009).

“Fearful people are more dependent, more easily manipulated and controlled, more susceptible to deceptively simple, strong, tough measures and hard-line postures.” -MEDIA RESEARCHER GEORGE GERBNER TO U.S. CONGRESSIONAL SUBCOMMITTEE ON COMMUNICATIONS, 1981

The point to remember: It is perfectly normal to fear purposeful violence from those who wish us harm. When terrorists strike again, we will all recoil in horror. But smart thinkers will check their fears against the facts and resist those who aim to create a culture of fear. By so doing, we take away the terrorists’ most omnipresent weapon: exaggerated fear.

Anticipating how much we will accomplish, we also overestimate our future leisure time (Zauberman & Lynch, 2005). Believing we will have more time next month than we do today, we happily accept invitations and assignments, only to discover we’re just as busy when the day rolls around. Failing to appreciate our potential for error and believing we will have more money next year, we take out loans or buy on credit. Despite our painful underestimates, we remain overly confident of our next prediction.

Overconfidence can have adaptive value. People who err on the side of overconfidence live more happily. They make tough decisions more easily, and they seem more credible than others (Baumeister, 1989; Taylor, 1989). Moreover, given prompt and clear feedback, as weather forecasters receive after each day’s predictions, people can learn to be more realistic about the accuracy of their judgments (Fischhoff, 1982). The wisdom to know when we know a thing and when we do not is born of experience.

Belief Perseverance

Our overconfidence in our judgments is startling; equally startling is our tendency to cling to our beliefs in the face of contrary evidence. **Belief perseverance** often fuels social conflict, as it did in a classic study of people with opposing views of capital punishment (Lord et al., 1979). Each side studied two supposedly new research findings, one supporting and the other refuting the claim that the death penalty deters crime. Each side was more impressed by the study supporting its own beliefs, and each readily disputed the other study. Thus, showing the pro- and anti-capital-punishment groups the *same* mixed evidence actually *increased* their disagreement.

Bianca Moscatelli/Worth Publishers

Predict your own behavior

When will you finish reading this module?

belief perseverance clinging to one’s initial conceptions after the basis on which they were formed has been discredited.

“When you know a thing, to hold that you know it; and when you do not know a thing, to allow that you do not know it; this is knowledge.” -CONFUCIUS (551–479 B.C.E.), *ANALECTS*

If you want to rein in the belief perseverance phenomenon, a simple remedy exists: *Consider the opposite*. When the same researchers repeated the capital-punishment study, they asked some participants to be “as *objective* and *unbiased* as possible” (Lord et al., 1984). The plea did nothing to reduce biased evaluations of evidence. They asked another group to consider “whether you would have made the same high or low evaluations had exactly the same study produced results on the *other* side of the issue.” Having imagined and pondered *opposite* findings, these people became much less biased in their evaluations of the evidence.

The more we come to appreciate why our beliefs might be true, the more tightly we cling to them. Once we have explained to ourselves why we believe a child is “gifted” or has a “specific learning disorder,” or why candidate X or Y will be a better commander-in-chief, or why company Z makes a product worth owning, we tend to ignore evidence undermining our belief. Prejudice persists. As we will see in Unit XIV, once beliefs form and are justified, it takes more compelling evidence to change them than it did to create them.

“I’m happy to say that my final judgment of a case is almost always consistent with my prejudgment of the case.”

framing the way an issue is posed; how an issue is framed can significantly affect decisions and judgments.

The Effects of Framing

Framing, the way we present an issue, sways our decisions and judgments. Imagine two surgeons explaining a surgery risk. One tells patients that 10 percent of people die during this surgery. The other tells patients that 90 percent will survive. The information is the same. The effect is not. In surveys, both patients and physicians said the risk seems greater when they hear that 10 percent will *die* (Marteau, 1989; McNeil et al., 1988; Rothman & Salovey, 1997). Similarly, 9 in 10 college students rated a condom as effective if told it had a supposed “95 percent success rate” in stopping the HIV virus. Only 4 in 10 judged it effective when told it had a “5 percent failure rate” (Linville et al., 1992). To scare people, frame risks as numbers, not percentages. People told that a chemical exposure is projected to kill 10 of every 10 million people (imagine 10 dead people!) feel more frightened than if told the fatality risk is an infinitesimal .000001 (Kraus et al., 1992).

Framing can be a powerful persuasion tool. Carefully posed options can nudge people toward decisions that could benefit them or society as a whole (Thaler & Sunstein, 2008).

- *Why choosing to be an organ donor depends on where you live.* In many European countries as well as the United States, people can decide whether they want to be organ donors when renewing their driver’s license. In some countries, the default option is *Yes*, but people can opt out. Nearly 100 percent of the people in opt-out countries agree to be donors. In the United States, Britain, and Germany, the default option is *No*, but people can “opt in.” There, only about 25 percent agree to be donors (Johnson & Goldstein, 2003).
- *How to help employees decide to save for their retirement.* A 2006 U.S. pension law recognized the framing effect. Before that law, employees who wanted to contribute to a 401(k) retirement plan typically had to choose a lower take-home pay, which few people will do. Companies can now automatically enroll their employees in the plan but allow them to opt out (which would raise the employees’ take-home pay). In both plans, the decision to contribute is the employee’s. But under the new “opt-out” arrangement, enrollments in one analysis of 3.4 million workers soared from 59 to 86 percent (Rosenberg, 2010).
- *How to help save the planet.* Some psychologists are asking: With the climate warming, but concerns lessening among the British and Americans, are there better ways to frame these issues (Krosnick, 2010; Rosenthal, 2010)? For example, although a “carbon tax” may be the most effective way to curb greenhouse gases, many people oppose new taxes. But they are more supportive of funding energy development or carbon capture with a “carbon offset” fee (Hardisty et al., 2010).

The point to remember: Those who understand the power of framing can use it to influence our decisions.

The Perils and Powers of Intuition

35-3 How do smart thinkers use intuition?

We have seen how our irrational thinking can plague our efforts to see problems clearly, make wise decisions, form valid judgments, and reason logically. Moreover, these perils of intuition feed gut fears and prejudices. And they persist even when people are offered extra pay for thinking smart, even when they are asked to justify their answers, and even when they are expert physicians or clinicians (Shafir & LeBoeuf, 2002). So, are our heads indeed filled with straw?

Good news: Cognitive scientists are also revealing intuition's powers. Here is a summary of some of the high points:

- *Intuition is huge.* Recall from Module 16 that through *selective attention*, we can focus our conscious awareness on a particular aspect of all we experience. Our mind's unconscious track, however, makes good use intuitively of what we are not consciously processing. Today's cognitive science offers many examples of unconscious influences on our judgments (Custers & Aarts, 2010). Consider: Most people guess that the more complex the choice, the smarter it is to make decisions rationally rather than intuitively (Inbar et al., 2010). Actually, Dutch psychologists have shown that in making complex decisions, we benefit by letting our brain work on a problem without thinking about it (Strick et al., 2010). In one series of experiments, they showed three groups of people complex information (about apartments or roommates or art posters or soccer football matches). They invited one group to state their preference immediately after reading information about each of four options. A second group, given several minutes to analyze the information, made slightly smarter decisions. But wisest of all, in study after study, was the third group, whose attention was distracted for a time, enabling their minds to process the complex information unconsciously. Critics of this research remind us that deliberate, conscious thought also is part of smart thinking (González-Vallejo et al., 2008; Lassiter et al., 2009; Newell et al., 2008; Payne et al., 2008). Nevertheless, letting a problem "incubate" while we attend to other things can pay dividends (Sio & Ormerod, 2009). Facing a difficult decision involving lots of facts, we're wise to gather all the information we can, and then say, "Give me some time *not* to think about this." By taking time to sleep on it, we let our unconscious mental machinery work on, and await, the intuitive result of our unconscious processing.
- *Intuition is usually adaptive.* Our instant, intuitive reactions enable us to react quickly. Our fast and frugal heuristics, for example, enable us to intuitively assume that fuzzy looking objects are far away—which they usually are, except on foggy mornings. Our learned associations surface as gut feelings, the intuitions of our two-track mind. If a stranger looks like someone who previously harmed or threatened us, we may—without consciously recalling the earlier experience—react warily. People's automatic, unconscious associations with a political position can even predict their future decisions *before* they consciously make up their minds (Galdi et al., 2008).
- *Intuition is recognition born of experience.* It is implicit knowledge—what we've learned but can't fully explain, such as how to ride a bike. We see this tacit expertise in chess masters playing "blitz chess," where every move is made after barely more than a glance. They can look at a board and intuitively know the right move (Burns, 2004). We see it in experienced nurses, firefighters, art critics, car mechanics, and hockey players. And in you, too, for anything in which you have developed a special skill. In each case, what feels like instant intuition is an acquired ability to size up a situation in an eyeblink. As Nobel laureate psychologist Herbert Simon (2001) observed, intuition is analysis "frozen into habit."

Hmm . . . male or female?

When acquired expertise becomes an automatic habit, as it is for experienced chicken sexers, it feels like intuition. At a glance, they just know the sex of the chick, yet cannot easily tell you how they know.

Jean-Philippe Kiszczek/AFP

The bottom line: Intuition can be perilous, especially when we overfeel and underthink, as we do when judging risks. Today's psychological science reminds us to check our intuitions against reality, but also enhances our appreciation for intuition. Our two-track mind makes sweet harmony as smart, critical thinking listens to the creative whispers of our vast unseen mind, and then evaluates evidence, tests conclusions, and plans for the future.

Try This

What time is it now? When I asked you (in the section on overconfidence) to estimate how quickly you would finish this module, did you underestimate or overestimate?

Before You Move On**▶ ASK YOURSELF**

People's perceptions of risk, often biased by vivid images from movies or the news, are surprisingly unrelated to actual risks. (People may hide in the basement during thunderstorms but fail to buckle their seat belts in the car.) What are the things you fear? Are some of those fears out of proportion to statistical risk? Are you failing, in other areas of your life, to take reasonable precautions?

▶ TEST YOURSELF

The availability heuristic is a quick-and-easy but sometimes misleading guide to judging reality. What is the availability heuristic?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 35 Review**35-1** What cognitive strategies assist our problem solving, and what obstacles hinder it?

- An *algorithm* is a methodical, logical rule or procedure (such as a step-by-step description for evacuating a building during a fire) that guarantees a solution to a problem.
- A *heuristic* is a simpler strategy (such as running for an exit if you smell smoke) that is usually speedier than an algorithm but is also more error-prone.
- *Insight* is not a strategy-based solution, but rather a sudden flash of inspiration that solves a problem.
- Obstacles to problem solving include *confirmation bias*, which predisposes us to verify rather than challenge our hypotheses, and fixation, such as *mental set*, which may prevent us from taking the fresh perspective that would lead to a solution.

35-2 What is intuition, and how can the representativeness and availability heuristics, overconfidence, belief perseverance, and framing influence our decisions and judgments?

- *Intuition* is the effortless, immediate, automatic feeling or thoughts we often use instead of systematic reasoning.
- Heuristics enable snap judgments. *The representativeness heuristic* leads us to judge the likelihood of things in terms of how they represent our prototype for a group of items. Using the *availability heuristic*, we judge the likelihood of things based on how readily they come to mind, which often leads us to fear the wrong things.
- *Overconfidence* can lead us to overestimate the accuracy of our beliefs.

- When a belief we have formed and explained has been discredited, belief perseverance may cause us to cling to that belief. A remedy for *belief perseverance* is to consider how we might have explained an opposite result.
- *Framing* is the way a question or statement is worded. Subtle wording differences can dramatically alter our responses.

Multiple-Choice Questions

1. What is another term for a methodical, logical rule that guarantees solving a particular problem?
 - a. Heuristic
 - b. Algorithm
 - c. Insight
 - d. Mental set
 - e. Confirmation bias
2. Which of the following is the tendency to search for supportive information of preconceptions while ignoring contradictory evidence?
 - a. Confirmation bias
 - b. Intuition
 - c. Mental set
 - d. Availability heuristic
 - e. Overconfidence
3. What is another word for the way an issue is presented to you?
 - a. Intuition
 - b. Insight
 - c. Framing
 - d. Overconfidence
 - e. Perseverance
4. When instances come readily to mind, we often presume such events are common. What of the following is the term for this phenomenon?
 - a. Intuition insight
 - b. Confirmation bias
 - c. Belief perseverance
 - d. Mental set
 - e. Availability heuristic

Practice FRQs

1. Name and define two problem-solving strategies. Next, explain an advantage each has over the other.
2. Explain how each of the following can lead to inaccurate judgments: overconfidence, mental set, and confirmation bias.

Answer

1 point: An algorithm is a step-by-step procedure that guarantees a solution.

1 point: A heuristic is a simple thinking strategy that often allows us to make quick judgments.

1 point: Algorithm advantage: More likely to produce a correct solution.

1 point: Heuristic advantage: Often faster than using an algorithm.

35-3 How do smart thinkers use intuition?

- Smart thinkers welcome their intuitions (which are usually adaptive), but when making complex decisions they gather as much information as possible and then take time to let their two-track mind process all available information.
- As people gain expertise, they grow adept at making quick, shrewd judgments.

(3 points)

Module 36

Thinking and Language

Module Learning Objectives

- 36-1** Describe the structural components of a language.
- 36-2** Identify the milestones in language development.
- 36-3** Describe how we acquire language.
- 36-4** Identify the brain areas involved in language processing and speech.
- 36-5** Describe the relationship between language and thinking, and discuss the value of thinking in images.

Vladimir Mucibabic/Shutterstock

language our spoken, written, or signed words and the ways we combine them to communicate meaning.

Imagine an alien species that could pass thoughts from one head to another merely by pulsating air molecules in the space between them. Perhaps these weird creatures could inhabit a future science fiction movie?

Actually, we are those creatures. When we speak, our brain and voice apparatus conjure up air pressure waves that we send banging against another's eardrum—enabling us to transfer thoughts from our brain into theirs. As cognitive scientist Steven Pinker (1998) has noted, we sometimes sit for hours “listening to other people make noise as they exhale, because those hisses and squeaks contain *information*.” And thanks to all those funny sounds created in our heads from the air pressure waves we send out, we get people's attention, we get them to do things, and we maintain relationships (Guerin, 2003). Depending on how you vibrate the air after opening your mouth, you may get slapped or kissed.

But **language** is more than vibrating air. As I create this paragraph, my fingers on a keyboard generate electronic binary numbers that are translated into squiggles of dried carbon pressed onto the page in front of you. When transmitted by reflected light rays into your retina, the printed squiggles trigger formless nerve impulses that project to several areas of your brain, which integrate the information, compare it with stored information, and decode meaning. Thanks to language, information is moving from my mind to yours. Monkeys mostly know what they see. Thanks to language (spoken, written, or signed) we comprehend much that we've never seen and that our distant ancestors never knew.

Language transmits knowledge Whether spoken, written, or signed, language—the original wireless communication—enables mind-to-mind information transfer, and with it the transmission of civilization's accumulated knowledge across generations.

AP Photo/M. Spencer Green

Today, notes Daniel Gilbert (2006), “The average newspaper boy in Pittsburgh knows more about the universe than did Galileo, Aristotle, Leonardo, or any of those other guys who were so smart they only needed one name.”

To Pinker (1990), language is “the jewel in the crown of cognition.” If you were able to retain one cognitive ability, make it language, suggests researcher Lera Boroditsky (2009). Without sight or hearing, you could still have friends, family, and a job. But without language, could you have these things? “Language is so fundamental to our experience, so deeply a part of being human, that it’s hard to imagine life without it.”

Language Structure

36-1 What are the structural components of a language?

Consider how we might go about inventing a language. For a spoken language, we would need three building blocks:

- **Phonemes** are the smallest distinctive sound units in a language. To say *bat*, English speakers utter the phonemes *b*, *a*, and *t*. (Phonemes aren’t the same as letters. *Chat* also has three phonemes—*ch*, *a*, and *t*.) Linguists surveying nearly 500 languages have identified 869 different phonemes in human speech, but no language uses all of them (Holt, 2002; Maddieson, 1984). English uses about 40; other languages use anywhere from half to more than twice that many. As a general rule, consonant phonemes carry more information than do vowel phonemes. *The treth ef thes stement shed be evedent frem thes bref demenstretien.*
- **Morphemes** are the smallest units that carry meaning in a given language. In English, a few morphemes are also phonemes—the personal pronoun *I* and the *s* that indicates plural, for instance. But most morphemes combine two or more phonemes. Some, like *bat* or *gentle*, are words. Others—like the prefix *pre-* in *preview* or the suffix *-ed* in *adapted*—are parts of words.
- **Grammar** is the system of rules that enables us to communicate with one another. Grammatical rules guide us in deriving meaning from sounds (*semantics*) and in ordering words into sentences (*syntax*).

Language becomes increasingly complex as we move from one level to the next. In English, for example, 40 or so phonemes can be combined to form more than 100,000 morphemes, which alone or in combination produce the 616,500 word forms in the *Oxford English Dictionary*. Using those words, we can then create an infinite number of sentences, most of which (like this one) are original. Like life constructed from the genetic code’s simple alphabet, language is complexity built of simplicity. I know that you can know why I worry that you think this sentence is starting to get too complex, but that complexity—and our capacity to communicate and comprehend it—is what distinguishes human language capacity (Hauser et al., 2002; Premack, 2007).

Language Development

Make a quick guess: How many words will you have learned during the years between your first birthday and your high school graduation? Although you use only 150 words for about half of what you say, you will have learned about 60,000 words in your native language during those years (Bloom, 2000; McMurray, 2007). That averages (after age 2) to nearly 3500 words each year, or nearly 10 each day! How you do it—how those 3500 words so far outnumber the roughly 200 words your schoolteachers are consciously teaching you each year—is one of the great human wonders.

phoneme in a language, the smallest distinctive sound unit.

morpheme in a language, the smallest unit that carries meaning; may be a word or a part of a word (such as a prefix).

grammar in a language, a system of rules that enables us to communicate with and understand others. In a given language, *semantics* is the set of rules for deriving meaning from sounds, and *syntax* is the set of rules for combining words into grammatically sensible sentences.

AP® Exam Tip

It is sometimes challenging to keep these building blocks straight. Phonemes are sounds. It may help to remember that phones carry sounds. Morphemes have meaning, and both words begin with the letter *m*.

“Let me get this straight now. Is what you want to build a jean factory or a gene factory?”

Could you even state all your language's rules of syntax (the correct way to string words together to form sentences)? Most of us cannot. Yet, before you were able to add $2 + 2$, you were creating your own original and grammatically appropriate sentences. As a preschooler, you comprehended and spoke with a facility that puts to shame college students struggling to learn a foreign language.

We humans have an astonishing facility for language. With remarkable efficiency, we sample tens of thousands of words in our memory, effortlessly assemble them with near-perfect syntax, and spew them out, three words a second (Vigliocco & Hartsuiker, 2002). Seldom do we form sentences in our minds before speaking them. Rather we organize them on the fly as we speak. And while doing all this, we also adapt our utterances to our social and cultural context, following rules for speaking (*How far apart should we stand?*) and listening (*Is it OK to interrupt?*). Given how many ways there are to mess up, it's amazing that we can master this social dance. So when and how does it happen?

When Do We Learn Language?

36-2 What are the milestones in language development?

RECEPTIVE LANGUAGE

Children's language development moves from simplicity to complexity. Infants start without language (*in fantis* means "not speaking"). Yet by 4 months of age, babies can recognize differences in speech sounds (Stager & Werker, 1997). They can also read lips: They prefer to look at a face that matches a sound, so we know they can recognize that *ah* comes from wide open lips and *ee* from a mouth with corners pulled back (Kuhl & Meltzoff, 1982). This marks the beginning of the development of babies' *receptive language*, their ability to understand what is said to and about them. At 7 months and beyond, babies grow in their power to do what you and I find difficult when listening to an unfamiliar language: to segment spoken sounds into individual words. Moreover, their adeptness at this task, as judged by their listening patterns, predicts their language abilities at ages 2 and 5 (Newman et al., 2006).

PRODUCTIVE LANGUAGE

Babies' *productive language*, their ability to produce words, matures after their receptive language. They recognize noun-verb differences—as shown by their responses to a misplaced noun or verb—earlier than they utter sentences with nouns and verbs (Bernal et al., 2010).

Before nurture molds babies' speech, nature enables a wide range of possible sounds in the **babbling stage**, beginning around 4 months of age. Many of these spontaneously uttered sounds are consonant-vowel pairs formed by simply bunching the tongue in the front of the mouth (*da-da*, *na-na*, *ta-ta*) or by opening and closing the lips (*ma-ma*), both of which babies do naturally for feeding (MacNeilage & Davis, 2000). Babbling is not an imitation of adult speech—it includes sounds from various languages, including those not spoken in the household. From this early babbling, a listener could not identify an infant as being, say, French, Korean, or Ethiopian. Deaf infants who observe their deaf parents signing begin to babble more with their hands (Petitto & Marentette, 1991).

By the time infants are about 10 months old, their babbling has changed so that a trained ear can identify the household language (de Boysson-Bardies et al., 1989). Without exposure to other languages, babies lose their ability to hear and produce sounds and tones found outside their native language (Meltzoff et al., 2009; Pallier et al., 2001). Thus, by adulthood, those who speak only English cannot discriminate certain sounds in Japanese speech.

babbling stage beginning at about 4 months, the stage of speech development in which the infant spontaneously utters various sounds at first unrelated to the household language.

Nor can Japanese adults with no training in English hear the difference between the English *r* and *l*. For a Japanese-speaking adult, *la-la-ra-ra* may sound like the same syllable repeated. (Does this astonish you as it does me?) A Japanese-speaking person told that the train station is “just after the next light” may wonder, “The next what? After the street veering right, or farther down, after the light?”

Around their first birthday, most children enter the **one-word stage**. They have already learned that sounds carry meanings, and if repeatedly trained to associate, say, *fish* with a picture of a fish, 1-year-olds will look at a fish when a researcher says, “Fish, fish! Look at the fish!” (Schafer, 2005). They now begin to use sounds—usually only one barely recognizable syllable, such as *ma* or *da*—to communicate meaning. But family members quickly learn to understand, and gradually the infant’s language conforms more to the family’s language. Across the world, baby’s first words are often nouns that label objects or people (Tardif et al., 2008). At this one-word stage, a single inflected word (“Doggy!”) may equal a sentence. (“Look at the dog out there!”)

At about 18 months, children’s word learning explodes from about a word per week to a word per day. By their second birthday, most have entered the **two-word stage** (TABLE 36.1). They start uttering two-word sentences in **telegraphic speech**. Like today’s text messages or yesterday’s telegrams that charged by the word (TERMS ACCEPTED. SEND MONEY), a 2-year-old’s speech contains mostly nouns and verbs (*Want juice*). Also like telegrams, it follows rules of syntax: The words are in a sensible order. English-speaking children typically place adjectives before nouns—*white house* rather than *house white*. Spanish reverses this order, as in *casa blanca*.

Table 36.1 Summary of Language Development

Month (approximate)	Stage
4	Infant babbles many speech sounds (“Ah-goo”).
10	Babbling resembles household language (“Ma-ma”).
12	Child enters one-word stage (“Kitty!”).
24	Child engages in two-word, telegraphic speech (“Get ball.”).
24+	Language develops rapidly into complete sentences.

Moving out of the two-word stage, children quickly begin uttering longer phrases (Fromkin & Rodman, 1983). If they get a late start on learning a particular language, such as after receiving a cochlear implant or being adopted by a family in another country, their language development still proceeds through the same sequence, although usually at a faster pace (Ertmer et al., 2007; Snedeker et al., 2007). By early elementary school, children understand complex sentences and begin to enjoy the humor conveyed by double meanings: “You never starve in the desert because of all the sand-which-is there.”

Explaining Language Development

36-3 How do we acquire language?

The world’s 7000 or so languages are structurally very diverse (Evans & Levinson, 2009). Linguist Noam Chomsky has nonetheless argued that all languages do share some basic elements, which he calls *universal grammar*. All human languages, for example, have nouns, verbs, and adjectives as grammatical building blocks. Moreover, said Chomsky, we humans are born with a built-in predisposition to learn grammar rules, which helps explain why preschoolers pick up language so readily and use grammar so well. It happens so naturally—as naturally as birds learn to fly—that training hardly helps.

“Got idea. Talk better. Combine words. Make sentences.”

one-word stage the stage in speech development, from about age 1 to 2, during which a child speaks mostly in single words.

two-word stage beginning about age 2, the stage in speech development during which a child speaks mostly in two-word statements.

telegraphic speech early speech stage in which a child speaks like a telegram—“go car”—using mostly nouns and verbs.

Creating a language Brought together as if on a desert island (actually a school), Nicaragua's young deaf children over time drew upon sign gestures from home to create their own Nicaraguan Sign Language, complete with words and intricate grammar. Our biological predisposition for language does not create language in a vacuum. But activated by a social context, nature and nurture work creatively together (Osborne, 1999; Sandler et al., 2005; Senghas & Coppola, 2001).

Susan Meiselas/Magnum Photos

We are not, however, born with a built-in *specific* language. Europeans and Native Australia–New Zealand populations, though geographically separated for 50,000 years, can readily learn each others' languages (Chater et al., 2009). And whatever language we experience as children, whether spoken or signed, we all readily learn its specific grammar and vocabulary (Bavelier et al., 2003). But no matter what language we learn, we start speaking it mostly in nouns (*kitty, da-da*) rather than in verbs and adjectives (Bornstein et al., 2004). Biology and experience work together.

STATISTICAL LEARNING

When adults listen to an unfamiliar language, the syllables all run together. A young Sudanese couple new to North America and unfamiliar with English might, for example, hear *United Nations* as “Uneye Tednay Shuns.” Their 7-month-old daughter would not have this problem. Human infants display a remarkable ability to learn statistical aspects of human speech. Their brains not only discern word breaks, they statistically analyze which syllables, as in “hap-py-ba-by,” most often go together. After just two minutes of exposure to a computer voice speaking an unbroken, monotone string of nonsense syllables (*bidakupadotigolabubidaku . . .*), 8-month-old infants were able to recognize (as indicated by their attention) three-syllable sequences that appeared repeatedly (Saffran et al., 1996, 2009).

In further testimony to infants' surprising knack for soaking up language, research shows that 7-month-olds can learn simple sentence structures. After repeatedly hearing syllable sequences that follow one rule (an ABA pattern, such as *ga-ti-ga* and *li-na-li*), infants listened longer to syllables in a different sequence (an ABB pattern, such as *wo-fe-fe*, rather than *wo-fe-wo*). Their detecting the difference between the two patterns supports the idea that babies come with a built-in readiness to learn grammatical rules (Marcus et al., 1999).

CRITICAL PERIODS

Could we train adults to perform this same feat of statistical analysis later in the human life span? Many researchers believe not. Childhood seems to represent a *critical* (or “sensitive”) *period* for mastering certain aspects of language before the language-learning window closes (Hernandez & Li, 2007). People who learn a second language as adults usually speak it with the accent of their native language, and they also have difficulty mastering the new grammar. In one experiment, Korean and Chinese immigrants considered 276 English sentences (“*Yesterday the hunter shoots a deer*”) and decided whether they were grammatically correct or incorrect (Johnson & Newport, 1991). All had been in the United States for approximately 10 years: Some had arrived in early childhood, others as adults. As **FIGURE 36.1** reveals, those who learned their second language early learned it best. The older one is when moving to a new country, the harder it will be to learn its language and to absorb its culture (Cheung et al., 2011; Hakuta et al., 2003).

The window on language learning closes gradually in early childhood. Later-than-usual exposure to language (at age 2 or 3) unleashes the idle language capacity of a child's brain, producing a rush of language. But

A natural talent We humans come with a remarkable capacity to soak up language. But the particular language we learn reflects our unique interactions with others.

©Roy Morsch/CORBIS

**Figure 36.1****Our ability to learn a new language diminishes with age**

Ten years after coming to the United States, Asian immigrants took an English grammar test. Although there is no sharply defined critical period for second language learning, those who arrived before age 8 understood American English grammar as well as native speakers did. Those who arrived later did not. (From Johnson & Newport, 1991.)

Don Smetzer/Photo Edit

by about age 7, those who have not been exposed to either a spoken or a signed language gradually lose their ability to master *any* language.

The impact of early experiences is evident in language learning in the 90+ percent of prelingually deaf children born to hearing-nonsigning parents. These children typically do not experience language during their early years. Natively deaf children who learn sign language after age 9 never learn it as well as those who lose their hearing at age 9 after learning English. They also never learn English as well as other natively deaf children who learned sign in infancy (Mayberry et al., 2002). Those who learn to sign as teens or adults are like immigrants who learn English after childhood: They can master basic words and learn to order them, but they never become as fluent as native signers in producing and comprehending subtle grammatical differences (Newport, 1990). As a flower's growth will be stunted without nourishment, so, too, children will typically become linguistically stunted if isolated from language during the critical period for its acquisition.

George Ancona

No means No—no matter how you say it!

Deaf children of deaf-signing parents and hearing children of hearing parents have much in common. They develop language skills at about the same rate, and they are equally effective at opposing parental wishes and demanding their way.

The Brain and Language

36-4 What brain areas are involved in language processing and speech?

We think of speaking and reading, or writing and reading, or singing and speaking as merely different examples of the same general ability—language. But consider this curious finding: **Aphasia**, an impairment of language, can result from damage to any of several cortical areas. Even more curious, some people with aphasia can speak fluently but cannot read (despite good vision), while others can comprehend what they read but cannot speak. Still others can write but not read, read but not write, read numbers but not letters, or sing but not speak. These cases suggest that language is complex, and that different brain areas must serve different language functions.

Indeed, in 1865, French physician Paul Broca reported that after damage to an area of the left frontal lobe (later called **Broca's area**) a person would struggle to *speak* words while still being able to sing familiar songs and comprehend speech.

In 1874, German investigator Carl Wernicke discovered that after damage to an area of the left temporal lobe (**Wernicke's area**) people could speak only meaningless words. Asked to describe a picture that showed two boys stealing cookies behind a woman's back, one patient responded: "Mother is away her working her work to get her better, but when

aphasia impairment of language, usually caused by left-hemisphere damage either to Broca's area (impairing speaking) or to Wernicke's area (impairing understanding).

Broca's area controls language expression—an area of the frontal lobe, usually in the left hemisphere, that directs the muscle movements involved in speech.

Wernicke's area controls language reception—a brain area involved in language comprehension and expression; usually in the left temporal lobe.

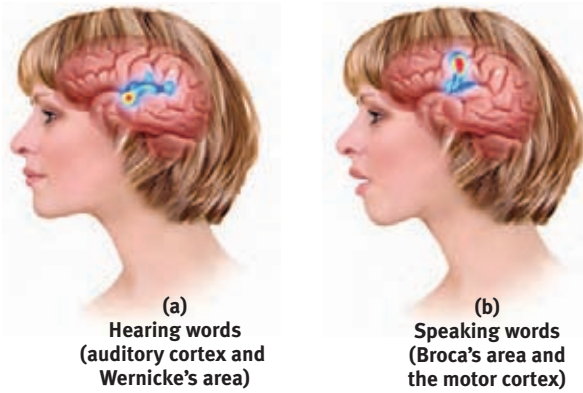

Figure 36.2
Brain activity when hearing and speaking words

"It is the way systems interact and have a dynamic interdependence that is—unless one has lost all sense of wonder—quite awe-inspiring." —SIMON CONWAY MORRIS, "THE BOYLE LECTURE," 2005

AP® Exam Tip

You'll notice that even though the brain was one of the major topics in Unit III, it keeps coming up. Each time it does provides you with an opportunity to go back and review what you learned previously about the brain. Rehearse frequently, and you will not have much to relearn before the AP® exam.

she's looking the two boys looking the other part. She's working another time" (Geschwind, 1979). Damage to Wernicke's area also disrupts understanding.

Today's neuroscience has confirmed brain activity in Broca's and Wernicke's areas during language processing (**FIGURE 36.2**). But neuroscience is refining our understanding of how our brain processes language. Language functions are distributed across other brain areas as well. Functional MRI scans show that different neural networks are activated by nouns and verbs, or objects and actions; by different vowels; and by reading stories of visual versus motor experiences (Shapiro et al., 2006; Speer et al., 2009). Different neural networks also enable one's native language and a second language learned later in life (Perani & Abutalebi, 2005).

And here's another funny fMRI finding. Jokes that play on meaning ("*Why don't sharks bite lawyers? . . . Professional courtesy*") are processed in a different brain area than jokes that play on words ("*What kind of lights did Noah use on the ark? . . . Flood lights*") (Goel & Dolan, 2001).

The big point to remember is this: In processing language, as in other forms of information processing, *the brain operates by dividing its mental functions—speaking, perceiving, thinking, remembering—into subfunctions*. Your conscious experience of reading this page *seems* indivisible, but your brain is computing each word's form, sound, and meaning using different neural networks (Posner & Carr, 1992). We saw this also in Module 18's discussion of vision, for which the brain engages specialized subtasks, such as discerning depth, movement, form, and color. And in vision as in language, a localized trauma that destroys one of these neural work teams may cause people to lose just one aspect of processing. In visual processing, a stroke may destroy the ability to perceive movement but not color. In language processing, a stroke may impair the ability to speak distinctly without harming the ability to read.

Think about it: What you experience as a continuous, indivisible stream of experience is actually but the visible tip of a subdivided information-processing iceberg.

* * *

Returning to our debate about how deserving we humans are of our name *Homo sapiens*, let's pause to issue an interim report card. On decision making and risk assessment, our error-prone species might rate a C+. On problem solving, where humans are inventive yet vulnerable to fixation, we would probably receive a better mark, perhaps a B. On cognitive efficiency, our fallible but quick heuristics earn us an A. And when it comes to our creativity, and our learning and using language, the awestruck experts would surely award the human species an A+.

Before You Move On

▶ ASK YOURSELF

There has been controversy at some universities about allowing fluency in sign language to fulfill a second-language requirement for an undergraduate degree. As you start planning for your own college years, what is your opinion?

▶ TEST YOURSELF

If children are not yet speaking, is there any reason to think they would benefit from parents and other caregivers reading to them?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Language and Thought

36-5 What is the relationship between language and thinking, and what is the value of thinking in images?

Thinking and language intricately intertwine. Asking which comes first is one of psychology's chicken-and-egg questions. Do our ideas come first and we wait for words to name them? Or are our thoughts conceived in words and therefore unthinkable without them?

Language Influences Thinking

Linguist Benjamin Lee Whorf (1956) contended that language determines the way we think: "Language itself shapes a [person's] basic ideas." The Hopi, who have no past tense for their verbs, could not readily *think* about the past, said Whorf.

Whorf's **linguistic determinism** hypothesis is too extreme. We all think about things for which we have no words. (Can you think of a shade of blue you cannot name?) And we routinely have *unsymbolized* (wordless, imageless) thoughts, as when someone, while watching two men carry a load of bricks, wondered whether the men would drop them (Heavey & Hurlburt, 2008; Hurlburt & Akhter, 2008).

Nevertheless, to those who speak two dissimilar languages, such as English and Japanese, it seems obvious that a person may think differently in different languages (Brown, 1986). Unlike English, which has a rich vocabulary for self-focused emotions such as anger, Japanese has more words for interpersonal emotions such as sympathy (Markus & Kitayama, 1991). Many bilingual individuals report that they have different senses of self, depending on which language they are using (Matsumoto, 1994). In one series of studies with bilingual Israeli Arabs (who speak both Arabic and Hebrew), participants thought differently about their social world, with differing automatic associations with Arabs and Jews, depending on which language the testing session used (Danziger & Ward, 2010).

Bilingual individuals may even reveal different personality profiles when taking the same test in their two languages (Dinges & Hull, 1992). This happened when China-born, bilingual students at the University of Waterloo in Ontario were asked to describe themselves in English or Chinese (Ross et al., 2002). The English-language self-descriptions fit typical Canadian profiles: Students expressed mostly positive self-statements and moods. Responding in Chinese, the same students gave typically Chinese self-descriptions: They reported more agreement with Chinese values and roughly equal positive and negative self-statements and moods. "Learn a new language and get a new soul," says a Czech proverb. Similar personality changes have been shown when bicultural, bilingual Americans and Mexicans shifted between the cultural frames associated with English and Spanish (Ramírez-Esparza et al., 2006).

So our words may not *determine* what we think, but they do *influence* our thinking (Boroditsky, 2011). We use our language in forming categories. In Brazil, the isolated Piraha tribespeople have words for the numbers 1 and 2, but numbers above that are simply "many." Thus, if shown 7 nuts in a row, they find it very difficult to lay out the same number from their own pile (Gordon, 2004).

Words also influence our thinking about colors. Whether we live in New Mexico, New South Wales, or New Guinea, we *see* colors much the same, but we use our native language to *classify* and *remember* colors (Davidoff, 2004; Roberson et al., 2004, 2005). If your language is English, you might view three colors and call two of them "yellow" and one of them "blue." Later you would likely see and recall the yellows as being more similar. But if you are a member of Papua New Guinea's Berinmo tribe, which has words for two different shades of yellow, you would more speedily perceive and better recall the distinctions between the two yellows. And if your language is Russian, which has distinct names for different shades of blue, such as *goluboy* and *sinly*, you might remember the blue better. Words matter.

Try This

To find out what we have learned about thinking and language in other animals, see Module 85.

Try This

Before reading on, use a pen or pencil to sketch this idea: "The girl pushes the boy." Now see the inverted comment below.

How did you illustrate "the girl pushes the boy"? Anne Mass and Aureo Russo (2003) report that people whose language reads from left to right mostly position the pushing girl on the left. Those who read and write Arabic, a right-to-left language, mostly place her on the right. This spatial bias appears only in those old enough to have learned their culture's writing system (Dobel et al., 2007).

linguistic determinism

Whorf's hypothesis that language determines the way we think.

Culture and color

In Papua New Guinea, Berinmo children have words for different shades of “yellow,” so they might more quickly spot and recall yellow variations. Here and everywhere, “the languages we speak profoundly shape the way we think, the way we see the world, the way we live our lives,” notes psychologist Lera Boroditsky (2009).

Prisma Bildagentur AG/Alamy

Perceived differences grow when we assign different names to colors. On the color spectrum, blue blends into green—until we draw a dividing line between the portions we call “blue” and “green.” Although equally different on the color spectrum, two different items that share the same color name (as the two “blues” do in **FIGURE 36.3**, contrast B) are harder to distinguish than two items with different names (“blue” and “green,” as in Figure 36.3, contrast A) (Özgen, 2004).

Given words’ subtle influence on thinking, we do well to choose our words carefully. Does it make any difference whether I write, “A child learns language as *he* interacts with *his* caregivers” or “Children learn language as *they* interact with *their* caregivers”? Many studies have

found that it does. When hearing the generic *he* (as in “the artist and his work”), people are more likely to picture a male (Henley, 1989; Ng, 1990). If *he* and *his* were truly gender free, we shouldn’t skip a beat when hearing that “man, like other mammals, nurses his young.”

To expand language is to expand the ability to think. As Unit IX points out, young children’s thinking develops hand in hand with their language (Gopnik & Meltzoff, 1986). Indeed, it is very difficult to think about or conceptualize certain abstract ideas (commitment, freedom, or rhyming) without language! And what is true for preschoolers is true for everyone: *It pays to increase your word power.* That’s why most textbooks, including this one, introduce new words—to teach new ideas and new ways of thinking. And that’s also why psychologist Steven Pinker (2007) titled his book on language *The Stuff of Thought*.

Increased word power helps explain what McGill University researcher Wallace Lambert (1992; Lambert et al., 1993) calls the *bilingual advantage*. Although their vocabulary in each language is somewhat smaller than that of people speaking a single language, bilingual people are skilled at inhibiting one language while using the other. And thanks to their well-practiced “executive control” over language, they also are better at inhibiting their attention to irrelevant information (Bialystock & Craik, 2010). This superior attentional control is evident from 7 months of age into adulthood (Emmorey et al., 2008; Kovacs & Mehler, 2009).

Lambert helped devise a Canadian program that immerses English-speaking children in French. (The number of non-Quebec children enrolled rose from 65,000 in 1981 to 300,000 in 2007 [Statistics Canada, 2010].) For most of their first three years in school, the English-speaking children are taught entirely in French, and thereafter gradually shift to classes mostly in English. Not surprisingly, the children attain a natural French fluency unrivaled by other methods of language teaching. Moreover, compared with similarly capable children in control groups, they do so without detriment to their English fluency, and with increased aptitude scores, creativity, and appreciation for French-Canadian culture (Genesee & Gándara, 1999; Lazaruk, 2007).

Whether we are in the linguistic minority or majority, language links us to one another. Language also connects us to the past and the future. “To destroy a people, destroy their language,” observed poet Joy Harjo.

“All words are pegs to hang ideas on.” -HENRY WARD BEECHER, *PROVERBS FROM PLYMOUTH PULPIT*, 1887

FYI

Perceived distances between cities also grow when two cities are in different countries or states rather than in the same (Burriss & Branscombe, 2005; Mishra & Mishra, 2010).

Figure 36.3

Language and perception When people view blocks of equally different colors, they perceive those with different names as more different. Thus the “green” and “blue” in contrast A may appear to differ more than the two similarly different blues in contrast B (Özgen, 2004).

Thinking in Images

When you are alone, do you talk to yourself? Is “thinking” simply conversing with yourself? Without a doubt, words convey ideas. But aren’t there times when ideas precede words? To turn on the cold water in your bathroom, in which direction do you turn the handle? To answer, you probably thought not in words but with *implicit* (nondeclarative, procedural) memory—a mental picture of how you do it (see Module 31).

Indeed, we often think in images. Artists think in images. So do composers, poets, mathematicians, athletes, and scientists. Albert Einstein reported that he achieved some of his greatest insights through visual images and later put them into words. Pianist Liu Chi Kung showed the value of thinking in images. One year after placing second in the 1958 Tchaikovsky piano competition, Liu was imprisoned during China’s cultural revolution. Soon after his release, after seven years without touching a piano, he was back on tour, the critics judging his musicianship better than ever. How did he continue to develop without practice? “I did practice,” said Liu, “every day. I rehearsed every piece I had ever played, note by note, in my mind” (Garfield, 1986).

For someone who has learned a skill, such as ballet dancing, even *watching* the activity will activate the brain’s internal simulation of it, reported one British research team after collecting fMRIs as people watched videos (Calvo-Merino et al., 2004). So, too, will imagining a physical experience, which activates some of the same neural networks that are active during the actual experience (Grèzes & Decety, 2001). Small wonder, then, that mental practice has become a standard part of training for Olympic athletes (Suinn, 1997).

One experiment on mental practice and basketball foul shooting tracked the University of Tennessee women’s team over 35 games (Savoy & Beitel, 1996). During that time, the team’s free-throw shooting increased from approximately 52 percent in games following standard physical practice to some 65 percent after mental practice. Players had repeatedly imagined making foul shots under various conditions, including being “trash-talked” by their opposition. In a dramatic conclusion, Tennessee won the national championship game in overtime, thanks in part to their foul shooting.

Mental rehearsal can also help you achieve an academic goal, as researchers demonstrated with two groups of introductory psychology students facing a midterm exam 1 week later (Taylor et al., 1998). (Scores of other students formed a control group, not engaging in any mental simulation.) The first group spent 5 minutes each day visualizing themselves scanning the posted grade list, seeing their A, beaming with joy, and feeling proud. This *outcome simulation* had little effect, adding only 2 points to their exam-scores average. Another group spent 5 minutes each day visualizing themselves effectively studying—reading the textbook, going over notes, eliminating distractions, declining an offer to go out. This *process simulation* paid off: This second group began studying sooner, spent more time at it, and beat the others’ average by 8 points. *The point to remember:* It’s better to spend your fantasy time planning how to get somewhere than to dwell on the imagined destination.

* * *

What, then, should we say about the relationship between thinking and language? As we have seen, language influences our thinking. But if thinking did not also affect language, there would never be any new words. And new words and new combinations of old words express new ideas. The basketball term *slam dunk* was coined after the act itself had become fairly common. So, let us say that *thinking affects our language, which then affects our thought* (FIGURE 36.4).

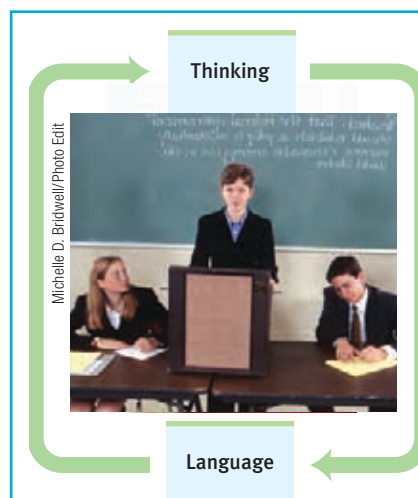

Figure 36.4

The interplay of thought and language The traffic runs both ways between thinking and language. Thinking affects our language, which affects our thought.

Psychological research on thinking and language mirrors the mixed views of our species by those in fields such as literature and religion. The human mind is simultaneously capable of striking intellectual failures and of striking intellectual power. Misjudgments are common and can have disastrous consequences. So we do well to appreciate our capacity for error. Yet our efficient heuristics often serve us well. Moreover, our ingenuity at problem solving and our extraordinary power of language mark humankind as almost “infinite in faculties.”

Before You Move On

▶ ASK YOURSELF

Do you use certain words or gestures that only your family or closest circle of friends would understand? Can you envision using these words or gestures to construct a language, as the Nicaraguan children did in building their version of sign language?

▶ TEST YOURSELF

To say that “words are the mother of ideas” assumes the truth of what concept?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 36 Review

36-1 What are the structural components of a language?

- *Phonemes* are a language’s basic units of sound.
- *Morphemes* are the elementary units of meaning.
- *Grammar*—the system of rules that enables us to communicate—includes semantics (rules for deriving meaning) and syntax (rules for ordering words into sentences).

36-2 What are the milestones in language development?

- Language development’s timing varies, but all children follow the same sequence.
- Receptive language (the ability to understand what is said to or about you) develops before productive language (the ability to produce words).
- At about 4 months of age, infants *babble*, making sounds found in languages from all over the world.
- By about 10 months, their babbling contains only the sounds found in their household language.
- Around 12 months of age, children begin to speak in single words. This *one-word stage* evolves into *two-word (telegraphic)* utterances before their second birthday, after which they begin speaking in full sentences.

36-3 How do we acquire language?

- Linguist Noam Chomsky has proposed that all human languages share a universal grammar—the basic building blocks of language—and that humans are born with a predisposition to learn language.
- We acquire specific language through learning as our biology and experience interact.
- Childhood is a critical period for learning to speak or sign fluently.

36-4 What brain areas are involved in language processing and speech?

- Two important language- and speech-processing areas are *Broca’s area*, a region of the frontal lobe that controls language expression, and *Wernicke’s area*, a region in the left temporal lobe that controls language reception (and also assists with expression).
- Language processing is spread across other brain areas as well, where different neural networks handle specific linguistic subtasks.

36-5

What is the relationship between language and thinking, and what is the value of thinking in images?

- Although Benjamin Lee Whorf's *linguistic determinism* hypothesis suggested that language determines thought, it is more accurate to say that language influences thought.
- Different languages embody different ways of thinking, and immersion in bilingual education can enhance thinking.
- We often think in images when we use nondeclarative (procedural) memory (our automatic memory system for motor and cognitive skills and classically conditioned associations).
- Thinking in images can increase our skills when we mentally practice upcoming events.

Multiple-Choice Questions

1. What do we call the smallest distinctive sound units in language?
 - a. Structure
 - b. Morphemes
 - c. Grammar
 - d. Phonemes
 - e. Thoughts
2. Which of the following best identifies the early speech stage in which a child speaks using mostly nouns and verbs?
 - a. Two-word stage
 - b. Babbling stage
 - c. One-word stage
 - d. Telegraphic speech
 - e. Grammar
3. The prefix "pre" in "preview" or the suffix "ed" in "adapted" are examples of
 - a. phonemes.
 - b. morphemes.
 - c. babbling.
 - d. grammar.
 - e. intuition.
4. Evidence of words' subtle influence on thinking best supports the notion of
 - a. Wernicke's area.
 - b. Broca's area.
 - c. linguistic determinism.
 - d. babbling.
 - e. aphasia.

Practice FRQs

1. Name and define the three building blocks of spoken language.

Answer

1 point: Phoneme: the smallest distinctive sound unit.

1 point: Morpheme: the smallest unit carrying meaning in language.

1 point: Grammar: the system of rules that enable communication.

2. What is aphasia, and how does it relate to Broca's and Wernicke's areas?

(3 points)

Unit VII Review

Key Terms and Concepts to Remember

- memory, p. 318
- encoding, p. 319
- storage, p. 319
- retrieval, p. 319
- parallel processing, p. 319
- sensory memory, p. 319
- short-term memory, p. 319
- long-term memory, p. 319
- working memory, 320
- explicit memory, p. 320
- effortful processing, p. 320
- automatic processing, p. 320
- implicit memory, p. 320
- iconic memory, p. 322
- echoic memory, p. 322
- chunking, p. 323
- mnemonics [nih-MON-iks], p. 323
- spacing effect, p. 324
- testing effect, p. 324
- shallow processing, p. 324
- deep processing, p. 325
- hippocampus, p. 330
- flashbulb memory, p. 332
- long-term potentiation (LTP), p. 333
- recall, p. 334
- recognition, p. 334
- relearning, p. 334
- priming, p. 336
- mood-congruent memory, p. 337
- serial position effect, p. 337
- anterograde amnesia, p. 342
- retrograde amnesia, p. 342
- proactive interference, p. 345
- retroactive interference, p. 345
- repression, p. 346
- misinformation effect, p. 347
- source amnesia, p. 349
- déjà vu, p. 349
- cognition, p. 356
- concept, p. 356
- prototype, p. 356
- creativity, p. 357
- convergent thinking, p. 357
- divergent thinking, p. 357
- algorithm, p. 361
- heuristic, p. 361
- insight, p. 361
- confirmation bias, p. 362
- mental set, p. 363
- intuition, p. 363
- representativeness heuristic, p. 364
- availability heuristic, p. 364
- overconfidence, p. 365
- belief perseverance, p. 367
- framing, p. 368
- language, p. 372
- phoneme, p. 373
- morpheme, p. 373
- grammar, p. 373
- babbling stage, p. 374
- one-word stage, p. 375
- two-word stage, p. 375
- telegraphic speech, p. 375
- aphasia, p. 377
- Broca's area, p. 377
- Wernicke's area, p. 377
- linguistic determinism, p. 379

Key Contributors to Remember

- Richard Atkinson, p. 319
- Richard Shiffrin, p. 319
- George A. Miller, p. 322
- Hermann Ebbinghaus, p. 324
- Eric Kandel, p. 332
- Elizabeth Loftus, p. 347
- Robert Sternberg, p. 357
- Wolfgang Köhler, p. 362
- Amos Tversky, p. 363
- Daniel Kahneman, p. 363
- Steven Pinker, p. 372
- Noam Chomsky, p. 375
- Paul Broca, p. 377
- Carl Wernicke, p. 377
- Benjamin Lee Whorf, p. 379

AP[®] Exam Practice Questions

Multiple-Choice Questions

1. What does the “magical number seven, plus or minus two” refer to?
 - a. The ideal number of times to rehearse information in the first encoding session
 - b. The number of seconds information stays in short-term memory without rehearsal
 - c. The capacity of short-term memory
 - d. The number of seconds information stays in echoic storage
 - e. The number of years most long-term memories last
2. Which of the following describes long-term potentiation (LTP)?
 - a. When attempting to retrieve information, it is easier to recognize than to recall.
 - b. Constructed memories have the potential to be either accurate or inaccurate.
 - c. Changes in synapses allow for more efficient transfer of information.
 - d. Implicit memories are processed by the cerebellum instead of by the hippocampus.
 - e. Information is transferred from working memory to long-term memory.
3. Which of the following abilities is an example of implicit memory?
 - a. Riding a bicycle while talking to your friend about something that happened in class
 - b. Retrieving from memory the details of an assignment that is due tomorrow
 - c. Vividly recalling significant events like the 9/11 attacks on New York City and Washington, D.C.
 - d. Remembering the details of your last birthday party
 - e. Recognizing names and pictures of your classmates many years after they have graduated
4. Which of the following statements concerning memory is true?
 - a. Hypnosis, when used as a component of therapy, usually improves the accuracy of memory.
 - b. One aspect of memory that is usually accurate is the source of the remembered information.
 - c. Children’s memories of abuse are more accurate than other childhood memories.
 - d. Memories we are more certain of are more likely to be accurate.
 - e. Memories are often a blend of correct and incorrect information.
5. The basketball players could remember the main points of their coach’s halftime talk, but not her exact words. This is because they encoded the information
 - a. semantically.
 - b. iconically.
 - c. implicitly.
 - d. shallowly.
 - e. automatically.
6. When someone provides his phone number to another person, he usually pauses after the area code and again after the next three numbers. This pattern underscores the importance of which memory principle?
 - a. Chunking
 - b. The serial position effect
 - c. Semantic encoding
 - d. Auditory encoding
 - e. Recognition
7. Which of the following is true regarding the role of the amygdala in memory?
 - a. The amygdala help process implicit memories.
 - b. The amygdala support Freud’s ideas about memory because they allow us to repress memories of trauma.
 - c. The amygdala produce long-term potentiation in the brain.
 - d. The amygdala help make sure we remember events that trigger strong emotional responses.
 - e. The amygdala are active when the retrieval of a long-term memory is primed.
8. Which of the following illustrates the serial position effect?
 - a. The only name Kensie remembers from the people she met at the party is Spencer because she thought he was particularly good looking.
 - b. Kimia has trouble remembering information from the book’s first unit when she reviews for semester finals.
 - c. It’s easy for Brittney to remember that carbon’s atomic number is 6 because her birthday is on December 6.
 - d. Kyle was not able to remember the names of all of his new co-workers after one week on the job, but he could remember them after two weeks.
 - e. Alp is unable to remember the middle of a list of vocabulary words as well as he remembers the first or last words on the list.

9. Mnemonic devices are *least* likely to be dependent upon which of the following?
- Imagery
 - Acronyms
 - Rhymes
 - Chunking
 - Massed rehearsal
10. You are more likely to remember psychology information in your psychology classroom than in other environments because of what memory principle?
- Mood congruence
 - Context effects
 - State-dependency
 - Proactive interference
 - Retroactive interference
11. Which of the following kinds of information is *not* likely to be automatically processed?
- Space information
 - Time information
 - Frequency information
 - New information
 - Rehearsed information
12. Which of the following is an example of source amnesia?
- Iva can't remember the details of a horrifying event because she has repressed them.
 - Mary has entirely forgotten about an incident in grade school until her friend reminds her of the event.
 - Michael can't remember this year's locker combination because he confuses it with last year's combination.
 - Stephen misremembers a dream as something that really happened.
 - Anna, who is trying to lose weight, is unable to remember several of the between-meal snacks she had yesterday.
13. Which of the following is an accurate conclusion based on Hermann Ebbinghaus' forgetting curve research?
- Most forgetting occurs early on and then levels off
 - We forget more rapidly as time passes
 - Forgetting is relatively constant over time
 - Forgetting is related to many factors, but time is not one of them
 - We are more likely to forget items in the middle of a list than at the beginning or the end
14. "Chair," "freedom," and "ball" are all examples of what?
- Phonemes
 - Heuristics
 - Concepts
 - Telegraphic utterances
 - Prototypes
15. People are more concerned about a medical procedure when told it has a 10 percent death rate than they are when told it has a 90 percent survival rate. Which psychological concept explains this difference in concern?
- Belief perseverance
 - Insight
 - Intuition
 - Framing
 - Confirmation bias
16. Which of the following illustrates a heuristic?
- Calculating the area of a rectangle by multiplying the length times the width
 - Using news reports of corporate fraud to estimate how much business fraud occurs in American business
 - Looking in each room of your home to find your sleeping cat
 - Following a new recipe to bake a cake for your friend
 - Trying every key on your mom's key ring until you find the one that unlocks the seldom-used storeroom in the basement
17. Which of the following most likely represents a prototype for the concept indicated in parentheses?
- A whale (mammal)
 - An ostrich (bird)
 - A beanbag chair (chair)
 - An igloo (house)
 - A golden retriever (dog)
18. The inability to see a problem from a fresh perspective is called what?
- Confirmation bias
 - Insight
 - Representativeness
 - Fixation
 - Availability
19. Which phrase best describes the concept of phonemes?
- Units of meaning in a language
 - A form of syntax
 - The basis of grammar
 - Units of sound in a language
 - A form of telegraphic speech
20. Which concept best explains why people often underestimate the amount of time it will take to complete a project?
- Belief perseverance
 - Framing
 - Intuition
 - The availability heuristic
 - Overconfidence

- 21.** Which of the following is not one of Robert Sternberg's components of creativity?
- A venturesome personality
 - Imaginative thinking skills
 - A creative environment
 - A position of ignorance
 - Intrinsic motivation
- 22.** Which of the following demonstrates the representativeness heuristic?
- Deciding that a new kid in school is a nerd because he looks like a nerd
 - Fearing air travel because of memories of plane crashes
 - Checking in every drawer to find some matches because matches are usually in drawers
 - Having the solution to a word problem pop into your head because you have just successfully solved a similar problem
 - Applying for jobs in several local grocery stores because your best friend just got a job in a grocery store
- 23.** Benjamin Lee Whorf's linguistic determinism hypothesis relates to what aspect of the power of language?
- How thinking influences language
 - How language influences thinking
 - The role of the language acquisition device
 - The importance of critical periods in language development
 - The development of language in nonhuman animals
- 24.** According to Noam Chomsky, what is the most essential environmental stimulus necessary for language acquisition?
- Exposure to language in early childhood
 - Instruction in grammar
 - Reinforcement for babbling and other early verbal behaviors
 - Imitation and drill
 - Linguistic determinism

Free-Response Questions

- 1.** Jacque learned to speak Italian when she was in the first grade and was able to speak, read, and write Italian fairly well by the fourth grade. She moved to a new school system that did not have Italian as a choice for World Languages, so she decided to take Spanish. Sometimes she found herself saying and writing words in Italian as she completed her Spanish assignments. Often, she remembered the vocabulary in Italian before she said the word in Spanish. Sometimes she felt like knowing Italian helped her learn Spanish, but sometimes she thought it just confused her! When Jacque was in her Spanish classroom, she felt more at ease with the Spanish language. When she went to an Italian restaurant, she enjoyed being able to read the menu to her friends if it was written in Italian.

Briefly define each concept and use an example to show how each concept is related to Jacque's experiences.

- Working memory
- Explicit memory
- Effortful processing
- Context-dependent memory
- Proactive interference

Explain how these brain structures play a role in Jacque's memory processing.

- Hippocampus
- Amygdala

Rubric for Free Response Question 1

1 point: Working memory is a newer understanding of short-term memory that focuses on conscious, active processing of incoming auditory and visual-spatial information, and of information retrieved from long-term memory. Possible example: Jacque has to focus on what the teacher is saying and recall the correct vocabulary word when she is asked a question. ↻ Page 319

1 point: Explicit memory is memory of facts and experiences that one can consciously know and “declare.” (Also called *declarative memory*.) Possible example: Defining vocabulary words in any language relies on explicit memory.

↻ Page 321

1 point: Effortful processing is encoding that requires attention and conscious effort. Possible example: When reading, Jacque has to pay attention to the words and sentence construction to understand what is being conveyed. ↻ Page 321

1 point: Context-dependent memory refers to the need to put yourself back in the context where you experienced something to prime your memory retrieval. Possible example: Jacque seems to be able to remember her Spanish best when in her Spanish classroom. ↻ Page 336

1 point: Proactive interference is the disruptive effect of prior learning on the recall of new information. Possible example: Jacque learned Italian before she learned Spanish, and so sometimes her prior knowledge of Italian interferes with her recall of Spanish words. ↻ Page 345

1 point: The hippocampus is a brain area important to the storage of new learning. Possible example: Since the left hippocampus is important to storage and recall of verbal information—new terms, vocabulary, and so on—Jacque’s hippocampus must be very active during her language classes. ↻ Page 330

1 point: The amygdala is involved in intense emotional experiences, which affect related memory formation. Possible example: When Jacque is stressed about mixing up her Spanish with Italian words, the stress may cause her to have trouble recalling the information because of hormones that are released. Her positive emotions, experienced in the Italian restaurant, may also be related to the amygdala.

↻ Pages 331–332

2. Our cognitive processes can enhance or inhibit memory, decision making, problem solving, and communication. Explain how each of the following may both help and hurt cognitive functioning.

- Mental set
- Availability heuristic
- Prototypes
- Critical (or sensitive) period for language development
- Stress effects on memory

(10 points)

3. George, a senior in high school, was reminiscing with his friends about their first homecoming dance.

A. Explain how each of the following psychological terms could *help* George’s recollection or memory of his freshman-year homecoming dance.

- Flashbulb memory
- Mood-congruent effect

B. Explain how each of the following psychological terms could *hinder* George’s recollection or memory of his freshman-year homecoming dance.

- Serial position effect
- Retroactive interference
- Misinformation effect

(5 points)

Unit VIII

Motivation, Emotion, and Stress

Modules

- 37 Motivational Concepts
- 38 Hunger Motivation
- 39 Sexual Motivation
- 40 Social Motivation: Affiliation Needs
- 41 Theories and Physiology of Emotion
- 42 Expressed Emotion
- 43 Stress and Health
- 44 Stress and Illness

After an ill-fated Saturday morning in the spring of 2003, experienced mountaineer Aron Ralston understood how motivation can energize and direct behavior. Having bagged nearly all of Colorado's tallest peaks, Ralston ventured some solo canyon hiking that seemed so risk-free he didn't bother to tell anyone where he was going. In Utah's narrow Bluejohn Canyon, just 150 yards above his final rappel, he was climbing over an 800-pound rock when disaster struck: It shifted and pinned his right wrist and arm. He was, as the title of his book says, caught *Between a Rock and a Hard Place*.

Realizing no one would be rescuing him, Ralston tried with all his might to dislodge the rock. Then, with a dull pocketknife, he tried chipping away at it. When that, too, failed, he rigged up ropes to lift the rock. Alas, nothing worked. Hour after hour, then cold night after cold night, he was stuck.

By Tuesday, he had run out of food and water. On Wednesday, as thirst and hunger gnawed, he began saving and sipping his own urine. Using his video recorder, he said good-bye to family and friends, for whom he now felt intense love: "So

Lucas Oleniuk/Toronto Star via Getty Images

again love to everyone. Bring love and peace and happiness and beautiful lives into the world in my honor. Thank you. Love you.”

On Thursday, surprised to find himself still alive, Ralston had a seemingly divine insight into his reproductive future, a vision of a preschool boy being scooped up by a one-armed man. With this inspiration, he summoned his remaining strength and his enormous will to live and, over the next hour, willfully broke his arm bones and then proceeded to use that dull knife to cut off his arm. He put on a tourniquet, chopped the last piece of skin, and, after 127 hours, broke free. He then rappelled with his bleeding half-arm down a 65-foot cliff and hiked 5 miles before finding someone. He was, in his own words, “just reeling with this euphoria . . . having been dead and standing in my grave, leaving my last will and testament, etching ‘Rest in peace’ on the wall, all of that, gone and then replaced with having my life again. It was undoubtedly the sweetest moment that I will ever experience” (Ralston, 2004). Ralston’s thirst and hunger, his sense of belonging to others, and his brute will to live and become a father highlight *motivation’s* energizing and directing power.

His intense emotional experiences of love and joy demonstrate the close ties between our feelings, or *emotions*, and our motivated behaviors. In this unit, we explore our motivations and emotions, and the health effects of intense or prolonged emotions such as anger and stress.

AP® Exam Tip

The introduction to Module 37 is important, because it informs you how the whole module is organized. Read it carefully now and perhaps return to it as a review when you are through with the module.

Module 37

Motivational Concepts

Module Learning Objective

37-1

Define *motivation* as psychologists use the term, and identify the perspectives useful for studying motivated behavior.

37-1

How do psychologists define *motivation*? From what perspectives do they view motivated behavior?

Our **motivations** arise from the interplay between nature (the bodily “push”) and nurture (the “pulls” from our thought processes and culture). Consider four perspectives for viewing motivated behaviors. *Instinct theory* (now replaced by the *evolutionary perspective*) focuses on genetically predisposed behaviors. *Drive-reduction theory* focuses on how our inner pushes and external pulls interact. *Arousal theory* focuses on finding the right level of stimulation. And Abraham Maslow’s *hierarchy of needs* describes how some of our needs take priority over others.

©The New Yorker Collection, 2000. Bob Zahn from cartoonbank.com. All Rights Reserved.

“What do you think . . . should we get started on that motivation research or not?”

Instincts and Evolutionary Psychology

Early in the twentieth century, as the influence of Charles Darwin's evolutionary theory grew, it became fashionable to classify all sorts of behaviors as instincts. If people criticized themselves, it was because of their "self-abasement instinct." If they boasted, it reflected their "self-assertion instinct." After scanning 500 books, one sociologist compiled a list of 5759 supposed human instincts! Before long, this fad for naming instincts collapsed under its own weight. Rather than *explaining* human behaviors, the early instinct theorists were simply *naming* them. It was like "explaining" a bright child's low grades by labeling the child an "underachiever." To name a behavior is *not* to explain it.

To qualify as an **instinct**, a complex behavior must have a fixed pattern throughout a species and be unlearned (Tinbergen, 1951). Such behaviors are common in other species (Module 26 described salmon returning to their birthplace, and Module 48 will describe imprinting in birds). Human behavior, too, exhibits certain unlearned fixed patterns, including infants' innate reflexes for rooting and sucking.

Although *instinct theory* failed to explain most human motives, *evolutionary psychology's* underlying assumption that genes predispose species-typical behavior remains as strong as ever. We saw this in Module 29's discussion of animals' biological predispositions to learn certain behaviors. And we will see this in later discussions of how evolution might influence our phobias, our helping behaviors, and our romantic attractions.

AP® Exam Tip

Note that this section illustrates psychology's biological perspective.

motivation a need or desire that energizes and directs behavior

instinct a complex, unlearned behavior that is rigidly patterned throughout a species.

Michael Ventura/Alamy

David Santiago Garcia/Science Source

Same motive, different wiring

The more complex the nervous system, the more adaptable the organism. Both humans and weaverbirds satisfy their need for shelter in ways that reflect their inherited capacities. Human behavior is flexible; we can learn whatever skills we need to build a house. The bird's behavior pattern is fixed; it can build only this kind of nest.

Drives and Incentives

When the original instinct theory of motivation collapsed, it was replaced by **drive-reduction theory**—the idea that a physiological need creates an aroused state that drives the organism to reduce the need by, say, eating or drinking. With few exceptions, when a physiological need increases, so does a psychological *drive*—an aroused, motivated state.

The physiological aim of drive reduction is **homeostasis**—the maintenance of a steady internal state. An example of homeostasis (literally "staying the same") is the body's temperature-regulation system, which works like a room thermostat. Both systems operate through feedback loops: Sensors feed room temperature to a control device. If the room temperature cools, the control device switches on the furnace. Likewise, if our body temperature cools, blood vessels constrict to conserve warmth, and we feel driven to put on more clothes or seek a warmer environment (**FIGURE 37.1**).

drive-reduction theory the idea that a physiological need creates an aroused tension state (a drive) that motivates an organism to satisfy the need.

homeostasis a tendency to maintain a balanced or constant internal state; the regulation of any aspect of body chemistry, such as blood glucose, around a particular level.

Figure 37.1

Drive-reduction theory Drive-reduction motivation arises from *homeostasis*—an organism's natural tendency to maintain a steady internal state. Thus, if we are water deprived, our thirst drives us to drink and to restore the body's normal state.

AP® Exam Tip

Read carefully! Homeostasis is *not* a motivation theory, but rather a biological principle that applies to some motivational theories (like drive-reduction).

FYI

Recall from Module 29 that we are also motivated by both *intrinsic* and *extrinsic* rewards.

Driven by curiosity Baby monkeys and young children are fascinated by things they've never handled before. Their drive to explore the relatively unfamiliar is one of several motives that do not fill any immediate physiological need.

Not only are we *pushed* by our need to reduce drives, we also are *pulled* by **incentives**—positive or negative stimuli that lure or repel us. This is one way our individual learning histories influence our motives. Depending on our learning, the aroma of good food, whether freshly baked pizza or freshly toasted ants, can motivate our behavior. So can the sight of those we find attractive or threatening.

When there is both a need and an incentive, we feel strongly driven. The food-deprived person who smells baking bread feels a strong hunger drive. In the presence of that drive, the baking bread becomes a compelling incentive. For each motive, we can therefore ask, “How is it pushed by our inborn physiological needs and pulled by incentives in the environment?”

Optimum Arousal

We are much more than homeostatic systems, however. *Optimal arousal theory* holds that some motivated behaviors actually *increase* arousal. Well-fed animals will leave their shelter to explore and gain information, seemingly in the absence of any need-based drive. Curiosity drives monkeys to monkey around trying to figure out how to unlock a latch that opens nothing or how to open a window that allows them to see outside their room (Butler, 1954). It drives the 9-month-old infant to investigate every accessible corner of the house. It drives you to read this text, and it drives the scientists whose work this text discusses. And it drives explorers and adventurers such as Aron Ralston and George Mallory. Asked why he wanted to climb Mount Everest, the *New York Times* reported that Mallory answered, “Because it is there.” Those who, like Mallory and Ralston, enjoy high arousal are most likely to seek out intense music, novel foods, and risky behaviors (Zuckerman, 1979). They are “sensation-seekers.”

So, human motivation aims not to eliminate arousal but to seek optimum levels of arousal. Having all our biological needs satisfied, we feel driven to experience stimulation and we hunger for information. We are “infovores,” said neuroscientists Irving Biederman and Edward Vessel (2006), after identifying brain mechanisms that reward us for acquiring information. Lacking stimulation, we feel bored and look for a way to increase arousal to some optimum level. However, with too much stimulation comes stress, and we then look for a way to decrease arousal.

Two early-twentieth-century psychologists studied the relationship of arousal to performance and identified what we now call the **Yerkes-Dodson law**, suggesting that moderate arousal would lead to optimal performance (Yerkes & Dodson, 1908). When taking an exam, for example, it pays to be moderately aroused—alert but not trembling with nervousness. We have since learned that optimal arousal levels depend the task as well, with more difficult tasks requiring lower arousal for best performance (Hembree, 1988) (**FIGURE 37.2**).

incentive a positive or negative environmental stimulus that motivates behavior.

Yerkes-Dodson law the principle that performance increases with arousal only up to a point, beyond which performance decreases.

A Hierarchy of Motives

Some needs take priority over others. At this moment, with your needs for air and water hopefully satisfied, other motives—such as your desire to achieve (discussed in Module 82)—are energizing and directing your behavior. Let your need for water go unsatisfied and your thirst will preoccupy you. Just ask Aron Ralston. Deprived of air, your thirst would disappear.

Abraham Maslow (1970) described these priorities as a **hierarchy of needs** (FIGURE 37.3). At the base of this pyramid are our physiological needs, such as those for food and water. Only if these needs are met are we prompted to meet our need for safety, and then to satisfy our needs to give and receive love and to enjoy self-esteem. Beyond this, said Maslow (1971), lies the need to actualize one's full potential. (More on self-esteem and self-actualization in Modules 57 and 59.)

Near the end of his life, Maslow proposed that some people also reach a level of self-transcendence. At the self-actualization level, people seek to realize their own potential.

hierarchy of needs Maslow's pyramid of human needs, beginning at the base with physiological needs that must first be satisfied before higher-level safety needs and then psychological needs become active.

"Hunger is the most urgent form of poverty." -ALLIANCE TO END HUNGER, 2002

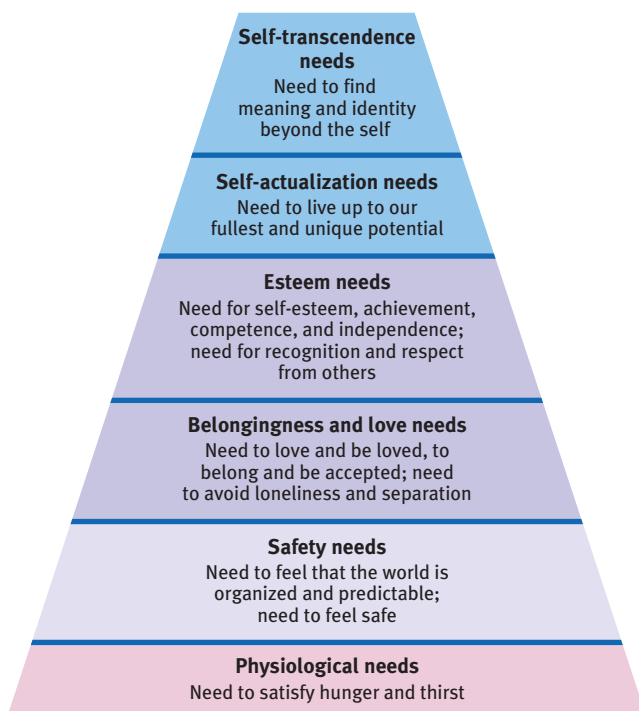

Figure 37.3

Maslow's hierarchy of needs Once our lower-level needs are met, we are prompted to satisfy our higher-level needs. (From Maslow, 1970.) For survivors of the disastrous tornadoes that swept across the Midwest and Southeastern United States in 2011, satisfying very basic needs for water, food, and safety became top priority. Higher-level needs on Maslow's hierarchy, such as respect, self-actualization, and meaning, become far less important during such times.

At the self-transcendence level, people strive for meaning, purpose, and communion that is beyond the self, that is *transpersonal* (Koltko-Rivera, 2006).

Maslow's hierarchy is somewhat arbitrary; the order of such needs is not universally fixed. People have starved themselves to make a political statement. Today's evolutionary psychologists concur with the first four levels of Maslow's needs pyramid. But they note that gaining and retaining mates, and parenting offspring, are also universal human motives (Kenrick et al., 2010).

Nevertheless, the simple idea that some motives are more compelling than others provides a framework for thinking about motivation. Worldwide life-satisfaction surveys support this basic idea (Oishi et al., 1999; Tay & Diener, 2011). In poorer nations that lack easy access to money and the food and shelter it buys, financial satisfaction more strongly predicts feelings of well-being. In wealthy nations, where most are able to meet basic needs, home-life satisfaction is a better predictor. Self-esteem matters most in individualist nations, whose citizens tend to focus more on personal achievements than on family and community identity. (TABLE 37.1 summarizes the strengths and weaknesses of the different perspectives on motivation.)

In the ensuing modules, we will consider four representative motives, beginning at the physiological level with hunger and working up through sexual motivation and the need to belong. At each level, we shall see how experience interacts with biology.

Table 37.1

Motivational Theory	Strength	Weakness
<i>Instinct Theory and Evolutionary Psychology</i>	Evolutionary psychology helps explain behavioral similarities due to adaptations from our ancestral past.	Instinct theory explains animal behavior better than human behavior; humans have few true instincts.
<i>Drive-Reduction Theory</i>	Explains our motivation to reduce arousal by meeting basic needs, such as hunger or thirst.	Does not explain why some motivated behaviors <i>increase</i> arousal.
<i>Optimal Arousal Theory</i>	Explains that motivated behaviors may decrease or increase arousal.	Does not explain our motivation to address our more complex social needs.
<i>Maslow's Hierarchy of Needs</i>	Incorporates the idea that we have various <i>levels</i> of needs, including lower-level physiological and safety needs, and higher-level social, self-esteem, actualization, and meaning needs.	The order of needs may change in some circumstances. Evolutionary psychologists note the absence in the hierarchy of the universal human motives to find a mate and reproduce.

Before You Move On

▶ ASK YOURSELF

Consider your own experiences in relation to Maslow's hierarchy of needs. Have you ever experienced true hunger or thirst that displaced your concern for other, higher-level needs? Do you usually feel safe? Loved? Confident? How often do you feel you are able to address what Maslow called your "self-actualization" needs?

▶ TEST YOURSELF

While on a long road trip, you suddenly feel very hungry. You see a diner that looks pretty deserted and creepy, but you are *really* hungry, so you stop anyway. What motivational perspective would most easily explain this behavior, and why?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 37 Review

37-1 How do psychologists define *motivation*? From what perspectives do they view motivated behavior?

- *Motivation* is a need or desire that energizes and directs behavior.
- The *instinct/evolutionary* perspective explores genetic influences on complex behaviors.
- *Drive-reduction theory* explores how physiological needs create aroused tension states (drives) that direct us to satisfy those needs. Environmental *incentives* can intensify

drives. Drive-reduction's goal is *homeostasis*, maintaining a steady internal state.

- Optimal arousal theory proposes that some behaviors (such as those driven by curiosity) do not reduce physiological needs but rather are prompted by a search for an optimum level of arousal.
- Abraham Maslow's *hierarchy of needs* proposes a pyramid of human needs, from basic needs such as hunger and thirst up to higher-level needs such as self-actualization and self-transcendence.

Multiple-Choice Questions

- Which of the following is an unlearned, complex behavior exhibited by all members of a species?
 - Reflex
 - Drive
 - Incentive
 - Instinct
 - Motive
- Which of the following is an aroused motivational state created by a physiological need?
 - Drive
 - Instinct
 - Incentive
 - Reflex
 - Motive
- Which of the following is a conclusion that can be drawn from the Yerkes-Dodson law?
 - Performance on easy tasks is best when arousal is low.
 - Performance is best when arousal is extremely high.
 - Performance is best when arousal is extremely low.
 - Performance on difficult tasks is best when arousal is high.
 - Performance is best when arousal is moderate.
- Which of the following is the lowest priority motive in Abraham Maslow's hierarchy of needs?
 - Belongingness and love needs
 - Physiological needs
 - Esteem needs
 - Self-actualization needs
 - Self-transcendence needs

Practice FRQs

- How can you use Maslow's hierarchy of needs to explain why a
 - hungry young person would steal?
 - lonely new student in a school would join a club?
 - successful artist would continue to invest tremendous effort in her career?
- Describe how three different motivational theories could explain a young man's desire to become an excellent soccer player. **(3 points)**

Answer

1 point: A hungry young person would steal because of a physiological need.

1 point: A lonely new student would join a club to meet belongingness and love needs.

1 point: A successful artist would still work hard to satisfy the need for self-actualization.

Module 38

Hunger Motivation

Module Learning Objectives

- 38-1** Describe the physiological factors that produce hunger.
- 38-2** Discuss cultural and situational factors that influence hunger.
- 38-3** Discuss the factors that predispose some people to become and remain obese.

Jim West/Photo Edit

The power of physiological needs was vividly demonstrated when Ancel Keys and his research team (1950) conducted a now-classic study of semistarvation. They first fed 36 male volunteers (all wartime conscientious objectors) just enough to maintain their initial weight. Then, for six months, they cut this food level in half. The effects soon became visible. Without thinking about it, the men began conserving energy. They appeared sluggish and dull. After dropping rapidly, their body weights stabilized at about 25 percent below their starting point.

As Maslow might have guessed, the men became food obsessed. They talked food. They daydreamed food. They collected recipes, read cookbooks, and feasted their eyes on delectable forbidden food. Preoccupied with their unmet basic need, they lost interest in sex and social activities. As one man reported, “If we see a show, the most interesting part of it is contained in scenes where people are eating. I couldn’t laugh at the funniest picture in the world, and love scenes are completely dull.”

The semistarved men’s preoccupations illustrate how activated motives can hijack our consciousness. As journalist Dorothy Dix (1861–1951) observed, “Nobody wants to kiss when they are hungry.” When we’re hungry, thirsty, fatigued, or sexually aroused, little else seems to matter. When we’re not, food, water, sleep, or sex just don’t seem like such big things in life, now or ever.

“Nature often equips life’s essentials—sex, eating, nursing—with built-in gratification.”
—FRANS DE WAAL, “MORALS WITHOUT GOD?,” 2010

© The New Yorker Collection, 2009, Mike Twibby from cartoonbank.com. All Rights Reserved.

“Never hunt when you’re hungry.”

In studies, people in a motivational “hot” state (from fatigue, hunger, or sexual arousal) have easily recalled such feelings in their own past and have perceived them as driving forces in others’ behavior (Nordgren et al., 2006, 2007). (You may recall from Module 32 a parallel effect of our current good or bad mood on our memories.) Grocery shop with an empty stomach and you are more likely to see those jelly-filled doughnuts as just what you’ve always loved and will be wanting tomorrow. *Motives matter mightily.*

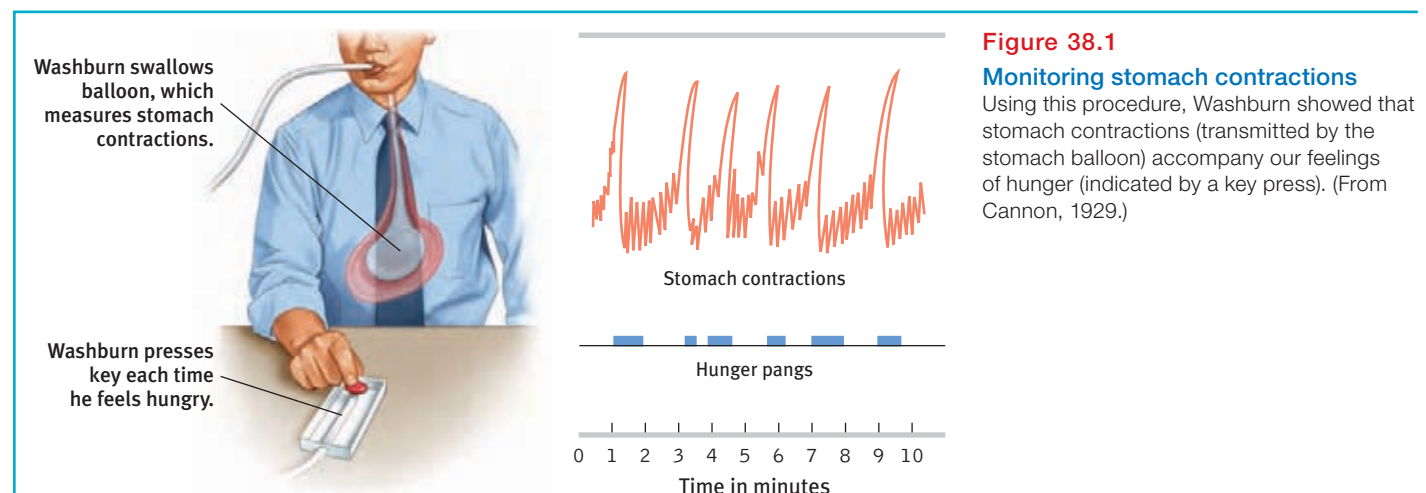

“The full person does not understand the needs of the hungry.” -IRISH PROVERB

The Physiology of Hunger

38-1 What physiological factors produce hunger?

Deprived of a normal food supply, Keys’ semistarved volunteers were clearly hungry. But what precisely triggers hunger? Are the pangs of an empty stomach the source of hunger? So it seemed to A. L. Washburn. Working with Walter Cannon (Cannon & Washburn, 1912), Washburn agreed to swallow a balloon attached to a recording device (**FIGURE 38.1**). When inflated to fill his stomach, the balloon transmitted his stomach contractions. Washburn supplied information about his *feelings* of hunger by pressing a key each time he felt a hunger pang. The discovery: Washburn was indeed having stomach contractions whenever he felt hungry.

Can hunger exist without stomach pangs? To answer that question, researchers removed some rats’ stomachs and created a direct path to their small intestines (Tsang, 1938). Did the rats continue to eat? Indeed they did. Some hunger persists similarly in humans whose stomachs have been removed as a treatment for ulcers or cancer. So the pangs of an empty stomach are not the *only* source of hunger. What else might trigger hunger?

Body Chemistry and the Brain

Somehow, somewhere, your body is keeping tabs on the energy it takes in and the energy it uses. If this weren’t true, you would be unable to maintain a stable body weight. A major source of energy in your body is the blood sugar **glucose**. If your blood glucose level drops, you won’t consciously feel this change, but your stomach, intestines, and liver will signal your brain to motivate eating. Your brain, which is automatically monitoring your blood chemistry and your body’s internal state, will then trigger hunger.

glucose the form of sugar that circulates in the blood and provides the major source of energy for body tissues. When its level is low, we feel hunger.

How does the brain integrate these messages and sound the alarm? The work is done by several neural areas, some housed deep in the brain within the hypothalamus (**FIGURE 38.2**). This neural traffic intersection includes areas that influence eating. For example, one neural arc (called the *arcuate nucleus*) has a center that secretes appetite-stimulating hormones, and another center that secretes appetite-suppressing hormones. Explorations of this neural area and others reveal that when an appetite-enhancing center is stimulated electrically, well-fed animals begin to eat. If the area is destroyed, even starving animals have no interest in food. The opposite occurs when an appetite-suppressing area is stimulated: Animals will stop eating. Destroy this area and animals will eat and eat, and become extremely fat (Duggan & Booth, 1986; Hoebel & Teitelbaum, 1966) (**FIGURE 38.3**).

Figure 38.2
The hypothalamus As we saw in Module 11, the hypothalamus (colored orange) performs various body maintenance functions, including control of hunger.

Figure 38.3
Evidence for the brain's control of eating The fat mouse on the left has nonfunctioning leptin receptors.

Olivier Voisin/Science Source

set point the point at which an individual's "weight thermostat" is supposedly set. When the body falls below this weight, an increase in hunger and a lowered metabolic rate may act to restore the lost weight.

basal metabolic rate the body's resting rate of energy expenditure.

FYI

Over the next 40 years you will eat about 20 tons of food. If, during those years, you increase your daily intake by just .01 ounce more than required for your energy needs, you will gain an estimated 24 pounds (Martin et al., 1991).

Blood vessels supply the hypothalamus, enabling it to respond to our current blood chemistry as well as to incoming neural information about the body's state. One of its tasks is monitoring levels of appetite hormones, such as *ghrelin*, a hunger-arousing hormone secreted by an empty stomach. During bypass surgery for severe obesity, surgeons seal off part of the stomach. The remaining stomach then produces much less ghrelin, and the person's appetite lessens (Lemonick, 2002). Other appetite hormones include *insulin*, *leptin*, *orexin*, and *PYY*; **FIGURES 38.3** and **38.4** illustrate and describe how they influence your feelings of hunger.

The interaction of appetite hormones and brain activity suggests that the body has some sort of "weight thermostat." When semistarved rats fall below their normal weight, this system signals the body to restore the lost weight. The rats' hunger increases and their energy output decreases. If body weight rises—as happens when rats are force fed—hunger decreases and energy expenditure increases. In this way, rats (and humans) tend to hover around a stable weight, or **set point**, influenced in part by heredity (Keesey & Corbett, 1983).

We humans (and other species, too) vary in our **basal metabolic rate**, a measure of how much energy we use to maintain basic body functions when our body is at rest. But we share a common response to decreased food intake: Our basal metabolic rate drops, as it did for participants in Keys' experiment. After 24 weeks of semistarvation, they stabilized at three-quarters of their normal weight, although they were taking in only *half* their previous calories. How did their bodies achieve this dieter's nightmare? They reduced their energy expenditure, partly by being less active, but partly by dropping their basal metabolic rate by 29 percent.

Some researchers have suggested that the idea of a biologically *fixed* set point is too rigid to explain some things. One thing it doesn't address is that slow, sustained changes in body weight can alter a person's set point (Assanand et al., 1998). Another is that when we

**Figure 38.4****The appetite hormones**

- *Insulin*: Hormone secreted by pancreas; controls blood glucose.
- *Ghrelin*: Hormone secreted by empty stomach; sends “I’m hungry” signals to the brain.
- *Orexin*: Hunger-triggering hormone secreted by hypothalamus.
- *Leptin*: Protein hormone secreted by fat cells; when abundant, causes brain to increase metabolism and decrease hunger.
- *PYY*: Digestive tract hormone; sends “I’m not hungry” signals to the brain.

have unlimited access to a wide variety of tasty foods, we tend to overeat and gain weight (Raynor & Epstein, 2001). And set points don’t explain why psychological factors influence hunger. For all these reasons, some prefer the looser term *settling point* or *set range* to indicate the level at which a person’s weight settles in response to caloric intake and energy use. As we will see next, these factors are influenced by environment as well as biology.

“Never get a tattoo when you’re drunk and hungry.”

The Psychology of Hunger

38-2 What cultural and situational factors influence hunger?

We have seen that our eagerness to eat is pushed by our body chemistry and brain activity. Yet there is more to hunger than meets the stomach. This was strikingly apparent when trickster researchers tested two patients who had no memory for events occurring more than a minute ago (Rozin et al., 1998). If offered a second lunch 20 minutes after eating a normal lunch, both patients readily consumed it . . . and usually a third meal offered 20 minutes after they finished the second. This suggests that one part of our decision to eat is our memory of the time of our last meal. As time passes, we think about eating again, and those thoughts trigger feelings of hunger.

Taste Preferences: Biology and Culture

Body chemistry and environmental factors together influence not only the when of hunger, but also the what—our taste preferences. When feeling tense or depressed, do you crave starchy, carbohydrate-laden foods? Carbohydrates such as pasta, chips, and sweets help boost levels of the neurotransmitter serotonin, which has calming effects. When stressed, even rats find it extra rewarding to scarf Oreos (Artiga et al., 2007; Boggiano et al., 2005).

An acquired taste People everywhere learn to enjoy the fatty, bitter, or spicy foods common in their culture. For these Alaska Natives (left), but not for most other North Americans, whale blubber is a tasty treat. For Peruvians (right), roasted guinea pig is similarly delicious.

RICHARD OLSEN/NGS Image Collection

Jeffrey Jackson/Alamy

Our preferences for sweet and salty tastes are genetic and universal, but conditioning can intensify or alter those preferences. People given highly salted foods may develop a liking for excess salt (Beauchamp, 1987). People sickened by a food may develop an aversion to it. (The frequency of children's illnesses provides many chances for them to learn to avoid certain foods.)

Our culture teaches us that some foods are acceptable but others are not. Bedouins enjoy eating the eye of a camel, which most North Americans would find repulsive. North Americans and Europeans also shun horse, dog, and rat meat, all of which are prized elsewhere.

But there is biological wisdom to many of our taste preferences. Environments can influence the human genetics that affect diet and taste. In places where agriculture has produced milk, for example, survival patterns have favored people with lactose tolerance (Arjamaa & Vuorisalo, 2010). And in hot climates (where foods spoil more quickly) recipes often include spices that inhibit the growth of bacteria (**FIGURE 38.5**). India averages nearly 10 spices per meat recipe; Finland, 2 spices. Pregnant women's food dislikes—and the nausea associated with them—peak about the tenth week, when the developing embryo is most vulnerable to toxins.

Rats tend to avoid unfamiliar foods (Sclafani, 1995). So do we, especially those that are animal based. This *neophobia* (dislike of things unfamiliar) surely was adaptive for our ancestors by protecting them from potentially toxic substances. In time, though, most people who repeatedly sample an initially novel fruit drink or ethnic food come to appreciate the new taste (Pliner, 1982, Pliner et al., 1993).

Figure 38.5
Hot cultures like hot spices

Situational Influences on Eating

To a surprising extent, situations also control our eating—a phenomenon psychologists have called the *ecology of eating*. Here are three situations you may have noticed but underestimated:

- Do you eat more when eating with others? Most of us do (Herman et al., 2003; Hetherington et al., 2006). After a party, you may realize you've overeaten. This happens because the presence of others tends to amplify our natural behavior tendencies. (You'll hear more about *social facilitation* in Module 76.)
- *Unit bias* occurs with similar mindlessness. Working with researchers at France's National Center for Scientific Research, Andrew Geier and his colleagues (2006) explored a possible explanation of why French waistlines are smaller than American waistlines. From soda drinks to yogurt sizes, the French offer foods in smaller portion sizes. Does it matter? (One could as well order two small sandwiches as one large one.) To find out, the investigators offered people varieties of free snacks. For example, in the lobby of an apartment house, they laid out either full or half pretzels, big or little Tootsie Rolls, or a big bowl of M&M's with either a small or

large serving scoop. Their consistent result: Offered a supersized standard portion, people put away more calories. In other studies (Wansink, 2006, 2007), even nutrition experts helped themselves to 31 percent more ice cream when given a big bowl rather than a small one, and 15 percent more when scooping with a big rather than a small scoop. Portion size matters.

- *Food variety* also stimulates eating. Offered a dessert buffet, we eat more than we do when asked to choose a portion from one favorite dessert. For our early ancestors, these behaviors were adaptive. When foods were abundant and varied, eating more provided a wide range of vitamins and minerals and produced fat that protected them during winter cold or famine. When a bounty of varied foods was unavailable, eating less extended the food supply until winter or famine ended (Polivy et al., 2008; Remick et al., 2009).

Obesity and Weight Control

38-3 What factors predispose some people to become and remain obese?

Obesity can be socially toxic, by affecting both how you are treated and how you feel about yourself. Obesity has been associated with lower psychological well-being, especially among women, and increased risk of depression (de Wit et al., 2010; Luppino et al., 2010; Mendes, 2010a). Obese 6- to 9-year-olds are 60 percent more likely to suffer bullying (Lumeng et al., 2010). And, as we will see, obesity has physical health risks as well. Yet few overweight people win the battle of the bulge. Why? And why do some people gain weight while others eat the same amount and seldom add a pound?

The Physiology of Obesity

Our bodies store fat for good reasons. Fat is an ideal form of stored energy—a high-calorie fuel reserve to carry the body through periods when food is scarce—a common occurrence in our prehistoric ancestors' world. No wonder that in many developing societies today (as in Europe in earlier centuries) people find heavier bodies attractive: Obesity signals affluence and social status (Furnham & Baguma, 1994; Swami et al., 2011).

In parts of the world where food and sweets are now abundantly available, the rule that once served our hungry distant ancestors—*When you find energy-rich fat or sugar, eat it!*—has become dysfunctional. Pretty much everywhere this book is being read, people have a growing problem. The World Health Organization (WHO) (2007) has estimated that more than 1 billion people worldwide are overweight, and 300 million of them are clinically *obese*, defined by the WHO as a *body mass index* (BMI) of 30 or more. (See www.cdc.gov/healthyweight/assessing/bmi to calculate your BMI.) In the United States, the adult obesity rate has more than doubled in the last 40 years, reaching 34 percent, and child-teen obesity has quadrupled (Flegal et al., 2010).

Significant obesity increases the risk of diabetes, high blood pressure, heart disease, gallstones, arthritis, and certain types of cancer, thus increasing health care costs and shortening life expectancy (de Gonzales et al., 2010; Jarrett et al., 2010; Sun et al., 2009). Recent research also has linked women's obesity to their risk of late-life cognitive decline, including Alzheimer's disease and brain tissue loss (Bruce-Keller et al., 2009; Whitmer et al., 2008). One experiment found improved memory performance 12 weeks after severely obese people had weight-loss surgery and lost significant weight. Those not having the surgery showed some further cognitive decline (Gunstad et al., 2011).

Research on the physiology of obesity challenges the stereotype of severely overweight people being weak-willed gluttons.

NBCU Photo Bank via Getty Images

Cooking shows increase appetites but not healthful home cooking

Julia Child was once the only chef on TV. Today dozens of U.S. cooking shows are broadcast to millions of viewers daily. Yet fewer Americans than ever are home cooking their own, more healthful meals (Pollan, 2009). Nations that devote more time to food preparation at home tend to have lower rates of obesity (Cutler et al., 2003).

"Americans, on average, report that they weigh 177 pounds, but would like to weigh 161."

—ELIZABETH MENDES,
WWW.GALLUP.COM, 2010

SET POINT AND METABOLISM

Once we become fat, we require less food to maintain our weight than we did to attain it. Fat has a lower metabolic rate than does muscle—it takes less food energy to maintain. When an overweight person’s body drops below its previous set (or settling) point, the person’s hunger increases and metabolism decreases. Thus, the body adapts to starvation by burning off fewer calories.

Lean people also seem naturally disposed to move about. They burn more calories than do energy-conserving overweight people who tend to sit still longer (Levine et al., 2005). These individual differences in resting metabolism help explain why two people of the same height, age, and activity level can maintain the same weight, even if one of them eats much less than the other does.

THE GENETIC FACTOR

Do our genes predispose us to fidget or sit still? Studies do reveal a genetic influence on body weight. Consider two examples:

- Despite shared family meals, adoptive siblings’ body weights are uncorrelated with one another or with those of their adoptive parents. Rather, people’s weights resemble those of their biological parents (Grilo & Pogue-Geile, 1991).
- Identical twins have closely similar weights, even when reared apart (Hjelmborg et al., 2008; Plomin et al., 1997). Across studies, their weight correlates $+0.74$. The much lower $+0.32$ correlation among fraternal twins suggests that genes explain two-thirds of our varying body mass (Maes et al., 1997).

THE FOOD AND ACTIVITY FACTORS

Genes tell an important part of the obesity story. But environmental factors are mighty important, too.

Studies in Europe, Japan, and the United States show that children and adults who suffer from *sleep loss* are more vulnerable to obesity (Keith et al., 2006; Nedeltcheva et al., 2010; Taheri, 2004a,b). With sleep deprivation, the levels of leptin (which reports body fat to the brain) fall, and ghrelin (the appetite-stimulating stomach hormone) rise.

Social influence is another factor. One 32-year study of 12,067 people found them most likely to become obese when a friend became obese (Christakis & Fowler, 2007). If the obese friend was a close one, the odds of likewise becoming obese almost tripled. Moreover, the correlation among friends’ weights was not simply a matter of seeking out similar people as friends. Friends matter.

The strongest evidence that environment influences weight comes from *our fattening world* (**FIGURE 38.6**). What explains this growing problem? Changing *food consumption* and *activity levels* are at work. We are eating more and moving less, with lifestyles approaching those of animal feedlots (where farmers fatten inactive animals). In the United States, jobs requiring moderate physical activity declined from about 50 percent in 1960 to 20 percent in 2011 (Church et al., 2011).

The “bottom” line: New stadiums, theaters, and subway cars—but not airplanes—are widening seats to accommodate the girth growth (Hampson, 2000; Kim & Tong, 2010). Washington State Ferries abandoned a 50-year-old standard: “Eighteen-inch butts are a thing of the past” (Shepherd, 1999). New York City, facing a large problem with Big Apple bottoms, has mostly replaced 17.5-inch bucket-style subway seats with bucketless seats (Hampson, 2000). In the end, today’s people need more room.

We will revisit this lesson in Unit XI’s study of individual differences. There can be high levels of heritability (genetic influence on individual differences in such things as intelligence) without heredity explaining group differences. Genes mostly determine why one person today is heavier than another. Environment mostly determines why people today

“We put fast food on every corner, we put junk food in our schools, we got rid of [physical education classes], we put candy and soda at the checkout stand of every retail outlet you can think of. The results are in. It worked.” -HAROLD GOLDSTEIN, EXECUTIVE DIRECTOR OF THE CALIFORNIA CENTER FOR PUBLIC HEALTH ADVOCACY, 2009, WHEN IMAGINING A VAST U.S. NATIONAL EXPERIMENT TO ENCOURAGE WEIGHT GAIN

Figure 38.6
Past and projected overweight rates, by the Organization for Economic Cooperation and Development

are heavier than their counterparts 50 years ago. Our eating behavior also demonstrates the now-familiar interaction among biological, psychological, and social-cultural factors. For tips on shedding unwanted pounds, see Close-up: Waist Management.

Close-up

Waist Management

Perhaps you are shaking your head: “Slim chance I have of becoming and staying thin.” People struggling with obesity are well advised to seek medical evaluation and guidance. For others who wish to take off a few pounds, researchers have offered these tips.

Begin only if you feel motivated and self-disciplined.

For most people, permanent weight loss requires making a career of staying thin—a lifelong change in eating habits combined with increased exercise.

Exercise and get enough sleep. Inactive people are often overweight (FIGURE 38.7). Especially when supported by 7 to 8 hours of sleep a night, exercise empties fat cells, builds muscle, speeds up metabolism, and helps lower your settling point (Bennett, 1995; Kolata, 1987; Thompson et al., 1982).

Minimize exposure to tempting food cues. Food shop only on a full stomach. Keep tempting foods out of the house, and store other appealing foods out of sight.

Limit variety and eat healthy foods. Given more variety, people consume more; eat simple meals with whole grains, fruits, and vegetables. Healthy fats, such as those found in olive oil and fish, help regulate appetite and artery-clogging cholesterol (Taubes, 2001, 2002). Better crispy greens than Krispy Kremes.

Reduce portion sizes. Serve food with smaller bowls, plates, and utensils.

Don’t starve all day and eat one big meal at night. This eating pattern, common among overweight people, slows metabolism. Moreover, those who eat a balanced breakfast are, by late morning, more alert and less fatigued (Spring et al., 1992).

Beware of the binge. Especially for men, eating slowly can lead to eating less (Martin et al., 2007). Among people who do consciously restrain their eating, drinking alcohol or feeling anxious or depressed can unleash the urge to eat (Herman & Polivy, 1980).

Before eating with others, decide how much you want to eat. Eating with friends can distract us from monitoring our own eating (Ward & Mann, 2000).

Remember, most people occasionally lapse. A lapse need not become a full collapse.

Connect to a support group. Join with others, either face-to-face or online, with whom you can share your goals and progress (Freedman, 2011).

Figure 38.7 American idle: Couch potatoes beware—TV watching correlates with obesity As lifestyles have become more sedentary and TV watching has increased, so has the percentage of overweight people in Britain, Canada, and the United States (Pagani et al., 2010). When California children were placed in a TV-reduction educational program, they watched less—and lost weight (Robinson, 1999). Don’t watch TV? Then watch out for other screen time that keeps your motor idling.

Before You Move On

▶ ASK YOURSELF

Do you feel in touch with your body's hunger signals? Do you eat when your body needs food? Or do you tend to be more externally influenced by enticing foods even when you're full?

▶ TEST YOURSELF

You've skipped lunch to meet with your guidance counselor so you haven't eaten anything in eight hours. As your favorite dish is placed in front of you, your mouth waters. Even imagining this may set your mouth to watering. What triggers this anticipatory salivation?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 38 Review

38-1 What physiological factors produce hunger?

- Hunger's pangs correspond to the stomach's contractions, but hunger also has other causes.
- Neural areas in the brain, some within the hypothalamus, monitor blood chemistry (including *glucose* level) and incoming information about the body's state.
- Appetite hormones include insulin (controls blood glucose); ghrelin (secreted by an empty stomach); orexin (secreted by the hypothalamus); leptin (secreted by fat cells); and PYY (secreted by the digestive tract).
- *Basal metabolic rate* is the body's resting rate of energy expenditure.
- The body may have a *set point* (a biologically fixed tendency to maintain an optimum weight) or a looser settling point (also influenced by the environment).

38-2 What cultural and situational factors influence hunger?

- Hunger also reflects our memory of when we last ate and our expectation of when we should eat again.
- Humans as a species prefer certain tastes (such as sweet and salty), but our individual preferences are also influenced by conditioning, culture, and situation.
- Some taste preferences, such as the avoidance of new foods, or of foods that have made us ill, have survival value.

38-3 What factors predispose some people to become and remain obese?

- Genes and environment interact to produce obesity.
 - Obesity correlates with depression, especially among women.
 - Twin and adoption studies indicate that body weight is also genetically influenced.
 - Environmental influences include lack of exercise, an abundance of high-calorie food, and social influence.
- Those wishing to lose weight are advised to make a lifelong change in habits: Get enough sleep; boost energy expenditure through exercise; limit variety and minimize exposure to tempting food cues; eat healthy foods and reduce portion sizes; space meals throughout the day; beware of the binge; monitor eating during social events; forgive the occasional lapse; and connect to a support group.

Multiple-Choice Questions

- Which of the following is the major source of energy in your body?
 - PYY
 - Arcuate nucleus
 - Hypothalamus
 - Ghrelin
 - Glucose
- Which of the following is the best term or phrase for the body's resting rate of energy expenditure?
 - Hunger
 - Set point
 - Basal metabolic rate
 - Body chemistry
 - Settling point
- Which of the following statements is true?
 - We eat less dessert when there are three different desserts available.
 - Serving sizes in France are generally larger than in the United States.
 - Offered a supersized portion, most of us consume fewer calories.
 - We eat more when we're around others.
 - Food variety generally decreases appetite.

Practice FRQs

- Explain the activity of the appetite hormones insulin and leptin.
- Explain the difference between set point and basal metabolic rate.

(2 points)

Answer

1 point: Insulin controls blood glucose.

1 point: Leptin causes the brain to increase metabolism and decrease hunger.

Module 39

Sexual Motivation

Module Learning Objectives

- 39-1** Describe the human sexual response cycle, and identify the dysfunctions that disrupt it.
- 39-2** Discuss the impact of hormones, and external and internal stimuli, on human sexual motivation.

Steve Cole/Getty Images

sexual response cycle the four stages of sexual responding described by Masters and Johnson—excitement, plateau, orgasm, and resolution.

"It is a near-universal experience, the invisible clause on one's birth certificate stipulating that one will, upon reaching maturity, feel the urge to engage in activities often associated with the issuance of more birth certificates." -SCIENCE WRITER NATALIE ANGIER, 2007

Sex is part of life. Had this not been so for all your ancestors, you would not be reading this book. Sexual motivation is nature's clever way of making people procreate, thus enabling our species' survival. When two people feel an attraction, they hardly stop to think of themselves as guided by their genes. As the pleasure we take in eating is nature's method of getting our body nourishment, so the desires and pleasures of sex are our genes' way of preserving and spreading themselves. Life is sexually transmitted.

The Physiology of Sex

Like hunger, sexual arousal depends on the interplay of internal and external stimuli. To understand sexual motivation, we must consider both.

The Sexual Response Cycle

- 39-1** What is the human sexual response cycle, and what dysfunctions disrupt it?

In the 1960s, gynecologist-obstetrician William Masters and his collaborator Virginia Johnson (1966) made headlines by recording the physiological responses of volunteers who masturbated or had intercourse. With the help of 382 female and 312 male volunteers—a somewhat atypical sample, consisting only of people able and willing to display arousal and orgasm while being observed in a laboratory—Masters and Johnson monitored or filmed more than 10,000 sexual "cycles." Their description of the **sexual response cycle** identified four stages. During the initial *excitement phase*, men's and women's genital areas become engorged with blood, a woman's vagina expands and secretes lubricant, and her breasts and nipples may enlarge.

In the *plateau phase*, excitement peaks as breathing, pulse, and blood pressure rates continue to increase. The penis becomes fully engorged and some fluid—frequently containing enough live sperm to enable conception—may appear at its tip. Vaginal secretion continues to increase.

Masters and Johnson observed muscle contractions all over the body during *orgasm*; these were accompanied by further increases in breathing, pulse, and blood pressure rates.

At orgasm, pulse rate surges from about 70 to 115 beats per minute (Jackson, 2009). A woman's arousal and orgasm facilitate conception by positioning the uterus to receive sperm, and drawing the sperm further inward. A woman's orgasm therefore not only reinforces intercourse, which is essential to natural reproduction, it also increases retention of deposited sperm (Furrow & Thornhill, 1996).

The pleasurable feeling of sexual release apparently is much the same for both sexes. In one study, a panel of experts could not reliably distinguish between descriptions of orgasm written by men and those written by women (Vance & Wagner, 1976). University of Groningen neuroscientist Gert Holstege and his colleagues (2003a,b) understand why. They discovered that when men and women undergo PET scans while having orgasms, the same subcortical brain regions glow. And when people who are passionately in love undergo fMRI scans while viewing photos of their beloved or of a stranger, men's and women's brain responses to their partner are pretty similar (Fisher et al., 2002).

The body gradually returns to its unaroused state as the engorged genital blood vessels release their accumulated blood—relatively quickly if orgasm has occurred, relatively slowly otherwise. (It's like the nasal tickle that goes away rapidly if you have sneezed, slowly otherwise.) During this *resolution phase*, the male enters a **refractory period**, lasting from a few minutes to a day or more, during which he is incapable of another orgasm. The female's much shorter refractory period may enable her to have more orgasms if restimulated during or soon after resolution.

Sexual Dysfunctions and Paraphilias

Masters and Johnson sought not only to describe the human sexual response cycle but also to understand and treat the inability to complete it. **Sexual dysfunctions** are problems that consistently impair sexual arousal or functioning. Some involve sexual motivation, especially lack of sexual energy and arousability. For men, others include *erectile disorder* (inability to have or maintain an erection) and *premature ejaculation*. For women, the problem may be pain or *female orgasmic disorder* (distress over infrequently or never experiencing orgasm). In separate surveys of some 3000 Boston women and 32,000 other American women, about 4 in 10 reported a sexual problem, such as orgasmic disorder or low desire, but only about 1 in 8 reported that this caused personal distress (Lutfey et al., 2009; Shifren et al., 2008). Most women who experience sexual distress relate it to their emotional relationship with the partner during sex (Bancroft et al., 2003).

Men and women with sexual dysfunctions can often be helped through therapy. In behaviorally oriented therapy, for example, men learn ways to control their urge to ejaculate, and women are trained to bring themselves to orgasm. Starting with the introduction of Viagra in 1998, erectile disorder has been routinely treated by taking a pill.

Sexual dysfunction involves problems with arousal or sexual functioning. People with *paraphilias* such as exhibitionism, fetishism, and pedophilia, do experience sexual arousal, but they direct it in unusual ways. The American Psychiatric Association (2013) only classifies such behavior as disordered if

- a person experiences distress from their unusual sexual interest or
- the sexual desire or behavior entails harm or risk of harm to others.

Hormones and Sexual Behavior

39-2

How do hormones, and external and internal stimuli, influence human sexual motivation?

Sex hormones have two effects: They direct the physical development of male and female sex characteristics, and (especially in nonhuman animals) they activate sexual behavior. In most mammals, nature neatly synchronizes sex with fertility. The female becomes sexually receptive

refractory period a resting period after orgasm, during which a man cannot achieve another orgasm.

sexual dysfunction a problem that consistently impairs sexual arousal or functioning.

FYI

In a National Center for Health Statistics survey of adult Americans, using computer-assisted self-interviews that guaranteed privacy, nearly 98 percent of 30- to 59-year-olds reported having had sex with someone (Fryar et al., 2007).

(in other animals, being “in heat”) when secretion of the female hormones, the **estrogens** (such as estradiol), peaks during ovulation. In experiments, researchers can stimulate receptivity by injecting female animals with an estrogen. Male hormone levels are more constant, and hormone injection does not so easily manipulate the sexual behavior of male animals (Feder, 1984). Nevertheless, castrated male rats—having lost their testes, which manufacture the male sex hormone **testosterone**—gradually lose much of their interest in receptive females. They gradually regain it if injected with testosterone.

In humans, hormones more loosely influence sexual behavior, although sexual desire rises slightly at ovulation among women with mates (Pillsworth et al., 2004). When at peak fertility in their menstrual cycle, women express increased preference for masculine faces and ability to detect sexual orientation, but also increased apprehensiveness of men perceived as potentially sexually coercive (Eastwick, 2009; Little et al., 2008; Navarrete et al., 2009; Rule et al., 2011). One study invited partnered women not at risk for pregnancy to keep a diary of their sexual activity. (These women were either using intrauterine devices or had undergone surgery to prevent pregnancy.) On the days around ovulation, intercourse was 24 percent more frequent (Wilcox et al., 2004).

Women’s sexuality differs from that of other mammalian females in being more responsive to testosterone level (van Anders & Dunn, 2009). If a woman’s natural testosterone level drops, as happens with removal of the ovaries or adrenal glands, her sexual interest may wane. But testosterone-replacement therapy sometimes restores diminished sexual appetite. That is the finding of experiments with hundreds of surgically or naturally menopausal women, for whom a testosterone-replacement patch restored sexual activity, arousal, and desire more than did a placebo (Braunstein et al., 2005; Buster et al., 2005; Petersen & Hyde, 2011). For men with abnormally low testosterone levels, testosterone-replacement therapy often increases sexual desire and also energy and vitality (Yates, 2000).

In men, normal fluctuations in testosterone levels, from man to man and hour to hour, have little effect on sexual drive (Byrne, 1982). Indeed, fluctuations in male hormones are partly a *response* to sexual stimulation. In the presence of an attractive female, Australian skateboarders’ testosterone surges, which contributes to riskier moves and more crash landings (Ronay & von Hippel, 2010). Thus, sexual arousal can be a cause as well as a consequence of increased testosterone levels.

Although normal short-term hormonal changes have little effect on men’s and women’s desire, large hormonal shifts over the life span have a greater effect. A person’s interest in dating and sexual stimulation usually increases with the pubertal surge in sex hormones. If the hormonal surge is precluded—as it was during the 1600s and 1700s for prepubertal boys who were castrated to preserve their soprano voices for Italian opera—the normal development of sex characteristics and sexual desire does not occur (Peschel & Peschel, 1987). When adult men are castrated, sex drive typically falls as testosterone levels decline sharply (Hucker & Bain, 1990). Male sex offenders taking Depo-Provera, a drug that reduces testosterone levels to that of a prepubertal boy, similarly lose much of their sexual urge (Bilefsky, 2009; Money et al., 1983). In later life, as sex hormone levels decline, the frequency of sexual fantasies and intercourse declines as well (Leitenberg & Henning, 1995).

To summarize: We might compare human sex hormones, especially testosterone, to the fuel in a car. Without fuel, a car will not run. But if the fuel level is minimally adequate, adding more fuel to the gas tank won’t change how the car runs. The analogy is imperfect, because hormones and sexual motivation interact. However, it correctly suggests that biology is a necessary but not sufficient explanation of human sexual behavior. The hormonal fuel is essential, but so are the psychological stimuli that turn on the engine, keep it running, and shift it into high gear.

AP® Exam Tip

The central principle here is that there are many biological processes that govern human behavior less rigidly than they govern the behaviors of other species. Because of our highly developed brain, sex hormones have less control over our behavior than they do over other animals’ behavior.

estrogens sex hormones, such as estradiol, secreted in greater amounts by females than by males and contributing to female sex characteristics. In nonhuman female mammals, estrogen levels peak during ovulation, promoting sexual receptivity.

testosterone the most important of the male sex hormones. Both males and females have it, but the additional testosterone in males stimulates the growth of the male sex organs in the fetus and the development of the male sex characteristics during puberty.

“Fill’er up with testosterone.”

The Psychology of Sex

Hunger and sex are different sorts of motivations. Hunger responds to a *need*. If we do not eat, we die. Sex is not in this sense a need. (We may feel like dying, but we do not.) Nevertheless, there are similarities between hunger and sexual motivation. Both depend on internal physiological factors. Both reflect the interplay of excitatory and inhibitory responses—the body’s acceleration and braking systems (Bancroft et al., 2009). And both are influenced by external and imagined stimuli, and by cultural expectations (**FIGURE 39.1**).

External Stimuli

Many studies confirm that men become aroused when they see, hear, or read erotic material. Surprising to many (because sexually explicit materials are marketed mostly to men) is that most women—at least the less-inhibited women who volunteer to participate in such studies—report or exhibit nearly as much arousal to the same stimuli (Heiman, 1975; Stockton & Murnen, 1992). (Their brains do, however, respond differently, with fMRI scans revealing a more active amygdala in men viewing erotica [Hamann et al., 2004].) In 132 such experiments, men’s feelings of sexual arousal have much more closely mirrored their (more obvious) genital response than have women’s (Chivers et al., 2010).

People may find sexual arousal either pleasing or disturbing. (Those who wish to control their arousal often limit their exposure to such materials, just as those wishing to control hunger limit their exposure to tempting cues.) With repeated exposure, the emotional response to any erotic stimulus often lessens, or *habituates*. During the 1920s, when Western women’s hemlines first reached the knee, an exposed leg was a mildly erotic stimulus.

Can sexually explicit material have adverse effects? Research indicates that it can. Depictions of women being sexually coerced—and liking it—tend to increase viewers’ acceptance of the false idea that women enjoy rape, and they tend to increase male viewers’ willingness to hurt women (Malamuth & Check, 1981; Zillmann, 1989). Viewing images of sexually attractive women and men may also lead people to devalue their own partners and relationships. After male collegians viewed TV or magazine depictions of sexually attractive women, they often found an average woman, or their own girlfriend or wife, less attractive (Kenrick & Gutierrez, 1980; Kenrick et al., 1989; Weaver et al., 1984). Viewing X-rated sex films similarly tends to diminish people’s satisfaction with their own sexual partner (Zillmann, 1989). Perhaps reading or watching erotica creates expectations that few men and women can fulfill.

“Ours is a society which stimulates interest in sex by constant titillation. . . . Cinema, television, and all the formidable array of our marketing technology project our very effective forms of titillation and our prejudices about man as a sexy animal into every corner of every hovel in the world.” -GERMAINE GREER, 1984

Imagined Stimuli

The brain, it has been said, is our most significant sex organ. The stimuli inside our heads—our imagination—can influence sexual arousal and desire. People who, because of a spinal-cord injury, have no genital sensation can still feel sexual desire (Willmuth, 1987). Consider, too, the erotic potential of dreams. Sleep researchers have discovered that genital arousal accompanies all types of dreams, even though most dreams have no sexual content. But in nearly all men and some 40 percent of women, dreams sometimes contain sexual imagery that leads to orgasm (Wells, 1986). In men, nighttime orgasm and nocturnal emissions (“wet dreams”) are more likely when orgasm has not occurred recently.

About 95 percent of both men and women say they have sexual fantasies. Men (whether gay or straight) fantasize about sex more often, more physically, and less romantically. They also prefer less personal and faster-paced sexual content in books and videos (Leitenberg & Henning, 1995). Fantasizing about sex does *not* indicate a sexual problem or dissatisfaction. If anything, sexually active people have more sexual fantasies.

Before You Move On

▶ ASK YOURSELF

What psychological and social-cultural factors have affected your sexual motivation?

▶ TEST YOURSELF

How might the evolutionary perspective, drive-reduction theory, and arousal theory explain our sexual motivation?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 39 Review

39-1

What is the human sexual response cycle, and what dysfunctions disrupt it?

- William Masters and Virginia Johnson described four stages in the human *sexual response cycle*: excitement, plateau, orgasm (which seems to involve similar feelings and brain activity in males and females), and resolution.
- In the resolution phase, males experience a *refractory period*, during which renewed arousal and orgasm are impossible.
- *Sexual dysfunctions* are problems that consistently impair sexual arousal or functioning. They can often be successfully treated by behaviorally oriented therapy or drug therapy.

39-2

How do hormones, and external and internal stimuli, influence human sexual motivation?

- The female *estrogen* and male *testosterone* hormones influence human sexual behavior less directly than they influence sexual behavior in other species. Short-term shifts in testosterone level are normal in men, partly in response to stimulation.
- External stimuli can trigger sexual arousal in both men and women, although the activated brain areas differ somewhat.
 - Men respond more specifically to sexual depictions involving their preferred sex.
 - Sexually explicit material may lead people to perceive their partners as comparatively less appealing and to devalue their relationships. Imagined stimuli (dreams and fantasies) also influence sexual arousal.

Multiple-Choice Questions

1. Which of the following best describes the relationship between gender and orgasm?
 - a. You can use fMRIs to identify when orgasm occurs in men, but this method is unreliable in women.
 - b. Men describe orgasm in physical terms and women describe orgasm in emotional terms.
 - c. Orgasm activates subcortical regions in men and cortical regions in women.
 - d. Men and women describe orgasm similarly.
 - e. Orgasm serves evolutionary purposes in women but not in men.
2. About _____ percent of the population experience sexual fantasies.
 - a. 95
 - b. 68
 - c. 50
 - d. 35
 - e. 20
3. Which of the following is true concerning the effect of sex hormones?
 - a. Hormone injections can be used to easily manipulate sexual behavior in males but not in females.
 - b. Hormone injections can be used to easily manipulate sexual behavior in both males and females.
 - c. Sex hormones have a more direct effect on nonhuman animals than on humans.
 - d. The levels of sex hormones are more constant in females than in males.
 - e. While studies have shown that ovulation is associated with changes in women's fantasies, they have not established an association between ovulation and women's sexual behavior.

Practice FRQs

1. Describe one influence on sexual motivation from each of the following categories:
 - Biological
 - Psychological
 - Social-cultural
2. Name and briefly describe the four stages of the sexual response cycle identified by Masters and Johnson.
(4 points)

Answer

1 point: Biological: hormones, sexual orientation.

1 point: Psychological: exposure to sexually stimulating material, fantasizing.

1 point: Social-cultural: religious and personal values, media.

Module 40

Social Motivation: Affiliation Needs

Module Learning Objectives

- 40-1** Describe the evidence that points to our human affiliation need—our need to belong.
- 40-2** Describe how social networking influences us.

40-1 What evidence points to our human affiliation need—our need to belong?

The social stigma attached to obesity may bother an overweight person as much as, or more than, the health concerns. Why? We are what Greek philosopher Aristotle called *the social animal*. Cut off from friends or family—alone in prison or at a new school or in a foreign land—most people feel keenly their lost connections with important others. This deep *need to belong*—our *affiliation need*—seems to be a basic human motivation (Baumeister & Leary, 1995). Although healthy people vary in their wish for privacy and solitude, most of us seek to affiliate with others, even to become strongly attached to certain others in enduring, close relationships. Human beings, contended personality theorist Alfred Adler, have an “urge to community” (Ferguson, 1989, 2001, 2010). Our psychological needs drive our adaptive behaviors and, when satisfied, enhance our psychological well-being (Sheldon, 2011).

The Benefits of Belonging

Social bonds boosted our early ancestors’ chances of survival. Adults who formed attachments were more likely to reproduce and to co-nurture their offspring to maturity. Attachment bonds helped keep those children close to their caregivers, protecting them from many threats. Indeed, to be “wretched” literally means, in its Middle English origin (*wrecche*), to be without kin nearby.

Cooperation also enhanced survival. In solo combat, our ancestors were not the toughest predators. But as hunters, they learned that six hands were better than two. As food gatherers, they gained protection from two-footed and four-footed enemies by traveling in groups. Those who felt a need to belong survived and reproduced most successfully, and their genes now predominate. We are innately social creatures. People in every society on Earth belong to groups and (as Module 77 explains) prefer and favor “us” over “them.”

Do you have close friends—people with whom you freely disclose your ups and downs? Having someone who rejoices with us over good news helps us feel even better about the good news, as well as about the friendship (Reis et al., 2010). The need to belong runs deeper, it seems, than the need to be rich. One study found that *very* happy university students were distinguished not by their money but by their “rich and satisfying close relationships” (Diener & Seligman, 2002).

“We must love one another or die.” -W. H. AUDEN, “SEPTEMBER 1, 1939”

The need to belong colors our thoughts and emotions. We spend a great deal of time thinking about actual and hoped-for relationships. When relationships form, we often feel joy. Falling in mutual love, people have been known to feel their cheeks ache from their irrepressible grins. Asked, “What is necessary for your happiness?” or “What is it that makes your life meaningful?” most people have mentioned—before anything else—close, satisfying relationships with family, friends, or romantic partners (Berscheid, 1985). Happiness hits close to home.

Consider: What was your most satisfying moment in the past week? Researchers asked that question of American and South Korean collegians, then asked them to rate how much that moment had satisfied various needs (Sheldon et al., 2001). In both countries, the peak moment had contributed most to satisfaction of self-esteem and relatedness-belonging needs. When our need for relatedness is satisfied in balance with two other basic psychological needs—*autonomy* (a sense of personal control) and *competence*—we experience a deep sense of well-being, and our self-esteem rides high (Deci & Ryan, 2002, 2009; Milyavskaya et al., 2009; Sheldon & Niemiec, 2006). Indeed, *self-esteem* is a gauge of how valued and accepted we feel (Leary et al., 1998).

Is it surprising, then, that so much of our social behavior aims to increase our feelings of belonging? To gain acceptance, we generally conform to group standards. We monitor our behavior, hoping to make a good impression. We spend billions on clothes, cosmetics, and diet and fitness aids—all motivated by our search for love and acceptance.

By drawing a sharp circle around “us,” the need to belong feeds both deep attachments and menacing threats. Out of our need to define a “we” come loving families, faithful friendships, and team spirit, but also teen gangs, ethnic rivalries, and fanatic nationalism.

For good or for bad, we work hard to build and maintain our relationships. Familiarity breeds liking, not contempt. Thrown together in groups at school, at band camp, on a hiking trip, we behave like magnets, moving closer, forming bonds. Parting, we feel distress. We promise to call, to write, to come back for reunions.

This happens in part because feelings of love activate brain reward and safety systems. In one experiment involving exposure to heat, deeply-in-love university students felt markedly less pain when looking at their beloved’s picture (rather than viewing someone else’s photo or being distracted by a word task) (Younger et al., 2010). Pictures of our loved ones also activate a brain region associated with safety—the prefrontal cortex—that dampens feelings of physical pain (Eisenberger et al., 2011). Love is a natural painkiller.

Even when bad relationships break, people suffer. In one 16-nation survey, and in repeated U.S. surveys, separated and divorced people have been half as likely as married people to say they were “very happy” (Inglehart, 1990; NORC, 2010). After such separations, loneliness and anger—and sometimes even a strange desire to be near the former partner—linger. For those in abusive relationships, the fear of being alone sometimes seems worse than the certainty of emotional or physical pain.

Children who move through a series of foster homes or through repeated family relocations know the fear of being alone. After repeated disruption of budding attachments, they may have difficulty forming deep attachments (Oishi & Schimmack, 2010b). The evidence is clearest at the extremes—the children who grow up in institutions without a sense of belonging to anyone, or who are locked away at home and severely neglected. Too many become withdrawn, frightened, speechless. Feeling insecurely attached to others during childhood can persist into adulthood, in two main forms (Fraley et al., 2011). Some display *insecure anxious attachment*, constantly craving acceptance but remaining vigilant to signs of possible rejection. Others are trapped in *insecure avoidant attachment*, feeling such discomfort over getting close to others that they employ avoidant strategies to maintain their distance.

The need to connect Six days a week, women from the Philippines work as “domestic helpers” in 154,000 Hong Kong households. On Sundays, they throng to the central business district to picnic, dance, sing, talk, and laugh. “Humanity could stage no greater display of happiness,” reported one observer (*Economist*, 2001).

AP Photo/Vincent Yu

No matter how secure our early years were, we all experience anxiety, loneliness, jealousy, or guilt when something threatens or dissolves our social ties. Much as life's best moments occur when close relationships begin—making a new friend, falling in love, having a baby—life's worst moments happen when close relationships end (Jaremka et al., 2011). Bereaved, we may feel life is empty, pointless. Even the first weeks living on a college campus away from home can be distressing.

For immigrants and refugees moving alone to new places, the stress and loneliness can be depressing. After years of placing individual families in isolated communities, U.S. immigration policies began to encourage *chain migration* (Pipher, 2002). The second refugee Sudanese family settling in a town generally has an easier adjustment than the first.

Social isolation can put us at risk for mental decline and ill health (Cacioppo & Hawkley, 2009). But if feelings of acceptance and connection increase, so will self-esteem, positive feelings, and the desire to help rather than hurt others (Blackhart et al., 2009; Buckley & Leary, 2001).

The Pain of Being Shut Out

Can you recall feeling excluded or ignored or shunned? Perhaps you received the silent treatment. Perhaps people avoided you or averted their eyes in your presence or even mocked you behind your back. If you are like others, even being in a group speaking a different language may have left you feeling excluded, a linguistic outsider (Dotan-Eliaz et al., 2009). In one mock-interview study, women felt more excluded if interviewers used gender-exclusive language (*he, his, him*) rather than inclusive (*his or her*) or neutral (*their*) language (Stout & Dasgupta, 2011).

All these experiences are instances of *ostracism*—of social exclusion (Williams 2007, 2009). Worldwide, humans use many forms of ostracism—exile, imprisonment, solitary confinement—to punish, and therefore control, social behavior. For children, even a brief timeout in isolation can be punishing. Asked to describe personal episodes that made them feel especially *bad* about themselves, people will—about four times in five—describe a relationship difficulty (Pillemer et al., 2007). Feelings of loneliness can also spread from person to person like a disease, through one's acquaintances (Cacioppo et al., 2009).

Being shunned—given the cold shoulder or the silent treatment, with others' eyes avoiding yours—threatens one's need to belong (Williams & Zadro, 2001). "It's the meanest thing you can do to someone, especially if you know they can't fight back. I never should have been born," said Lea, a lifelong victim of the silent treatment by her mother and grandmother. Like Lea, people often respond to ostracism with depressed moods, initial efforts to restore their acceptance, and then withdrawal. After two years of silent treatment by his employer, Richard reported, "I came home every night and cried. I lost 25 pounds, had no self-esteem and felt that I wasn't worthy."

To experience ostracism is to experience real pain, as social psychologist Kipling Williams and his colleagues were surprised to discover in their studies of *cyber-ostracism* (Gonsalkorale & Williams, 2006). (Perhaps you can recall the feeling of being unfriended or having few followers on a social networking site, being ignored in a chat room, or having a text message or e-mail go unanswered.) Such ostracism, they discovered, takes a toll: It elicits increased activity in brain areas, such as the *anterior cingulate cortex*, that also activate in response to physical pain (Kross et al., 2011; Lieberman & Eisenberger, 2009). That helps explain another surprising finding: The pain-reliever acetaminophen (as in Tylenol and Anacin) lessens *social* as well as physical pain (DeWall et al., 2010). Across cultures, people use the same words (for example, *hurt, crushed*) for social pain and physical pain (MacDonald & Leary, 2005). Psychologically, we seem to experience social pain with the same emotional unpleasantness that marks physical pain.

Enduring the pain of ostracism

Caucasian cadets at the United States Military Academy at West Point ostracized Henry Flipper for years, hoping he would drop out. He somehow resisted their cruelty and in 1877 became the first African-American West Point graduate.

CBS/Getty Images

Social acceptance and rejection

Successful participants on the reality TV show *Survivor* form alliances and gain acceptance among their peers. The rest receive the ultimate social punishment as they are “voted off the island.”

Pain, whatever its source, focuses our attention and motivates corrective action. Rejected and unable to remedy the situation, people may seek new friends or relieve stress in a strengthened religious faith (Aydin et al., 2010). Or they may turn nasty. In a series of experiments, researchers (Baumeister et al., 2002; Twenge et al., 2001, 2002, 2007) told some students (who had taken a personality test) that they were “the type likely to end up alone later in life,” or that people they had met didn’t want them in a group that was forming. They told other students that they would have “rewarding relationships throughout life,” or that “everyone chose you as someone they’d like to work with.” Those excluded became much more likely to engage in self-defeating behaviors and to underperform on aptitude tests. The rejection also interfered with their empathy for others and made them more likely to act in disparaging or aggressive ways against those who had excluded them (blasting them with noise, for example). “If intelligent, well-adjusted, successful . . . students can turn aggressive in response to a small laboratory experience of social exclusion,” noted the research team, “it is disturbing to imagine the aggressive tendencies that might arise from . . . chronic exclusion from desired groups in actual social life.” Indeed, as Williams (2007) has observed, ostracism “weaves through case after case of school violence.”

FYI

Note: The researchers later debriefed and reassured the participants.

Connecting and Social Networking

40-2 How does social networking influence us?

As social creatures, we live for connection. Asked what he had learned from studying 238 Harvard University men from the 1930s to the end of their lives, researcher George Vaillant (2009) replied, “The only thing that really matters in life are your relationships to other people.” A South African Zulu saying captures the idea: *Umuntu ngumuntu ngabantu*—“a person is a person through other persons.”

Mobile Networks and Social Media

Look around and see humans connecting: talking, texting, posting, chatting, social gaming, e-mailing. The changes in how we connect have been fast and vast:

- Cell phones have been history’s most rapidly adopted technology. At the end of 2010, the world had 7.1 billion people and 6.8 billion mobile cell-phone subscriptions (ITU, 2013). Asia and Europe have lead the way. In 2012 in India, 925 million people had mobile phone access—more than had a home toilet (Krishna, 2012; Mishra, 2013). American youth have kept up with the world: In 2013, 78 percent of 12- to 17-year-olds were cell-phone users (Pew, 2013).

AP® Exam Tip

Free-response questions on the AP® exam often ask students to apply psychological principles to real-life situations. It’s easy to imagine a question that deals with social media.

“There’s no question in my mind about what stands at the heart of the communication revolution—the human desire to connect.”
—SKYPE PRESIDENT JOSH SILVERMAN, 2009

Image Source/SuperStock

- Texting and e-mailing have been displacing phone talking, which by 2009 accounted for less than half of U.S. mobile network traffic (Wortham, 2010). In Canada and elsewhere, e-mailing has declined, displaced by texting, Facebook, and other messaging technology (IPSOS, 2010a). Speedy texting is not really writing, said one observer (McWhorter, 2012), but rather a new form of conversation—“fingered speech.”
- For many, it’s as though friends, for better or worse, are always present. How many of us are using social networking sites, such as Facebook or Twitter? Among 2010’s entering American collegians, 94 percent were (Pryor et al., 2011). With a “critical mass” of your friends on a social network, its lure becomes hard to resist. Such is our need to belong. Check in or miss out.

The Social Effects of Social Networking

By connecting like-minded people, the Internet serves as a social amplifier. It also functions as an online dating matchmaker (more on those topics in Module 79). As electronic communication has become part of our “new normal,” researchers have explored how these changes have affected our relationships.

HAVE SOCIAL NETWORKING SITES MADE US MORE, OR LESS, SOCIALLY ISOLATED?

In the Internet’s early years, when online communication in chat rooms and during social games was mostly between strangers, the adolescents and adults who spent more time online spent less time with friends (Kraut et al., 1998; Mesch, 2001; Nie, 2001). As a result, their offline relationships suffered. Even in more recent times, lonely people have tended to spend greater-than-average time online (Bonetti et al., 2010; Stepanikova et al., 2010). Social networkers have been less likely to know their real-world neighbors and “64 percent less likely than non-Internet users to rely on neighbors for help in caring for themselves or a family member” (Pew, 2009).

But the Internet has also diversified our social networks. I am now connected to other hearing-technology advocates across the world and perhaps you, too, have found a group of kindred spirits online. Despite the decrease in neighborliness, social networking seems mostly to have strengthened our connections with people we already know (DiSalvo, 2010; Valkenburg & Peter, 2009). If your social networking helps you connect with friends, stay in touch with extended family, or find support in facing challenges, then you are not alone (Rainie et al., 2011). For many, though, being alone is not the problem. If you are like other students, two days of social networking deprivation would be followed by a glut of online time, much as you would eat voraciously after a two-day food fast (Sheldon et al., 2011). Social networks connect us, but they can also become gigantic time- and attention-sucking diversions. For some research-based strategies, see Close-up: Managing Your Social Networking.

Close-up**Managing Your Social Networking**

In today's world, each of us is challenged to find a healthy balance between our real-world time with people and our online sharing. In both Taiwan and the United States, excessive online socializing and gaming have been associated with lower grades (Chen & Fu, 2008; Kaiser Family Foundation, 2010). In one U.S. survey, 47 percent of the heaviest users of the Internet and other media were receiving mostly C grades or lower, as were just 23 percent of the lightest users (Kaiser Family Foundation, 2010). The heaviest users may be almost constantly connected, sometimes even awakening during the night long enough to reply to a text but not long enough to remember it the next day.

If you're trying to maintain a healthy balance between online connecting and real-world responsibilities, experts offer these practical suggestions:

- *Monitor your time.* Keep a log of how you use your time. Then ask yourself, "Does my time use reflect my priorities? Am I spending more time online than I intended? Is my time online interfering with school or work performance? Have family or friends commented on this?"
- *Monitor your feelings.* Again, ask yourself, "Am I emotionally distracted by online preoccupations? When I disconnect and move on to another activity, how do I feel?"
- *"Hide" your more distracting online friends.* And in your own postings, practice the golden rule. Before you post,

ask yourself, "Is this something I'd care about reading if someone else posted it?"

- *Try turning off your mobile devices or leaving them elsewhere.* Selective attention—the flashlight of your mind—can be in only one place at a time. When you want to study or work productively, squelch the temptation to check for messages, posts, or e-mails. And disable sound alerts and pop-ups. These distractions can interrupt your work and hijack your attention just when you've managed to get focused.
- *Try a social networking fast (give it up for an hour, a day, or a week) or a time-controlled social media diet (check in only after homework is done, or only during a predetermined break).* Take notes on what you're losing and gaining on your new "diet."
- *Replenish your focus with a nature walk.* University of Michigan researchers have reported that a walk in the woods, unlike walking on a busy street, replenishes people's capacity for focused attention (Berman et al., 2008). People learn better after a peaceful walk that restores their fatigued attention.

"The solution is not to bemoan technology but to develop strategies of self-control, as we do with every other temptation in life." -PSYCHOLOGIST STEVEN PINKER, "MIND OVER MASS MEDIA," 2010

DOES ELECTRONIC COMMUNICATION STIMULATE HEALTHY SELF-DISCLOSURE?

As we will see in Module 84, confiding in others can be a healthy way of coping with day-to-day challenges. When communicating electronically rather than face to face, we often are less focused on others' reactions, less self-conscious, and thus less inhibited. We become more willing to share joys, worries, and vulnerabilities. Sometimes this is taken to an extreme, as when teens send photos of themselves they later regret, or cyberbullies hound a victim, or hate groups post messages promoting bigotry or crimes. More often, however, the increased self-disclosure serves to deepen friendships (Valkenburg & Peter, 2009).

Although electronic networking pays dividends, nature has designed us for face-to-face communication, which appears to be the better predictor of life satisfaction (Killingsworth & Gilbert, 2010; Lee et al., 2011). Texting and e-mailing are rewarding, but eye-to-eye conversation with family and friends is even more so.

DO SOCIAL NETWORKING PROFILES AND POSTS REFLECT PEOPLE'S ACTUAL PERSONALITIES?

We've all heard stories of Internet predators hiding behind false personalities, values, and motives. Generally, however, social networks reveal people's real personalities. In one study, participants completed a personality test twice. In one test, they described their "actual personality"; in the other, they described their "ideal self." Volunteers then used the participants' Facebook profiles to create an independent set of personality ratings. The ratings based on Facebook profiles were much closer to the participants' actual personalities than to

their ideal personalities (Back et al., 2010). In another study, people who seemed most likable on their Facebook page also seemed most likable in face-to-face meetings (Weisbuch et al., 2009). Your online profiles may indeed reflect the real you!

DOES SOCIAL NETWORKING PROMOTE NARCISSISM? *Narcissism* is self-esteem gone awry. Narcissistic people are self-important, self-focused, and self-promoting. Some personality tests assess narcissism with items such as “I like to be the center of attention.” Given our constant social comparison—our measuring ourselves against others—many social networkers can’t resist comparing numbers of friends. (Evolutionary psychologist Robin Dunbar [1992, 2010] estimates we can have meaningful, supportive relationships with about 150 people—a typical size of tribal villages.)

Those who score high on narcissism are especially active on social networking sites. They collect more superficial “friends.” They offer more staged, glamorous photos. And, not surprisingly, they *seem* more narcissistic to strangers viewing their pages (Buffardi & Campbell, 2008).

For narcissists, social networking sites are more than a gathering place; they are a feeding trough. In one study, college students were randomly assigned either to edit and explain their online profile for 15 minutes, or to use that time to study and explain a Google Maps routing (Freeman & Twenge, 2010). After completing their tasks, all were tested. Who then scored higher on a narcissism measure? Those who had spent the time focused on themselves.

* * *

We have seen that identifiable physiological mechanisms drive some motives, such as hunger (though learned tastes and cultural expectations matter, too). Other motives, such as our need for affiliation, are more obviously driven by psychological factors, such as the social rewards that come from belonging. What unifies all motives is their common effect: the energizing and directing of behavior.

Before You Move On

▶ ASK YOURSELF

Have there been times when you felt out of the loop with family and friends, or even ostracized by them? How did you respond?

▶ TEST YOURSELF

How might the evolutionary perspective, drive-reduction theory, and arousal theory explain our affiliation needs?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 40 Review

40-1 What evidence points to our human affiliation need—our need to belong?

- Our need to affiliate or belong—to feel connected and identified with others—had survival value for our ancestors, which may explain why humans in every society live in groups.
- Because of their need to belong, people suffer when socially excluded, and they may engage in self-defeating behaviors (performing below their ability) or in antisocial behaviors.
- Feeling loved activates brain regions associated with reward and safety systems.
- Social isolation can put us at risk mentally and physically.

40-2 How does social networking influence us?

- We connect with others through social networking, strengthening our relationships with those we already know.
- When networking, people tend toward increased self-disclosure.
- Working out strategies for self-control and disciplined use can help people maintain a healthy balance between social networking and school and work performance.

Multiple-Choice Questions

1. If you are trying to maintain a healthy balance between connecting with others online and a real-world perspective, which of the following suggestions should you follow?
 - a. Monitor your feelings.
 - b. Dismiss the notion of logging online time.
 - c. Interact often with your more distracting online friends.
 - d. Decrease physical activity.
 - e. Try a social networking marathon.
2. Which of the following statements about mobile networks and social media is accurate?
 - a. There are more home toilets in India than there are cell phones.
 - b. Cell phones have been history's most rapidly adopted technology.
 - c. Fewer than 75 percent of American youth are cell-phone users.
 - d. Phone calling has displaced texting.
 - e. Texting has declined in Canada and elsewhere because of e-mail.
3. Which of the following words or phrases best identifies our gauge of how valued and accepted we feel?
 - a. Hope
 - b. Autonomy
 - c. Competence
 - d. Self-esteem
 - e. Ostracism

Practice FRQs

1. Explain three potentially negative effects of social networking.

Answer

1 point each for explaining any of the following:

- Isolates us from others
- Can become a time-sucking diversion
- Can become an attention-sucking diversion
- People may self-disclose too much
- Can make us feel emotionally distracted
- Other effects (use teacher discretion)

2. Explain three things you can do to manage your social networking.

(3 points)

Module 41

Theories and Physiology of Emotion

Module Learning Objectives

- 41-1** Describe how arousal and expressive behaviors interact in emotion.
- 41-2** Explain whether we can experience emotions without consciously interpreting and labeling them.
- 41-3** Describe the link between emotional arousal and the autonomic nervous system, and discuss the relationship between arousal and performance.
- 41-4** Discuss whether different emotions activate different physiological and brain-pattern responses.
- 41-5** Discuss the effectiveness of polygraphs in using body states to detect lies.

Paul Simrock/Corbis

Motivated behavior often is driven by powerful emotions that color and sometimes disrupt our lives. I will never forget the day I went to a huge store to drop off film and brought along Peter, my toddler first-born child. As I set Peter down on his feet and prepared to complete the paperwork, a passerby warned, “You’d better be careful or you’ll lose that boy!” Not more than a few breaths later, after dropping the film in the slot, I turned and found no Peter beside me.

With mild anxiety, I peered around one end of the counter. No Peter in sight. With slightly more anxiety, I peered around the other end. No Peter there, either. Now, with my heart accelerating, I circled the neighboring counters. Still no Peter anywhere. As anxiety turned to panic, I began racing up and down the store aisles. He was nowhere to be found.

Apprised of my alarm, the store manager used the public-address system to ask customers to assist in looking for a missing child. Soon after, I passed the customer who had warned me. “I told you that you were going to lose him!” he now scorned. With visions of kidnapping (strangers routinely adored that beautiful child), I braced for the possibility that my negligence had caused me to lose what I loved above all else, and that I might have to return home and face my wife without our only child.

But then, as I passed the customer service counter yet again, there he was, having been found and returned by some obliging customer. In an instant, the arousal of terror spilled into ecstasy. Clutching my son, with tears suddenly flowing, I found myself unable to speak my thanks and stumbled out of the store awash in grateful joy.

Courtesy of David G. Myers

Where do such emotions come from? Why do we have them? What are they made of? Emotions don't exist just to give us interesting experiences. They are our body's adaptive response, increasing our chances of survival. When we face challenges, emotions focus our attention and energize our actions (Cyders & Smith, 2008). Our heart races. Our pace quickens. All our senses go on high alert. Receiving unexpected good news, we may find our eyes tearing up. We raise our hands triumphantly. We feel exuberance and a newfound confidence. Yet negative and prolonged emotions can harm our health.

Cognition and Emotion

41-1 How do arousal and expressive behaviors interact in emotion?

As my panicked search for Peter illustrates, **emotions** are a mix of *bodily arousal* (heart pounding); *expressive behaviors* (quickened pace); and *conscious experience*, including thoughts ("Is this a kidnapping?") and feelings (panic, fear, joy).

The puzzle for psychologists is figuring out how these three pieces fit together. To do that, we need answers to two big questions:

- A chicken-and-egg debate: Does your bodily arousal come *before, after, or at the same time as* your emotional feelings? (Did I first notice my racing heart and faster step, and then feel terror about losing Peter? Or did my sense of fear come first, stirring my heart and legs to respond?)
- How do *thinking* (cognition) and *feeling* interact? Does cognition always come before emotion? (Did I think about a kidnapping threat before I reacted emotionally?)

Historical emotion theories, as well as current research, have sought to answer these questions.

Historical Emotion Theories

JAMES-LANGE THEORY: AROUSAL COMES BEFORE EMOTION

Common sense tells most of us that we cry because we are sad, lash out because we are angry, tremble because we are afraid. First comes conscious awareness, then the feeling. But to pioneering psychologist William James, this commonsense view of emotion had things backwards. Rather, "We feel sorry because we cry, angry because we strike, afraid because we tremble" (1890, p. 1066). James' idea was also proposed by Danish physiologist Carl Lange, and so is called the **James-Lange theory**. James and Lange would guess that I noticed my racing heart and then, shaking with fright, felt the whoosh of emotion. My feeling of fear followed my body's response.

FYI

Not only emotion, but most psychological phenomena (vision, sleep, memory, sex, and so forth) can be approached these three ways—physiologically, behaviorally, and cognitively.

emotion a response of the whole organism, involving
 (1) physiological arousal,
 (2) expressive behaviors, and
 (3) conscious experience.

James-Lange theory the theory that our experience of emotion is our awareness of our physiological responses to emotion-arousing stimuli.

Steve Pope/AF Photo

Joy expressed According to the James-Lange theory, we don't just smile because we share our teammates' joy. We also share the joy because we are smiling with them.

Cannon-Bard theory the theory that an emotion-arousing stimulus simultaneously triggers
(1) physiological responses and
(2) the subjective experience of emotion.

two-factor theory the Schachter-Singer theory that to experience emotion one must (1) be physically aroused and (2) cognitively label the arousal.

AP® Exam Tip

Be prepared for at least a multiple-choice question that tests your ability to tell the difference between the James-Lange theory and the Cannon-Bard theory.

The spillover effect Arousal from a soccer match can fuel anger, which can descend into rioting or other violent confrontations.

Reuters/CORBIS

CANNON-BARD THEORY: AROUSAL AND EMOTION OCCUR SIMULTANEOUSLY

Physiologist Walter Cannon (1871–1945) disagreed with James and Lange. Does a racing heart signal fear or anger or love? The body's responses—heart rate, perspiration, and body temperature—are too similar, and they change too slowly, to *cause* the different emotions, said Cannon. He, and later another physiologist, Philip Bard, concluded that our bodily responses and experienced emotions occur separately but simultaneously. So, according to the **Cannon-Bard theory**, my heart began pounding *as* I experienced fear. The emotion-triggering stimulus traveled to my sympathetic nervous system, causing my body's arousal. *At the same time*, it traveled to my brain's cortex, causing my awareness of my emotion. My pounding heart did not cause my feeling of fear, nor did my feeling of fear cause my pounding heart.

The Cannon-Bard theory has been challenged by studies of people with severed spinal cords, including a survey of 25 soldiers who suffered such injuries in World War II (Hohmann, 1966). Those with *lower-spine injuries*, who had lost sensation only in their legs, reported little change in their emotions' intensity. Those with *high spinal cord injury*, who could feel nothing below the neck, did report changes. Some reactions were much less intense than before the injuries. Anger, one man confessed, "just doesn't have the heat to it that it used to. It's a mental kind of anger." Other emotions, those expressed mostly in body areas above the neck, were felt *more* intensely. These men reported increases in weeping, lumps in the throat, and getting choked up when saying good-bye, worshipping, or watching a touching movie. Our bodily responses seemingly feed our experienced emotions.

But most researchers now agree that our emotions also involve cognition (Averill, 1993; Barrett, 2006). Whether we fear the man behind us on the dark street depends entirely on whether we interpret his actions as threatening or friendly.

Cognition Can Define Emotion: Schachter and Singer

41-2 To experience emotions, must we consciously interpret and label them?

Stanley Schachter and Jerome Singer (1962) believed that an emotional experience requires a conscious interpretation of arousal: Our physical reactions and our thoughts (perceptions, memories, and interpretations) together create emotion. In their **two-factor theory**, emotions therefore have two ingredients: physical arousal and cognitive appraisal.

Consider how arousal spills over from one event to the next. Imagine arriving home after an invigorating run and finding a message that you got a longed-for job. With arousal lingering from the run, would you feel more elated than if you received this news after awakening from a nap?

To explore this *spillover effect*, Schachter and Singer injected college men with the hormone epinephrine, which triggers feelings of arousal. Picture yourself as a participant: After receiving the injection, you go to a waiting room, where you find yourself with another person (actually an accomplice of the experimenters) who is acting either euphoric or irritated. As you observe this person, you begin to feel your heart race, your body flush, and your breathing become more rapid. If you had been told to expect these effects from the injection, what would you feel? The actual volunteers felt little emotion—because they attributed their arousal to the drug. But if you had been told the injection would produce no effects, what would you feel? Perhaps you would react as another group of participants did. They "caught" the apparent emotion of the other person in the waiting room. They became happy if the accomplice was acting euphoric, and testy if the accomplice was acting irritated.

This discovery—that a stirred-up state can be experienced as one emotion or another, depending on how we interpret and label it—has been replicated in dozens of experiments (Reisenzein, 1983; Sinclair et al., 1994; Zillmann, 1986). As researcher Daniel Gilbert (2006) has noted, “Feelings that one interprets as fear in the presence of a sheer drop may be interpreted as lust in the presence of a sheer blouse.” *The point to remember:* Arousal fuels emotion; cognition channels it.

Cognition May Not Precede Emotion: Zajonc, LeDoux, and Lazarus

But is the heart always subject to the mind? Must we *always* interpret our arousal before we can experience an emotion? Robert Zajonc [ZI-yence] (1980, 1984a) contended that we actually have many emotional reactions apart from, or even before, our interpretation of a situation. Perhaps you can recall liking something or someone immediately, without knowing why.

In earlier modules, we noted that when people repeatedly view stimuli flashed too briefly for them to interpret, they come to prefer those stimuli. Unaware of having previously seen them, they nevertheless rather like them. We have an acutely sensitive automatic radar for emotionally significant information, such that even a subliminally flashed stimulus can prime us to feel better or worse about a follow-up stimulus (Murphy et al., 1995; Zeelenberg et al., 2006). In experiments, thirsty people were given a fruit-flavored drink after viewing a subliminally flashed (thus unperceived) face. Those exposed to a happy face drank about 50 percent more than those exposed to a neutral face (Berridge & Winkielman, 2003). Those flashed an angry face drank substantially less.

Neuroscientists are charting the neural pathways of both “bottom-up” and “top-down” emotions (Ochsner et al., 2009). Our emotional responses can follow two different brain pathways. Some emotions (especially more complex feelings like hatred and love) travel a “high road.” A stimulus following this path would travel (by way of the thalamus) to the brain’s cortex (**FIGURE 41.1a**). There, it would be analyzed and labeled before the command is sent out, via the amygdala (an emotion-control center), to respond.

But sometimes our emotions (especially simple likes, dislikes, and fears) take what Joseph LeDoux (2002) has called the “low road,” a neural shortcut that bypasses the cortex. Following the low-road pathway, a fear-provoking stimulus would travel from the eye or ear (again via the thalamus) directly to the amygdala (Figure 41.1b). This shortcut, bypassing the cortex, enables our greased-lightning emotional response before our intellect intervenes. Like speedy

AP® Exam Tip

Note the connections here to previous units. This paragraph relates to the nature of consciousness. The next paragraph relates to sensation and perception.

Figure 41.1

The brain's pathways for emotions In the two-track brain, sensory input may be routed (a) to the cortex (via the thalamus) for analysis and then transmission to the amygdala; or (b) directly to the amygdala (via the thalamus) for an instant emotional reaction.

Figure 41.2**The brain's sensitivity to threats**

Even when fearful eyes (left) were flashed too briefly for people to consciously perceive them, fMRI scans revealed that their hypervigilant amygdala was alerted (Whalen et al., 2004). The eyes on the right did not have this effect.

reflexes that also operate apart from the brain's thinking cortex, the amygdala reactions are so fast that we may be unaware of what's transpired (Dimberg et al., 2000). In one fascinating experiment, researchers used fMRI scans to observe the amygdala's response to subliminally presented fearful eyes (**FIGURE 41.2**) (Whalen et al., 2004). Although they were flashed too quickly for people to consciously perceive them, the fearful eyes triggered increased amygdala activity. A control condition that presented happy eyes did not trigger this activity.

The amygdala sends more neural projections up to the cortex than it receives back, which makes it easier for our feelings to hijack our thinking than for our thinking to rule our feelings (LeDoux & Armony, 1999). Thus, in the forest, we can jump at the sound of rustling bushes nearby and leave it to our cortex to decide later whether the sound was made by a snake or by the wind. Such experiences support Zajonc's belief that *some* of our emotional reactions involve no deliberate thinking.

Emotion researcher Richard Lazarus (1991, 1998) conceded that our brain processes vast amounts of information without our conscious awareness, and that some emotional responses do not require *conscious* thinking. Much of our emotional life operates via the automatic, speedy low road. But, he asked, how would we *know* what we are reacting to if we did not in some way appraise the situation? The appraisal may be effortless and we may not be conscious of it, but it is still a mental function. To know whether a stimulus is good or bad, the brain must have some idea of what it is (Storbeck et al., 2006). Thus, said Lazarus, emotions arise when we *appraise* an event as harmless or dangerous, whether we truly *know* it is or not. We appraise the sound of the rustling bushes as the presence of a threat. Later, we realize that it was "just the wind."

So, as Zajonc and LeDoux have demonstrated, some emotional responses—especially simple likes, dislikes, and fears—involve no conscious thinking (**FIGURE 41.3**). We may fear a big spider, even if we "know" it is harmless. Such responses are difficult to alter by changing our thinking. We may automatically like one person more than another. This instant appeal can even influence our political decisions if we vote (as many people do) for a candidate we *like* over the candidate expressing positions closer to our own (Westen, 2007).

But as Lazarus, Schachter, and Singer predicted, our memories, expectations, and interpretations also influence our feelings about politics. Moreover, highly emotional people are intense partly because of their interpretations. They may *personalize* events as being somehow directed at them, and they may *generalize* their experiences by blowing single

incidents out of proportion (Larsen et al., 1987). Thus, learning to *think* more positively can help people *feel* better. Although the emotional low road functions automatically, the thinking high road allows us to retake some control over our emotional life. Together, automatic emotion and conscious thinking weave the fabric of our emotional lives. (**TABLE 41.1** summarizes these emotion theories.)

Figure 41.3**Two pathways for emotions**

Zajonc and LeDoux have emphasized that some emotional responses are immediate, before any conscious appraisal. Lazarus, Schachter, and Singer emphasized that our appraisal and labeling of events also determine our emotional responses.

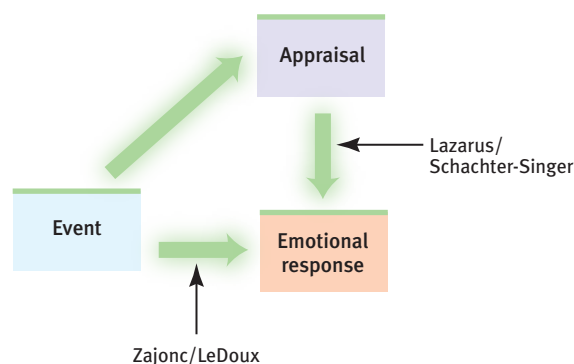

Table 41.1 Summary of Emotion Theories

Theory	Explanation of Emotions	Example
<i>James-Lange</i>	Emotions arise from our awareness of our specific bodily responses to emotion-arousing stimuli.	We observe our heart racing after a threat and then feel afraid.
<i>Cannon-Bard</i>	Emotion-arousing stimuli trigger our bodily responses and simultaneous subjective experience.	Our heart races at the same time that we feel afraid.
<i>Schachter-Singer</i>	Our experience of emotion depends on two factors: general arousal and a conscious cognitive label.	We may interpret our arousal as fear or excitement, depending on the context.
<i>Zajonc; LeDoux</i>	Some embodied responses happen instantly, without conscious appraisal.	We automatically feel startled by a sound in the forest before labeling it as a threat.
<i>Lazarus</i>	Cognitive appraisal (“Is it dangerous or not?”)—sometimes without our awareness—defines emotion.	The sound is “just the wind.”

AP® Exam Tip

Table 41.1 is an excellent summary of the theories of emotion. They are presented in the order of appearance historically. Notice that cognition, a hugely important factor in the modern theories, is not mentioned in the first two theories.

Before You Move On**▶ ASK YOURSELF**

Can you remember a time when you began to feel upset or uneasy and only later labeled those feelings?

▶ TEST YOURSELF

Christine is holding her 8-month-old baby when a fierce dog appears out of nowhere and, with teeth bared, leaps for the baby’s face. Christine immediately ducks for cover to protect the baby, screams at the dog, then notices that her heart is banging in her chest and she’s broken out in a cold sweat. How would the James-Lange, Cannon-Bard, and two-factor theories explain Christine’s emotional reaction?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Embodied Emotion

Whether you are falling in love or grieving a death, you need little convincing that emotions involve the body. Feeling without a body is like breathing without lungs. Some physical responses are easy to notice. Other emotional responses we experience without awareness.

Emotions and the Autonomic Nervous System**41-3**

What is the link between emotional arousal and the autonomic nervous system? How does arousal affect performance?

As we saw in Module 10, in a crisis, the *sympathetic division* of your *autonomic nervous system* (ANS) mobilizes your body for action, directing your adrenal glands to release the stress hormones epinephrine (adrenaline) and norepinephrine (noradrenaline)

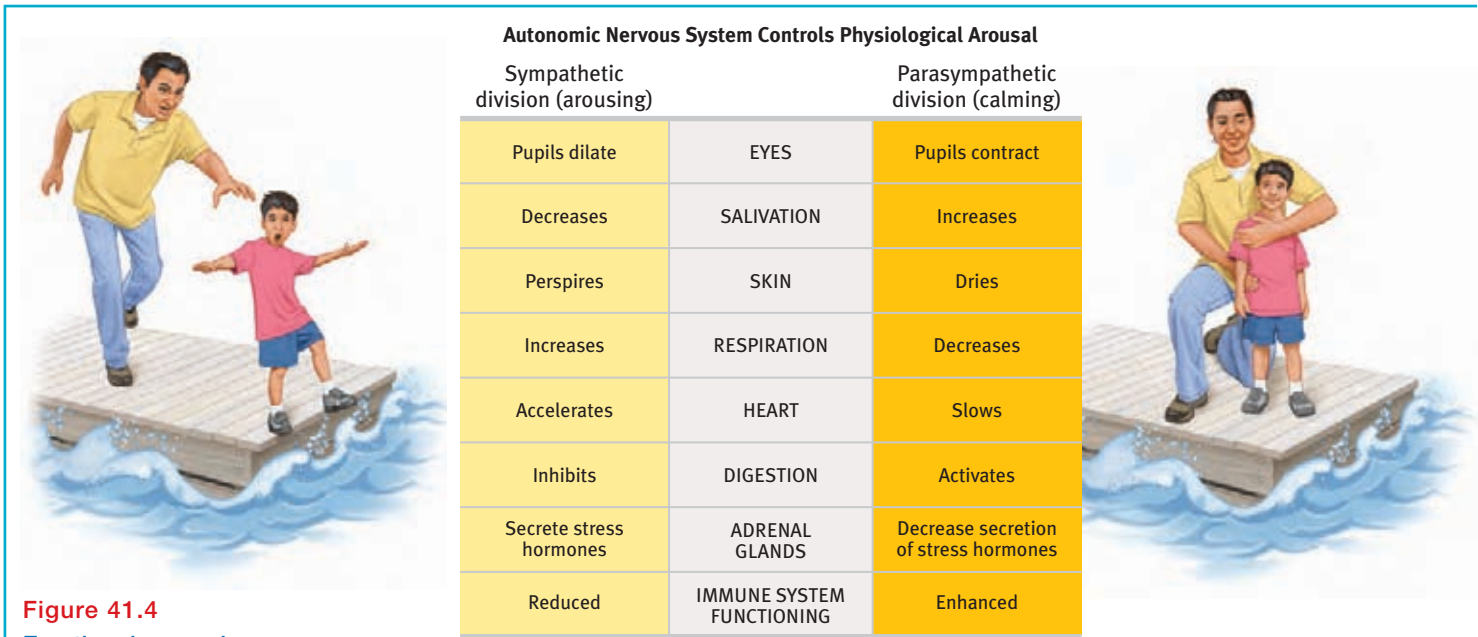

Figure 41.4

Emotional arousal Like a crisis control center, the autonomic nervous system arouses the body in a crisis and calms it when danger passes.

(**FIGURE 41.4**). To provide energy, your liver pours extra sugar into your bloodstream. To help burn the sugar, your respiration increases to supply needed oxygen. Your heart rate and blood pressure increase. Your digestion slows, diverting blood from your internal organs to your muscles. With blood sugar driven into the large muscles, running becomes easier. Your pupils dilate, letting in more light. To cool your stirred-up body, you perspire. If wounded, your blood would clot more quickly.

As we saw in Module 37, the *Yerkes-Dodson law* explains that arousal affects performance in different ways, depending on the task. When taking an exam, it pays to be moderately aroused—alert but not trembling with nervousness (**FIGURE 41.5**). But too little arousal (as when sleepy) can be disruptive, and, as we’ll see later in this unit, prolonged high arousal can tax the body.

When the crisis passes, the *parasympathetic division* of your ANS gradually calms your body, as stress hormones slowly leave your bloodstream. After your next crisis, think of this: Without any conscious effort, your body’s response to danger is wonderfully coordinated and adaptive—preparing you to *fight or flee*.

Figure 41.5

Arousal and performance

Performance peaks at lower levels of arousal for difficult tasks, and at higher levels for easy or well-learned tasks. (1) How might this phenomenon affect runners? (2) How might this phenomenon affect anxious test-takers facing a difficult exam? (3) How might the performance of anxious students be affected by relaxation training?

ANSWERS: (1) Runners tend to excel when aroused by competition. (2) High anxiety in test-takers may disrupt their performance. (3) Teaching anxious students how to relax before an exam can enable them to perform better (Hembree, 1988).

The Physiology of Emotions

41-4 Do different emotions activate different physiological and brain-pattern responses?

Imagine conducting an experiment measuring the physiological responses of emotion. In each of four rooms, you have someone watching a movie: In the first, the person is viewing a horror show; in the second, an anger-provoking film; in the third, a sexually arousing film; in the fourth, a boring film. From the control center you monitor each person's perspiration, breathing, and heart rate. Could you tell who is frightened? Who is angry? Who is sexually aroused? Who is bored?

With training, you could probably pick out the bored viewer. But discerning physiological differences among fear, anger, and sexual arousal would be much more difficult (Barrett, 2006). Different emotions do not have sharply distinct biological signatures.

Nor do they engage sharply distinct brain regions. Consider the broad emotional portfolio of the *insula*, a neural center deep inside the brain. The *insula* is activated when we experience various social emotions, such as lust, pride, and disgust. In brain scans, it becomes active when people bite into some disgusting food, smell the same disgusting food, think about biting into a disgusting cockroach, or feel moral disgust over a sleazy business exploiting a saintly widow (Sapolsky, 2010).

Nevertheless, despite their similarities, sexual arousal, fear, anger, and disgust *feel* different to you and me, and they often *look* different to others. We may appear “paralyzed with fear” or “ready to explode.” Research has pinpointed some real, though subtle, physiological distinctions and brain-pattern distinctions among the emotions. For example, the finger temperatures and hormone secretions that accompany fear and rage do sometimes differ (Ax, 1953; Levenson, 1992). Fear and joy, although they prompt similar increased heart rate, stimulate different facial muscles. During fear, your brow muscles tense. During joy, muscles in your cheeks and under your eyes pull into a smile (Witvliet & Vrana, 1995).

Some emotions also differ in their brain circuits (Panksepp, 2007). Compared with observers watching angry faces, those watching (and subtly mimicking) fearful faces show more activity in their amygdala (Whalen et al., 2001). Brain scans and EEG recordings show that emotions also activate different areas of the brain's cortex. When you experience negative emotions such as disgust, your right prefrontal cortex tends to be more active than the left. Depression-prone people, and those with generally negative personalities, also show more right frontal lobe activity (Harmon-Jones et al., 2002).

Positive moods tend to trigger more left frontal lobe activity. People with positive personalities—exuberant infants and alert, enthusiastic, energized, and persistently goal-directed adults—also show more activity in the left frontal lobe than in the right (Davidson, 2000, 2003; Urry et al., 2004). Indeed, the more a person's baseline frontal lobe activity tilts left—or is made to tilt left by perceptual activity—the more upbeat the person typically is (Drake & Myers, 2006).

To sum up, we can't easily see differences in emotions from tracking heart rate, breathing, and perspiration. But facial expressions and brain activity can vary with the emotion. So, do we, like Pinocchio, give off telltale signs when we lie? For more on that question, see Thinking Critically About: Lie Detection.

Emotional arousal
Elated excitement and panicky fear involve similar physiological arousal. That allows us to flip rapidly between the two emotions.

FotoStarcook/Alamy

“No one ever told me that grief felt so much like fear. I am not afraid, but the sensation is like being afraid. The same fluttering in the stomach, the same restlessness, the yawning. I keep on swallowing.” -C. S. LEWIS, *A GRIEF OBSERVED*, 1961

FYI

In 1966, a young man named Charles Whitman killed his wife and mother and then climbed to the top of a tower at the University of Texas and shot 38 people. An autopsy later revealed a tumor pressing against his amygdala, which may have contributed to his violence.

Thinking Critically About

Lie Detection

DreamPictures/Getty Images

Can polygraph tests like this identify liars? To learn more, read on.

41-5 How effective are polygraphs in using body states to detect lies?

Can a *lie detector*—a **polygraph**—reveal lies? Polygraphs don't literally detect lies. Instead, they measure emotion-linked changes in breathing, cardiovascular activity, and perspiration. If you were taking this test, an examiner would monitor these responses as you answered questions. She might ask, "In the last 20 years, have you ever taken something that didn't belong to you?" This item is a control question, aimed at making everyone a little nervous. If you lie and say "No!" (as many people do) the polygraph will detect arousal. This response will establish a baseline, a useful comparison for your responses to *critical questions* ("Did you ever steal anything from your previous employer?"). If your responses to critical questions are weaker than to control questions, the examiner will infer you are telling the truth.

Critics point out two problems: First, our physiological arousal is much the same from one emotion to another. Anxiety, irritation, and guilt all prompt similar physiological reactivity. Second, many innocent people do respond with heightened tension to the accusations implied by the critical questions (**FIGURE 41.6**). Many rape victims, for example, "fail" these tests when reacting emotionally but truthfully (Lykken, 1991).

polygraph a machine, commonly used in attempts to detect lies, that measures several of the physiological responses (such as perspiration and cardiovascular and breathing changes) accompanying emotion.

A 2002 U.S. National Academy of Sciences report noted that "no spy has ever been caught [by] using the polygraph." It is not for lack of trying. The FBI, CIA, and Departments of Defense and Energy in the United States have tested tens of thousands of employees, and polygraph use in Europe has also increased (Meijer & Verschuere, 2010). Meanwhile Aldrich Ames, a Russian spy within the CIA, went undetected. Ames took many "polygraph tests and passed them all," noted Robert Park (1999). "Nobody thought to investigate the source of his sudden wealth—after all, he was passing the lie detector tests."

A more effective approach to lie detection uses a *guilty knowledge test*, which also assesses a suspect's physiological responses to crime-scene details known only to the police and the guilty person (Ben-Shakhar & Elaad, 2003). If a camera and computer had been stolen, for example, only a guilty person should react strongly to the brand names of the stolen items. Given enough such specific probes, an innocent person will seldom be wrongly accused.

Research teams are now exploring new ways to nab liars. Psychologist Paul Ekman (2003) has done research (and has trained law enforcement officers) in detecting fleeting signals of deceit in facial expressions. Eyeblinks, for example, decrease during the cognitive demands of lying and increase afterward (Leal & Vrij, 2008). Other researchers are developing software that analyzes facial microexpressions (Adelson, 2004; Newman et al., 2003) or compares the language of truth-tellers and of liars (who use fewer first-person pronouns and more negative-emotion words).

"Forensic neuroscience" researchers are going straight to the seat of deceit—the brain. EEG recordings have revealed brain waves that indicate familiarity with crime information. fMRI scans have shown liars' brains activating in places that honest people's brains do not (Langleben et al., 2006, 2008; Lui & Rosenfeld, 2009). Pinocchio's giveaway signal of lying may be not the length of his nose, but rather the telltale activity in places such as his left frontal lobe and anterior cingulate cortex, which become active when the brain inhibits truth telling. A new U.S. \$10 million Law and Neuroscience Project, led by psychologist Michael Gazzaniga, aims to assess appropriate uses of the new technology in identifying terrorists, convicting criminals, and protecting the

Thinking Critically About *(continued)*

innocent. In 2010, a U.S. federal court declared that fMRI lie detection is not yet ready for courtroom use (Miller, 2010). Many neuroscientists concur (Gazzaniga, 2011; Wagner, 2010). Others argue that jurors' and judges' seat-of-the-pants judgments "are worse than the science that is excluded" (Schauer, 2010).

Figure 41.6 How often do lie detection tests lie? In one study, polygraph experts interpreted the polygraph data of 100 people who had been suspects in theft crimes (Kleinmuntz & Szucko, 1984). Half the suspects were guilty and had confessed; the other half had been proven innocent. Had the polygraph experts been the judges, more than one-third of the innocent would have been declared guilty, and one-fourth of the guilty would have been declared innocent.

Before You Move On**▶ ASK YOURSELF**

Can you think of a recent time when you noticed your body's reactions to an emotionally charged situation, such as a difficult social setting or perhaps even a test or game you were worrying about in advance? Did you perceive the situation as a challenge or a threat? How well did you do?

▶ TEST YOURSELF

How do the two divisions of the autonomic nervous system affect our emotional responses?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 41 Review

41-1 How do arousal and expressive behaviors interact in emotion?

- *Emotions* are psychological responses of the whole organism involving an interplay among physiological arousal, expressive behaviors, and conscious experience.
- Theories of emotion generally address two major questions: (1) Does physiological arousal come before, after, or at the same time as emotional feelings, and (2) how do cognition and feeling interact?
- The *James-Lange theory* maintains that emotional feelings follow our body's response to emotion-inducing stimuli.
- The *Cannon-Bard theory* proposes that our body responds to emotion at the same time that we experience the emotion (one does not cause the other).

41-2 To experience emotions, must we consciously interpret and label them?

- The Schachter-Singer *two-factor theory* holds that our emotions have two ingredients, physical arousal and a cognitive label, and the cognitive labels we put on our states of arousal are an essential ingredient of emotion.
- Lazarus agreed that many important emotions arise from our interpretations or inferences.
- Zajonc and LeDoux, however, believe that some simple emotional responses occur instantly, not only outside our conscious awareness, but before any cognitive processing occurs. This interplay between emotion and cognition illustrates our dual-track mind.

41-3 What is the link between emotional arousal and the autonomic nervous system? How does arousal affect performance?

- The arousal component of emotion is regulated by the autonomic nervous system's sympathetic (arousing) and parasympathetic (calming) divisions.
- Performance peaks at lower levels of arousal for difficult tasks, and at higher levels for easy or well-learned tasks.

41-4 Do different emotions activate different physiological and brain-pattern responses?

- Emotions may be similarly arousing, but some subtle physiological responses, such as facial muscle movements, distinguish them.
- More meaningful differences have been found in activity in some brain pathways and cortical areas and in the hormone secretions associated with different emotions.

41-5 How effective are polygraphs in using body states to detect lies?

- *Polygraphs*, which measure several physiological indicators of emotion, are not accurate enough to justify widespread use in business and law enforcement. The use of guilty knowledge questions and new forms of technology may produce better indications of lying.

Multiple-Choice Questions

1. One night Samar became frightened when she was startled by a noise while walking down the street alone. Which theory of emotion would say that her fear resulted from the startle response alone?
 - a. James-Lange
 - b. Cannon-Bard
 - c. Two-factor
 - d. Lazarus
 - e. Schachter-Singer
2. The Cannon-Bard theory of emotion states that
 - a. emotional response occurs before cognition.
 - b. physiological response occurs before emotional response.
 - c. emotional response occurs before physiological response.
 - d. cognition occurs before emotional response.
 - e. physiological response and emotion occur independently and simultaneously.

- 3.** Which of the following is an example of cognitive appraisal?
- Randal is happy all day because he is savoring the wonderful events of yesterday.
 - Charles is frightened in a dark alley because he remembers stories of others being attacked in dark alleys.
 - Sherika labels the arousal she is feeling as attraction because she is in the presence of a good-looking young man.
 - Dora is angry because she cannot figure out how to convince her husband to take her to Hawaii.
 - Ann is frustrated because traffic has made her late for an important meeting.
- 4.** Which of the following characterizes the “low road” neural pathway to emotions?
- Information travels directly from the thalamus to the amygdala.
 - The emotion results more slowly than it would via the “high road.”
 - It is an example of top-down processing.
 - It is more likely to be utilized for complex feelings.
 - It passes through the brain’s cortex.

Practice FRQs

- 1.** Explain the role of conscious thinking in emotion according to the theory that some emotions take the high road while others take the low road.

Answer

1 point: The high-road theory argues that conscious thinking occurs before the emotion.

1 point: The low-road theory argues that conscious awareness does not occur until after the emotional response.

- 2.** Lynn’s boyfriend has not replied to her last three text messages. Lynn is experiencing anger, increased blood pressure, and rapid breathing. Analyze this situation using both the James-Lange and the Cannon-Bard theories of emotion.

(2 points)

Module 42

Expressed Emotion

Module Learning Objectives

- 42-1** Describe our ability to communicate nonverbally, and discuss gender differences in this capacity.
- 42-2** Discuss the culture-specific and culturally universal aspects of nonverbal expressions of emotion.
- 42-3** Describe how facial expressions influence our feelings.

“Your face, my thane, is a book where men may read strange matters.” -LADY MACBETH TO HER HUSBAND, IN WILLIAM SHAKESPEARE’S *MACBETH*

FYI

To learn more about our experienced emotions of anger and happiness, see Module 83.

Expressive behavior implies emotion. Dolphins, with smiles seemingly plastered on their faces, appear happy. To decipher people’s emotions we read their bodies, listen to their voice tones, and study their faces. Does nonverbal language vary with culture—or is it universal? And do our expressions influence our experienced emotions?

Detecting Emotion in Others

- 42-1** How do we communicate nonverbally? How do the genders differ in this capacity?

To Westerners, a firm handshake conveys an outgoing, expressive personality (Chaplin et al., 2000). A gaze, an averted glance, or a stare communicate intimacy, submission, or dominance (Kleinke, 1986). When two people are passionately in love, they typically spend time—quite a bit of time—gazing into each other’s eyes (Rubin, 1970). Would such gazes stir these feelings between strangers? To find out, researchers asked unacquainted male-female

pairs to gaze intently for two minutes either at each other’s hands or into each other’s eyes. After separating, the eye gazers reported feeling a tingle of attraction and affection (Kellerman et al., 1989).

Most of us read nonverbal cues well. Shown 10 seconds of video from the end of a speed-dating interaction, people can often detect whether one person is attracted to another (Place et al., 2009). We are especially good at detecting nonverbal threats. In a series of subliminally flashed words, we more often sense the presence of negative ones, such as *snake* or *bomb* (Dijksterhuis & Aarts, 2003). In a crowd of faces, a single angry face “pops out” faster than a single happy one (Hansen & Hansen, 1988; Pinkham et al., 2010). And even when hearing another language, most of us readily detect anger (Scherer et al., 2001).

A silent language of emotion Hindu classic dance uses the face and body to effectively convey 10 different emotions (Hejmadi et al., 2000).

Pollak, S.D., and Kistler, D.J. (2002). *Proceedings of the National Academy of Sciences USA*, 99: 13, 9072–9076.

Figure 42.1
Experience influences how we perceive emotions

Viewing the morphed middle face, evenly mixing fear with anger, physically abused children were more likely than nonabused children to perceive the face as angry (Pollak & Kistler, 2002; Pollak & Tolley-Schell, 2003).

Experience can sensitize us to particular emotions, as shown by experiments using a series of faces (like those in **FIGURE 42.1**) that morph from fear (or sadness) to anger. Viewing such faces, physically abused children are much quicker than other children to spot the signals of anger. Shown a face that is 60 percent fear and 40 percent anger, they are as likely to perceive anger as fear. Their perceptions become sensitively attuned to glimmers of danger that nonabused children miss.

Hard-to-control facial muscles reveal signs of emotions you may be trying to conceal. Lifting just the inner part of your eyebrows, which few people do consciously, reveals distress or worry. Eyebrows raised and pulled together signal fear. Activated muscles under the eyes and raised cheeks suggest a natural smile, called a *Duchenne smile* in honor of the French physician who described it. A feigned smile, such as one we make for a photographer, often is frozen in place for several seconds, then suddenly switched off. Authentic smiles tend to be briefer and to fade less abruptly (Bugental, 1986).

Our brains are rather amazing detectors of subtle expressions. Just *how* amazing was clear when researchers filmed teachers talking to unseen schoolchildren (Babad et al., 1991). A mere 10-second clip of either the teacher’s voice or face provided enough clues for both young and old viewers to determine whether the teacher liked and admired a child. In other experiments, even glimpsing a face for one-tenth of a second enabled people to judge people’s attractiveness or trustworthiness or to rate politicians’ competence and predict their voter support (Willis & Todorov, 2006). “First impressions . . . occur with astonishing speed,” note Christopher Olivola and Alexander Todorov (2010).

Despite our brain’s emotion-detecting skill, we find it difficult to detect deceiving expressions (Porter & ten Brinke, 2008). In one digest of 206 studies of discerning truth from lies, people were just 54 percent accurate—barely better than a coin toss (Bond & DePaulo, 2006). Moreover, contrary to claims that some experts can spot lies, the available research indicates that virtually no one—save perhaps police professionals in high-stakes situations—beats chance by much (Bond & DePaulo, 2008; O’Sullivan et al., 2009). The behavioral differences between liars and truth-tellers are too minute for most people to detect (Hartwig & Bond, 2011).

Some of us are, however, more sensitive than others to physical cues. In one study, hundreds of people were asked to name the emotion in brief film clips they watched. The clips showed portions of a person’s emotionally expressive face or body, sometimes accompanied by a garbled voice (Rosenthal et al., 1979). For example, after a 2-second scene revealing only the face of an upset woman, the researchers would ask whether the woman was criticizing someone for being late or was talking about her divorce. Given such “thin slices,” some people were much better emotion detectors than others. Introverts tend to excel at reading others’ emotions, while extraverts are generally easier to read (Ambady et al., 1995).

Gestures, facial expressions, and voice tones, which are absent in written communication, convey important information. Those who listen to 30 seconds of people describing their marital separation can better predict their current and future adjustment than can those who read a script of the recording (Mason et al., 2010). Electronic communications provide impoverished nonverbal cues. To partly remedy that, we sometimes accompany our text messages, e-mails, and online posts with emotion cues (ROFL!). The absence of expressive e-motion

Paul Ekman

Which of researcher Paul Ekman’s smiles is feigned, which natural? The smile on the right engages the facial muscles of a natural smile.

can make for ambiguous emotion. Without the vocal nuances that signal whether a statement is serious, kidding, or sarcastic, we are in danger of communicating our own egocentrism, as people misinterpret our “just kidding” message (Kruger et al., 2005).

Gender, Emotion, and Nonverbal Behavior

Is women’s intuition, as so many believe, superior to men’s? After analyzing 125 studies of sensitivity to nonverbal cues, Judith Hall (1984, 1987) concluded that women generally do surpass men at reading people’s emotional cues when given “thin slices” of behavior. Women have also surpassed men in other assessments of emotional cues, such as deciding whether a male-female couple is a genuine romantic couple or a posed phony couple, and in discerning which of two people in a photo is the other’s supervisor (Barnes & Sternberg, 1989).

Women’s nonverbal sensitivity helps explain their greater emotional literacy. Invited by Lisa Feldman Barrett and her colleagues (2000) to describe how they would feel in certain situations, men described simpler emotional reactions. You might like to try this yourself: Ask some people how they might feel when saying good-bye to friends after graduation. Barrett’s work suggests you are more likely to hear young men say, simply, “I’ll feel bad,” and to hear young women express more complex emotions: “It will be bittersweet; I’ll feel both happy and sad.”

Women’s skill at decoding others’ emotions may also contribute to their greater emotional responsiveness (Vigil, 2009). In studies of 23,000 people from 26 cultures around the world, women more than men reported themselves open to feelings (Costa et al., 2001). That helps explain the extremely strong perception that emotionality is “more true of women”—a perception expressed by nearly 100 percent of 18- to 29-year-old Americans (Newport, 2001). But the perception of women’s emotionality also feeds—and is fed by—people’s attributing women’s emotionality to their disposition and men’s to their circumstances: “She’s emotional. He’s having a bad day” (Barrett & Bliss-Moreau, 2009).

One exception: Anger strikes most people as a more masculine emotion. Quickly: Imagine an angry face. What gender is the person? If you’re like 3 in 4 Arizona State University students, you imagined a male (Becker et al., 2007). The researchers also found that when a gender-neutral face was made to look angry, most people perceived it as male. If the face was smiling, they were more likely to perceive it as female (**FIGURE 42.2**).

When surveyed, women are also far more likely than men to describe themselves as empathic. If you have *empathy*, you identify with others and imagine what it must be like to walk in their shoes. You rejoice with those who rejoice and weep with those who weep. Children and adults who skillfully infer others’ thoughts and feelings tend to enjoy positive peer relationships (Gleason et al., 2009).

Images.com/Corbis

Obvious emotions Graphic novel authors use facial expressions and other design elements to express emotion, reducing the need to explain how the characters are feeling.

Figure 42.2

Male or female? Researchers manipulated a gender-neutral face. People were more likely to see it as a male when it wore an angry expression, and as a female when it wore a smile (Becker et al., 2007).

©APA/Vaughn Becker

Physiological measures of empathy, such as one's heart rate while seeing another's distress, confirm a gender gap, though a smaller one than is indicated in survey self-reports (Eisenberg & Lennon, 1983; Rueckert et al., 2010). Females are also more likely to *express* empathy—to cry and to report distress when observing someone in distress. As **FIGURE 42.3** shows, this gender difference was clear in videotapes of male and female students watching film clips that were sad (children with a dying parent), happy (slapstick comedy), or frightening (a man nearly falling off the ledge of a tall building) (Kring & Gordon, 1998). Women also tend to experience emotional events, such as viewing pictures of mutilation, more deeply, with more brain activation in areas sensitive to emotion. And they are better at remembering the scenes three weeks later (Canli et al., 2002).

Figure 42.3
Gender and expressiveness

Male and female film viewers did not differ dramatically in self-reported emotions or physiological responses. But the women's faces *showed* much more emotion. (From Kring & Gordon, 1998.)

Culture and Emotional Expression

42-2 How are nonverbal expressions of emotion understood within and across cultures?

The meaning of *gestures* varies with the culture. Former U.S. President Richard Nixon learned this while traveling in Brazil; he made the North American “A-OK” sign, not realizing it was a crude insult to Brazilians. The importance of cultural definitions of gestures and other body language was again demonstrated in 1968, when North Korea publicized photos of supposedly happy officers from a captured U.S. Navy spy ship. In the photo, three men had raised their middle finger, telling their captors it was a “Hawaiian good luck sign” (Fleming & Scott, 1991).

Do facial expressions also have different meanings in different cultures? To find out, two investigative teams showed photographs of various facial expressions to people in different parts of the world and asked them to guess the emotion (Ekman et al., 1975, 1987, 1994; Izard, 1977, 1994). You can try this matching task yourself by pairing the six faces with the six faces of **FIGURE 42.4**.

1988 Matsumoto, Japanese & Caucasian Facial Expression of Emotion

Figure 42.4
Culture-specific or culturally universal expressions?

As people of differing cultures and races, do our faces speak differing languages? Which face expresses disgust? Anger? Fear? Happiness? Sadness? Surprise? (From Matsumoto & Ekman, 1989.) See inverted answers below.

From left to right, top to bottom:
happiness, surprise, fear, sadness,
anger, disgust.

Regardless of your cultural background, you probably did pretty well. A smile's a smile the world around. Ditto for anger, and to a lesser extent the other basic expressions (Elfenbein & Ambady, 1999). (There is no culture where people frown when they are happy.)

Facial expressions do convey some nonverbal accents that provide clues to one's culture (Marsh et al., 2003). Thus data from 182 studies show slightly enhanced accuracy when people judge emotions from their own culture (Elfenbein & Ambady, 2002, 2003a,b). Still, the telltale signs of emotion generally cross cultures. The world over, children cry when distressed, shake their heads when defiant, and smile when they are happy. So, too, with blind children who have never seen a face (Eibl-Eibesfeldt, 1971). People blind from birth spontaneously exhibit the common facial expressions associated with such emotions as joy, sadness, fear, and anger (Galati et al., 1997).

"For news of the heart, ask the face." -GUINEAN PROVERB

Musical expressions also cross cultures. Happy and sad music feels happy and sad around the world. Whether you live in an African village or a European city, fast-paced music seems happy, and slow-paced music seems sadder (Fritz et al., 2009).

Do these shared emotional categories reflect shared cultural experiences, such as movies and TV broadcasts seen around the world? Apparently not. Paul Ekman and his team asked isolated people in New Guinea to respond to such statements as, "Pretend your child has died." When North American collegians viewed the taped responses, they easily read the New Guineans' facial reactions.

So we can say that facial muscles speak a universal language. This discovery would not have surprised Charles Darwin (1809–1882) who argued that in prehistoric times, before our ancestors communicated in words, they communicated threats, greetings, and submission with facial expressions. Their shared expressions helped them survive (Hess & Thibault, 2009). A sneer, for example, retains elements of an animal baring its teeth in a snarl. Emotional expressions may enhance our survival in other ways, too. Surprise raises the eyebrows and widens the eyes, enabling us to take in more information. Disgust wrinkles the nose, closing it from foul odors.

FYI

While weightless, astronauts' internal bodily fluids move toward their upper body and their faces become puffy. This makes nonverbal communication more difficult, especially among multinational crews (Gelman, 1989).

Smiles are social as well as emotional events. Bowlers seldom smile when they score a strike; they smile when they turn to face their companions (Jones et al., 1991; Kraut & Johnston, 1979). Euphoric Olympic gold-medal winners typically don't smile when they are awaiting their ceremony. But they wear broad grins when interacting with officials and facing the crowd and cameras (Fernández-Dols & Ruiz-Belda, 1995). Thus, a glimpse at competitors' spontaneous expressions following an Olympic judo competition gives a very good clue to who won, no matter their country (Matsumoto et al., 2006). Even natively blind athletes, who have never observed smiles, display the same social smiles in such situations (Matsumoto & Willingham, 2009).

Although we share a universal facial language, it has been adaptive for us to interpret faces in particular contexts (**FIGURE 42.5**). People judge an angry face set in a frightening situation as afraid. They judge a fearful face set in a painful situation as pained (Carroll & Russell, 1996). Movie directors harness this phenomenon by creating contexts and soundtracks that amplify our perceptions of particular emotions.

Although cultures share a universal facial language for basic emotions, they differ in how *much* emotion they express. Those that encourage individuality, as in Western Europe, Australia, New Zealand, and North America, display mostly visible emotions (van Hemert et al., 2007). Those that encourage people to adjust to others, as in China, tend to have less visible displays of personal emotions (Matsumoto et al., 2009; Tsai et al., 2007). In Japan, people infer emotion more from the surrounding context. Moreover, the mouth, which is so expressive in North Americans, conveys less emotion than do the telltale eyes (Masuda et al., 2008; Yuki et al., 2007).

Cultural differences also exist *within* nations. The Irish and their Irish-American descendants tend to be more expressive than Scandinavians and their Scandinavian-

Angry, Disgusted, or Afraid?: Studies on the Malleability of Emotion Perception; Hillel Aviezer, Ran R. Hassin, Jennifer Ryan, Cheryl Grady, Josh Susskind, Adam Anderson, Morris Moscovitch, Shlomo Benin

R.R. Provine, Emotional tears and NGF: A biographical appreciation and research beginning; Archives Italiennes de Biologie, 149, 271–276.

Figure 42.5

We read faces in context

Whether we perceive the man in the top row as disgusted or angry depends on which body his face appears on (Aviezer et al., 2008). In the second row, tears on a face make its expression seem sadder (Provine et al., 2009).

American descendants (Tsai & Chentsova-Dutton, 2003). And that reminds us of a familiar lesson: Like most psychological events, emotion is best understood not only as a biological and cognitive phenomenon, but also as a social-cultural phenomenon.

The Effects of Facial Expressions

42-3 How do our facial expressions influence our feelings?

As William James (1890) struggled with feelings of depression and grief, he came to believe that we can control emotions by going “through the outward movements” of any emotion we want to experience. “To feel cheerful,” he advised, “sit up cheerfully, look around cheerfully, and act as if cheerfulness were already there.”

Studies of the emotional effects of facial expressions reveal precisely what James might have predicted. Expressions not only communicate emotion, they also amplify and regulate it. In *The Expression of the Emotions in Man and Animals*, Charles Darwin (1872) contended that “the free expression by outward signs of an emotion intensifies it. . . . He who gives way to violent gestures will increase his rage.”

Was Darwin right? You can test his hypothesis: Fake a big grin. Now scowl. Can you feel the “smile therapy” difference? Participants in dozens of experiments have felt a difference. For example, James Laird and his colleagues (1974, 1984, 1989) subtly induced students to make a frowning expression by asking them to “contract these muscles” and “pull your brows together” (supposedly to help the researchers attach facial electrodes). The results? The students reported feeling a little angry. So, too, for other basic emotions. For example, people reported feeling more fear than anger, disgust, or sadness when made to construct a fearful expression: “Raise your eyebrows. And open your eyes wide. Move your whole head back, so that your chin is tucked in a little bit, and let your mouth relax and hang open a little” (Duclos et al., 1989).

“Whenever I feel afraid
I hold my head erect
And whistle a happy tune.”
—RICHARD RODGERS AND OSCAR
HAMMERSTEIN, *THE KING AND I*, 1958

facial feedback effect

the tendency of facial muscle states to trigger corresponding feelings such as fear, anger, or happiness.

This **facial feedback effect** has been repeated many times, in many places, for many basic emotions (**FIGURE 42.6**). Just activating one of the smiling muscles by holding a pen in the teeth (rather than with the lips, which activates a frowning muscle) is enough to make cartoons seem more amusing (Strack et al., 1988). A heartier smile—made not just with the mouth but with raised cheeks that crinkle the eyes—enhances positive feelings even more when you are reacting to something pleasant or funny (Soussignan, 2001). Smile warmly on the outside and you feel better on the inside. When smiling, you will even more quickly understand sentences that describe pleasant events (Havas et al., 2007). Scowl and the whole world seems to scowl back.

So your face is more than a billboard that displays your feelings; it also feeds your feelings. No wonder depressed patients reportedly feel better after between-the-eyebrows Botox injections that paralyze the frowning muscles (Finzi & Wasserman, 2006). Two months after the treatment, 9 of the 10 nonfrowning patients given this treatment were no longer depressed. Follow-up studies have found that Botox paralysis of the frowning muscles slows people's reading of sadness or anger-related sentences, and it slows activity in emotion-related brain circuits (Havas et al., 2010; Hennenlotter et al., 2008). In such ways, Botox smooths life's emotional wrinkles.

Other researchers have observed a similar *behavior feedback* phenomenon (Snodgrass et al., 1986). You can duplicate the participants' experience: Walk for a few minutes with short, shuffling steps, keeping your eyes downcast. Now walk around taking long strides, with your arms swinging and your eyes looking straight ahead. Can you feel your mood shift? Going through the motions awakens the emotions.

Likewise, people perceive ambiguous behaviors differently depending on which finger they move up and down while reading a story. (This was said to be a study of the effect of using finger muscles "located near the reading muscles on the motor cortex.") If participants read the story while moving an extended middle finger, the story behaviors seemed more hostile. If read with a thumb up, they seemed more positive. Hostile gestures prime hostile perceptions (Chandler & Schwarz, 2009; Goldin-Meadow & Beilock, 2010).

You can use your understanding of feedback effects to become more empathic: Let your own face mimic another person's expression. Acting as another acts helps us feel what another feels (Vaughn & Lanzetta, 1981). Indeed, natural mimicry of others' emotions helps explain why emotions are contagious (Dimberg et al., 2000; Neumann & Strack, 2000). Primates also ape one another, and such synchronized expressions help bond them (and us) together (de Waal, 2009). One social worker with Moebius syndrome, a rare facial paralysis disorder, struggled to make emotional connections with Hurricane Katrina refugees. When people made a sad expression, "I wasn't able to return it. I tried to do so with words and tone of voice, but it was no use. Stripped of the facial expression, the emotion just dies there, unshared" (Carey, 2010).

Figure 42.6**How to make people smile without telling them to smile**

Do as Kazuo Mori and Hideko Mori (2009) did with students in Japan: Attach rubber bands to the sides of the face with adhesive bandages, and then run them either over the head or under the chin. (1) Based on the facial feedback effect, how might students report feeling when the rubber bands raise their cheeks as though in a smile? (2) How might students report feeling when the rubber bands pull their cheeks downward?

ANSWERS: (1) Most students report feeling more happy than sad when their cheeks are raised upward. (2) Most students report feeling more sad than happy when their cheeks are pulled downward.

* * *

How do our emotions, personality, attitudes, and behaviors influence our risk of disease? What can we do to prevent illness and promote health? To study how stress and healthy and unhealthy behaviors influence health and illness, psychologists and physicians created the interdisciplinary field of *behavioral medicine*, integrating behavioral and medical knowledge. **Health psychology** provides psychology's contribution to behavioral medicine. Let's consider some of psychology's findings on stress and ways of coping with it.

health psychology a subfield of psychology that provides psychology's contribution to behavioral medicine.

Before You Move On

▶ ASK YOURSELF

Can you think of one situation in which you would like to change the way you feel, and create a simple plan for doing so? For instance, if you would like to feel more cheerful on your way to class tomorrow morning rather than dragging yourself there, you might try walking briskly—with head held high and a pleasant expression on your face.

▶ TEST YOURSELF

Who tends to express more emotion—men or women? How do we know the answer to that question?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 42 Review

42-1 How do we communicate nonverbally? How do the genders differ in this capacity?

- Much of our communication is through body movements, facial expressions, and voice tones. Even seconds-long filmed slices of behavior can reveal feelings.
- Women tend to read emotional cues more easily and to be more empathic.

42-2 How are nonverbal expressions of emotion understood within and across cultures?

- The meaning of gestures varies with culture, but facial expressions, such as those of happiness and fear, are common the world over.
- Cultures also differ in the amount of emotion they express.

42-3 How do our facial expressions influence our feelings?

- Research on the *facial feedback effect* shows that our facial expressions can trigger emotional feelings and signal our body to respond accordingly.
- We also mimic others' expressions, which helps us empathize.

Multiple-Choice Questions

1. What do we call the tendency of facial muscle states to trigger corresponding feelings such as fear, anger, or happiness?
 - a. Culture-specific expression
 - b. Moebius syndrome
 - c. Botox
 - d. Facial feedback effect
 - e. Culturally universal expression
2. Which of the following statements is most accurate regarding emotion?
 - a. Smiles are neither social nor emotional events.
 - b. Inhabitants of individualist countries are more likely to display nonverbal emotions than inhabitants of collectivist countries.
 - c. Mouths convey more emotion than eyes.
 - d. Natively blind people who have never seen a smile will never generate a smile.
 - e. Cultures share a universal facial language for basic emotions.
3. Which subfield of psychology provides psychology's contribution to behavioral medicine?
 - a. Cognitive
 - b. Health
 - c. Clinical
 - d. Educational
 - e. Community

Practice FRQs

1. Name the phenomenon describing the impact facial expressions can have on our disposition, and give an example.
2. Name four pieces of evidence that suggest women are more empathic than men.

(4 points)

Answer

1 point: The facial feedback effect.

1 point: For example, smiling makes you feel happy and frowning makes you feel a little angry.

Module 43

Stress and Health

Module Learning Objective

- 43-1** Identify events that provoke stress responses, and describe how we respond and adapt to stress.

How often do you experience stress in your daily life? Never? Rarely? Sometimes? Or frequently? When pollsters put a similar question to college students, some 85 percent recalled experiencing stress during the last three months—and most said it had disrupted their schoolwork at least once (AP, 2009). On entering college or university, 18 percent of men and 41 percent of women reported having been “frequently overwhelmed” by all they had to do during the past year (Pryor et al., 2012).

For many students, the high school years, with their new relationships and more demanding challenges, prove stressful. Deadlines become relentless and intense at the end of each term. The time demands of volunteering, sports, music and theater, work, college prep courses, and college applications combine with occasional family tensions and success pressures. Sometimes it’s enough to give you a headache or disrupt sleep.

Stress often strikes without warning. Imagine being 21-year-old Ben Carpenter on the world’s wildest and fastest wheelchair ride. As he crossed an intersection on a sunny summer afternoon in 2007, the light changed. A large truck, whose driver didn’t see him, started moving into the intersection. As they bumped, Ben’s wheelchair turned to face forward, and its handles got stuck in the truck’s grille. Off they went, the driver unable to hear Ben’s cries for help. As they sped down the highway about an hour from my home, passing motorists caught the bizarre sight of a truck pushing a wheelchair at 50 miles per hour and started calling 911. (The first caller: “You are not going to believe this. There is a semi truck pushing a guy in a wheelchair on Red Arrow highway!”) Lucky for Ben, one passerby was an undercover police officer. Pulling a quick U-turn, he followed the truck to its destination a couple of miles from where the wild ride had started, and informed the disbelieving driver that he had a passenger hooked in his grille. “It was very scary,” said Ben, who has muscular dystrophy. In this section, we explore stress—what it is and how it affects us.

FYI

In Module 84, we take a close look at some ways we can reduce the stress in our lives, so that we can flourish in both body and mind.

Extreme stress Ben Carpenter experienced the wildest of rides after his wheelchair got stuck in a truck’s grille.

Stress: Some Basic Concepts

43-1

What events provoke stress responses, and how do we respond and adapt to stress?

stress the process by which we perceive and respond to certain events, called *stressors*, that we appraise as threatening or challenging.

Stress is a slippery concept. We sometimes use the word informally to describe threats or challenges (“Ben was under a lot of stress”), and at other times our responses (“Ben experienced acute stress”). To a psychologist, the dangerous truck ride was a *stressor*. Ben’s physical and emotional responses were a *stress reaction*. And the process by which he related to the threat was *stress*. Thus, **stress** is the process of appraising and responding to a threatening or challenging event (**FIGURE 43.1**). Stress arises less from events themselves than from how we appraise them (Lazarus, 1998). One person, alone in a house, ignores its creaking sounds and experiences no stress; someone else suspects an intruder and becomes alarmed. One person regards a new job as a welcome challenge; someone else appraises it as risking failure.

When short-lived, or when perceived as challenges, stressors can have positive effects. A momentary stress can mobilize the immune system for fending off infections and healing wounds (Segerstrom, 2007). Stress also arouses and motivates us to conquer problems. In a Gallup World Poll, those who were stressed but not depressed reported being energized and satisfied with their lives—the opposite of the lethargy of those depressed but not stressed (Ng et al., 2009). Championship athletes, successful entertainers, and great teachers and leaders all thrive and excel when aroused by a challenge (Blascovich et al., 2004). Having conquered cancer or rebounded from a lost job, some people emerge with stronger self-esteem and a deepened spirituality and sense of purpose. Indeed, some stress early in life is conducive to later emotional resilience (Landauer & Whiting, 1979). Adversity can beget growth.

Extreme or prolonged stress can harm us. Children who suffer severe or prolonged abuse are later at risk of chronic disease (Repetti et al., 2002). Troops who had posttraumatic stress reactions to heavy combat in the Vietnam war later suffered greatly elevated rates of circulatory, digestive, respiratory, and infectious diseases (Boscarino, 1997). People who lose their jobs, especially later in their working life, are at increased risk of heart problems and death (Gallo et al., 2006; Sullivan & von Wachter, 2009).

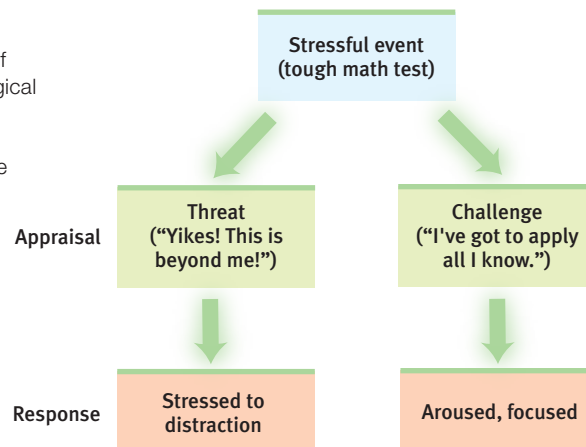

So there is an interplay between our heads and our health. Before exploring that interplay, let’s look more closely at stressors and stress reactions.

Stressors—Things That Push Our Buttons

Stressors fall into three main types: catastrophes, significant life changes, and daily hassles. All can be toxic.

Figure 43.1

Stress appraisal The events of our lives flow through a psychological filter. How we appraise an event influences how much stress we experience and how effectively we respond.

Roy Mehra/Getty Images

CATASTROPHES

Catastrophes are unpredictable large-scale events, such as wars, earthquakes, floods, wildfires, and famines. Nearly everyone appraises catastrophes as threatening. We often give aid and comfort to one another after such events, but damage to emotional and physical health can be significant. In surveys taken in the three weeks after the 9/11 terrorist attacks, for example, two-thirds of Americans said they were having some trouble concentrating and sleeping (Wahlberg, 2001). In the New York area, people were especially likely to report such symptoms, and sleeping pill prescriptions rose by a reported 28 percent (HMHL, 2002a; NSF, 2001). In the four months after Hurricane Katrina, New Orleans' suicide rate reportedly tripled (Saulny, 2006).

For those who respond to catastrophes by relocating to another country, the stress is twofold. The trauma of uprooting and family separation combine with the challenges of adjusting to the new culture's language, ethnicity, climate, and social norms (Pipher, 2002; Williams & Berry, 1991). In the first half-year, before their morale begins to rebound, newcomers often experience culture shock and deteriorating well-being (Markovizky & Samid, 2008). Such relocations may become increasingly common because of climate change in years to come.

SIGNIFICANT LIFE CHANGES

Life transitions are often keenly felt. Even happy events, such as getting married, can be stressful. Other changes—graduating from high school, leaving home for college, losing a job, having a loved one die—often happen during young adulthood. The stress of those years was clear in a survey in which 15,000 Canadian adults were asked whether “You are trying to take on too many things at once.” Responses indicated highest stress levels among young adults (Statistics Canada, 1999). Young adult stress appeared again when 650,000 Americans were asked if they had experienced a lot of stress “yesterday” (**FIGURE 43.2**).

Some psychologists study the health effects of life changes by following people over time. Others compare the life changes recalled by those who have or have not suffered a specific health problem, such as a heart attack. These studies indicate that people recently widowed, fired, or divorced are more vulnerable to disease (Dohrenwend et al., 1982; Strully, 2009). In one Finnish study of 96,000 widowed people, their risk of death doubled in the week following their partner's death (Kaprio et al., 1987). Experiencing a cluster of crises—losing a job, home, and partner, for example—puts one even more at risk.

AP/Getty Images

Toxic stress Unpredictable large-scale events, such as the severe earthquake that devastated Haiti in 2010, trigger significant levels of stress-related illness. When an earthquake struck Los Angeles in 1994, sudden-death heart attacks increased fivefold. Most occurred in the first two hours after the quake and near its center and were unrelated to physical exertion (Muller & Verrier, 1996).

Figure 43.2
Age and stress
A Gallup-Healthways survey of more than 650,000 Americans during 2008 and 2009 found daily stress highest among younger adults (Newport & Pelham, 2009).

DAILY HASSLES

Events don't have to remake our lives to cause stress. Stress also comes from *daily hassles*—rush-hour traffic, aggravating siblings, long lunch lines, too many things to do, family frustrations, and friends who don't respond to calls or texts (Kohn & Macdonald, 1992; Repetti et al., 2009; Ruffin, 1993). Some people can simply shrug off such hassles. For others, however, the everyday annoyances add up and take a toll on health and well-being.

Many people face more significant daily hassles. As the Great Recession of 2008–2009 bottomed out, Americans' most oft-cited stressors related to money (76 percent), work (70 percent), and the economy (65 percent) (APA, 2010). Such stressors are well-known to residents of impoverished areas, where many people routinely face inadequate income, unemployment, solo parenting, and overcrowding.

Prolonged stress takes a toll on our cardiovascular system. Daily pressures may be compounded by anti-gay prejudice or racism, which—like other stressors—can have both psychological and physical consequences (Pascoe & Richman, 2009; Rostosky et al., 2010; Swim et al., 2009). Thinking that some of the people you encounter each day will dislike you, distrust you, or doubt your abilities makes daily life stressful. Such stress takes a toll on the health of many African-Americans, driving up blood pressure levels (Ong et al., 2009; Mays et al., 2007).

The Stress Response System

Medical interest in stress dates back to Hippocrates (460–377 B.C.E.). In the 1920s, Walter Cannon (1929) confirmed that the stress response is part of a unified mind-body system. He observed that extreme cold, lack of oxygen, and emotion-arousing events all trigger an outpouring of the stress hormones epinephrine and norepinephrine from the core of the adrenal glands. When alerted by any of a number of brain pathways, the sympathetic nervous system (see Figure 41.4) increases heart rate and respiration, diverts blood from digestion to the skeletal muscles, dulls feelings of pain, and releases sugar and fat from the body's stores. All this prepares the body for the wonderfully adaptive response that Cannon called *fight or flight*.

Since Cannon's time, physiologists have identified an additional stress response system. On orders from the cerebral cortex (via the hypothalamus and pituitary gland), the outer part of the adrenal glands secretes *glucocorticoid* stress hormones such as *cortisol*. The two systems work at different speeds, explains biologist Robert Sapolsky (2003): “In a fight-or-flight scenario, epinephrine is the one handing out guns; glucocorticoids are the ones drawing up blueprints for new aircraft carriers needed for the war effort.” The epinephrine guns were firing at high speed during an experiment inadvertently conducted on a British Airways San Francisco to London flight. Three hours after takeoff, a mistakenly played message told passengers the plane was about to crash into the sea. Although the flight crew immediately recognized the error and tried to calm the terrified passengers, several required medical assistance (Associated Press, 1999).

Canadian scientist Hans Selye's (1936, 1976) 40 years of research on stress extended Cannon's findings. His studies of animals' reactions to various stressors, such as electric shock and surgery, helped make stress a major concept in both psychology and medicine. Selye proposed that the body's adaptive response to stress is so general that, like a single burglar alarm, it sounds, no matter what intrudes. He named this response the **general adaptation syndrome (GAS)**, and he saw it as a three-phase process (**FIGURE 43.3**). Let's say you suffer a physical or an emotional trauma. In Phase 1, you have an *alarm reaction*, as your sympathetic nervous system is suddenly activated. Your heart rate zooms. Blood is diverted to your skeletal muscles. You feel the faintness of shock.

With your resources mobilized, you are now ready to fight back. During Phase 2, *resistance*, your temperature, blood pressure, and respiration remain high. Your adrenal glands

“You've got to know when to hold 'em; know when to fold 'em. Know when to walk away, and know when to run.” -KENNY ROGERS, “THE GAMBLER,” 1978

general adaptation syndrome (GAS) Selye's concept of the body's adaptive response to stress in three phases—alarm, resistance, exhaustion.

Figure 43.3

Selye's general adaptation syndrome When a gold and copper mine in Chile collapsed in 2010, family and friends rushed to the scene, fearing the worst. Many of those holding vigil outside the mine were nearly exhausted with the stress of waiting and worrying when, after 18 days, they received news that all 33 of the miners inside were alive and well.

pump hormones into your bloodstream. You are fully engaged, summoning all your resources to meet the challenge.

As time passes, with no relief from stress, your body's reserves begin to run out. You have reached Phase 3, *exhaustion*. With exhaustion, you become more vulnerable to illness or even, in extreme cases, collapse and death.

Selye's basic point: Although the human body copes well with temporary stress, prolonged stress can damage it. The brain's production of new neurons slows and some neural circuits degenerate (Dias-Ferreira et al., 2009; Mirescu & Gould, 2006). One study found shortening of *telomeres*, pieces of DNA at the ends of chromosomes, in women who suffered enduring stress as caregivers for children with serious disorders (Epel et al., 2004). Telomere shortening is a normal part of the aging process; when telomeres get too short, the cell can no longer divide and it ultimately dies. The most stressed women had cells that looked a decade older than their chronological age, which may help explain why severe stress seems to age people. Even fearful, easily stressed rats have been found to die sooner (after about 600 days) than their more confident siblings, which average 700-day life spans (Cavigelli & McClintock, 2003).

Fortunately, there are other options for dealing with stress. One is a common response to a loved one's death: Withdraw. Pull back. Conserve energy. Faced with an extreme disaster, such as a ship sinking, some people become paralyzed by fear. Another stress response, found especially among women, is to seek and give support (Taylor et al., 2000, 2006). This **tend-and-befriend** response is demonstrated in the outpouring of help after natural disasters.

Facing stress, men more often than women tend to socially withdraw, turn to alcohol, or become aggressive. Women more often respond to stress by nurturing and banding together. This may in part be due to *oxytocin*, a stress-moderating hormone associated with pair bonding in animals and released by cuddling, massage, and breast feeding in humans

"You may be suffering from what's known as full-nest syndrome."

tend-and-befriend response under stress, people (especially women) often provide support to others (tend) and bond with and seek support from others (befriend).

(Campbell, 2010; Taylor, 2006). Gender differences in stress responses are reflected in brain scans: Women's brains become more active in areas important for face processing and empathy; men's become less active (Mather et al., 2010).

It often pays to spend our resources in fighting or fleeing an external threat. But we do so at a cost. When stress is momentary, the cost is small. When stress persists, we may pay a much higher price, with lowered resistance to infections and other threats to mental and physical well-being.

Before You Move On

▶ ASK YOURSELF

How often is your stress response system activated? What are some of the things that have triggered a fight-or-flight response for you?

▶ TEST YOURSELF

What two processes happen simultaneously when our stress response system is activated? What happens if the stress is continuous?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 43 Review

43-1

What events provoke stress responses, and how do we respond and adapt to stress?

- *Stress* is the process by which we appraise and respond to stressors (catastrophic events, significant life changes, and daily hassles) that challenge or threaten us.
- Walter Cannon viewed the stress response as a “fight-or-flight” system.
- Later researchers identified an additional stress-response system in which the adrenal glands secrete glucocorticoid stress hormones.
- Hans Selye proposed a general three-phase (alarm-resistance-exhaustion) *general adaptation syndrome (GAS)*.
- Prolonged stress can damage neurons, hastening cell death.
- Facing stress, women may have a *tend-and-befriend* response; men may withdraw socially, turn to alcohol, or become aggressive.

Multiple-Choice Questions

- Which of the following is an example of stress?
 - Ray is tense and anxious as he has to decide which college to attend.
 - Sunga is assigned an extra shift at work.
 - Joe's parents are allowing him to stay home alone while they go away for a weekend.
 - Linda remembers to repay a friend the \$10 she owes her.
 - Enrico learns of a traffic accident on the Interstate.
- The general adaptation syndrome (GAS) begins with
 - resistance.
 - appraisal.
 - exhaustion.
 - alarm.
 - challenge.
- Which of the following is likely to result from the release of oxytocin?
 - A fight-or-flight response
 - A tend-and-befriend response
 - Social isolation
 - Elevated hunger
 - Exhaustion

Practice FRQs

- 1.** Xavier has a huge math test coming up next Tuesday. Explain two ways appraisal can determine how stress will influence his test performance.

Answer

1 point: If Xavier interprets the test as a challenge he will be aroused and focused in a way that could improve his test performance.

1 point: If Xavier interprets the test as a threat he will be distracted by stress in a way that is likely to harm his test performance.

- 2.** Name and briefly describe the three phases of Hans Selye's general adaptation syndrome (GAS).

(3 points)

Module 44

Stress and Illness

Module Learning Objectives

- 44-1** Describe how stress makes us more vulnerable to disease.
- 44-2** Explain why some of us are more prone than others to coronary heart disease.

Aaron Haupt/Getty Images

44-1 How does stress make us more vulnerable to disease?

Not so long ago, the term *psychosomatic* described psychologically caused physical symptoms. In common usage, the term came to mean that the symptoms were unreal—“merely” psychosomatic. To avoid such connotations and to better describe the genuine physiological effects of psychological states, most experts today refer instead to stress-related **psychophysiological illnesses**, such as hypertension and some headaches. Stress also leaves us less able to fight off disease. The field of **psychoneuroimmunology** studies these mind-body interactions (Kiecolt-Glaser, 2009). This awkward name makes sense when said slowly: Your thoughts and feelings (*psycho*) influence your brain (*neuro*), which influences the endocrine hormones that affect your disease-fighting *immune* system. And this field is the study of (*ology*) those interactions.

Hundreds of experiments reveal the nervous and endocrine systems’ influence on the immune system (Sternberg, 2009). You can think of the immune system as a complex surveillance system. When it functions properly, it keeps you healthy by isolating and destroying bacteria, viruses, and other invaders. Four types of cells are active in these search-and-destroy missions (**FIGURE 44.1**). Two are types of white blood cells, called **lymphocytes**. *B lymphocytes* mature in the bone marrow and release antibodies that fight bacterial infections. *T lymphocytes* form in the thymus and other lymphatic tissue and attack cancer cells, viruses, and foreign substances—even “good” ones, such as transplanted organs. The third agent is the *macrophage* (“big eater”), which identifies, pursues, and ingests harmful invaders and worn-out cells. And, finally, the *natural killer cells* (NK cells) pursue diseased cells (such as those infected by viruses or cancer). Your age, nutrition, genetics, body temperature, and stress all influence your immune system’s activity.

When your immune system doesn’t function properly, it can err in two directions. Responding too strongly, it may attack the body’s own tissues, causing some forms of arthritis or an allergic reaction. Underreacting, it may allow a dormant herpes virus to erupt or cancer cells to multiply. Women are immunologically stronger than men, making them less susceptible to infections, but this very strength also makes them more susceptible to self-attacking diseases, such as lupus and multiple sclerosis (Morell, 1995; Pido-Lopez et al., 2001).

Your immune system is not a headless horseman. The brain regulates the secretion of stress hormones, which suppresses the disease-fighting lymphocytes. Immune suppression appears when animals are stressed by physical restraints, unavoidable electric shocks, noise, crowding, cold water, social defeat, or separation from their mothers (Maier et al., 1994). One six-month study monitored immune responses in 43 monkeys (Cohen et al., 1992).

psychophysiological illness literally, “mind-body” illness; any stress-related physical illness, such as hypertension and some headaches.

psychoneuroimmunology the study of how psychological, neural, and endocrine processes together affect the immune system and resulting health.

lymphocytes the two types of white blood cells that are part of the body’s immune system: *B lymphocytes* form in the bone marrow and release antibodies that fight bacterial infections; *T lymphocytes* form in the thymus and other lymphatic tissue and attack cancer cells, viruses, and foreign substances.

Figure 44.1
A simplified view of immune responses

Twenty-one were stressed by being housed with new roommates—three or four new monkeys—each month. By the end of the experiment, the socially disrupted monkeys' immune systems were weaker than those of monkeys left in stable groups. Human immune systems react similarly. Two examples:

- *Surgical wounds heal more slowly in stressed people.* In one experiment, dental students received punch wounds (precise small holes punched in the skin). Compared with wounds placed during summer vacation, those placed three days before a major exam healed 40 percent more slowly (Kiecolt-Glaser et al., 1998). Marriage conflict also slows punch-wound healing (Kiecolt-Glaser et al., 2005).
- *Stressed people are more vulnerable to colds.* Researchers dropped a cold virus into the noses of stressed and relatively unstressed people (**FIGURE 44.2**). Among those living stress-filled lives, 47 percent developed colds. Among those living relatively free of stress, only 27 percent did. In follow-up research, the happiest and most relaxed people were likewise markedly less vulnerable to an experimentally delivered cold virus (Cohen et al., 2003, 2006). Other studies reveal that major life stress increases the risk of a respiratory infection (Pedersen et al., 2010).

Figure 44.2
Stress and colds In an experiment by Sheldon Cohen and colleagues (1991), people with the highest life stress scores were also most vulnerable when exposed to an experimentally delivered cold virus.

The stress effect on immunity makes physiological sense. It takes energy to track down invaders, produce swelling, and maintain fevers. Thus, when diseased, your body reduces muscular energy output by inactivity and increased sleep. Stress does the opposite. It creates a competing energy need. During an aroused fight-or-flight reaction, your stress responses divert energy from your disease-fighting immune system and send it to your muscles and brain (see Figure 41.4). This renders you more vulnerable to illness. *The bottom line:* Stress does not make us sick, but it does alter our immune functioning, which leaves us less able to resist infection.

Let's consider some ways that stress might affect AIDS, cancer, and heart disease.

Stress and Susceptibility to Disease

Stress and AIDS

We know that stress suppresses immune functioning. What does this mean for people with AIDS (*acquired immune deficiency syndrome*)? As its name tells us, AIDS is an immune disorder, caused by the *human immunodeficiency virus* (HIV). AIDS has become the world's fourth leading cause of death and Africa's number one killer.

Ironically, if a disease is spread by human contact (as AIDS is, through the exchange of

bodily fluids, primarily semen and blood), and if it kills slowly (as AIDS does), it can be lethal to more people. Those who acquire HIV often spread it in the highly contagious first few weeks before they know they are infected. Worldwide, some 2.6 million people—slightly more than half of them women—became infected with HIV in 2009, often without their awareness (UNAIDS, 2010). Years after the initial infection, when AIDS appears, people have difficulty fighting off other diseases, such as pneumonia. More than 25 million people worldwide have died of AIDS (UNAIDS, 2010). (In the United States, where “only” a half-million of these fatalities have occurred, AIDS has killed more people than did combat in all the twentieth-century wars.)

Stress cannot give people AIDS. But could stress and negative emotions speed the transition from HIV infection to AIDS in someone already infected? Might stress predict a faster decline in those with AIDS? The answer to both questions seems to be *Yes* (Bower et al., 1998; Kiecolt-Glaser & Glaser, 1995; Leserman et al., 1999). HIV-infected men who experience stressful events, such as the loss of a partner, exhibit somewhat greater immune suppression and travel a faster course in this disease.

Would efforts to reduce stress help control the disease? Again, the answer appears to be *Yes*. Educational initiatives, bereavement support groups, cognitive therapy, relaxation training, and exercise programs that reduce stress have all had positive consequences for HIV-positive people (Baum & Posluszny, 1999; McCain et al., 2008; Schneiderman, 1999). But the benefits are small, compared with available drug treatments.

Although AIDS is now more treatable than ever before, preventing HIV infection is a far better option. This is the focus of many educational programs, such as the ABC (*abstinence, being faithful, condom use*) program that has been used with seeming success in Uganda (Altman, 2004; USAID, 2004). In addition to such programs that seek to influence sexual norms and behaviors, today's “combination prevention” programs also include medical strategies (such as drugs and male circumcision that reduce HIV transmission) and efforts to reduce social inequalities that increase HIV risk (UNAIDS, 2010).

PhotoFusion/ UIG via Getty Images

Africa is ground zero for AIDS In Ghana, the Ministry of Health uses these informative billboards as part of prevention efforts.

FYI

In North America and Western Europe, 74 percent of people with AIDS are men. In Sub-Saharan Africa, 60 percent of people with AIDS are women (UNAIDS, 2010).

Stress and Cancer

Stress does not create cancer cells. But in a healthy, functioning immune system, lymphocytes, macrophages, and NK cells search out and destroy cancer cells and cancer-damaged cells. If stress weakens the immune system, might this weaken a person's ability to fight off cancer? To explore a possible connection between stress and cancer, experimenters have implanted tumor cells in rodents or given them *carcinogens* (cancer-producing substances). They then exposed some rodents to uncontrollable stress, such as inescapable shocks, which weakened their immune systems. Those rodents were indeed more prone to developing cancer (Sklar & Anisman, 1981). Their tumors developed sooner and grew larger than in nonstressed rodents.

Does this stress-cancer link also hold with humans? The results are mixed. Some studies find that people are at increased risk for cancer within a year after experiencing depression, helplessness, or bereavement (Chida et al., 2008; Steptoe et al., 2010). In one large Swedish study, the risk of colon cancer was 5.5 times greater among people with a history of workplace stress than among those who reported no such problems. This difference was not attributable to group differences in age, smoking, drinking, or physical characteristics (Courtney et al., 1993). Other studies, however, have found no link between stress and human cancer (Coyne et al., 2010; Petticrew et al., 1999, 2002). Concentration camp survivors and former prisoners of war, for example, do not have elevated cancer rates.

One danger in hyping reports on emotions and cancer is that some patients may then blame themselves for their illness: "If only I had been more expressive, relaxed, and hopeful." A corollary danger is a "wellness macho" among the healthy, who take credit for their "healthy character" and lay a guilt trip on the ill: "She has cancer? That's what you get for holding your feelings in and being so nice." Dying thus becomes the ultimate failure.

It's important enough to repeat: *Stress does not create cancer cells*. At worst, it may affect their growth by weakening the body's natural defenses against multiplying malignant cells (Antoni & Lutgendorf, 2007). Although a relaxed, hopeful state may enhance these defenses, we should be aware of the thin line that divides science from wishful thinking. The powerful biological processes at work in advanced cancer or AIDS are not likely to be completely derailed by avoiding stress or maintaining a relaxed but determined spirit (Anderson, 2002; Kessler et al., 1991). And that explains why research consistently indicates that psychotherapy does not extend cancer patients' survival (Coyne et al., 2007, 2009; Coyne & Tennen, 2010).

Stress and Heart Disease

44-2

Why are some of us more prone than others to coronary heart disease?

Stress is much more closely linked to **coronary heart disease**, North America's leading cause of death. In this disease, the blood vessels that nourish the heart muscle gradually close. Hypertension and a family history of the disease increase the risk of coronary heart disease. So do many behavioral factors (smoking, obesity, a high-fat diet, physical inactivity), physiological factors (an elevated cholesterol level), and psychological factors (stress responses and personality traits).

In some classic studies, Meyer Friedman, Ray Rosenman, and their colleagues tested the idea that stress increases vulnerability to heart disease by measuring the blood cholesterol level and clotting speed of 40 U.S. male tax accountants at different times of year (Friedman & Rosenman, 1974; Friedman & Ulmer, 1984). From January through March, the test results were completely normal. Then, as the accountants began scrambling to finish their clients' tax returns before the April 15 filing deadline, their cholesterol and clotting measures rose to dangerous levels. In May and June, with the deadline past, the measures returned to normal. Stress predicted heart attack risk for these men. The researchers' hunch had paid off, launching a classic nine-year study of more than 3000 healthy men, aged 35 to 59.

"I didn't give myself cancer."

-MAYOR BARBARA BOGGS SIGMUND
(1939–1990), PRINCETON,
NEW JERSEY

FYI

When organic causes of illness are unknown, it is tempting to invent psychological explanations. Before the germ that causes tuberculosis (TB) was discovered, personality explanations of TB were popular (Sontag, 1978).

coronary heart disease

the clogging of the vessels that nourish the heart muscle; the leading cause of death in many developed countries.

FYI

In both India and America, Type A bus drivers are literally hard-driving: They brake, pass, and honk their horns more often than their more easygoing Type B colleagues (Evans et al., 1987).

Tony Freeman/Photo Edit

“The fire you kindle for your enemy often burns you more than him.” -CHINESE PROVERB

Type A Friedman and Rosenman’s term for competitive, hard-driving, impatient, verbally aggressive, and anger-prone people.

Type B Friedman and Rosenman’s term for easygoing, relaxed people.

At the start of the study, the researchers interviewed each man for 15 minutes, noting his work and eating habits, manner of talking, and other behavioral patterns. Those who seemed the most reactive, competitive, hard-driving, impatient, time-conscious, supermotivated, verbally aggressive, and easily angered they called **Type A**. The roughly equal number who were more easygoing they called **Type B**. Which group do you suppose turned out to be the most coronary-prone?

Nine years later, 257 men had suffered heart attacks, and 69 percent of them were Type A. Moreover, not one of the “pure” Type Bs—the most mellow and laid back of their group—had suffered a heart attack.

As often happens in science, this exciting discovery provoked enormous public interest. But after that initial honeymoon period, researchers wanted to know more. Was the finding reliable? If so, what is the toxic component of the Type A profile: Time-consciousness? Competitiveness? Anger?

More than 700 studies have now explored possible psychological correlates or predictors of cardiovascular health (Chida & Hamer, 2008; Chida & Steptoe, 2009). These reveal that Type A’s toxic core is negative emotions—especially the anger associated with an aggressively reactive temperament. As we will see in Module 83’s discussion of anger, when we are harassed or challenged, our active sympathetic nervous system redistributes bloodflow to our muscles, pulling it away from our internal organs. One of those organs, the liver, which normally removes cholesterol and fat from the blood, can’t do its job. Type A individuals are more often “combat ready.” Thus, excess cholesterol and fat may continue to circulate in their blood and later get deposited around the heart. Further stress—sometimes conflicts brought on by their own abrasiveness—may trigger altered heart rhythms. In people with weakened hearts, this altered pattern can cause sudden death (Kamarck & Jennings, 1991). Hostility also correlates with other risk factors, such as smoking, drinking, and obesity (Bunde & Suls, 2006). In important ways, people’s minds and hearts interact.

Hundreds of other studies of young and middle-aged men and women have confirmed the finding that people who react with anger over little things are the most coronary-prone. Suppressing negative emotions only heightens the risk (Kupper & Denollet, 2007). One study followed 13,000 middle-aged people for 5 years. Among those with normal blood pressure, people who had scored high on anger were three times more likely to have had heart attacks, even after researchers controlled for smoking and weight (Williams et al., 2000). Another study followed 1055 male medical students over an average of 36 years. Those who had reported being hot tempered were five times more likely to have had a heart attack by age 55 (Chang et al., 2002). As others have noted, rage “seems to lash back and strike us in the heart muscle” (Spielberger & London, 1982).

Pessimism seems to be similarly toxic. One study followed 1306 initially healthy men who a decade earlier had scored as optimists, pessimists, or neither. Even after other risk factors such as smoking had been ruled out, pessimists were more than twice as likely as optimists to develop heart disease (**FIGURE 44.3**) (Kubzansky et al., 2001).

Figure 44.3

Pessimism and heart disease A Harvard School of Public Health team found pessimistic men at doubled risk of developing heart disease over a 10-year period. (From Kubzansky et al., 2001.)

Depression, too, can be lethal. Happy people tend to be healthier and to outlive their unhappy peers (Diener & Chan, 2011; Siahpush et al., 2008). Even a big, happy smile predicts longevity, as Ernest Abel and Michael Kruger (2010) discovered when they examined the photographs of 150 Major League Baseball players who had appeared in the 1952 *Baseball Register* and had died by 2009. On average, the nonsmilers had died at 73, compared with an average 80 years for those with a broad, genuine smile.

The accumulated evidence from 57 studies suggests that “depression substantially increases the risk of death, especially death by unnatural causes and cardiovascular disease” (Wulsin et al., 1999). After following 63,469 women over a dozen years, researchers found more than a doubled rate of heart attack death among those who initially scored as depressed (Whang et al., 2009). In the years following a heart attack, people with high scores for depression are four times more likely than their low-scoring counterparts to develop further heart problems (Frasure-Smith & Lesperance, 2005). Depression is disheartening.

Depressed people tend to smoke more and exercise less (Whooley et al., 2008), but stress itself is also disheartening:

- When following 17,415 middle-aged American women, researchers found an 88 percent increased risk of heart attacks among those facing significant work stress (Slopen et al., 2010).
- In Denmark, a study of 12,116 female nurses found that those reporting “much too high” work pressures had a 40 percent increased risk of heart disease (Allesøe et al., 2010).
- In the United States, a 10-year study of middle-aged workers found that involuntary job loss more than doubled their risk of a heart attack (Gallo et al., 2006). A 14-year study of 1059 women found that those with five or more trauma-related stress symptoms had three times the normal risk of heart disease (Kubzansky et al., 2009).

Research suggests that heart disease and depression may both result when chronic stress triggers persistent inflammation (Matthews, 2005; Miller & Blackwell, 2006). After a heart attack, stress and anxiety increase the risk of death or of another attack (Roest et al., 2010). As we have seen, stress disrupts the body’s disease-fighting immune system, enabling the body to focus its energies on fleeing or fighting the threat. Yet stress hormones enhance one immune response, the production of proteins that contribute to inflammation. Thus, people who experience social threats, including children raised in harsh families, are more prone to inflammation responses (Dickerson et al., 2009; Miller & Chen, 2010). Inflammation fights infections; if you cut yourself, inflammation recruits infection-fighting cells. But persistent inflammation can produce problems such as asthma or clogged arteries, and worsen depression (see **FIGURE 44.4**). Researchers are now uncovering the molecular mechanisms by which stress, in some people, activates genes that control inflammation (Cole et al., 2010).

* * *

We can view the stress effect on our disease resistance as a price we pay for the benefits of stress (**FIGURE 44.5** on the next page). Stress invigorates our lives by arousing and motivating us. An unstressed life would hardly be challenging or productive.

Photo File/Getty Images

“A cheerful heart is a good medicine, but a downcast spirit dries up the bones.” -PROVERBS 17:22

Figure 44.4

Stress→inflammation→heart disease and depression

Gregory Miller and Ekin Blackwell (2006) report that chronic stress leads to persistent inflammation, which heightens the risk of both depression and clogged arteries.

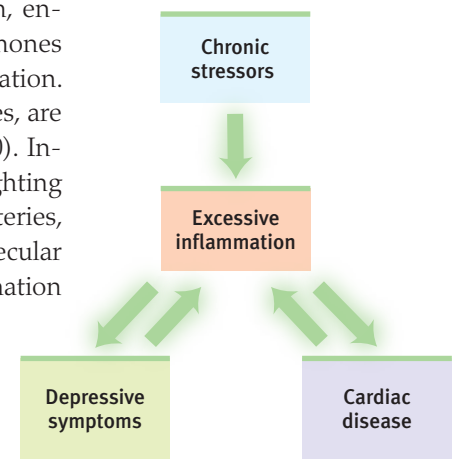

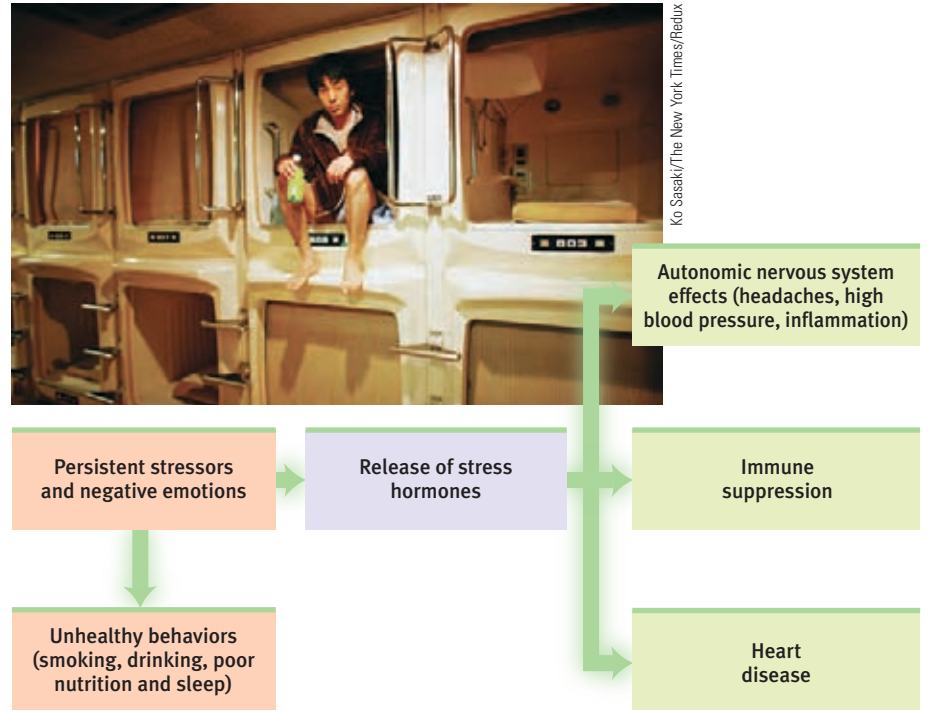

Figure 44.5**Stress can have a variety of health-related consequences**

This is especially so when stress is experienced by angry, depressed, or anxious people. Job and income loss caused by the recent economic recession has created stress for many people, such as this jobless Japanese man living in a Tokyo “capsule hotel.”

Behavioral medicine research provides a reminder of one of contemporary psychology's overriding themes: *Mind and body interact; everything psychological is simultaneously physiological*. Psychological states are physiological events that influence other parts of our physiological system. Just pausing to *think* about biting into an orange section—the sweet, tangy juice from the pulpy fruit flooding across your tongue—can trigger salivation. As the Indian sage Santi Parva recognized more than 4000 years ago, “Mental disorders arise from physical causes, and likewise physical disorders arise from mental causes.” There is an interplay between our heads and our health. We are biopsychosocial systems.

Before You Move On

▶ ASK YOURSELF

Are there changes you could make to avoid the persistent stressors in your life?

▶ TEST YOURSELF

Which component of the Type A personality has been linked most closely to coronary heart disease?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 44 Review

44-1 How does stress make us more vulnerable to disease?

- *Psychoneuroimmunologists* study mind-body interactions, including *psychophysiological* illnesses, such as hypertension and some headaches.
- Stress diverts energy from the immune system, inhibiting the activities of its *B* and *T lymphocytes*, macrophages, and NK cells.
- Stress does not cause diseases such as AIDS and cancer, but by altering our immune functioning it may make us more vulnerable to them and influence their progression.

44-2 Why are some of us more prone than others to coronary heart disease?

- *Coronary heart disease*, North America's number one cause of death, has been linked with the reactive, anger-prone *Type A* personality.
- Compared with relaxed, easygoing *Type B* personalities, *Type A* people secrete more of the hormones that accelerate the buildup of plaque on the heart's artery walls.
- Chronic stress also contributes to persistent inflammation, which heightens the risk of clogged arteries and depression.

Multiple-Choice Questions

- Which of the following best identifies any stress-related physical illness, such as hypertension and some headaches?
 - Bacterial infection
 - Psychoneuroimmunology
 - Allergic reaction
 - Psychophysiological illness
 - Viral infection
- What is North America's leading cause of death?
 - Psychosomatic disorders
 - Coronary heart disease
 - Cancer
 - Depression
 - Stroke
- What did a famous Harvard University public health study identify as a factor that doubles the risk of heart disease?
 - Optimism
 - Apathy
 - Pessimism
 - Competitiveness
 - AIDS

Practice FRQs

- Explain the two types of people identified by Friedman and Rosenman in their study on stress responses and personality traits.
- Explain the difference between *B* lymphocytes and *T* lymphocytes.

(2 points)

Answer

1 point: Type A people are competitive, hard-driving, impatient, verbally aggressive, and anger prone.

1 point: Type B people are easygoing and relaxed.

Key Contributors to Remember

Abraham Maslow, p. 393	Virginia Johnson, p. 406	Stanley Schachter, p. 422
William Masters, p. 406	William James, p. 421	Hans Selye, p. 444

AP[®] Exam Practice Questions

Multiple-Choice Questions

- Which theory explains that physiological needs create an aroused state that motivates an organism to reduce the need?
 - Instinct theory
 - Drive-reduction theory
 - Achievement motivation
 - Arousal theory
 - Hierarchy of needs
- Attempts to control social behavior by using the punishing effects of isolation is an example of
 - attachment disorder.
 - ostracism.
 - exploitation.
 - wanting to belong.
 - conforming.
- Which theory explains why, even when our biological needs are satisfied, we may still feel driven to experience stimulation?
 - Incentive
 - Homeostasis
 - Instinct
 - Arousal theory
 - Physiology
- Why does further weight loss come slowly following a rapid loss during the initial three weeks of a rigorous diet?
 - The number of fat cells makes further weight loss impossible.
 - When a person's hunger increases, metabolism increases.
 - When an obese person's set point has been reached, weight loss increases dramatically.
 - The body reacts as if it's being starved and metabolic rates drop.
 - An obese person cannot maintain a rigorous weight loss diet.

5. Research on semistarvation found that men who were given just enough food to stabilize their weight at 25 percent below their starting weight
 - a. became obsessed with physical exercise.
 - b. were more interpersonally outgoing.
 - c. showed increases in mental cognition.
 - d. were in a state of homeostasis.
 - e. lost interest in social activities.
6. Which of the following is the best biological explanation for why the human body stores fat?
 - a. Fat signals affluence and social status.
 - b. Fat is a fuel reserve during periods when food is scarce.
 - c. Fat is a display of abundant food sources.
 - d. Fat keeps the body warm in winter climates.
 - e. Fat combats the global epidemic of diabetes.
7. What do we call a need or desire that energizes and directs behavior?
 - a. Incentive
 - b. Refractory period
 - c. Emotion
 - d. Motivation
 - e. Instinct
8. Which of the following actions is a violation of Maslow's hierarchy of needs?
 - a. A person who moves to a new city gets an apartment before beginning to make friends.
 - b. A very hungry reality show contestant searches for food before trying to win a competition.
 - c. A professor spends time socially with her colleagues before she works on her own research.
 - d. An artist works to win a local award before spending time on his own personal projects.
 - e. An athlete follows a "no pain, no gain" motto rather than stopping for rest and nourishment.
9. What term refers to the ability of the body's physiological processes to maintain a balanced or constant internal state?
 - a. Hierarchy of needs
 - b. Basal metabolic rate
 - c. Homeostasis
 - d. Instinct
 - e. Motivation
10. A person who eats excessively and never seems to feel full may have which of the following conditions?
 - a. Tumor in the hypothalamus
 - b. Too much insulin
 - c. Stomach ulcer
 - d. Stomach bypass surgery
 - e. Too much of the hormone PYY
11. Which of the following is one of the stages of the sexual response cycle described by Masters and Johnson?
 - a. Expulsion
 - b. Plateau
 - c. Attraction
 - d. Compensation
 - e. Depolarization
12. Emotions are a mix of consciously experienced thoughts, expressive behaviors, and physiological arousal. Which theory emphasized the importance of consciously experienced thoughts?
 - a. Facial feedback theory
 - b. James-Lange theory
 - c. Arousal and performance theory
 - d. Fight-or-flight theory
 - e. Schachter-Singer two-factor theory
13. Surveys conducted with people who have high spinal cord injuries suggest to researchers that emotions are
 - a. entirely cognitive, requiring no physical response to be intense.
 - b. largely dependent upon our bodily responses and behaviors.
 - c. mostly a social response to surrounding factors.
 - d. mostly a cultural reaction to context.
 - e. mostly psychological.
14. The stress hormones epinephrine and norepinephrine are released from where?
 - a. Parasympathetic nervous system
 - b. Hippocampus
 - c. Brain stem
 - d. Adrenal glands
 - e. Hypothalamus
15. When hearing emotions conveyed in another language, what emotion can people most readily detect?
 - a. Sadness
 - b. Happiness
 - c. Anger
 - d. Fear
 - e. Surprise
16. Brain scans and EEG recordings indicate that positive emotions are associated with high levels of activity in which brain section?
 - a. Right temporal lobe
 - b. Cerebellum
 - c. Left frontal lobe
 - d. Left temporal lobe
 - e. Right parietal lobe

- 17.** Which one of the following statements about stress is *true*?
- Surgical wounds heal more slowly in stressed humans.
 - Stress has no effect on those exposed to cold viruses.
 - There is no correlation between stress and longevity.
 - Stress makes us more resistant to infection and heart disease.
 - Anxiety, irritation, and guilt all prompt very different physiological responses.
- 18.** Which of the following statements about nonverbal expression is *true*?
- People blind from birth do not usually exhibit common facial expressions.
 - The meaning of gestures is the same across cultures.
 - Facial signs of emotion are generally understood across world cultures.
 - People from different cultures have difficulty understanding nonverbal expressions.
 - Nonverbal expression is not reliably interpreted within a culture.
- 19.** Which psychological concept would predict that smiling warmly on the outside would cause you to feel better on the inside?
- Relative deprivation
 - Mimicry
 - Empathy
 - Facial feedback
 - Catharsis
- 20.** After an alarming event, your temperature, blood pressure, and respiration are high, and you have an outpouring of hormones. Hans Selye would most likely guess that you are in which general adaptation syndrome phase?
- Exhaustion
 - Resistance
 - Immobilization
 - Collapse
 - Shock

Free-Response Questions

- 1.** Bill is applying for admission to the University of Michigan and has completed the entire process except for writing his application essay. He is very nervous about writing the essay because it is such an important part of the acceptance process and the topic he was assigned is very challenging.

Explain how each of the following psychological concepts might relate to how Bill feels five months later when he receives a letter of acceptance from the University of Michigan.

- Maslow's hierarchy
- James-Lange theory
- Cannon-Bard theory
- Schachter-Singer two-factor theory

Rubric for Free Response Question 1

1 point: According to Maslow's hierarchy, Bill's decision to apply to the University of Michigan is the result of a need or drive (motivation) to achieve the higher psychological needs of belonging, esteem, self-actualization, or self-transcendence. Bill is able to focus on these higher-level needs because his physiological and safety needs have already been met.  Page 393

1 point: According to the James-Lange theory, when Bill receives the letter in the mail, his heart races and his breathing increases, which causes his brain to automatically interpret this experience as the emotion of excitement.

Note: Bill may exhibit any emotion as long as the physical arousal occurs prior to the experience of the emotion.

 Page 421

1 point: According to the Cannon-Bard theory, when Bill receives the letter in the mail, his heart races and his breathing increases at the same time that he experiences the emotion of excitement. He simultaneously experiences an increase in physiological arousal and the emotion of happiness.

 Page 422

1 point: According to the Schachter-Singer two-factor theory, when Bill opens his letter, he experiences an increase in physical arousal and determines that he is experiencing happiness based on his memories and thoughts.

Note: Bill may exhibit any emotion as long as the response includes a physical arousal and a cognitive labeling of that emotion.  Page 422

2. Hope's soccer team is playing in the championship game today. Hope knows the opposing team is the defending champion and that this will be a challenging game. Explain how the following theories apply to Hope's performance and reactions during the game.

- Yerkes-Dodson law
- Affiliation needs
- Schachter-Singer theory of emotion

(3 points)

3. Franz is 17 and wants to lose 15 pounds. Explain how the following factors might contribute to the success or failure of his weight-loss attempt.

- Social influence
- Set point
- Sleep
- Incentive theory

(4 points)

Unit IX

Developmental Psychology

Modules

45 Developmental Issues, Prenatal Development, and the Newborn

46 Infancy and Childhood: Physical Development

47 Infancy and Childhood: Cognitive Development

48 Infancy and Childhood: Social Development

49 Gender Development

50 Parents, Peers, and Early Experiences

51 Adolescence: Physical and Cognitive Development

52 Adolescence: Social Development and Emerging Adulthood

53 Sexual Development

54 Adulthood: Physical, Cognitive, and Social Development

Life is a journey, from womb to tomb. So it is for me, and so it will be for you. My story, and yours, began when a man and a woman together contributed 20,000+ genes to an egg that became a unique person. Those genes coded the protein building blocks that, with astonishing precision, formed our bodies and predisposed our traits. My grandmother bequeathed to my mother a rare hearing loss pattern, which she, in turn, gave to me (the least of her gifts). My father was an amiable extravert, and sometimes I forget to stop talking. As a child, my talking was impeded by painful stuttering, for which Seattle Public Schools gave me speech therapy.

Along with my parents' nature, I also received their nurture. Like you, I was born into a particular family and culture, with its own way of viewing the world. My values have been shaped by a family culture filled with talking and laughter, by

a religious culture that speaks of love and justice, and by an academic culture that encourages critical thinking (asking, What do you mean? How do you know?).

We are formed by our genes, and by our contexts, so our stories will differ. But in many ways we are each like nearly everyone else on Earth. Being human, you and I have a need to belong. My mental video library, which began after age 4, is filled with scenes of social attachment. Over time, my attachments to parents loosened as peer friendships grew. After lacking confidence to date in high school, I fell in love with a college classmate and married at age 20. Natural selection disposes us to survive and perpetuate our genes. Sure enough, two years later a child entered our lives, and I experienced a new form of love that surprised me with its intensity.

But life is marked by change. That child now lives 2000 miles away, and one of his two siblings has found her calling in South Africa. The tight rubber bands linking parent and child have loosened, as yours likely have as well.

Change also marks most vocational lives, which for me transitioned from a teen working in the family insurance agency, to a premed chemistry major and hospital aide, to (after discarding my half-completed medical school applications) a psychology professor and author. I predict that in 10 years you, too, will be doing things you do not currently anticipate.

Stability also marks our development: We experience a continuous self. When I look in the mirror, I do not see the person I once was, but I feel like the person I have always been. I am the same person who, as a late teen, played basketball and discovered love. A half-century later, I still play basketball and still love (with less passion but more security) the life partner with whom I have shared life's griefs and joys.

Continuity morphs through stages—growing up, raising children, enjoying a career, and, eventually, life's final stage, which will demand my presence. As I wend my way through this cycle of life and death, I am mindful that life is a journey, a continuing process of development, seeded by nature and shaped by nurture, animated by love and focused by work, begun with wide-eyed curiosity and completed, for those blessed to live to a good old age, with peace and never-ending hope.

Module 45

Developmental Issues, Prenatal Development, and the Newborn

Module Learning Objectives

- 45-1** Identify three issues that have engaged developmental psychologists.
- 45-2** Discuss the course of prenatal development, and explain how teratogens affect that development.
- 45-3** Describe some abilities of the newborn, noting how researchers are able to identify their mental abilities.

David Greedy/Lonely Planet Images/Getty Images

developmental psychology a branch of psychology that studies physical, cognitive, and social change throughout the life span.

AP® Exam Tip

All three of these issues are important for development. Nature and nurture, of course, weaves its way through almost every module. It is one of the topics most likely to be on the AP® exam.

“Nature is all that a man brings with him into the world; nurture is every influence that affects him after his birth.” -FRANCIS GALTON, *ENGLISH MEN OF SCIENCE*, 1874

Developmental Psychology’s Major Issues

- 45-1** What three issues have engaged developmental psychologists?

Developmental psychology examines our physical, cognitive, and social development across the life span, with a focus on three major issues:

- Nature and nurture:* How does our genetic inheritance (our *nature*) interact with our experiences (our *nurture*) to influence our development?
- Continuity and stages:* What parts of development are gradual and continuous, like riding an escalator? What parts change abruptly in separate stages, like climbing rungs on a ladder?
- Stability and change:* Which of our traits persist through life? How do we change as we age?

Let’s reflect now on these three development issues.

Nature and Nurture

The gene combination created when our mother’s egg engulfed our father’s sperm helped form us, as individuals. Genes predispose both our shared humanity and our individual differences.

But it is also true that our experiences form us. In the womb, in our families, and in our peer social relationships, we learn ways of thinking and acting. Even differences initiated by our nature may be amplified by our nurture. We are not formed by either nature or nurture, but by their interrelationships—their *interaction*. Biological, psychological, and social-cultural forces interact.

Stability and Change

As we follow lives through time, do we find more evidence for stability or change? If reunited with a long-lost grade-school friend, do we instantly realize that “it’s the same old Andy”? Or do people we befriend during one period of life seem like strangers at a later period? (At least one acquaintance of mine would choose the second option. He failed to recognize a former classmate at his 40-year college reunion. The aghast classmate pointed out that she was his long-ago first wife.)

Research reveals that we experience both stability and change. Some of our characteristics, such as *temperament* (our emotional reactivity and intensity), are very stable:

- One study followed 1000 3-year-old New Zealanders through time. It found that preschoolers who were low in conscientiousness and self-control were more vulnerable to ill health, substance abuse, arrest, and single parenthood by age 32 (Moffitt et al., 2011).
- Another study found that hyperactive, inattentive 5-year-olds required more teacher effort at age 12 (Houts et al., 2010).
- Another research team interviewed adults who, 40 years earlier, had their talkativeness, impulsiveness, and humility rated by their elementary school teachers (Nave et al., 2010). To a striking extent, the personalities persisted.

Smiles predict marital stability

In one study of 306 college alums, one in four with yearbook expressions like the one on the left later divorced, as did only 1 in 20 with smiles like the one on the right (Hertenstein et al., 2009).

Tom Prokop/Shutterstock

Photodisc/Getty Images

“At 70, I would say the advantage is that you take life more calmly. You know that ‘this, too, shall pass!’” —ELEANOR ROOSEVELT, 1954

“As at 7, so at 70,” says a Jewish proverb. The widest smilers in childhood and college photos are, years later, the ones most likely to enjoy enduring marriages (Hertenstein et al., 2009). While one in four of the weakest college smilers eventually divorced, only 1 in 20 of the widest smilers did so. As people grow older, personality gradually stabilizes (Ferguson, 2010; Hopwood et al., 2011; Kandler et al., 2010). The struggles of the present may be laying a foundation for a happier tomorrow.

We cannot, however, predict all of our eventual traits based on our early years of life (Kagan et al., 1978, 1998). Some traits, such as social attitudes, are much less stable than temperament, especially during the impressionable late adolescent years (Krosnick & Alwin, 1989; Moss & Susman, 1980). Older children and adolescents learn new ways of coping. Although delinquent children have elevated rates of later work problems, substance abuse, and crime, many confused and troubled children blossom into mature, successful adults (Moffitt et al., 2002; Roberts et al., 2001; Thomas & Chess, 1986). Happily for them, life is a process of becoming.

In some ways, we *all* change with age. Most shy, fearful toddlers begin opening up by age 4, and most people become more conscientious, stable, agreeable, and self-confident in the years after adolescence (Lucas & Donnellan, 2009; Roberts et al., 2003, 2006, 2008; Shaw et al., 2010). Many irresponsible 16-year-olds have matured into 40-year-old business or cultural leaders. (If you are the former, you aren’t done yet.) Such changes can occur without changing a person’s position *relative to others* of the same age. The hard-driving young adult may mellow by later life, yet still be a relatively driven senior citizen.

Life requires *both* stability and change. Stability provides our identity. It enables us to depend on others and be concerned about the healthy development of the children in our lives. Our trust in our ability to change gives us our hope for a brighter future. It motivates our concerns about present influences and lets us adapt and grow with experience.

BEFORE

AFTER

As adults grow older, there is continuity of self.

Before You Move On

▶ ASK YOURSELF

Are you the same person you were as a preschooler? As an 8-year-old? As a 12-year-old? How are you different? How are you the same?

▶ TEST YOURSELF

What findings in psychology support the concept of stages in development and the idea of stability in personality across the life span? What findings challenge these ideas?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

AP® Exam Tip

Almost every topic in psychology holds personal relevance, but development stands out. As you work your way through this unit, think of how the material relates to you, your relatives, and your friends. The more often you do this, the easier it will be to remember the material.

Prenatal Development and the Newborn

45-2

What is the course of prenatal development, and how do teratogens affect that development?

Conception

Nothing is more natural than a species reproducing itself. And nothing is more wondrous. With humans, the process starts when a woman's ovary releases a mature egg—a cell roughly the size of the period at the end of this sentence. The woman was born with all the immature eggs she would ever have, although only 1 in 5000 will ever mature and be released. A man, in contrast, begins producing sperm cells at puberty. For the rest of his life, 24 hours a day, he will be a nonstop sperm factory, with the rate of production—in the beginning more than 1000 sperm during the second it takes to read this phrase—slowing with age.

Like space voyagers approaching a huge planet, the 200 million or more deposited sperm begin their race upstream, approaching a cell 85,000 times their own size. The relatively few reaching the egg release digestive enzymes that eat away its protective coating (**FIGURE 45.2a**). As soon as one sperm penetrates that coating and is welcomed in (Figure 45.2b), the egg's surface blocks out the others. Before half a day elapses, the egg nucleus and the sperm nucleus fuse. The two have become one. Consider it your

Life is sexually transmitted

(a) Sperm cells surround an egg. (b) As one sperm penetrates the egg's jellylike outer coating, a series of chemical events begins that will cause sperm and egg to fuse into a single cell. If all goes well, that cell will subdivide again and again to emerge 9 months later as a 100-trillion-cell human being.

zygote the fertilized egg; it enters a 2-week period of rapid cell division and develops into an embryo.

embryo the developing human organism from about 2 weeks after fertilization through the second month.

fetus the developing human organism from 9 weeks after conception to birth.

most fortunate of moments. Among 200 million sperm, the one needed to make you, in combination with that one particular egg, won the race. And so it was for innumerable generations before us. If any one of our ancestors had been conceived with a different sperm or egg, or died before conceiving, or not chanced to meet the partner or . . . the mind boggles at the improbable, unbroken chain of events that produced you and me.

Prenatal Development

Fewer than half of all fertilized eggs, called **zygotes**, survive beyond the first 2 weeks (Grobstein, 1979; Hall, 2004). But for you and me, good fortune prevailed. One cell became 2, then 4—each just like the first—until this cell division had produced some 100 identical cells within the first week. Then the cells began to differentiate—to specialize in structure and function. How identical cells do this—as if one decides “I’ll become a brain, you become intestines!”—is a puzzle that scientists are just beginning to solve.

About 10 days after conception, the zygote attaches to the mother’s uterine wall, beginning approximately 37 weeks of the closest human relationship. The zygote’s inner cells become the **embryo** (FIGURE 45.3a). The outer cells become the *placenta*, the life-link that transfers nutrients and oxygen from mother to embryo. A healthy and well-nourished mother helps form a healthy baby-to-be. Over the next 6 weeks, the embryo’s organs begin to form and function. The heart begins to beat.

For 1 in 270 sets of parents, though, there is a bonus. Two heartbeats will reveal that the zygote, during its early days of development, has split into two. If all goes well, two genetically identical babies will start life together some 8 months later (Module 14).

By 9 weeks after conception, an embryo looks unmistakably human (Figure 45.3b). It is now a **fetus** (Latin for “offspring” or “young one”). During the sixth month, organs such as the stomach have developed enough to give the fetus a good chance of survival if born prematurely.

At each prenatal stage, genetic and environmental factors affect our development. By the sixth month, microphone readings taken inside the uterus reveal that the fetus is responsive to sound and is exposed to the sound of its mother’s muffled voice (Ecklund-Flores, 1992; Hepper, 2005). Immediately after birth, emerging from living 38 or so weeks underwater, newborns prefer her voice to another woman’s or to their father’s (Busnel et al., 1992; DeCasper et al., 1984, 1986, 1994). They also prefer hearing their mother’s language. If she spoke two languages during pregnancy, they display interest in both (Byers-Heinlein et al., 2010). And just after birth, the melodic ups and downs of newborns’ cries bear the tuneful signature of their mother’s native tongue (Mampe et al., 2009). Babies born

to French-speaking mothers tend to cry with the rising intonation of French; babies born to German-speaking mothers cry with the falling tones of German. Would you have guessed? The learning of language begins in the womb.

In the 2 months before birth, fetuses demonstrate learning in other ways, as when they adapt to a vibrating, honking device placed on their mother's abdomen (Dirix et al., 2009). Like people who adapt to the sound of trains in their neighborhood, fetuses get used to the honking. Moreover, 4 weeks later, they recall the sound (as evidenced by their blasé response, compared with reactions of those not previously exposed).

Sounds are not the only stimuli fetuses are exposed to in the womb. In addition to transferring nutrients and oxygen from mother to fetus, the placenta screens out many harmful substances, but some slip by. **Teratogens**, agents such as viruses and drugs, can damage an embryo or fetus. This is one reason pregnant women are advised not to drink alcoholic beverages. A pregnant woman never drinks alone. As alcohol enters her bloodstream, and her fetus', it depresses activity in both their central nervous systems. Alcohol use during pregnancy may prime the woman's offspring to like alcohol and may put them at risk for heavy drinking and alcohol use disorder during their teens. In experiments, when pregnant rats drank alcohol, their young offspring later displayed a liking for alcohol's taste and odor (Youngtob et al., 2007, 2009).

Even light drinking or occasional binge drinking can affect the fetal brain (Braun, 1996; Ikonomidou et al., 2000; Sayal et al., 2009). Persistent heavy drinking puts the fetus at risk for birth defects and for future behavior problems, hyperactivity, and lower intelligence. For 1 in about 800 infants, the effects are visible as **fetal alcohol syndrome (FAS)**, marked by lifelong physical and mental brain abnormalities (May & Gossage, 2001). The fetal damage may occur because alcohol has an *epigenetic effect*: It leaves chemical marks on DNA that switch genes abnormally on or off (Liu et al., 2009).

The Competent Newborn

45-3

What are some newborn abilities, and how do researchers explore infants' mental abilities?

Babies come with software preloaded on their neural hard drives. Having survived prenatal hazards, we as newborns came equipped with automatic reflex responses ideally suited for our survival. We withdrew our limbs to escape pain. If a cloth over our face interfered with our breathing, we turned our head from side to side and swiped at it.

New parents are often in awe of the coordinated sequence of reflexes by which their baby gets food. Thanks to the *rooting reflex*, when something touches their cheek, babies turn toward that touch, open their mouth, and vigorously root for a nipple. Finding one, they automatically close on it and begin *sucking*—which itself requires a coordinated sequence of reflexive *tonguing*, *swallowing*, and *breathing*. Failing to find satisfaction, the hungry baby may cry—a behavior parents find highly unpleasant and very rewarding to relieve.

Prepared to feed and eat Animals are predisposed to respond to their offspring's cries for nourishment.

The pioneering American psychologist William James presumed that the newborn experiences a “blooming, buzzing confusion,” an assumption few people challenged until the 1960s. But then scientists discovered that babies can tell you a lot—if you know how to ask. To ask, you must capitalize on what babies can do—gaze, suck, turn their heads. So, equipped with eye-tracking machines and pacifiers wired to electronic gear, researchers set out to answer parents’ age-old questions: What can my baby see, hear, smell, and think?

habituation decreasing responsiveness with repeated stimulation. As infants gain familiarity with repeated exposure to a visual stimulus, their interest wanes and they look away sooner.

Consider how researchers exploit **habituation**—a decrease in responding with repeated stimulation. We saw this earlier when fetuses adapted to a vibrating, honking device placed on their mother’s abdomen. The novel stimulus gets attention when first presented. With repetition, the response weakens. This seeming boredom with familiar stimuli gives us a way to ask infants what they see and remember.

An example: Researchers have used *visual preference* to “ask” 4-month-olds how they recognize cats and dogs (Quinn, 2002; Spencer et al., 1997). First, they showed the infants a series of images of either cats or dogs. Then they showed them hybrid cat-dog images (**FIGURE 45.4**). Which of those two animals do you think the infants would find more novel (measured in looking time) after seeing a series of cats? It was the hybrid animal with the dog’s head (and vice versa if they previously viewed dogs). This suggests that infants, like adults, focus first on the face, not the body.

Figure 45.4

Quick—which is the cat?

Researchers used cat-dog hybrid images such as these to test how infants categorize animals.

Indeed, even as newborns, we prefer sights and sounds that facilitate social responsiveness. We turn our heads in the direction of human voices. We gaze longer at a drawing of a face-like image (**FIGURE 45.5**). We prefer to look at objects 8 to 12 inches away. Wonder of wonders, that just happens to be the approximate distance between a nursing infant’s eyes and its mother’s (Maurer & Maurer, 1988).

Figure 45.5

Newborns’ preference for faces

When shown these two stimuli with the same elements, Italian newborns spent nearly twice as many seconds looking at the face-like image (Johnson & Morton, 1991). Canadian newborns display the same apparently inborn preference to look toward faces (Mondloch et al., 1999).

Within days after birth, our brain’s neural networks were stamped with the smell of our mother’s body. Week-old nursing babies, placed between a gauze pad from their mother’s bra and one from another nursing mother, have usually turned toward the smell of their own mother’s pad (MacFarlane, 1978). What’s more, that smell preference lasts. One experiment capitalized on the fact that some nursing mothers in a French maternity ward applied a

balm with a chamomile scent to prevent nipple soreness (Delaunay-El Allam, et al., 2010). Twenty-one months later, their toddlers preferred playing with chamomile-scented toys! Their peers who had not sniffed the scent while breast feeding showed no such preference. (This makes one wonder: Will adults who as babies associated chamomile scent with their mother's breast become devoted chamomile tea drinkers?)

Before You Move On

▶ ASK YOURSELF

Are you surprised by the news of infants' competencies? Remember hindsight bias from Module 4? Is this one of those cases where it feels like you "knew it all along"?

▶ TEST YOURSELF

Your friend's older sister—a regular drinker—hopes to become pregnant soon and has stopped drinking. Why is this a good idea? What negative effects might alcohol consumed during pregnancy have on a developing fetus?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 45 Review

45-1 What three issues have engaged developmental psychologists?

- *Developmental psychologists* study physical, mental, and social changes throughout the life span.
- They focus on three issues: nature and nurture (the interaction between our genetic inheritance and our experiences); continuity and stages (whether development is gradual and continuous or a series of relatively abrupt changes); and stability and change (whether our traits endure or change as we age).

45-2 What is the course of prenatal development, and how do teratogens affect that development?

- The life cycle begins at conception, when one sperm cell unites with an egg to form a *zygote*.
- The zygote's inner cells become the *embryo*, and in the next 6 weeks, body organs begin to form and function.
- By 9 weeks, the *fetus* is recognizably human.
- *Teratogens* are potentially harmful agents that can pass through the placental screen and harm the developing embryo or fetus, as happens with *fetal alcohol syndrome*.

45-3 What are some newborn abilities, and how do researchers explore infants' mental abilities?

- Babies are born with sensory equipment and reflexes that facilitate their survival and their social interactions with adults. For example, they quickly learn to discriminate their mother's smell and sound.
- Researchers use techniques that test *habituation*, such as the visual-preference procedure, to explore infants' abilities.

Multiple-Choice Questions

- Alcohol is a teratogen that can slip through the _____ and damage the fetus or embryo.
 - placenta
 - nervous system
 - womb
 - brainstem
 - zygote
- Even as newborns, we prefer sights and sounds that facilitate social responsiveness. This can be seen by a newborn's preference for
 - soft music.
 - face-like images.
 - low pitched sounds.
 - soft colors.
 - loud music.
- As infants gain familiarity with repeated exposure to a visual stimulus, their interest wanes and they look away sooner. The decrease in an infant's responsiveness is called
 - concentration.
 - teratogens.
 - habituation.
 - stability.
 - transference.
- Which question expresses the developmental issue of stability and change?
 - Are individuals more similar or different from each other?
 - How much of development occurs in distinct stages?
 - How much of development is determined by genetics?
 - To what extent do certain traits persist through the life span?
 - Which traits are most affected by life changes and experience?
- What is the prenatal development sequence?
 - Zygote, embryo, fetus
 - Fetus, zygote, embryo
 - Embryo, zygote, fetus
 - Zygote, fetus, embryo
 - Fetus, embryo, zygote
- Some people think development occurs much in the way a tree grows, slowly and steadily adding one ring each year. Others think that there are rather abrupt developmental jumps, like the transformation of a tadpole into a frog. Which of the following issues would this difference of opinion relate to?
 - Nature and nurture
 - Maturation and learning
 - Prenatal and neonatal
 - Stability and change
 - Continuity and stages
- Which of the following is the longest prenatal stage?
 - Teratogen
 - Conception
 - Zygote
 - Embryo
 - Fetus

Practice FRQs

- What is habituation? How is this phenomenon used by researchers in examining newborns' abilities?
- Three major issues are addressed by psychologists in the study of human development. Identify and state how all three might be considered to explain how children's traits and abilities develop.

Answer

1 point: Habituation is the decrease in responding with repeated stimulation.

1 point: Researchers use habituation to see what infants recognize and remember.

(3 points)

Module 46

Infancy and Childhood: Physical Development

Module Learning Objectives

- 46-1** Describe some developmental changes in brain and motor abilities during infancy and childhood.
- 46-2** Describe how an infant's developing brain begins processing memories.

- 46-1** During infancy and childhood, how do the brain and motor skills develop?

During infancy, a baby grows from newborn to toddler, and during childhood from toddler to teenager. We all traveled this path, with its physical, cognitive, and social milestones.

As a flower unfolds in accord with its genetic instructions, so do we. **Maturation**—the orderly sequence of biological growth—decrees many of our commonalities. We stand before walking. We use nouns before adjectives. Severe deprivation or abuse can retard development. Yet the genetic growth tendencies are inborn. Maturation (nature) sets the basic course of development; experience (nurture) adjusts it. Once again, we see genes and scenes interacting.

“It is a rare privilege to watch the birth, growth, and first feeble struggles of a living human mind.”
—ANNIE SULLIVAN, IN HELEN KELLER'S *THE STORY OF MY LIFE*, 1903

maturation biological growth processes that enable orderly changes in behavior, relatively uninfluenced by experience.

Brain Development

In your mother's womb, your developing brain formed nerve cells at the explosive rate of nearly one-quarter million per minute. The developing brain cortex actually overproduces neurons, with the number peaking at 28 weeks and then subsiding to a stable 23 billion or so at birth (Rabinowicz et al., 1996, 1999; de Courten-Myers, 2002).

From infancy on, brain and mind—neural hardware and cognitive software—develop together. On the day you were born, you had most of the brain cells you would ever have. However, your nervous system was immature: After birth, the branching neural networks that eventually enabled you to walk, talk, and remember had a wild growth spurt (**FIGURE 46.1** on the next page). From ages 3 to 6, the most rapid growth was in your frontal lobes, which enable rational planning. This explains why preschoolers display a rapidly developing ability to control their attention and behavior (Garon et al., 2008).

The association areas—those linked with thinking, memory, and language—are the last cortical areas to develop. As they do, mental abilities surge (Chugani & Phelps, 1986; Thatcher et al., 1987). Fiber pathways supporting language and agility proliferate into puberty. A use-it-or-lose-it *pruning process* shuts down unused links and strengthens others (Paus et al., 1999; Thompson et al., 2000).

AP® Exam Tip

Note that maturation, to developmental psychologists, is a biological sequence. This is much more precise than the general notion that maturation means to become more adult-like.

Figure 46.1

Drawings of human cerebral cortex sections In humans, the brain is immature at birth. As the child matures, the neural networks grow increasingly more complex.

At birth

3 months

15 months

Motor Development

The developing brain enables physical coordination. As an infant's muscles and nervous system mature, skills emerge. With occasional exceptions, the motor development sequence is universal. Babies roll over before they sit unsupported, and they usually crawl on all fours before they walk (**FIGURE 46.2**). These behaviors reflect not imitation but a maturing nervous system; blind children, too, crawl before they walk.

There are, however, individual differences in timing. In the United States, for example, 25 percent of all babies walk by age 11 months, 50 percent within a week after their first birthday, and 90 percent by age 15 months (Frankenburg et al., 1992). The recommended infant *back-to-sleep position* (putting babies to sleep on their backs to reduce the risk of a smothering crib death) has been associated with somewhat later crawling but not with later walking (Davis et al., 1998; Lipsitt, 2003).

FYI

In the eight years following the 1994 launch of a U.S. Back to Sleep educational campaign, the number of infants sleeping on their stomach dropped from 70 to 11 percent—and SIDS (Sudden Infant Death Syndrome) deaths fell by half (Braiker, 2005).

Renee Altier for Worth Publishers

John Lund/Annabelle Breakley/Blend Images/Corbis

© Blue Jean Images/Alamy

© Radius Images/Alamy

Figure 46.2

Triumphant toddlers Sit, crawl, walk, run—the sequence of these motor development milestones is the same the world around, though babies reach them at varying ages.

Genes guide motor development. Identical twins typically begin walking on nearly the same day (Wilson, 1979). Maturation—including the rapid development of the cerebellum at the back of the brain—creates our readiness to learn walking at about age 1. Experience before that time has a limited effect. The same is true for other physical skills, including bowel and bladder control. Before necessary muscular and neural maturation, don't expect pleading or punishment to produce successful toilet training.

Brain Maturation and Infant Memory

46-2 How does an infant's developing brain begin processing memories?

Can you recall your first day of preschool or your third birthday party? Our earliest memories seldom predate our third birthday. We see this *infantile amnesia* in the memories of some preschoolers who experienced an emergency fire evacuation caused by a burning popcorn maker. Seven years later, they were able to recall the alarm and what caused it—if they were 4 to 5 years old at the time. Those experiencing the event as 3-year-olds could not remember the cause and usually misrecalled being already outside when the alarm sounded (Pillemer, 1995). Other studies confirm that the average age of earliest conscious memory is 3½ years (Bauer, 2002, 2007). As children mature, from 4 to 6 to 8 years, childhood amnesia is giving way, and they become increasingly capable of remembering experiences, even for a year or more (Bruce et al., 2000; Morris et al., 2010). The brain areas underlying memory, such as the hippocampus and frontal lobes, continue to mature into adolescence (Bauer, 2007).

Apart from constructed memories based on photos and family stories, we *consciously* recall little from before age 4. Yet our brain was processing and storing information during those early years. In 1965, while finishing her doctoral work in psychology, Carolyn Rovee-Collier observed a nonverbal infant memory. She was also a new mom, whose colicky 2-month-old, Benjamin, could be calmed by moving a crib mobile. Weary of hitting the mobile, she strung a cloth ribbon connecting the mobile to Benjamin's foot. Soon, he was kicking his foot to move the mobile. Thinking about her unintended home experiment, Rovee-Collier realized that, contrary to popular opinion in the 1960s, babies are capable of learning. To know for sure that her son wasn't just a whiz kid, she repeated the experiment with other infants (Rovee-Collier, 1989, 1999). Sure enough, they, too, soon kicked more when hitched to a mobile, both on the day of the experiment and the day after. They had learned the link between moving legs and moving mobiles. If, however, she hitched them to a different mobile the next day, the infants showed no learning, indicating that they remembered the original mobile and recognized the difference. Moreover, when tethered to the familiar mobile a month later, they remembered the association and again began kicking (**FIGURE 46.3**).

Traces of forgotten childhood languages may also persist. One study tested English-speaking British adults who had no conscious memory of the Hindi or Zulu they had spoken as children. Yet, up to age 40, they could relearn subtle sound contrasts in these languages that other people could *not* learn (Bowers et al., 2009). What the conscious mind does not know and cannot express in words, the nervous system somehow remembers.

"This is the path to adulthood. You're here."

Exactstock/SuperStock

Figure 46.3
Infant at work Babies only 3 months old can learn that kicking moves a mobile, and they can retain that learning for a month. (From Rovee-Collier, 1989, 1997.)

Before You Move On

▶ ASK YOURSELF

What do you tend to regard as your earliest memory? Now that you know about infantile amnesia, has your opinion changed about the accuracy of that memory?

▶ TEST YOURSELF

What is the biological growth process that explains why most children begin walking by about 12 to 15 months?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 46 Review

46-1

During infancy and childhood, how do the brain and motor skills develop?

- The brain's nerve cells are sculpted by heredity and experience. Their interconnections multiply rapidly after birth, a process that continues until puberty, when a pruning process begins shutting down unused connections.
- Complex motor skills—sitting, standing, walking—develop in a predictable sequence, though the timing of that sequence is a function of individual *maturation* and culture.

46-2

How does an infant's developing brain begin processing memories?

- We have no conscious memories of events occurring before about age 3½, in part because major brain areas have not yet matured.

Multiple-Choice Questions

1. As the infant's brain develops, some neural pathways will decay if not used. This use-it-or-lose-it process is known as
 - a. motor development.
 - b. pruning.
 - c. spacing.
 - d. accommodation.
 - e. maturation.
2. Which of the following depends least on the maturation process?
 - a. Riding a bike
 - b. Writing
 - c. Talking
 - d. Bladder control
 - e. Telling time
3. Which of the following is true of the early formation of brain cells?
 - a. They form at a constant rate throughout the prenatal period.
 - b. They begin forming slowly, and then the rate increases throughout prenatal development.
 - c. They form slowly during the prenatal period, and then the rate increases after birth.
 - d. They form at a constantly increasing rate prenatally and in early childhood.
 - e. They are overproduced early in the prenatal period, and then the rate decreases and stabilizes.
4. Neural networks grow more complex by
 - a. branching outward to form multiple connections.
 - b. keeping the nervous system immature.
 - c. controlling one another with a restricted response system.
 - d. limiting connections.
 - e. associating behaviors that would not normally be associated together.

Practice FRQs

1. Define and give an example of maturation. Define infantile amnesia and explain how maturation contributes to this phenomenon.

Answer

1 point: Maturation is the orderly changes in behavior that result from biological processes that are relatively unaffected by experience.

1 point: Various examples will serve here, such as the normal development of motor skills (e.g., rolling over, crawling) or bladder and bowel control.

1 point: Infantile amnesia is our inability to remember events that occurred before we are about 3½ years old.

1 point: The brain areas underlying memory need to mature before we can remember accurately. This maturation doesn't happen until after the age of 3.

2. Three types of development are listed below. Give a specific example of each.

- Brain development
- Motor development
- Infant memory

(3 points)

Module 47

Infancy and Childhood: Cognitive Development

Module Learning Objectives

- 47-1** Describe how a child's mind develops from the perspectives of Piaget, Vygotsky, and today's researchers.
- 47-2** Explain how autism spectrum disorder affects development.

Image Source/Getty Images

47-1 From the perspectives of Piaget, Vygotsky, and today's researchers, how does a child's mind develop?

Somewhere on your precarious journey “from egghood to personhood” (Broks, 2007), you became conscious. When was that, and how did your mind unfold from there? Developmental psychologist Jean Piaget [pee-ah-ZHAY]

spent his life searching for the answers to such questions. He studied children's **cognitive** development—all the mental activities associated with thinking, knowing, remembering, and communicating. His interest began in 1920, when he was in Paris developing questions for children's intelligence tests. While administering the tests, Piaget became intrigued by children's wrong answers, which were often strikingly similar among same-age children. Where others saw childish mistakes, Piaget saw intelligence at work.

A half-century spent with children convinced Piaget that a child's mind is not a miniature model of an adult's. Thanks partly to his work, we now understand that children reason

differently than adults, in “wildly illogical ways about problems whose solutions are self-evident to adults” (Brainerd, 1996).

Piaget's studies led him to believe that a child's mind develops through a series of stages, in an upward march from the newborn's simple reflexes to the adult's abstract reasoning power. Thus, an 8-year-old can comprehend things a toddler cannot, such as the analogy that “getting an idea is like having a light turn on in your head,” or that a miniature slide is too small for sliding, and a miniature car is much too small to get into (**FIGURE 47.1**).

Piaget's core idea is that the driving force behind our intellectual progression is an unceasing struggle to make sense of our experiences. To this end, the maturing brain

Jean Piaget (1896–1980) “If we examine the intellectual development of the individual or of the whole of humanity, we shall find that the human spirit goes through a certain number of stages, each different from the other” (1930).

AP® Exam Tip

Jean Piaget is such an important person in the history of psychology that it's likely there will be at least one question about him on the AP® exam.

Figure 47.1

Scale errors Psychologists report that 18- to 30-month-old children may fail to take the size of an object into account when trying to perform impossible actions with it (DeLoache, Uttal, & Rosengren, 2004). At left, a 21-month-old attempts to slide down a miniature slide. At right, a 24-month-old opens the door to a miniature car and tries to step inside.

builds **schemas**, concepts or mental molds into which we pour our experiences (**FIGURE 47.2**). By adulthood we have built countless schemas, ranging from *cats* and *dogs* to our concept of *love*.

Figure 47.2

An impossible object Look carefully at the “devil’s tuning fork.” Now look away—no, better first study it some more—and then look away and draw it. . . . Not so easy, is it? Because this tuning fork is an impossible object, you have no schema for such an image.

To explain how we use and adjust our schemas, Piaget proposed two more concepts. First, we **assimilate** new experiences—we interpret them in terms of our current understandings (schemas). Having a simple schema for *dog*, for example, a toddler may call all four-legged animals *dogs*. But as we interact with the world, we also adjust, or **accommodate**, our schemas to incorporate information provided by new experiences. Thus, the child soon learns that the original *dog* schema is too broad and accommodates by refining the category (**FIGURE 47.3**).

(a) Two-year-old Alexandra has learned the schema for *doggy* from her picture books.

(b) Alexandra sees a cat and calls it a *doggy*. She is trying to assimilate this new animal into an existing schema. Her mother tells her, “No, it’s a *cat*.”

(c) Alexandra accommodates her schema for furry four-legged animals, distinguishing dogs from cats. Over time her schemas become more sophisticated as she learns to distinguish the pets of family and friends by name.

Figure 47.3

Pouring experience into mental molds We use our existing schemas to *assimilate* new experiences. But sometimes we need to *accommodate* (adjust) our schemas to include new experiences.

Piaget’s Theory and Current Thinking

Piaget believed that children construct their understanding of the world while interacting with it. Their minds experience spurts of change, followed by greater stability as they move from one cognitive plateau to the next, each with distinctive characteristics that permit specific kinds of thinking. In Piaget’s view, cognitive development consisted of four major stages—*sensorimotor*, *preoperational*, *concrete operational*, and *formal operational*.

schema a concept or framework that organizes and interprets information.

assimilation interpreting our new experiences in terms of our existing schemas.

accommodation adapting our current understandings (schemas) to incorporate new information.

Sensorimotor Stage

In the **sensorimotor stage**, from birth to nearly age 2, babies take in the world through their senses and actions—through looking, hearing, touching, mouthing, and grasping. As their hands and limbs begin to move, they learn to make things happen.

Very young babies seem to live in the present: Out of sight is out of mind. In one test, Piaget showed an infant an appealing toy and then flopped his beret over it. Before the age of 6 months, the infant acted as if it ceased to exist. Young infants lack **object permanence**—the awareness that objects continue to exist when not perceived. By 8 months, infants begin exhibiting memory for things no longer seen. If you hide a toy, the infant will momentarily look for it (**FIGURE 47.4**). Within another month or two, the infant will look for it even after being restrained for several seconds.

© Doug Goodman/Science Source

Figure 47.4

Object permanence Infants younger than 6 months seldom understand that things continue to exist when they are out of sight. But for this older infant, out of sight is definitely not out of mind.

So does object permanence in fact blossom at 8 months, much as tulips blossom in spring? Today's researchers think not. They believe object permanence unfolds gradually, and they see development as more continuous than Piaget did. Even young infants will at least momentarily look for a toy where they saw it hidden a second before (Wang et al., 2004).

Researchers also believe Piaget and his followers underestimated young children's competence. Consider these simple experiments:

- *Baby physics*: Like adults staring in disbelief at a magic trick (the “Whoa!” look), infants look longer at an unexpected and unfamiliar scene of a car seeming to pass through a solid object, a ball stopping in midair, or an object violating object permanence by magically disappearing (Baillargeon, 1995, 2008; Wellman & Gelman, 1992).
- *Baby math*: Karen Wynn (1992, 2000) showed 5-month-olds one or two objects (**FIGURE 47.5a**). Then she hid the objects behind a screen, and visibly removed or added one (Figure 47.5d). When she lifted the screen, the infants sometimes did a double take, staring longer when shown a wrong number of objects (Figure 47.5f). But were they just responding to a greater or smaller *mass* of objects, rather than a change in *number* (Feigenson et al., 2002)? Later experiments showed that babies' number sense extends to larger numbers, to ratios, and to such things as drumbeats and motions (Libertus & Brannon, 2009; McCrink & Wynn, 2004; Spelke & Kinzler, 2007). If accustomed to a Daffy Duck puppet jumping three times on stage, they showed surprise if it jumped only twice.

Clearly, infants are smarter than Piaget appreciated. Even as babies, we had a lot on our minds.

sensorimotor stage in Piaget's theory, the stage (from birth to about 2 years of age) during which infants know the world mostly in terms of their sensory impressions and motor activities.

object permanence the awareness that things continue to exist even when not perceived.

Figure 47.5

Baby math Shown a numerically impossible outcome, 5-month-old infants stare longer. (From Wynn, 1992.)

Then either: possible outcome
(e) Screen drops revealing 1 object

or: impossible outcome
(f) Screen drops revealing 2 objects

Preoperational Stage

Piaget believed that until about age 6 or 7, children are in a **preoperational stage**—too young to perform *mental operations* (such as imagining an action and mentally reversing it). For a 5-year-old, the milk that seems “too much” in a tall, narrow glass may become an acceptable amount if poured into a short, wide glass. Focusing only on the height dimension, this child cannot perform the operation of mentally pouring the milk back. Before about age 6, said Piaget, children lack the concept of **conservation**—the principle that quantity remains the same despite changes in shape (**FIGURE 47.6**).

Piaget did not view the stage transitions as abrupt. Even so, *symbolic thinking* (representing things with words and images) appears at an earlier age than he supposed. Judy DeLoache (1987) discovered this when she showed children a model of a room and hid a model toy in it (a miniature stuffed dog behind a miniature couch). The 2½-year-olds easily remembered where to find the miniature toy, but they could not use the model to locate an actual stuffed dog behind a couch in a real room. Three-year-olds—only 6 months older—usually went right to the actual stuffed animal in the real room, showing they *could* think of the model as a symbol for the room. Piaget probably would have been surprised.

EGOCENTRISM

Piaget contended that preschool children are **egocentric**: They have difficulty perceiving things from another’s point of view. Asked to “show Mommy your picture,” 2-year-old Gabriella holds the picture up facing her own eyes. Three-year-old Gray makes himself “invisible” by putting his hands over his eyes, assuming that if he can’t see his grandparents,

preoperational stage

in Piaget’s theory, the stage (from about 2 to about 6 or 7 years of age) during which a child learns to use language but does not yet comprehend the mental operations of concrete logic.

conservation the principle (which Piaget believed to be a part of concrete operational reasoning) that properties such as mass, volume, and number remain the same despite changes in the forms of objects.

egocentrism in Piaget’s theory, the preoperational child’s difficulty taking another’s point of view.

AP® Exam Tip

Careful! *Egocentric* is not the same as egotistical. Egocentric means you can’t take someone else’s point of view. Egotistical means you’re pretty full of yourself.

Figure 47.6

Piaget’s test of conservation

This preoperational child does not yet understand the principle of conservation of substance. When the milk is poured into a tall, narrow glass, it suddenly seems like “more” than when it was in the shorter, wider glass. In another year or so, she will understand that the quantity stays the same.

theory of mind people's ideas about their own and others' mental states—about their feelings, perceptions, and thoughts, and the behaviors these might predict.

"It's too late, Roger—they've seen us."

Roger has not outgrown his early childhood egocentrism.

they can't see him. Children's conversations also reveal their egocentrism, as one young boy demonstrated (Phillips, 1969, p. 61):

"Do you have a brother?"

"Yes."

"What's his name?"

"Jim."

"Does Jim have a brother?"

"No."

Like Gabriella, TV-watching preschoolers who block your view of the TV assume that you see what they see. They simply have not yet developed the ability to take another's viewpoint. Even teens

and adults often overestimate the extent to which others share our opinions and perspectives, a trait known as the *curse of knowledge*. We assume that something will be clear to others if it is clear to us, or that text message recipients will "hear" our "just kidding" intent (Epley et al., 2004; Kruger et al., 2005). Children are even more susceptible to this tendency.

THEORY OF MIND

When Little Red Riding Hood realized her "grandmother" was really a wolf, she swiftly revised her ideas about the creature's intentions and raced away. Preschoolers, although still egocentric, develop this ability to infer others' mental states when they begin forming a **theory of mind** (a term first coined by psychologists to describe chimpanzees' seeming ability to read intentions [Premack & Woodruff, 1978]).

Infants as young as 7 months show some knowledge of others' beliefs (Kovács et al., 2010). With time, the ability to take another's perspective develops. They come to understand what made a playmate angry, when a sibling will share, and what might make a parent buy a toy. And they begin to tease, empathize, and persuade. Between about 3½ and 4½, children worldwide come to realize that others may hold false beliefs (Callaghan et al., 2005; Sabbagh et al., 2006). Researchers showed Toronto children a Band-Aids box and asked them what was inside (Jenkins & Astington, 1996). Expecting Band-Aids, the children were surprised to discover that the box actually contained pencils. Asked what a child who had never seen the box would think was inside, 3-year-olds typically answered "pencils." By age 4 to 5, the children's theory of mind had leapt forward, and they anticipated their friends' false belief that the box would hold Band-Aids.

In a follow-up experiment, children viewed a doll named Sally leaving her ball in a red cupboard (**FIGURE 47.7**). Another doll, Anne, then moves the ball to a blue cupboard. Researchers then pose a question: When Sally returns, where will she look for the ball? Children with *autism spectrum disorder* (ASD; see Close-up: Autism Spectrum Disorder and "Mind-Blindness") have difficulty understanding that Sally's state of mind differs from their own—that Sally, not knowing the ball has been moved, will return to the red cupboard. They also have difficulty reflecting on their own mental states. They are, for example, less likely to use the personal pronouns *I* and *me*. Deaf children with hearing parents and minimal communication opportunities have had similar difficulty inferring others' states of mind (Peterson & Siegal, 1999).

Figure 47.7

Testing children's theory of mind

This simple problem illustrates how researchers explore children's presumptions about others' mental states. (Inspired by Baron-Cohen et al., 1985.)

Close-up

Autism Spectrum Disorder and “Mind-Blindness”

47-2 How does autism spectrum disorder affect development?

Diagnoses of **autism spectrum disorder (ASD)**, a disorder marked by social deficiencies and repetitive behaviors, have been increasing, according to recent estimates. Once believed to affect 1 in 2500 children, ASD now affects 1 in 110 American children and about 1 in 100 in Britain (CDC, 2009; Lillienfeld & Arkowitz, 2007; NAS, 2011). The increase in ASD diagnoses has been offset by a decrease in the number of children considered “cognitively disabled” or “learning disabled,” which suggests a relabeling of children’s disorders (Gernsbacher et al., 2005; Grinker, 2007; Shattuck, 2006). A massive \$6.7 billion National Children’s Study now under way aims to enroll 100,000 pregnant women in 105 countries and to follow their babies until they turn 21—partly in hopes of explaining the rising rates of ASD, as well as premature births, childhood obesity, and asthma (Belluck, 2010; Murphy, 2008).

The underlying source of ASD’s symptoms seems to be poor communication among brain regions that normally work together to let us take another’s viewpoint. This effect appears to result from ASD-related genes interacting with the environment (State & Šestan, 2012). People with ASD are therefore said to have an *impaired theory of mind* (Rajendran & Mitchell, 2007; Senju et al., 2009). They have difficulty inferring others’ thoughts and feelings. They do not appreciate that playmates and parents might view things differently. Mind reading that most of us find intuitive (*Is that face conveying a smirk or a sneer?*) is difficult for those with ASD. Most children learn that another child’s pouting mouth signals sadness, and that twinkling eyes mean happiness or mischief. A child with ASD fails to understand these signals (Frith & Frith, 2001).

Ozler Muhammad/The New York Times

Autism spectrum disorder This speech-language pathologist is helping a boy with ASD learn to form sounds and words. ASD is marked by deficient social communication and difficulty grasping others’ states of mind.

autism spectrum disorder (ASD) a disorder that appears in childhood and is marked by significant deficiencies in communication and social interaction, and by rigidly fixated interests and repetitive behaviors.

“Autism” case number 1 In 1943, Donald Gray Triplett, an “odd” child with unusual gifts and social deficits, was the first person to receive the diagnosis of a previously unreported condition, which psychiatrist Leo Kanner termed “autism.” (After a 2013 change in the diagnosis manual, his condition is now called autism spectrum disorder.) In 2010, at age 77, Triplett was still living in his family home and Mississippi town, where he often played golf (Donvan & Zucker, 2010).

In hopes of a cure, desperate parents have sometimes subjected children to dubious therapies (Shute, 2010).

ASD (formerly referred to as “autism”) has differing levels of severity. “High-functioning” individuals generally have normal intelligence, and they often have an exceptional skill or talent in a specific area. But they lack social and communication skills, and they tend to become distracted by minor and unimportant stimuli (Remington et al., 2009). Those at the spectrum’s lower end are unable to use language at all.

ASD afflicts four boys for every girl. Psychologist Simon Baron-Cohen believes this hints at one way to understand this disorder. He has argued that ASD represents an “extreme male brain” (2008, 2009). Although there is some overlap between the sexes, he believes that boys are better “systemizers.” They tend to understand things according to rules or laws, for example, as in mathematical and mechanical systems. Children exposed to high levels of the male sex hormone *testosterone* in the womb may develop more masculine and autistic traits (Auyeung et al, 2009).

In contrast, girls are naturally predisposed to be “empathizers,” Baron-Cohen contends. They are better at reading facial

(Continued on next page)

Close-up (continued)

expressions and gestures, though less so if given testosterone (van Honk et al., 2011).

Biological factors, including genetic influences and abnormal brain development, contribute to ASD (State & Šestan, 2012). Childhood MMR vaccinations do not (Demicheli et al., 2012). Based on a fraudulent 1998 study—“the most damaging medical hoax of the last 100 years” (Flaherty, 2011)—some parents were misled into thinking that the childhood MMR vaccine increased risk of ASD. The unfortunate result was a drop in vaccination rates and an increase in cases of measles and mumps. Some unvaccinated children suffered long-term harm or even death.

Twin and sibling studies provide some evidence for biology’s influence. If one identical twin is diagnosed with ASD, the chances are 50 to 70 percent that the co-twin will be as well (Lichtenstein et al., 2010; Sebat et al., 2007). A younger sibling of a child with ASD also is at a heightened risk (Sutcliffe, 2008). Random genetic mutations in sperm-producing cells may also play a role. As men age, these mutations become more frequent, which may help explain why an over-40 man has a much higher risk of fathering a child with ASD than does a man under 30 (Reichenberg et al., 2007). Researchers are now sleuthing ASD’s telltale signs in the brain’s synaptic and gray matter (Crawley, 2007; Ecker et al., 2010; Garber, 2007).

Biology’s role in ASD also appears in brain-function studies. People without ASD often yawn after seeing others yawn. And as they view and imitate another’s smiling or frowning, they feel something of what the other is feeling. Not so among those with ASD, who are less imitative and show much less activity in brain areas involved in mirroring others’ actions (Dapretto et al., 2006; Perra et al., 2008; Senju et al., 2007). When people with ASD watch another person’s hand move-

ments, for example, their brain displays less than normal mirroring activity (Oberman & Ramachandran, 2007; Théoret et al., 2005). Scientists are continuing to explore and vigorously debate the idea that the brains of people with ASD have “broken mirrors” (Gallese et al., 2011).

Seeking to “systemize empathy,” Baron-Cohen and his Cambridge University colleagues (2007; Golan et al., 2010) collaborated with Britain’s National Autistic Society and a film production company. Knowing that television shows with vehicles have been popular among kids with ASD, they created animations that grafted emotion-conveying faces onto toy tram, train, and tractor characters in a pretend boy’s bedroom (FIGURE 47.8). After the boy leaves for school, the characters come to life and have experiences that lead them to display various emotions (which I predict you would enjoy viewing at www.thetransporters.com). The children were surprisingly able to generalize what they had learned to a new, real context. By the intervention’s end, their previously deficient ability to recognize emotions on real faces now equaled that of children without ASD.

Figure 47.8

Transported into a world of emotion (a) A research team at Cambridge University’s Autism Research Centre introduced children with ASD to emotions experienced and displayed by toy vehicles. (b) After 4 weeks of viewing animations, the children displayed a markedly increased ability to recognize emotions not only in the toy faces but also in humans.

(a) Emotion-conveying faces were grafted onto toy trains.

“The neighbor’s dog has bitten people before. He is barking at Louise.”

Point to the face that shows how Louise is feeling.

(b) Children matched the correct face with the story and photo. (The graph above shows data from two trials.)

Concrete Operational Stage

By age 6 or 7, said Piaget, children enter the **concrete operational stage**. Given concrete (physical) materials, they begin to grasp conservation. Understanding that change in form does not mean change in quantity, they can mentally pour milk back and forth between glasses of different shapes. They also enjoy jokes that use this new understanding:

Mr. Jones went into a restaurant and ordered a whole pizza for his dinner. When the waiter asked if he wanted it cut into 6 or 8 pieces, Mr. Jones said, “Oh, you’d better make it 6, I could never eat 8 pieces!” (McGhee, 1976)

Piaget believed that during the concrete operational stage, children become able to comprehend mathematical transformations and conservation. When my daughter, Laura, was 6, I was astonished at her inability to reverse simple arithmetic. Asked, “What is 8 plus 4?” she required 5 seconds to compute “12,” and another 5 seconds to then compute 12 minus 4. By age 8, she could answer a reversed question instantly.

Formal Operational Stage

By age 12, our reasoning expands from the purely concrete (involving actual experience) to encompass abstract thinking (involving imagined realities and symbols). As children approach adolescence, said Piaget, many become capable of thinking more like scientists. They can ponder hypothetical propositions and deduce consequences: *If this, then that*. Systematic reasoning, what Piaget called **formal operational** thinking, is now within their grasp.

Although full-blown logic and reasoning await adolescence, the rudiments of formal operational thinking begin earlier than Piaget realized. Consider this simple problem:

If John is in school, then Mary is in school. John is in school. What can you say about Mary?

Formal operational thinkers have no trouble answering correctly. But neither do most 7-year-olds (Suppes, 1982). **TABLE 47.1** summarizes the four stages in Piaget’s theory.

concrete operational stage in Piaget’s theory, the stage of cognitive development (from about 6 or 7 to 11 years of age) during which children gain the mental operations that enable them to think logically about concrete events.

formal operational stage in Piaget’s theory, the stage of cognitive development (normally beginning about age 12) during which people begin to think logically about abstract concepts.

AP® Exam Tip

One good way to master the developmental milestones in Piaget’s theory is to see them in action. If you know children of various ages, you can test them using some of the ideas presented in this section. Hide a toy from an infant to see object permanence in action. Pour water between two differently shaped glasses to see if a preschooler understands conservation.

Table 47.1 Piaget’s Stages of Cognitive Development

Typical Age Range	Description of Stage	Developmental Phenomena
Birth to nearly 2 years	<i>Sensorimotor</i> Experiencing the world through senses and actions (looking, hearing, touching, mouthing, and grasping)	<ul style="list-style-type: none"> • Object permanence • Stranger anxiety
About 2 to about 6 or 7 years	<i>Preoperational</i> Representing things with words and images (symbolic thinking); using intuitive rather than logical reasoning	<ul style="list-style-type: none"> • Pretend play • Egocentrism
6 or 7 to 11 years	<i>Concrete operational</i> Thinking logically about concrete events; grasping concrete analogies and performing arithmetical operations	<ul style="list-style-type: none"> • Conservation • Mathematical transformations
About 12 through adulthood	<i>Formal operational</i> Abstract reasoning	<ul style="list-style-type: none"> • Abstract logic • Potential for mature moral reasoning

Pretend play

Lev Vygotsky (1896–1934)

Vygotsky, a Russian developmental psychologist pictured here with his daughter, studied how a child's mind feeds on the language of social interaction.

An Alternative Viewpoint: Lev Vygotsky's Scaffolding

As Piaget was forming his theory of cognitive development, Russian psychologist Lev Vygotsky was also studying how children think and learn. He noted that by age 7, they increasingly think in words and use words to solve problems. They do this, he said, by internalizing their culture's language and relying on inner speech (Fernyhough, 2008). Parents who say “No, no!” when pulling a child's hand away from a cake are giving the child a self-control tool. When the child later needs to resist temptation, he may likewise say “No, no!” Second graders who muttered to themselves while doing math problems grasped third-grade math better the following year (Berk, 1994). Whether out loud or inaudibly, talking to themselves helps children control their behavior and emotions and master new skills.

Where Piaget emphasized how the child's mind grows through interaction with the physical environment, Vygotsky emphasized how the child's mind grows through interaction with the *social* environment. If Piaget's child was a young scientist, Vygotsky's was a young apprentice. By mentoring children and giving them new words, parents and others provide a temporary *scaffold* from which children can step to higher levels of thinking (Renninger & Granott, 2005). Language, an important ingredient of social mentoring, provides the building blocks for thinking, noted Vygotsky (who was born the same year as Piaget, but died prematurely of tuberculosis).

Effective mentoring occurs when children are developmentally ready to learn a new skill. For Vygotsky, a child's *zone of proximal development* was the zone between what a child can and can't do—it's what a child can do with help. When learning to ride a bike, it's the developmental zone in which a child can ride with training wheels or a steady parental hand.

Reflecting on Piaget's Theory

What remains of Piaget's ideas about the child's mind? Plenty—enough to merit his being singled out by *Time* magazine as one of the twentieth century's 20 most influential scientists and thinkers and rated in a survey of British psychologists as the last century's greatest psychologist (*Psychologist*, 2003). Piaget identified significant cognitive milestones and stimulated worldwide interest in how the mind develops. His emphasis was less on the ages at which children typically reach specific milestones than on their sequence. Studies around the globe, from aboriginal Australia to Algeria to North America, have confirmed that human cognition unfolds basically in the sequence Piaget described (Lourenco & Machado, 1996; Segall et al., 1990).

However, today's researchers see development as more continuous than did Piaget. By detecting the beginnings of each type of thinking at earlier ages, they have revealed conceptual abilities Piaget missed. Moreover, they see formal logic as a smaller part of cognition than he did. Piaget would not be surprised that today, as part of our own cognitive development, we are adapting his ideas to accommodate new findings.

Implications for Parenting and Teaching

Future parents and teachers remember: Young children are incapable of adult logic. Preschoolers who block one's view of the TV simply have not learned to take another's viewpoint. What seems simple and obvious to us—pestering a cat will lead to scratches—may be incomprehensible to a 3-year-old. Also remember that children are not passive receptacles waiting to be filled with knowledge. Better to build on what they already know, engaging them in concrete

“Assessing the impact of Piaget on developmental psychology is like assessing the impact of Shakespeare on English literature.” -DEVELOPMENTAL PSYCHOLOGIST HARRY BEILIN (1992)

“Childhood has its own way of seeing, thinking, and feeling, and there is nothing more foolish than the attempt to put ours in its place.” -PHILOSOPHER JEAN-JACQUES ROUSSEAU, 1798

demonstrations and stimulating them to think for themselves. And, finally, accept children's cognitive immaturity as adaptive. It is nature's strategy for keeping children close to protective adults and providing time for learning and socialization (Bjorklund & Green, 1992).

Before You Move On

▶ ASK YOURSELF

Can you recall a time when you misheard some song lyrics because you assimilated them into your own schema? (For hundreds of examples of this phenomenon, visit www.kissthisguy.com.)

▶ TEST YOURSELF

Use Piaget's first three stages of cognitive development to explain why children are not just miniature adults in the way they think.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 47 Review

47-1

From the perspectives of Piaget, Vygotsky, and today's researchers, how does a child's mind develop?

- In his theory of *cognitive* development, Jean Piaget proposed that children actively construct and modify their understanding of the world through the processes of *assimilation* and *accommodation*. They form *schemas* that help them organize their experiences.
- Progressing from the simplicity of the *sensorimotor stage* of the first two years, in which they develop *object permanence*, children move to more complex ways of thinking.
- In the *preoperational stage* (about age 2 to about 6 or 7), they develop a *theory of mind*, but they are *egocentric* and unable to perform simple logical operations.
- At age 6 or 7, they enter the *concrete operational stage* and are able to comprehend the principle of *conservation*.
- By about age 12, children enter the *formal operational stage* and can reason systematically.
- Research supports the sequence Piaget proposed, but it also shows that young children are more capable, and their development is more continuous, than he believed.
- Lev Vygotsky's studies of child development focused on the ways a child's mind grows by interacting with the social environment. In his view, parents and caretakers provide temporary scaffolds enabling children to step to higher levels of learning.

47-2

How does autism spectrum disorder affect development?

- ASD is marked by social deficiencies and repetitive behaviors.
- Genetic influences contribute to ASD, as does the male hormone testosterone.

Multiple-Choice Questions

1. Your friend's baby brother, Matt, loves to play with his pet cat. When he sees a puppy, he points and calls it "Mi Mi," which is what he calls his cat. Matt is demonstrating Piaget's process of
 - a. conservation.
 - b. accommodation.
 - c. cognition.
 - d. object permanence.
 - e. assimilation.
2. If you showed a 2-year-old that you'd hidden a toy behind the bed in a model of her bedroom, she would not be able to find the toy in her real bedroom because she lacks
 - a. analytical thinking.
 - b. random thinking.
 - c. symbolic thinking.
 - d. schematic thinking.
 - e. egocentric thinking.
3. Vygotsky called the space between what a child could learn with and without help the
 - a. theory of mind.
 - b. zone of abstract logic.
 - c. zone of abstract reasoning.
 - d. zone of proximal development.
 - e. zone of developmental readiness.
4. Which of the following is a current belief of researchers that differs from Piaget's original theories?
 - a. Infants simply have less information about the world than older children and adults.
 - b. Object permanence develops earlier than Piaget believed.
 - c. Infants learn more by verbal explanations than Piaget believed.
 - d. Accommodation is a process that doesn't occur in young children.
 - e. Schemas don't form until later than Piaget believed.
5. Which of the following cognitive abilities is possible only at the formal operational stage?
 - a. Reversing arithmetic operations
 - b. Using a theory of mind to predict the behavior of others
 - c. Using hypothetical situations as the basis of moral reasoning
 - d. Using symbolic thinking for pretend play
 - e. Understanding basic physics to recognize impossible situations
6. Which of the following identifies children's difficulty seeing another's perspective?
 - a. Abstract thinker
 - b. Role player
 - c. Egocentric thinker
 - d. A child who understands conservation
 - e. A child who demonstrates high mental operations
7. Which of the following would indicate that a child understood conservation?
 - a. She would continue to seek a toy hidden under a blanket.
 - b. She would "hide" in a game of hide-and-seek by covering her eyes with her hands.
 - c. She would believe that a clay snake would have the same amount of clay as the clay ball that was used to make it.
 - d. She would recognize that $7 + 3$ involves the same mathematical relationship as $10 - 7$.
 - e. She would be able to comprehend the logic of if-then statements.

Practice FRQs

1. Describe Lev Vygotsky's ideas on the role of language, scaffolding, and the zone of proximal development in cognitive development. How did his theory differ from that of Jean Piaget?

Answer

1 point: Vygotsky believed that as children grow, they increasingly use words to solve problems and think. Adults help with this process by giving them words to internalize behaviors.

1 point: Scaffolding is the way in which parents and others mentor children to promote cognitive growth, often through providing new words to describe a situation.

1 point: The zone of proximal development marks the border between what children can learn on their own or with help.

1 point: The major difference is that Piaget thought cognitive development resulted from children's interactions with their physical environment, while Vygotsky believed they learned through social interactions.

2. Define and give an example of each of the cognitive milestones listed below:

- Object permanence
- Conservation
- Theory of mind

(3 points)

Module 48

Infancy and Childhood: Social Development

Module Learning Objectives

- 48-1** Describe how parent-infant attachment bonds form.
- 48-2** Describe how psychologists study attachment differences, and discuss their findings about the effect of temperament and parenting.
- 48-3** Discuss how childhood neglect, abuse, or family disruption affect children's attachments.
- 48-4** Discuss the effect of day care on children.
- 48-5** Trace the onset and development of children's self-concept.
- 48-6** Describe three parenting styles, and explain how children's traits relate to them.

48-1 How do parent-infant attachment bonds form?

From birth, babies in all cultures are social creatures, developing an intense bond with their caregivers. Infants come to prefer familiar faces and voices, then to coo and gurgle when given a parent's attention. At about 8 months, soon after object permanence emerges and children become mobile, a curious thing happens: They develop **stranger anxiety**. They may greet strangers by crying and self-protectively reaching for familiar caregivers. "No! Don't leave me!" their distress seems to say. Children this age have schemas for familiar faces; when they cannot assimilate the new face into these remembered schemas, they become distressed (Kagan, 1984). Once again, we see an important principle: *The brain, mind, and social-emotional behavior develop together.*

stranger anxiety the fear of strangers that infants commonly display, beginning by about 8 months of age.

attachment an emotional tie with another person; shown in young children by their seeking closeness to the caregiver and showing distress on separation.

Origins of Attachment

One-year-olds typically cling tightly to a parent when they are frightened or expect separation. Reunited after being apart, they shower the parent with smiles and hugs. No social behavior is more striking than the intense and mutual infant-parent bond. This **attachment** bond is a powerful survival impulse that keeps infants close to their caregivers. Infants become attached to those—typically their parents—who are comfortable and familiar. For many years, psychologists reasoned that infants became attached to those who satisfied their need for nourishment. It made sense. But an accidental finding overturned this explanation.

Body Contact

During the 1950s, University of Wisconsin psychologists Harry Harlow and Margaret Harlow bred monkeys for their learning studies. To equalize experiences and to isolate any disease, they separated the infant monkeys from their mothers shortly after birth and raised them in sanitary individual cages, which included a cheesecloth baby blanket (Harlow et al., 1971). Then came a surprise: When their blankets were taken to be laundered, the monkeys became distressed.

The Harlows recognized that this intense attachment to the blanket contradicted the idea that attachment derives from an association with nourishment. But how could they show this more convincingly? To pit the drawing power of a food source against the contact comfort of the blanket, they created two artificial mothers. One was a bare wire cylinder with a wooden head and an attached feeding bottle, the other a cylinder with no bottle but covered with foam rubber and wrapped with terry cloth.

When raised with both, the monkeys overwhelmingly preferred the comfy cloth mother (**FIGURE 48.1**). Like other infants clinging to their live mothers, the monkey babies would cling to their cloth mothers when anxious. When exploring their environment, they used her as a *secure base*, as if attached to her by an invisible elastic band that stretched only so far before pulling them back. Researchers soon learned that other qualities—rocking, warmth, and feeding—made the cloth mother even more appealing.

Human infants, too, become attached to parents who are soft and warm and who rock, feed, and pat. Much parent-infant emotional communication occurs via touch (Hertenstein et al., 2006), which can be either soothing (snuggles) or arousing (tickles). Human attachment also consists of one person providing another with a secure base from which to explore and a safe haven when distressed. As we mature, our secure base and safe haven shift—from parents to peers and partners (Cassidy & Shaver, 1999). But at all ages we are social creatures. We gain strength when someone offers, by words and actions, a safe haven: “I will be here. I am interested in you. Come what may, I will support you” (Crowell & Waters, 1994).

Figure 48.1

The Harlows' monkey mothers

Psychologists Harry Harlow and Margaret Harlow raised monkeys with two artificial mothers—one a bare wire cylinder with a wooden head and an attached feeding bottle, the other a cylinder with no bottle but covered with foam rubber and wrapped with terry cloth. The Harlows' discovery surprised many psychologists: The infants much preferred contact with the comfortable cloth mother, even while feeding from the nourishing mother.

Harlow Primate Laboratory

FYI

For some people, a perceived relationship with God functions as do other attachments, by providing a secure base for exploration and a safe haven when threatened (Granqvist et al., 2010; Kirkpatrick, 1999).

Familiarity

Contact is one key to attachment. Another is familiarity. In many animals, attachments based on familiarity form during a **critical period**—an optimal period when certain events must take place to facilitate proper development (Bornstein, 1989). For goslings, ducklings, or chicks, that period falls in the hours shortly after hatching, when the first moving object they see is normally their mother. From then on, the young fowl follow her, and her alone.

Konrad Lorenz (1937) explored this rigid attachment process, called **imprinting**. He wondered: What would ducklings do if he was the first moving creature they observed? What they did was follow him around: Everywhere that Konrad went, the ducks were sure to go. Although baby birds imprint best to their own species, they also will imprint to a variety of moving objects—an animal of another species, a box on wheels, a bouncing ball (Colombo, 1982; Johnson, 1992). Once formed, this attachment is difficult to reverse.

critical period an optimal period early in the life of an organism when exposure to certain stimuli or experiences produces normal development.

imprinting the process by which certain animals form strong attachments during an early-life critical period.

Imprinting Whooping cranes normally learn to migrate by following their parents. These cranes, hand-raised from eggs, have imprinted on a crane-costumed ultralight pilot, who then guided them to winter nesting grounds (Mooallem, 2009).

Mark Peterson/Hertix

Children—unlike ducklings—do not imprint. However, they do become attached, during a less precisely defined *sensitive period*, to what they've known. *Mere exposure* to people and things fosters fondness (see Module 79). Children like to reread the same books, rewatch the same movies, reenact family traditions. They prefer to eat familiar foods, live in the same familiar neighborhood, attend school with the same old friends. You may even have noticed your own preference for familiar music, familiar daily routines, and familiar class seating locations. Familiarity is a safety signal. Familiarity breeds content.

Attachment Differences: Temperament and Parenting

48-2

How have psychologists studied attachment differences, and what have they learned about the effects of temperament and parenting?

What accounts for children's attachment differences? To answer this question, Mary Ainsworth (1979) designed the *strange situation* experiment. She observed mother-infant pairs at home during their first 6 months. Later she observed the 1-year-old infants in a strange situation (usually a laboratory playroom). Such research has shown that about 60 percent of infants display *secure attachment*. In their mother's presence they play comfortably, happily exploring their new environment. When she leaves, they become distressed; when she returns, they seek contact with her.

Other infants avoid attachment or show *insecure attachment*, marked either by anxiety or avoidance of trusting relationships. They are less likely to explore their surroundings; they may even cling to their mother. When she leaves, they either cry loudly and remain upset or seem indifferent to her departure and return (Ainsworth, 1973, 1989; Kagan, 1995; van IJzendoorn & Kroonenberg, 1988).

Ainsworth and others found that sensitive, responsive mothers—those who noticed what their babies were doing and responded appropriately—had infants who exhibited secure attachment (De Wolff & van IJzendoorn, 1997). Insensitive, unresponsive mothers—mothers who attended to their babies when they felt like doing so but ignored them at other times—often had infants who were insecurely attached. The Harlows' monkey studies, with unresponsive artificial mothers, produced even more striking effects. When put in strange situations without their artificial mothers, the deprived infants were terrified (**FIGURE 48.2**).

But is attachment style the *result* of parenting? Or is attachment style the result of genetically influenced **temperament**—a person's characteristic emotional reactivity and intensity?

As most parents will tell you after having their second child, babies differ even before gulping their first breath. Heredity predisposes temperament differences (Rothbart, 2007).

temperament a person's characteristic emotional reactivity and intensity.

AP® Exam Tip

Note that temperament is a contribution from the nature side of the nature–nurture debate.

From their first weeks of life, some infants are reactive, intense, and fidgety. Others are easygoing, quiet, and placid. *Difficult* babies are more irritable, intense, and unpredictable. *Easy* babies are cheerful, relaxed, and predictable in feeding and sleeping. *Slow-to-warm-up* infants tend to resist or withdraw from new people and situations (Chess & Thomas, 1987; Thomas & Chess, 1977). And temperament differences typically persist. Consider:

- The most emotionally reactive newborns tend also to be the most reactive 9-month-olds (Wilson & Matheny, 1986; Worobey & Blajda, 1989).
- Exceptionally inhibited and fearful 2-year-olds often are still relatively shy as 8-year-olds; about half will become introverted adolescents (Kagan et al., 1992, 1994).
- The most emotionally intense preschoolers tend to be relatively intense young adults (Larsen & Diener, 1987). In one study of more than 900 New Zealanders, emotionally reactive and impulsive 3-year-olds developed into somewhat more impulsive, aggressive, and conflict-prone 21-year-olds (Caspi, 2000).

The genetic effect appears in physiological differences. Anxious, inhibited infants have high and variable heart rates and a reactive nervous system. When facing new or strange situations, they become more physiologically aroused (Kagan & Snidman, 2004). One form of a gene that regulates the neurotransmitter serotonin predisposes a fearful temperament and, in combination with unsupportive caregiving, an inhibited child (Fox et al., 2007). Such evidence adds to the emerging conclusion that our biologically rooted temperament helps form our enduring personality (McCrae et al., 2000, 2007; Rothbart et al., 2000).

By neglecting such inborn differences, the parenting studies, noted Judith Harris (1998), are like “comparing foxhounds reared in kennels with poodles reared in apartments.” So to separate nature and nurture, we would need to vary parenting while controlling temperament. (Pause and think: If you were the researcher, how might you have done this?)

One Dutch researcher’s solution was to randomly assign 100 temperamentally difficult 6- to 9-month-olds to either an experimental group, in which mothers received personal training in sensitive responding, or to a control group, in which they did not (van den Boom, 1990, 1995). At 12 months of age, 68 percent of the infants in the experimental group were rated securely attached, as were only 28 percent of the control group infants. Other studies support the idea that intervention programs can increase parental sensitivity and, to a lesser extent, infant attachment security (Bakermans-Kranenburg et al., 2003; Van Zeijl et al., 2006).

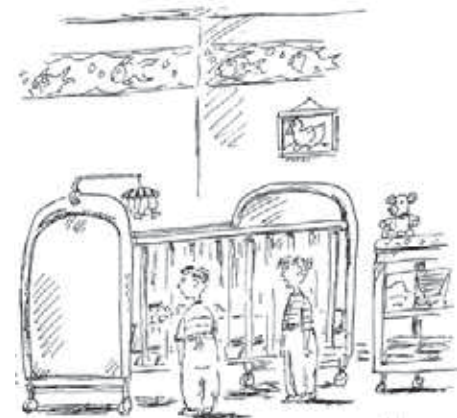

As these examples indicate, researchers have more often studied mother care than father care. Infants who lack a caring mother are said to suffer “maternal deprivation”;

Full-time dad Financial analyst Walter Cranford, shown here with his baby twins, is one of a growing number of stay-at-home dads. Cranford says the experience has made him appreciate how difficult the work can be: “Sometimes at work you can just unplug, but with this you’ve got to be going all the time.”

Figure 48.3
Infants' distress over separation from parents In an experiment, groups of infants were left by their mothers in an unfamiliar room. In both groups, the percentage who cried when the mother left peaked at about 13 months. Whether the infant had experienced day care made little difference. (From Kagan, 1976.)

Jouke van Keulen/Shutterstock

those lacking a father's care merely experience "father absence." This reflects a wider attitude in which "fathering a child" has meant impregnating, and "mothering" has meant nurturing. But fathers are more than just mobile sperm banks. Across nearly 100 studies worldwide, a father's love and acceptance have been comparable to a mother's love in predicting their offspring's health and well-being (Rohner & Veneziano, 2001). In one mammoth British study following 7259 children from

birth to adulthood, those whose fathers were most

involved in parenting (through outings, reading to them, and taking

an interest in their education) tended to achieve more in school, even after controlling for other factors such as parental education and family wealth (Flouri & Buchanan, 2004).

Children's anxiety over separation from parents peaks at around 13 months, then gradually declines (**FIGURE 48.3**). This happens whether they live with one parent or two, are cared for at home or in a day-care center, live in North America, Guatemala, or the Kalahari Desert. Does this mean our need for and love of others also fades away? Hardly. Our capacity for love grows, and our pleasure in touching and holding those we love never ceases. The power of early attachment does nonetheless gradually relax, allowing us to move out into a wider range of situations, communicate with strangers more freely, and stay emotionally attached to loved ones despite distance.

Attachment Styles and Later Relationships

Developmental theorist Erik Erikson (1902–1994), working with his wife, Joan Erikson, believed that securely attached children approach life with a sense of **basic trust**—a sense that the world is predictable and reliable. He attributed basic trust not to environment or inborn temperament, but to early parenting. He theorized that infants blessed with sensitive, loving caregivers form a lifelong attitude of trust rather than fear. (Later, we'll consider Erikson's other stages of development.)

Although debate continues, many researchers now believe that our early attachments form the foundation for our adult relationships and our comfort with affection and intimacy (Birnbaum et al., 2006; Fraley et al., 2013). Our adult styles of romantic love tend to exhibit either secure, trusting attachment; insecure, anxious attachment; or the avoidance of attachment (Feeney & Noller, 1990; Rholes & Simpson, 2004; Shaver & Mikulincer, 2007). These adult attachment styles in turn affect relationships with one's own children, as avoidant people find parenting more stressful and unsatisfying (Rholes et al., 2006).

Attachment style is also associated with motivation (Elliot & Reis, 2003). Securely attached people exhibit less fear of failure and a greater drive to achieve. But say this for those (nearly half of all humans) who exhibit insecure attachments: Anxious or avoidant tendencies have helped our groups detect or escape dangers (Ein-Dor et al., 2010).

"Out of the conflict between trust and mistrust, the infant develops hope, which is the earliest form of what gradually becomes faith in adults." -ERIK ERIKSON (1983)

basic trust according to Erik Erikson, a sense that the world is predictable and trustworthy; said to be formed during infancy by appropriate experiences with responsive caregivers.

"What is learned in the cradle, lasts to the grave." -FRENCH PROVERB

Deprivation of Attachment

48-3

Does childhood neglect, abuse, or family disruption affect children's attachments?

If secure attachment nurtures social trust, what happens when circumstances prevent a child from forming attachments? In all of psychology, there is no sadder research literature. Babies locked away at home under conditions of abuse or extreme neglect are often withdrawn, frightened, even speechless. The same is true of those raised in institutions without the stimulation and attention of a regular caregiver, as was tragically illustrated during the

Mike Abrahams/Alamy

The deprivation of attachment

In this Romanian orphanage, the 250 children between ages 1 and 5 outnumbered caregivers 15 to 1.

1970s and 1980s in Romania. Having decided that economic growth for his impoverished country required more human capital, Nicolae Ceaușescu, Romania's Communist dictator, outlawed contraception, forbade abortion, and taxed families with fewer than five children. The birthrate indeed skyrocketed. But unable to afford the children they had been coerced into having, many families abandoned them to government-run orphanages with untrained and overworked staff. Child-to-caregiver ratios often were 15 to 1 (and you thought babysitting triplets was a strain), so the children were deprived of healthy attachment with at least one adult. When tested after Ceaușescu was assassinated in 1989, these children had lower intelligence scores and double the 20 percent rate of anxiety symptoms found in children assigned to quality foster care settings (Nelson et al., 2009). Dozens of other studies across 19 countries have confirmed that orphaned children tend to fare better on later intelligence tests if raised in family homes. This is especially so for those placed at an early age (van IJzendoorn et al., 2008).

Most children growing up under adversity (as did the surviving children of the Holocaust) are *resilient*; they withstand the trauma and become normal adults (Helmreich, 1992; Masten, 2001). So do most victims of childhood sexual abuse, noted Harvard researcher Susan Clancy (2010), while emphasizing that using children for sex is revolting and never the victim's fault.

But others, especially those who experience no sharp break from their abusive past, don't bounce back so readily. The Harlows' monkeys raised in total isolation, without even an artificial mother, bore lifelong scars. As adults, when placed with other monkeys their age, they either cowered in fright or lashed out in aggression. When they reached sexual maturity, most were incapable of mating. If artificially impregnated, females often were neglectful, abusive, even murderous toward their first-born. Another primate experiment confirmed the abuse-breeds-abuse phenomenon. In one study, 9 of 16 females who had been abused by their mothers became abusive parents, as did *no* female raised by a nonabusive mother (Maestripieri, 2005).

In humans, too, the unloved may become the unloving. Most abusive parents—and many condemned murderers—have reported being neglected or battered as children (Kempe & Kempe, 1978; Lewis et al., 1988). Some 30 percent of people who have been abused later abuse their children—a rate lower than that found in the primate study, but four times the U.S. national rate of child abuse (Dumont et al., 2007; Kaufman & Zigler, 1987).

Although most abused children do *not* later become violent criminals or abusive parents, extreme early trauma may nevertheless leave footprints on the brain. Abused children exhibit hypersensitivity to angry faces (Pollak, 2008). As adults, they exhibit stronger startle responses (Jovanovic et al., 2009). If repeatedly threatened and attacked while young, normally placid golden hamsters grow up to be cowards when caged with same-sized hamsters, or bullies when caged with weaker ones (Ferris, 1996). Such animals show changes in

the brain chemical serotonin, which calms aggressive impulses. A similarly sluggish serotonin response has been found in abused children who become aggressive teens and adults. “Stress can set off a ripple of hormonal changes that permanently wire a child’s brain to cope with a malevolent world,” concluded abuse researcher Martin Teicher (2002).

Such findings help explain why young children who have survived severe or prolonged physical abuse, childhood sexual abuse, or wartime atrocities are at increased risk for health problems, psychological disorders, substance abuse, and criminality (Freyd et al., 2005; Kendall-Tackett et al., 1993, 2004; Wegman & Stetler, 2009). Abuse victims are at considerable risk for depression *if* they carry a gene variation that spurs stress-hormone production (Bradley et al., 2008). As we will see again and again, behavior and emotion arise from a particular environment interacting with particular genes.

Adults also suffer when attachment bonds are severed. Whether through death or separation, a break produces a predictable sequence. Agitated preoccupation with the lost partner is followed by deep sadness and, eventually, the beginnings of emotional detachment and a return to normal living (Hazan & Shaver, 1994). Newly separated couples who have long ago ceased feeling affection are sometimes surprised at their desire to be near the former partner. Deep and longstanding attachments seldom break quickly. Detaching is a process, not an event.

Day Care

48-4 How does day care affect children?

In the mid-twentieth century, when mom-at-home was the social norm, researchers asked, “Is day care bad for children? Does it disrupt children’s attachments to their parents?” For the high-quality day-care programs usually studied, the answer was *No*. In *Mother Care/Other Care*, developmental psychologist Sandra Scarr (1986) explained that children are “biologically sturdy individuals . . . who can thrive in a wide variety of life situations.” Scarr spoke for many developmental psychologists, whose research has uncovered no major impact of maternal employment on children’s development, attachments, and achievements (Friedman & Boyle, 2008; Goldberg et al., 2008; Lucas-Thompson et al., 2010).

Research then shifted to the effects of differing quality of day care on different types and ages of children (Vandell et al., 2010). Scarr (1997) explained: Around the world, “high-quality child care consists of warm, supportive interactions with adults in a safe, healthy, and stimulating environment. . . . Poor care is boring and unresponsive to children’s needs.” Even well-run orphanages can produce healthy, thriving children. In Africa and Asia, where more and more children are losing parents to AIDS and other diseases, orphanages typically are unlike those in Ceaușescu’s Romania, and the children living in quality orphanages fare about as well as those living in communities (Whetten et al., 2009).

Children’s ability to thrive under varied types of responsive caregiving should not surprise us, given cultural variations in attachment patterns. Westernized attachment features one or two caregivers and their offspring. In other cultures, such as the Efe of Zaire, multiple caregivers are the norm (Field, 1996; Whaley et al., 2002). Even before the mother holds her newborn, the baby is passed among several women. In the weeks to come, the infant will be constantly held (and fed) by other women. The result is strong multiple attachments.

One ongoing study in 10 American cities has followed 1100 children since the age of 1 month. The researchers found that

An example of high-quality day care Research has shown that young children thrive socially and intellectually in safe, stimulating environments with a ratio of one caregiver for every three or four children.

AP Photo/Imperial Valley Press, Cuahtemoc Beltran

at ages 4½ to 6, children who had spent the most time in day care had slightly advanced thinking and language skills. They also had an increased rate of aggressiveness and defiance (NICHD, 2002, 2003, 2006). To developmental psychologist Eleanor Maccoby (2003), the positive correlation between the increased rate of problem behaviors and time spent in child care suggested “some risk for some children spending extended time in some day-care settings as they’re now organized.” But the child’s temperament, the parents’ sensitivity, and the family’s economic and educational level influenced aggression more than time spent in day care.

There is little disagreement that the children who merely exist for 9 hours a day in understaffed centers deserve better. What all children need is a consistent, warm relationship with people whom they can learn to trust. The importance of such relationships extends beyond the preschool years, as Finnish psychologist Lea Pulkkinen (2006) observed in her career-long study of 285 individuals tracked from age 8 to 42. Her finding—that adult monitoring of children predicts favorable outcomes—led her to undertake, with support from Finland’s parliament, a nationwide program of adult-supervised activities for all first and second graders (Pulkkinen, 2004; Rose, 2004).

Self-Concept

48-5 How do children’s self-concepts develop?

Infancy’s major social achievement is attachment. *Childhood’s* major social achievement is a positive sense of self. By the end of childhood, at about age 12, most children have developed a **self-concept**—an understanding and assessment of who they are. (Their *self-esteem* is how they feel about who they are.) Parents often wonder when and how this sense of self develops. “Is my baby girl aware of herself—does she know she is a person distinct from everyone else?”

Of course we cannot ask the baby directly, but we can again capitalize on what she can do—letting her *behavior* provide clues to the beginnings of her self-awareness. In 1877, biologist Charles Darwin offered one idea: Self-awareness begins when we recognize ourselves in a mirror. To see whether a child recognizes that the girl in the mirror is indeed herself, researchers sneakily dabbed color on the nose. At about 6 months, children reach out to touch their mirror image as if it were another child (Courage & Howe, 2002; Damon & Hart, 1982, 1988, 1992). By 15 to 18 months, they begin to touch their own noses when they see the colored spot in the mirror (Butterworth, 1992; Gallup & Suarez, 1986). Apparently, 18-month-olds have a schema of how their face should look, and they wonder, “What is that spot doing on *my* face?”

Kate Nurre/Worth Publishers

Self-awareness Mirror images fascinate infants from the age of about 6 months. Only at about 18 months, however, does the child recognize that the image in the mirror is “me.”

AP Photo/National Academy of Sciences, Courtesy of Joshua Plotnik, Frans de Waal, and Diana Reiss

Self-aware animals After prolonged exposure to mirrors, several species—chimpanzees, orangutans, gorillas, dolphins, elephants, and magpies—have similarly demonstrated self-recognition of their mirror image (Gallup, 1970; Reis & Marino, 2001; Prior et al., 2008). In an experiment by Joshua Plotnik and colleagues (2006), Happy, an Asian elephant, when facing a mirror, repeatedly used her trunk to touch an “X” painted above her eye (but not a similar mark above the other eye that was visible only under black light). As one report said, “She’s Happy and she knows it!”

self-concept all our thoughts and feelings about ourselves, in answer to the question, “Who am I?”

By school age, children's self-concept has blossomed into more detailed descriptions that include their gender, group memberships, psychological traits, and similarities and differences compared with other children (Newman & Ruble, 1988; Stipek, 1992). They come to see themselves as good and skillful in some ways but not others. They form a concept of which traits, ideally, they would like to have. By age 8 or 10, their self-image is quite stable.

Children's views of themselves affect their actions. Children who form a positive self-concept are more confident, independent, optimistic, assertive, and sociable (Maccoby, 1980). So how can parents encourage a positive yet realistic self-concept?

Parenting Styles

48-6 What are three parenting styles, and how do children's traits relate to them?

Some parents spank, some reason. Some are strict, some are lax. Some show little affection, some liberally hug and kiss. Do such differences in parenting styles affect children?

The most heavily researched aspect of parenting has been how, and to what extent, parents seek to control their children. Investigators have identified three parenting styles:

1. **Authoritarian** parents impose rules and expect obedience: "Don't interrupt." "Keep your room clean." "Don't stay out late or you'll be grounded." "Why? Because I said so."
2. **Permissive** parents submit to their children's desires. They make few demands and use little punishment.
3. **Authoritative** parents are both demanding and responsive. They exert control by setting rules and enforcing them, but they also explain the reasons for rules. And, especially with older children, they encourage open discussion when making the rules and allow exceptions.

Too hard, too soft, and just right, these styles have been called, especially by pioneering researcher Diana Baumrind and her followers. Research indicates that children with the highest self-esteem, self-reliance, and social competence usually have warm, concerned, *authoritative* parents (Baumrind, 1996; Buri et al., 1988; Coopersmith, 1967). Those with authoritarian parents tend to have less social skill and self-esteem, and those with permissive parents tend to be more aggressive and immature. The participants in most studies have been middle-class White families, and some critics suggest that effective parenting may vary by culture. Yet studies with families of other races and in more than 200 cultures worldwide have confirmed the social and academic correlates of loving and authoritative parenting (Rohner & Veneziano, 2001; Sorkhabi, 2005; Steinberg & Morris, 2001). For example, two studies of thousands of Germans found that those whose parents had maintained a curfew exhibited better adjustment and greater achievements in young adulthood than did those with permissive parents (Haase et al., 2008). And the effects are stronger when children are embedded in *authoritative communities* with connected adults who model a good life (Commission on Children at Risk, 2003).

A word of caution: The association between certain parenting styles (being firm but open) and certain childhood outcomes (social competence) is correlational. *Correlation is not causation.* Here are two possible alternative explanations for this parenting-competence link.

- Children's traits may influence parenting. Parental warmth and control vary somewhat from child to child, even in the same family (Holden & Miller, 1999). Perhaps socially mature, agreeable, easygoing children *evoke* greater trust and warmth from their parents. Twin studies have supported this possibility (Kendler, 1996).
- Some underlying third factor may be at work. Perhaps, for example, competent parents and their competent children share genes that predispose social competence. Twin studies have also supported this possibility (South et al., 2008).

AP® Exam Tip

It's understandable if you are struggling to remember the differences between authoritarian and authoritative—these words are exactly the same through the first nine letters! Maybe it will help to realize that authoritative parents will engage in a little more give and take, and that the words *give* and *authoritative* both end in the letters *ive*.

Parents who struggle with conflicting advice should remember that *all advice reflects the advice-giver's values*. For those who prize unquestioning obedience from a child, an authoritarian style may have the desired effect. For those who value children's sociability and self-reliance, authoritative firm-but-open parenting is advisable.

Culture and Child Raising

Child-raising practices reflect cultural values that vary across time and place. Do you prefer children who are independent or children who comply? If you live in a Westernized culture, the odds are you prefer independence. "You are responsible for yourself," Western families and schools tell their children. "Follow your conscience. Be true to yourself. Discover your gifts. Think through your personal needs." A half-century and more ago, Western cultural values placed greater priority on obedience, respect, and sensitivity to others (Alwin, 1990; Remley, 1988). "Be true to your traditions," parents then taught their children. "Be loyal to your heritage and country. Show respect toward your parents and other superiors." Cultures can change.

Many Asians and Africans live in cultures that value emotional closeness. Rather than being given their own bedrooms and entrusted to day care, infants and toddlers may sleep with their mothers and spend their days close to a family member (Morelli et al., 1992; Whiting & Edwards, 1988). These cultures encourage a strong sense of *family self*—a feeling that what shames the child shames the family, and what brings honor to the family brings honor to the self.

Children across place and time have thrived under various child-raising systems. Upper-class British parents traditionally handed off routine caregiving to nannies, then sent their 10-year-olds off to boarding school. These children generally grew up to be pillars of British society, as did their parents and their boarding-school peers. In the African Gusii society, babies nurse freely but spend most of the day on their mother's back—with lots of body contact but little face-to-face and language interaction. When the mother becomes pregnant again, the toddler is weaned and handed over to someone else, often an older sibling. Westerners may wonder about the negative effects of this lack of verbal interaction, but then the African Gusii may in turn wonder about Western mothers pushing their babies around in strollers and leaving them in playpens (Small, 1997). Such diversity in child raising cautions us against presuming that our culture's way is the only way to raise children successfully.

© Steve Reehl

Cultures vary Parents everywhere care about their children, but raise and protect them differently depending on the surrounding culture. Parents raising children in New York City keep them close. In Scotland's Orkney Islands' town of Stromness, social trust has enabled parents to park their toddlers outside shops.

Indeed/Getty Images

Parental involvement promotes development

Parents in every culture facilitate their children's discovery of their world, but cultures differ in what they deem important. Asian cultures place more emphasis on school and hard work than do North American cultures. This may help explain why Japanese and Taiwanese children get higher scores on mathematics achievement tests.

“You are the bows from which your children as living arrows are sent forth.” -KAHLIL GIBRAN, *THE PROPHET*, 1923

* * *

The investment in raising a child buys many years not only of joy and love but of worry and irritation. Yet for most people who become parents, a child is one’s biological and social legacy—one’s personal investment in the human future. To paraphrase psychiatrist Carl Jung, we reach backward into our parents and forward into our children, and through their children into a future we will never see, but about which we must therefore care.

Before You Move On

▶ ASK YOURSELF

How would you describe your own temperament? Is it similar to that of other family members, or quite different?

▶ TEST YOURSELF

What distinguishes imprinting from attachment?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 48 Review

48-1 How do parent-infant attachment bonds form?

- At about 8 months, soon after object permanence develops, children separated from their caregivers display *stranger anxiety*.
- Infants form *attachments* not simply because parents gratify biological needs but, more important, because they are comfortable, familiar, and responsive.
- Ducks and other animals have a more rigid attachment process, called *imprinting*, that occurs during a *critical period*.

48-2 How have psychologists studied attachment differences, and what have they learned about the effects of temperament and parenting?

- Attachment has been studied in strange situation experiments, which show that some children are securely attached and others are insecurely attached.
- Sensitive, responsive parents tend to have securely attached children.
- Adult relationships seem to reflect the attachment styles of early childhood, lending support to Erik Erikson’s idea that *basic trust* is formed in infancy by our experiences with responsive caregivers.

- Yet it’s become clear that *temperament*—our characteristic emotional reactivity and intensity—also plays a huge role in how our attachment patterns form.

48-3 Does childhood neglect, abuse, or family disruption affect children’s attachments?

- Children are very resilient, but those who are moved repeatedly, severely neglected by their parents, or otherwise prevented from forming attachments by an early age may be at risk for attachment problems.

48-4 How does day care affect children?

- Quality day care, with responsive adults interacting with children in a safe and stimulating environment, does not appear to harm children’s thinking and language skills.
- Some studies have linked extensive time in day care with increased aggressiveness and defiance, but other factors—the child’s temperament, the parents’ sensitivity, and the family’s economic and educational levels and culture—also matter.

48-5 How do children’s self-concepts develop?

- *Self-concept*, an understanding and evaluation of who we are, emerges gradually.
 - At 15 to 18 months, children recognize themselves in a mirror.
 - By school age, they can describe many of their own traits, and by ages 8 to 10 their self-image is stable.

48-6 What are three parenting styles, and how do children’s traits relate to them?

- Parenting styles—authoritarian, permissive, and authoritative—reflect varying degrees of control.
- Children with high self-esteem tend to have authoritative parents and to be self-reliant and socially competent, but the direction of cause and effect in this relationship is not clear.

Multiple-Choice Questions

1. An 18-month-old typically recognizes herself in a mirror. This self-awareness contributes to
 - a. self-assurance.
 - b. self-concept.
 - c. self-esteem.
 - d. self-actualization.
 - e. self-determination.
2. In the attachment studies conducted with infant monkeys, what did the Harlows find?
 - a. Nutrition was the most important factor in attachment.
 - b. Contact comfort was the most important factor in attachment.
 - c. The surrogate mother’s appearance was the most important attachment factor.
 - d. Monkeys were equally likely to become attached to either surrogate mother.
 - e. The monkeys didn’t form attachments to the surrogate mothers.
3. What do we call an optimal window of opportunity for proper development?
 - a. Attachment
 - b. The critical period
 - c. The social period
 - d. Imprinting
 - e. Mere exposure
4. Which of the following identifies the parenting style most likely to ground a teen who had missed a curfew—and to explain the rationale for doing so, after considering the teen’s reasons?
 - a. Authoritative
 - b. Authoritarian
 - c. Permissive
 - d. Secure attachment
 - e. Insecure attachment
5. Which of the following would be considered a sign of secure attachment in a 1-year-old?
 - a. Showing no sign of stranger anxiety, whether the parent is present or not
 - b. Paying no attention to a parent who returns after a brief separation
 - c. Showing anger at the parent after a brief separation
 - d. Becoming distressed when the parent leaves and seeking contact on return
 - e. Not reacting to a parent leaving or returning after a brief separation
6. Who identified secure and insecure attachment?
 - a. Sigmund Freud
 - b. Konrad Lorenz
 - c. Jean Piaget
 - d. Mary Ainsworth
 - e. Jerome Kagan

Practice FRQs

1. Name and describe the three types of infant temperaments.
2. Name and describe Diana Baumrind’s three parenting styles.

(3 points)

Answer

1 point: Easy: These babies are easygoing, cheerful, predictable, and placid.

1 point: Difficult: These babies are emotionally reactive, intense, irritable, and unpredictable.

1 point: Slow to warm up: These babies resist and withdraw from new people or situations.

Module 49

Gender Development

Module Learning Objectives

- 49-1** Discuss gender similarities and differences in psychological traits.
- 49-2** Discuss the importance of gender roles and gender typing in development.

gender the socially constructed roles and characteristics by which a culture defines *male* and *female*.

FYI

Pink and blue baby outfits offer another example of how cultural norms vary and change. “The generally accepted rule is pink for the boy and blue for the girl,” declared the publication *Earnshaw’s Infants’ Department* in June 1918 (Maglaty, 2011). “The reason is that pink being a more decided and stronger color is more suitable for the boy, while blue, which is more delicate and dainty, is prettier for the girls.”

AP® Exam Tip

There is a lot of information in this section. One good way to process these differences and similarities between genders is to consider which facts fit prevailing stereotypes and which don’t. You may even want to keep a list.

As we saw in Module 34, we humans share an irresistible urge to organize our worlds into simple categories. Among the ways we classify people—as tall or short, fat or slim, smart or dull—one stands out: Before or at your birth, everyone wanted to know, “Boy or girl?” From that time on, your sex (your biological status, defined by your chromosomes and anatomy) helped define your **gender**, the socially constructed roles and characteristics by which your culture defines *male* and *female*. Guided by our culture, our gender influences our social development.

How Are We Alike? How Do We Differ?

- 49-1** What are some gender similarities and differences in aggression, social power, and social connectedness?

Having faced similar adaptive challenges, we are in most ways alike. Tell me whether you are male or female and you give me virtually no clues to your vocabulary, intelligence, and happiness, or to the mechanisms by which you see, hear, learn, and remember. Your “opposite” sex is, in reality, your very similar sex. At conception, you received 23 chromosomes from your mother and 23 from your father. Of those 46 chromosomes, 45 are unisex—the same for males and females. (In Module 53, we’ll return to that forty-sixth chromosome.)

But males and females do differ, and differences command attention—stimulating more than 18,000 studies (Ellis et al., 2008). Some much-talked-about gender differences are actually quite modest, as Janet Shibley Hyde (2005) illustrated by graphically representing male and female self-esteem scores across many studies (**FIGURE 49.1**). Other differences are more striking. Compared with the average man, the average woman enters puberty 2 years sooner, and her life span is 5 years longer. She carries 70 percent more fat, has 40 percent less muscle, and is 5 inches shorter. She expresses emotions more freely, can smell fainter odors, and is offered help more often. She can become sexually re-aroused soon after orgasm. She is also doubly vulnerable to depression and anxiety, and her risk of developing an eating disorder is 10 times greater than the average man’s. Yet, he is some 4 times more likely to commit suicide or develop alcohol use disorder. He is also more likely to be diagnosed with autism spectrum disorder, color-blindness, attention-deficit/hyperactivity disorder as a child, and antisocial personality disorder as an adult. Choose your gender and pick your vulnerability.

**Figure 49.1**

Much ado about a small difference in self-esteem These two normal distributions differ by the approximate magnitude of the gender difference in self-esteem, averaged over all available samples (Hyde, 2005). Moreover, such comparisons illustrate differences between the average woman and man. The variation among individual women greatly exceeds this difference, as it also does among individual men.

Gender differences appear throughout this book. For now, let's consider some gender differences in aggression, social power, and social connectedness. (Note that these differences between the *average* woman and man do not necessarily describe any individual woman or man.)

Gender and Aggression

In surveys, men admit to more **aggression** than women do. This aggression gender gap pertains to harmful physical aggression, rather than indirect or verbal relational aggression such as ostracism or spreading rumors. As John Archer (2004, 2006, 2009) has noted, based on statistical digests of dozens of studies, women may be slightly more likely to commit acts of relational aggression, such as passing along malicious gossip. The gap appears in everyday life at various ages and in various cultures, especially cultures with gender inequality (Archer, 2009).

Men's tendency to behave more aggressively can be seen in experiments where they deliver what they believe are more painful electric shocks (Card et al., 2008). Violent crime rates illustrate the gender difference even more strikingly. The male-to-female arrest ratio for murder, for example, is 9 to 1 in the United States and 8 to 1 in Canada (FBI, 2009; Statistics Canada, 2010). Throughout the world, fighting, warring, and hunting are primarily men's activities (Wood & Eagly, 2002, 2007). Men also express more support for war. The Iraq war, for example, was consistently supported more by American men than by American women (Newport et al., 2007).

Gender and Social Power

Close your eyes and imagine two adults standing side by side. The one on the left is dominant, forceful, and independent. The one on the right is submissive, nurturing, and socially connected.

Did you see the person on the left as a man, and the one on the right as a woman? If so, you are not alone.

Around the world, from Nigeria to New Zealand, people perceive such power differences between men and women (Williams & Best, 1990). Indeed, in most societies men *do* place more importance on power and achievement and *are* socially dominant (Schwartz &

VLADIMIR FEDORENKO/AFP/GettyImages

Gender difference in aggression Around the world, fighting, violent crime, and blowing things up are mostly men's activities. This is why many were surprised to hear that female suicide bombers were responsible for the 2010 Moscow subway bombing that killed dozens.

aggression any physical or verbal behavior intended to hurt or destroy.

FYI

Women's 2011 representation in national parliaments ranged from 11 percent in the Arab States to 42 percent in Scandinavia (IPU, 2011).

FYI

Question: Why does it take 200 million sperm to fertilize one egg?
Answer: Because they won't stop for directions.

Rubel-Lifschitz, 2009). When groups form, whether as juries or companies, leadership tends to go to males (Colarelli et al., 2006). When salaries are paid, those in traditionally male occupations receive more. And when political leaders are elected, they usually are men, who held 80 percent of the seats in the world's governing parliaments in 2011 (IPU, 2011). If perceived to be hungry for political power (thus violating gender norms), women more than men suffer voter backlash (Okimoto & Brescoll, 2010). Men's power hunger is more expected and accepted.

As leaders, men tend to be more *directive*, even autocratic. Women tend to be more *democratic*, more welcoming of subordinates' input in decision making (Eagly & Carli, 2007; van Engen & Willemsen, 2004). When people interact, men are more likely to utter opinions, women to express support (Aries, 1987; Wood, 1987). In everyday behavior, men tend to act as powerful people often do: They are more likely to talk assertively, interrupt, initiate touches, and stare. And they smile and apologize less (Leaper & Ayres, 2007; Major et al., 1990; Schumann & Ross, 2010). Such behaviors help sustain social power inequities.

Gender and Social Connectedness

In the 1980s, many developmental psychologists believed that all children struggle to create a separate, independent identity. Research by Carol Gilligan and her colleagues (1982, 1990), however, suggested that this struggle describes Western individualist males more than relationship-oriented females. Gilligan believed females tend to differ from males both in being less concerned with viewing themselves as separate individuals and in being more concerned with "making connections." Indeed, later research has found that females are more *interdependent* than males, and this difference surfaces early. In children's play, boys typically form large groups. Their games tend to be active and competitive, with little intimate discussion (Rose & Rudolph, 2006). Studies have found that girls usually play in smaller groups, often with one friend. Their play is less competitive and more imitative of social relationships (Maccoby, 1990; Roberts, 1991).

As adults, women take more pleasure in talking face to face, and they more often use conversation to explore relationships. Men enjoy doing activities side by side and tend to use conversation to communicate solutions (Tannen, 1990; Wright, 1989). The communication difference is apparent in student e-mails: In one New Zealand study, people could correctly guess the author's gender two-thirds of the time (Thomson & Murachver, 2001).

Gender differences also appear in phone-based communication. In the United States, the average teen girl sends double the number of text messages of the average teen boy (Lenhart, 2010). In France, women have made 63 percent of phone calls and, when talking to a woman, stayed connected longer (7.2 minutes) than have men when talking to other men (4.6 minutes) (Smoreda & Licoppe, 2000).

Every man for himself, or tend and befriend?

Gender differences in the way we interact with others begin to appear at a very young age.

Gallo Images/Getty Images

Svetlana Bekyarova Photography/Getty Images

Women worldwide have oriented their interests and vocations more to people and less to things (Eagly, 2009; Lippa, 2005, 2006, 2008). One analysis of more than a half-million people's responses to various interest inventories revealed that "men prefer working with things and women prefer working with people" (Su et al., 2009). On entering college, American men are seven times more likely than women to express interest in computer science, and they contribute 87 percent of Wikipedia articles (Cohen, 2011; Pryor et al., 2011). In the workplace, women have been less driven by money and status and more often opted for reduced work hours (Pinker, 2008). In the home, they have been five times more likely than men to claim primary responsibility for taking care of children (*Time*, 2009).

Women's emphasis on caring helps explain another interesting finding: Although 69 percent of people have said they have a close relationship with their father, 90 percent said they feel close to their mother (Hugick, 1989). When wanting understanding and someone with whom to share worries and hurts, both men and women usually turn to women, and both have reported their friendships with women to be more intimate, enjoyable, and nurturing (Rubin, 1985; Sapadin, 1988). And when coping with their own stress, women more than men turn to others for support—they *tend and befriend* (Tamres et al., 2002; Taylor, 2002).

Gender differences in social connectedness, power, and other traits peak in late adolescence and early adulthood—the very years most commonly studied (also the years of dating and mating). As teenagers, girls become progressively less assertive and more flirtatious; boys become more domineering and unexpressive. Following the birth of a first child, parents (women especially) become more traditional in their gender-related attitudes and behavior (Ferriman et al., 2009; Katz-Wise et al., 2010). But studies have shown that by age 50, parenthood-related gender differences subside. Men become more empathic and less domineering, and women—especially those with paid employment—become more assertive and self-confident (Kasen et al., 2006; Maccoby, 1998).

What explains our diversity? How much does biology bend the genders? To what extent are we shaped by our cultures? A biopsychosocial view suggests both are important, thanks to the interplay among our biological dispositions, our developmental experiences, and our current situations (Eagly, 2009).

"In the long years liker must they grow; The man be more of woman, she of man." -ALFRED LORD TENNYSON, *THE PRINCESS*, 1847

The Nurture of Gender: Our Culture

49-2 How do gender roles and gender typing influence gender development?

For most people, their biological sex and their gender are tightly intertwined. What biology initiates (as we will see in Module 53), culture accentuates.

Gender Roles

Culture is everything shared by a group and transmitted across generations. We can see culture's shaping power in **gender roles**—the social expectations that guide men's and women's behavior. (In psychology, as in the theater, a **role** refers to a cluster of prescribed actions, the behaviors we expect of those who occupy a particular social position.)

Gender roles vary over time and place. In North America, men were traditionally expected to initiate dates, drive the car, and pick up the check. Women were expected to decorate the home, buy and care for the children's clothes, and select the wedding gifts. Up through the 1990s, Mom (about 90 percent of the time in two-parent U.S. families) stayed home with a sick child, arranged for the babysitter, and called the doctor (Maccoby, 1995). Even in recent years, compared with employed women, employed men in the United States have daily spent about an hour and a half more on

gender role a set of expected behaviors for males or for females.

role a set of expectations (norms) about a social position, defining how those in the position ought to behave.

"Sex brought us together, but gender drove us apart."

The gendered tsunami In Sri Lanka, Indonesia, and India, the gendered division of labor helps explain the excess of female deaths from the 2004 tsunami. In some villages, 80 percent of those killed were women, who were mostly at home while the men were more likely to be at sea fishing or doing out-of-the-home chores (Oxfam, 2005).

DPA/The Image Works

the job and about one hour less on household activities and caregiving (Amato et al., 2007; Bureau of Labor Statistics, 2004; Fisher et al., 2006). Ditto Australia, where, compared with men, women have devoted 54 percent more time to unpaid household work and 71 percent more time to child care (Trewin, 2001).

Other societies have different expectations. In nomadic societies of food-gathering people, there is little division of labor by sex. Boys and girls receive much the same upbringing. In agricultural societies, where women work in the nearby fields and men roam while herding livestock, children have typically been socialized into more distinct gender roles (Segall et al., 1990; Van Leeuwen, 1978).

Among industrialized countries, gender roles and attitudes vary widely. Australia and the Scandinavian countries offer the greatest gender equity, Middle Eastern and North African countries the least (Social Watch, 2006). And consider: Would you agree that “when jobs are scarce, men should have more rights to a job?” In the United States, Britain, and Spain, about one in eight adults agree. In Nigeria, Pakistan, and India, about four in five do (Pew, 2010). We are one species, but my, how we differ.

To see how gender role attitudes vary over time, consider women’s voting rights. At the opening of the twentieth century, only one country—New Zealand—granted women the right to vote (Briscoe, 1997). By the late 1960s and early 1970s, women had become a force in the voting booth and the workplace in many countries. Nearly 50 percent of employed Americans are now women, as are 54 percent of college graduates, up from 36 percent in just four decades (Fry & Cohn, 2010). In today’s postindustrial economy, the jobs expected to grow the most in the years ahead are the ones women have gravitated toward—those that require not size and strength but social intelligence, open communication, and the ability to sit still and focus (Rosin, 2010). These are big gender changes in but a thin slice of history.

Gender roles can smooth social relations, avoiding irritating discussions about whose job it is to get the car fixed and who should buy the birthday presents. But these quick and easy assumptions come at a cost: If we deviate from conventions, we may feel anxious.

How Do We Learn to Be Male or Female?

Gender identity is a person’s sense of being male or female. **Social learning theory** assumes that children acquire this identity by observing and imitating others’ gender-linked behaviors and by being rewarded or punished for acting in certain ways themselves (“Nicole, you’re such a good mommy to your dolls”; “Big boys don’t cry, Alex.”). Some critics have objected, saying that parental modeling and rewarding of male-female differences aren’t enough to explain **gender typing**, the way some children seem more attuned than others to traditional male or female roles (Lytton & Romney, 1991). In fact, even in families that discourage traditional gender typing, children organize themselves into “boy worlds” and “girl worlds,” each guided by rules for what boys and girls do.

Cognition (thinking) also matters. In your own childhood you formed concepts that helped you make sense of your world. One of these was your *gender schema*, your framework for organizing boy-girl characteristics (Bem, 1987, 1993). This gender schema then became a lens through which you viewed your experiences.

Gender schemas form early in life, and social learning helps form them. Before age 1, you began to discriminate male and female voices and faces (Martin et al., 2002). After age 2, language forced you to begin organizing your world on the basis of gender. English, for example, uses the pronouns *he* and *she*; other languages classify objects as masculine (“*le train*”) or feminine (“*la table*”).

FYI

In Module 30, we explored how children can learn—including the aggressive behavior modeled in Albert Bandura’s famous Bobo doll experiment—by observing others.

gender identity our sense of being male or female.

social learning theory the theory that we learn social behavior by observing and imitating and by being rewarded or punished.

gender typing the acquisition of a traditional masculine or feminine role.

Young children are “gender detectives” (Martin & Ruble, 2004). Once they grasp that two sorts of people exist—and that they are of one sort—they search for clues about gender, and they find them in language, dress, toys, and songs. Girls, they may decide, are the ones with long hair. Having divided the human world in half, 3-year-olds will then like their own kind better and seek them out for play. And having compared themselves with their concept of gender, they will adjust their behavior accordingly. (“I am male—thus, masculine, strong, aggressive,” or “I am female—therefore, feminine, sweet, and helpful.”) These rigid boy-girl stereotypes peak at about age 5 or 6. If the new neighbor is a boy, a 6-year-old girl may assume he just cannot share her interests. For young children, gender looms large.

The social learning of gender Children observe and imitate parental models.

For some people, comparing themselves with their culture’s concepts of gender produces feelings of confusion and discord. **Transgender** people’s *gender identity* (their sense of being male or female) or *gender expression* (their communication of gender identity through behavior or appearance) differs from that typical of their birth sex (APA, 2010). A person may feel like a man in a woman’s body, or a woman in a man’s body. These include *transsexual* people, who live, or wish to live, as members of the gender opposite to their birth sex, often aided by medical treatment that supports gender reassignment. Note that gender identity is distinct from *sexual orientation* (the direction of one’s sexual attraction). Transgender people may be heterosexual, homosexual, bisexual, or asexual.

Some transgender persons express their gender identity by dressing as a person of the other biological sex typically would. Most cross-dressers are biological males, the majority of whom feel an attraction to females (APA, 2010).

Transgender contestant In 2012, Jenna Talackova became the first transgender beauty pageant contestant in this Miss Universe Canada contest in Toronto. Talackova was born a male but had sex-reassignment surgery.

“The more I was treated as a woman, the more woman I became.” -WRITER JAN MORRIS, MALE-TO-FEMALE TRANSSEXUAL

Before You Move On

▶ ASK YOURSELF

Do you consider yourself strongly gender typed or not strongly gender typed? What factors do you think have contributed to your feelings of masculinity or femininity?

▶ TEST YOURSELF

What are gender roles, and what do their variations tell us about our human capacity for learning and adaptation?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

transgender an umbrella term describing people whose gender identity or expression differs from that associated with their birth sex.

Module 49 Review

49-1

What are some gender similarities and differences in aggression, social power, and social connectedness?

- *Gender* refers to the socially constructed roles and characteristics by which a culture defines “male” and “female.”
- We are more alike than different, thanks to our similar genetic makeup—we see, hear, learn, and remember similarly. Males and females do differ in body fat, muscle, height, age of onset of puberty, life expectancy, and vulnerability to certain disorders.
- Men admit to more *aggression* than women do, and they are more likely to be physically aggressive. Women’s aggression is more likely to be relational.
- In most societies, men have more social power, and their leadership style tends to be directive, whereas women’s is more democratic.
- Women focus more on social connectedness, and they “tend and befriend.”

49-2

How do gender roles and gender typing influence gender development?

- *Gender roles*, the behaviors a culture expects from its males and females, vary across place and time.
- *Social learning theory* proposes that we learn *gender identity*—our sense of being male or female—as we learn other things: through reinforcement, punishment, and observation. Critics argue that cognition also plays a role because modeling and rewards cannot explain *gender typing*.
- *Transgender* people’s gender identity or expression differs from their birth sex. Their sexual orientation may be heterosexual, homosexual, bisexual, or asexual.

Multiple-Choice Questions

1. According to research, which type of aggression is more common among males than females?
 - a. Harmful physical aggression
 - b. Indirect nonphysical aggression
 - c. Verbal aggression
 - d. Ostracism
 - e. Spreading rumors
2. Gender _____ are the social expectations that guide men and women’s behavior. Gender _____ is a person’s sense of being male or female.
 - a. concepts; role
 - b. preferences; role
 - c. roles; preference
 - d. roles; identity
 - e. roles; preference
3. Which of the following is generally true of males?
 - a. They have a longer life span.
 - b. They are more likely to have a democratic leadership style.
 - c. They are more likely to commit suicide.
 - d. They are more likely to be diagnosed with depression.
 - e. They are more likely to be diagnosed with anxiety.
4. Diego likes to play sports and video games whereas Sara likes to sing, dance, and play “house.” This example best depicts which of the following?
 - a. Gender identity
 - b. Gender typing
 - c. Gender schema
 - d. Social learning theory
 - e. Gender expression
5. Carol Gilligan’s research emphasizes prominent female characteristics, especially
 - a. spatial abilities.
 - b. making social connections.
 - c. playing in large groups.
 - d. talking a great deal.
 - e. playing in competitive groups.

Practice FRQs

1. What are gender roles? What are gender schemas? How does social learning contribute to the formation of each?

Answer

1 point: Gender roles are the cultural norms for expected behaviors for males and females.

1 point: Gender schemas are the cognitive ways in which we organize boy-girl characteristics.

1 point: Social learning contributes to gender schema formation by the observation of gender roles, the rewarding of gender-appropriate behaviors, and the ways in which gender is discussed.

2. Give an example of a biological, a psychological, and a social factor that might contribute to gender differences.

(3 points)

Module 50

Parents, Peers, and Early Experiences

Module Learning Objectives

- 50-1** Describe how early experiences can modify the brain.
- 50-2** Describe the ways in which parents and peers shape children's development.

Our genes, as expressed in specific environments, influence our developmental differences. We are not “blank slates,” note Douglas Kenrick and his colleagues (2009). We are more like coloring books, with certain lines predisposed and experience filling in the full picture. We are formed by nature *and* nurture. But what are the most influential components of our nurture? How do our early experiences, our family and peer relationships, and all our other experiences guide our development and contribute to our diversity?

Experience and Brain Development

- 50-1** How do early experiences modify the brain?

The formative nurture that conspires with nature begins at conception, as we have seen, with the prenatal environment in the womb. Embryos receive differing nutrition and varying levels of exposure to toxic agents. Nurture then continues outside the womb, where our early experiences foster brain development.

Our genes dictate our overall brain architecture, but experience fills in the details, developing neural connections and preparing our brain for thought and language and other later experiences. So how do early experiences leave their “marks” in the brain? Mark Rosenzweig, David Krech, and their colleagues (1962) opened a window on that process when they raised some young rats in solitary confinement and others in a communal playground. When they later analyzed the rats’ brains, those raised in the enriched environment, which simulated a natural environment, usually developed a heavier and thicker brain cortex (**FIGURE 50.1**).

Rosenzweig was so surprised by this discovery that he repeated the experiment several times before publishing his findings (Renner & Rosenzweig, 1987; Rosenzweig, 1984). So great are the effects that, shown brief video clips of rats, you could tell from their activity and curiosity whether their environment had been impoverished or enriched (Renner & Renner, 1993). After 60 days in the enriched environment, the rats’ brain weights increased 7 to 10 percent and the number of synapses mushroomed by about 20 percent (Kolb & Whishaw, 1998).

Courtesy of C. Brune

Stringing the circuits young

String musicians who started playing before age 12 have larger and more complex neural circuits controlling the note-making left-hand fingers than do string musicians whose training started later (Elbert et al., 1995).

**Figure 50.1****Experience affects brain development**

Mark Rosenzweig, David Krech, and their colleagues raised rats either alone in an environment without playthings, or with other rats in an environment enriched with playthings changed daily. In 14 of 16 repetitions of this basic experiment, rats in the enriched environment developed significantly more cerebral cortex (relative to the rest of the brain's tissue) than did those in the impoverished environment.

Such results have motivated improvements in environments for laboratory, farm, and zoo animals—and for children in institutions. Stimulation by touch or massage also benefits infant rats and premature babies (Field et al., 2007). “Handled” infants of both species develop faster neurologically and gain weight more rapidly. By giving preemies massage therapy, neonatal intensive care units now help them to go home sooner (Field et al., 2006).

Both nature and nurture sculpt our synapses. After brain maturation provides us with an abundance of neural connections, our experiences trigger a pruning process. Sights and smells, touches and tugs activate and strengthen connections. Unused neural pathways weaken. Like forest pathways, popular tracks are broadened and less-traveled ones gradually disappear. The result by puberty is a massive loss of unemployed connections.

Here at the juncture of nurture and nature is the biological reality of early childhood learning. During early childhood—while excess connections are still on call—youngsters can most easily master such skills as the grammar and accent of another language. Lacking any exposure to language before adolescence, a person will never master any language (see Module 36). Likewise, lacking visual experience during the early years, those whose vision is restored by cataract removal never achieve normal perceptions (see Module 19). The brain cells normally assigned to vision have died or been diverted to other uses. The maturing brain's rule: Use it or lose it.

Although normal stimulation during the early years is critical, the brain's development does not end with childhood. As we saw in Module 12's discussion of brain plasticity, our neural tissue is ever changing and new neurons are born. If a monkey pushes a lever with the same finger several thousand times a day, brain tissue controlling that finger changes to reflect the experience. Human brains work similarly (**FIGURE 50.2**). Whether learning to keyboard or skateboard, we perform with increasing skill as our brain incorporates the learning (Ambrose, 2010).

“Genes and experiences are just two ways of doing the same thing—wiring synapses.” —JOSEPH LEDOUX, *THE SYNAPTIC SELF*, 2002

**Figure 50.2**

A trained brain A well-learned fingertapping task activates more motor cortex neurons (orange area, right) than were active in the same brain before training (left). (From Karni et al., 1998.)

How Much Credit or Blame Do Parents Deserve?

50-2 In what ways do parents and peers shape children's development?

© The New Yorker Collection, 2007, Julia Suits from cartoonbank.com. All Rights Reserved.

"To be frank, officer, my parents never set boundaries."

FYI

Even among chimpanzees, when one infant is hurt by another, the victim's mother will often attack the offender's mother (Goodall, 1968).

© The New Yorker Collection, 2001, Barbara Smaller from cartoonbank.com. All Rights Reserved.

"So I blame you for everything—whose fault is that?"

"If you want to blame your parents for your own adult problems, you are entitled to blame the genes they gave you, but you are not entitled—by any facts I know—to blame the way they treated you. . . . We are not prisoners of our past." -MARTIN SELIGMAN, *WHAT YOU CAN CHANGE AND WHAT YOU CAN'T*, 1994

In procreation, a woman and a man shuffle their gene decks and deal a life-forming hand to their child-to-be, who is then subjected to countless influences beyond their control. Parents, nonetheless, feel enormous satisfaction in their children's successes, and feel guilt or shame over their failures. They proudly display their "my child is on the honor roll" bumper sticker. And they wonder where they went wrong with the teenager who is repeatedly suspended from school. Freudian psychiatry and psychology have been among the sources of such ideas, by blaming problems from asthma to schizophrenia on "bad mothering." Society has reinforced such parent blaming: Believing that parents shape their offspring as a potter molds clay, people readily praise parents for their children's virtues and blame them for their children's vices. Popular culture endlessly proclaims the psychological harm toxic parents inflict on their fragile children. No wonder having and raising children can seem so risky.

But do parents really produce future adults with an inner wounded child by being (take your pick from the toxic-parenting lists) overbearing—or uninvolved? Pushy—or ineffectual? Overprotective—or distant? Are children really so easily wounded? If so, should we then blame our parents for our failings, and ourselves for our children's failings? Or does talk of wounding fragile children through normal parental mistakes trivialize the brutality of real abuse?

Parents do matter. The power of parenting is clearest at the extremes: the abused children who become abusive, the neglected who become neglectful, the loved but firmly handled who become self-confident and socially competent. The power of the family environment also appears in the remarkable academic and vocational successes of children of people who fled from Vietnam and Cambodia—successes attributed to close-knit, supportive, even demanding families (Caplan et al., 1992).

Yet in personality measures, shared environmental influences from the womb onward typically account for less than 10 percent of children's differences. In the words of behavior geneticists Robert Plomin and Denise Daniels (1987; Plomin, 2011), "Two children in the same family are [apart from their shared genes] as different from one another as are pairs of children selected randomly from the population." To developmental psychologist Sandra Scarr (1993), this implied that "parents should be given less credit for kids who turn out great and blamed less for kids who don't." Knowing children are not easily sculpted by parental nurture, perhaps parents can relax a bit more and love their children for who they are.

Peer Influence

As children mature, what other experiences do the work of nurturing? At all ages, but especially during childhood and adolescence, we seek to fit in with our groups and are influenced by them (Harris, 1998, 2000):

- Preschoolers who disdain a certain food often will eat that food if put at a table with a group of children who like it.
- Children who hear English spoken with one accent at home and another in the neighborhood and at school will invariably adopt the accent of their peers, not their parents. Accents (and slang) reflect culture, "and children get their culture from their peers," notes Judith Rich Harris (2007).

- Teens who start smoking typically have friends who model smoking, suggest its pleasures, and offer cigarettes (J. S. Rose et al., 1999; R. J. Rose et al., 2003). Part of this peer similarity may result from a *selection effect*, as kids seek out peers with similar attitudes and interests. Those who smoke (or don't) may select as friends those who also smoke (or don't).

"Men resemble the times more than they resemble their fathers."
-ANCIENT ARAB PROVERB

Howard Gardner (1998) has concluded that parents and peers are complementary:

Parents are more important when it comes to education, discipline, responsibility, orderliness, charitableness, and ways of interacting with authority figures. Peers are more important for learning cooperation, for finding the road to popularity, for inventing styles of interaction among people of the same age. Youngsters may find their peers more interesting, but they will look to their parents when contemplating their own futures. Moreover, parents [often] choose the neighborhoods and schools that supply the peers.

This power to select a child's neighborhood and schools gives parents an ability to influence the culture that shapes the child's peer group. And because neighborhood influences matter, parents may want to become involved in intervention programs that aim at a whole school or neighborhood. If the vapors of a toxic climate are seeping into a child's life, that climate—not just the child—needs reforming. Even so, peers are but one medium of cultural influence. As a purported African proverb declares, and former U.S. Secretary of State Hillary Clinton has popularized, "It takes a village to raise a child."

Allan Shoemaker/Getty Images

Peer power As we develop, we play, date, and partner with peers. No wonder children and youths are so sensitive and responsive to peer influences.

Before You Move On

▶ ASK YOURSELF

To what extent, and in what ways, have your peers and your parents helped shape who you are?

▶ TEST YOURSELF

To predict whether a teenager smokes, ask how many of the teen's friends smoke. One explanation for this correlation is peer influence. What's another?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 50 Review

50-1 How do early experiences modify the brain?

- As a child's brain develops, neural connections grow more numerous and complex. Experiences then trigger a pruning process, in which unused connections weaken and heavily used ones strengthen.
- Early childhood is an important period for shaping the brain, but throughout our lives our brain modifies itself in response to our learning.

50-2 In what ways do parents and peers shape children's development?

- Parents influence their children in areas such as manners and political and religious beliefs, but not in other areas, such as personality.
- As children attempt to fit in with their peers, they tend to adopt their culture—styles, accents, slang, attitudes.
- By choosing their children's neighborhoods and schools, parents exert some influence over peer group culture.

Multiple-Choice Questions

1. According to Plomin and Daniels, "Two children in the same family are [apart from their shared genes] as different from _____ as are pairs of children selected randomly from the population."
 - a. their parents
 - b. their grandparents
 - c. their friends
 - d. one another
 - e. their cousins
2. Compared with rats raised in an enriched environment, which of the following is true of rats raised in isolation?
 - a. Their brain cortex is less developed.
 - b. Though neurologically similar, they fear other rats.
 - c. Their brains have more connections.
 - d. They have a thicker brain cortex.
 - e. The differences between the two groups are not statistically significant.
3. What is the *primary* means by which parents influence the behavior of their children?
 - a. Parenting style
 - b. Genetic contributions
 - c. Prenatal environment
 - d. Teaching cooperation
 - e. Rewarding achievement
4. Neurologically, what is the function of pruning?
 - a. Pruning creates new connections between synapses through repeated experiences.
 - b. Pruning reduces the negative effects of teratogens by eliminating neural waste.
 - c. Pruning increases the weight of the brain through enriching experiences.
 - d. Pruning creates areas in the brain used in learning mathematics.
 - e. Pruning eliminates unused neural pathways.

Practice FRQs

1. Compare and contrast the influence parents and peers have on a child's development, giving one example for each.
2. Provide two examples of how children seek to fit in with their groups and are influenced by them.

(2 points)

Answer

2 points: Parents influence a child's (1) quality of life, (2) attachments and beliefs, (3) exposure to peer culture via neighborhood and schools.

2 points: Peers influence a child's (1) tastes and styles, (2) accents and slang, and (3) substance use.

Module 51

Adolescence: Physical and Cognitive Development

Module Learning Objectives

- 51-1** Define *adolescence*, and identify the major physical changes during this period.
- 51-2** Describe adolescent cognitive and moral development, according to Piaget, Kohlberg, and later researchers.

- 51-1** How is *adolescence* defined, and what physical changes mark this period?

Many psychologists once believed that childhood sets our traits. Today's developmental psychologists see development as lifelong. As this *life-span perspective* emerged, psychologists began to look at how maturation and experience shape us not only in infancy and childhood, but also in adolescence and beyond. Your story is still being written. **Adolescence**—the years spent morphing from child to adult—starts with the physical beginnings of sexual maturity and ends with the social achievement of independent adult status. In some cultures, where teens are self-supporting, this means that adolescence hardly exists.

G. Stanley Hall (1904), one of the first psychologists to describe adolescence, believed that the tension between biological maturity and social dependence creates a period of “storm and stress.” Indeed, after age 30, many who grew up in independence-fostering Western cultures look back on their teenage years as a time they would not want to relive, a time when their peers' social approval was imperative, their sense of direction in life was in flux, and their feeling of alienation from their parents was deepest (Arnett, 1999; Macfarlane, 1964).

But for many, adolescence is a time of vitality without the cares of adulthood, a time of rewarding friendships, heightened idealism, and a growing sense of life's exciting possibilities.

Physical Development

Adolescence begins with *puberty*, the time when we mature sexually. Puberty follows a surge of hormones, which may intensify moods and which trigger a series of bodily changes, described in Module 53.

Just as in the earlier life stages, the *sequence* of physical changes in puberty (for example, breast buds and visible pubic hair before *menarche*—the first menstrual period) is far more predictable than their *timing*. Some girls start their growth spurt at 9, some boys as late as age 16. Though such variations have little effect on height at maturity, they may have psychological consequences: It is not only when we mature that counts, but how people react to our physical development.

adolescence the transition period from childhood to adulthood, extending from puberty to independence.

Try This

How will you look back on your life 10 years from now? Are you making choices that someday you will recollect with satisfaction?

Erik Isakson/JupiterImages

For boys, early maturation has mixed effects. Boys who are stronger and more athletic during their early teen years tend to be more popular, self-assured, and independent, though also more at risk for alcohol use, delinquency, and premature sexual activity (Conley & Rudolph, 2009; Copeland et al., 2010; Lynne et al., 2007).

For girls, early maturation can be a challenge (Mendle et al., 2007). If a young girl's body and hormone-fed feelings are out of sync with her emotional maturity and her friends' physical development and experiences, she may begin associating with older adolescents or may suffer teasing or sexual harassment (Ge & Natsuaki, 2009).

An adolescent's brain is also a work in progress. Until puberty, brain cells increase their connections, like trees growing more roots and branches. Then, during adolescence comes a selective pruning of unused neurons and connections (Blakemore, 2008). What we don't use, we lose.

As teens mature, their frontal lobes also continue to develop. The growth of *myelin*, the fatty tissue that forms around axons and speeds neurotransmission, enables better communication with other brain regions (Kuhn, 2006; Silveri et al., 2006). These developments bring improved judgment, impulse control, and long-term planning.

Maturation of the frontal lobes nevertheless lags behind that of the emotional limbic system. Puberty's hormonal surge and limbic system development help explain teens' occasional impulsiveness, risky behaviors, and emotional storms—slamming doors and turning up the music (Casey et al., 2008). No wonder younger teens (whose unfinished frontal lobes aren't yet fully equipped for making long-term plans and curbing impulses) so often succumb to the tobacco corporations, which most adult smokers could tell them they will later regret. Teens actually don't underestimate the risks of smoking—or fast driving or unprotected sex. They just, when reasoning from their gut, weigh the immediate benefits more heavily (Reyna & Farley, 2006; Steinberg, 2007, 2010). They seek thrills and rewards, but they can't yet locate the brake pedal controlling their impulses.

So, when Junior drives recklessly and academically self-destructs, should his parents reassure themselves that “he can't help it; his frontal cortex isn't yet fully grown”? They can at least take hope: The brain with which Junior begins his teens differs from the brain with which he will end his teens. Unless he slows his brain development with heavy drinking—leaving him prone to impulsivity and addiction—his frontal lobes will continue maturing until about age 25 (Beckman, 2004; Crews et al., 2007).

In 2004, the American Psychological Association joined seven other medical and mental health associations in filing U.S. Supreme Court briefs arguing against the death penalty for 16- and 17-year-olds. The briefs documented the teen brain's immaturity “in areas that bear upon adolescent decision making.” Teens are “less guilty by reason of adolescence,” suggested psychologist Laurence Steinberg and law professor Elizabeth Scott (2003; Steinberg et al., 2009). In 2005, by a 5-to-4 margin, the Court concurred, declaring juvenile death penalties unconstitutional.

Cognitive Development

51-2

How did Piaget, Kohlberg, and later researchers describe adolescent cognitive and moral development?

During the early teen years, reasoning is often self-focused. Adolescents may think their private experiences are unique, something parents just could not understand: “But, Mom, you don't really know how it feels to be in love” (Elkind, 1978). Capable of thinking about

© The New Yorker Collection, 2006. Barbara Smaller from cartoonbank.com. All Rights Reserved.

“Young man, go to your room and stay there until your cerebral cortex matures.”

“If a gun is put in the control of the prefrontal cortex of a hurt and vengeful 15-year-old, and it is pointed at a human target, it will very likely go off.” -NATIONAL INSTITUTES OF HEALTH BRAIN SCIENTIST DANIEL R. WEINBERGER, “A BRAIN TOO YOUNG FOR GOOD JUDGMENT,” 2001

their own thinking, and about other people's thinking, they also begin imagining what others are thinking about *them*. (They might worry less if they understood their peers' similar self-absorption.) Gradually, though, most begin to reason more abstractly.

Developing Reasoning Power

When adolescents achieve the intellectual summit Jean Piaget called *formal operations*, they apply their new abstract reasoning tools to the world around them. They may think about what is ideally possible and compare that with the imperfect reality of their society, their parents, and even themselves. They may debate human nature, good and evil, truth and justice. Their sense of what's fair changes from simple equality to equity—to what's proportional to merit (Almås et al., 2010). Having left behind the concrete images of early childhood, they may now seek a deeper conception of God and existence (Elkind, 1970; Worthington, 1989). Reasoning hypothetically and deducing consequences also enables adolescents to detect inconsistencies and spot hypocrisy in others' reasoning. This can lead to heated debates with parents and silent vows never to lose sight of their own ideals (Peterson et al., 1986).

"When the pilot told us to brace and grab our ankles, the first thing that went through my mind was that we must all look pretty stupid." -JEREMIAH RAWLINGS, AGE 12, AFTER A 1989 DC-10 CRASH IN SIOUX CITY, IOWA

SHANNON STAPLETON/REUTERS/Newscom

LARRY DOWNING/REUTERS/Newscom

Demonstrating their reasoning ability

Although they supported different candidates in the 2012 U.S. presidential election, these teens were all demonstrating their ability to think logically about abstract topics. According to Piaget, they were in the final cognitive stage, formal operations.

Developing Morality

Two crucial tasks of childhood and adolescence are discerning right from wrong and developing character—the psychological muscles for controlling impulses. To be a moral person is to *think* morally and *act* accordingly. Jean Piaget and Lawrence Kohlberg proposed that moral reasoning guides moral actions. A newer view builds on psychology's game-changing new recognition that much of our functioning occurs not on the "high road" of deliberate, conscious thinking but on the "low road" of unconscious, automatic thinking.

MORAL REASONING

Piaget (1932) believed that children's moral judgments build on their cognitive development. Agreeing with Piaget, Lawrence Kohlberg (1981, 1984) sought to describe the development of *moral reasoning*, the thinking that occurs as we consider right and wrong. Kohlberg posed moral dilemmas (for example, whether a person should steal medicine to save a loved one's life) and asked children, adolescents, and adults whether the action was right or wrong. He then analyzed their answers for evidence of stages of moral thinking. His findings led him to propose three basic levels of moral thinking: preconventional, conventional, and postconventional (**TABLE 51.1** on the next page).

Moral reasoning Some Staten Island, New York, residents faced a moral dilemma in 2012 when Superstorm Sandy caused disastrous flooding. Should they risk their lives to try to rescue family, friends, and neighbors in dangerously flooded areas?

ADAM HUNGER/Reuters/Landov

AP® Exam Tip

Kohlberg's is an important stage theory. There are often AP® exam questions on this topic. It's very important to understand that the stage you're in doesn't depend on *what* you decide to do (for example, steal the medicine), it depends on *why* you decide to do it.

Table 51.1 Kohlberg's Levels of Moral Thinking

Level (approximate age)	Focus	Example
<i>Preconventional morality</i> (before age 9)	Self-interest; obey rules to avoid punishment or gain concrete rewards.	"If you save your wife, you'll be a hero."
<i>Conventional morality</i> (early adolescence)	Uphold laws and rules to gain social approval or maintain social order.	"If you steal the drug, everyone will think you're a criminal."
<i>Postconventional morality</i> (adolescence and beyond)	Actions reflect belief in basic rights and self-defined ethical principles.	"People have a right to live."

Kohlberg claimed these levels form a moral ladder. As with all stage theories, the sequence is unvarying. We begin on the bottom rung and ascend to varying heights. Kohlberg's critics have noted that his postconventional stage is culturally limited, appearing mostly among people who prize individualism (Eckensberger, 1994; Miller & Bersoff, 1995).

Moral Intuition

Psychologist Jonathan Haidt (2002, 2006, 2010) believes that much of our morality is rooted in *moral intuitions*—"quick gut feelings, or affectively laden intuitions." According to this intuitionist view, the mind makes moral judgments as it makes aesthetic judgments—quickly and automatically. We *feel* disgust when seeing people engaged in degrading or subhuman acts. Even a disgusting taste in the mouth heightens people's disgust over various moral digressions (Eskine et al., 2011). We *feel* elevation—a tingly, warm, glowing feeling in the chest—when seeing people display exceptional generosity, compassion, or courage. These feelings in turn trigger moral reasoning, says Haidt.

One woman recalled driving through her snowy neighborhood with three young men as they passed "an elderly woman with a shovel in her driveway. I did not think much of it, when one of the guys in the back asked the driver to let him off there. . . . When I saw him jump out of the back seat and approach the lady, my mouth dropped in shock as I realized that he was offering to shovel her walk for her." Witnessing this unexpected goodness triggered elevation: "I felt like jumping out of the car and hugging this guy. I felt like singing and running, or skipping and laughing. I felt like saying nice things about people" (Haidt, 2000).

"Could human morality really be run by the moral emotions," Haidt wonders, "while moral reasoning struts about pretending to be in control?" Consider the desire to punish. Laboratory games reveal that the desire to punish wrongdoings is mostly driven not by reason (such as an objective calculation that punishment deters crime) but rather by emotional reactions, such as moral outrage (Darley, 2009). After the emotional fact, moral reasoning—our mind's press secretary—aims to convince us and others of the logic of what we have intuitively felt.

This intuitionist perspective on morality finds support in a study of moral paradoxes. Imagine seeing a runaway trolley headed for five people. All will certainly be killed unless you throw a switch that diverts the trolley onto another track, where it will kill one person. Should you throw the switch? Most say *Yes*. Kill one, save five.

Now imagine the same dilemma, except that your opportunity to save the five requires you to push a large stranger onto the tracks, where he will die as his body stops the trolley. Kill one, save five? The logic is the same, but most say *No*. Seeking to understand why, a Princeton research team led by Joshua Greene (2001) used brain imaging to spy on people's neural responses as they contemplated such dilemmas. Only when given the body-pushing type of moral dilemma did their brain's emotion areas activate. Despite the identical logic, the personal dilemma engaged emotions that altered moral judgment.

While the new moral psychology illustrates the many ways moral intuitions trump moral reasoning, others reaffirm the importance of moral reasoning. The religious and moral reasoning of the Amish, for example, shapes their practices of forgiveness, communal life, and modesty (Narvaez, 2010). Joshua Greene (2010) likens our moral cognition to a camera. Usually, we rely on the automatic point-and-shoot. But sometimes we use reason to manually override the camera's automatic impulse.

MORAL ACTION

Our moral thinking and feeling surely affect our moral talk. But sometimes talk is cheap and emotions are fleeting. Morality involves *doing* the right thing, and what we do also depends on social influences. As political theorist Hannah Arendt (1963) observed, many Nazi concentration camp guards during World War II were ordinary “moral” people who were corrupted by a powerfully evil situation.

Today's character education programs tend to focus on the whole moral package—thinking, feeling, and *doing* the right thing. As children's *thinking* matures, their *behavior* also becomes less selfish and more caring (Krebs & Van Hesteren, 1994; Miller et al., 1996). Today's programs also teach children *empathy* for others' feelings, and the self-discipline needed to restrain one's own impulses—to delay small gratifications now to enable bigger rewards later. Those who do learn to *delay gratification* become more socially responsible, academically successful, and productive (Funder & Block, 1989; Mischel et al., 1988, 1989). In service-learning programs, teens tutor, clean up their neighborhoods, and assist the elderly. The result? The teens' sense of competence and desire to serve increase, and their school absenteeism and drop-out rates diminish (Andersen, 1998; Piliavin, 2003). Moral action feeds moral attitudes.

“It is a delightful harmony when doing and saying go together.”
—MICHEL EYQUEM DE MONTAIGNE

“This might not be ethical. Is that a problem for anybody?”

Before You Move On

▶ ASK YOURSELF

Can you recall making an impulsive decision when you were younger that you later regretted? Would you approach the situation differently today?

▶ TEST YOURSELF

Describe Kohlberg's three levels of moral reasoning.

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 51 Review

51-1

How is *adolescence* defined, and what physical changes mark this period?

- *Adolescence* is the transition period from childhood to adulthood, extending from puberty to social independence.
- For boys, early maturation has mixed effects; for girls, early maturation can be a challenge.
- The brain's frontal lobes mature and myelin growth increases during adolescence and the early twenties, enabling improved judgment, impulse control, and long-term planning.

51-2

How did Piaget, Kohlberg, and later researchers describe adolescent cognitive and moral development?

- Piaget theorized that adolescents develop a capacity for formal operations and that this development is the foundation for moral judgment.
- Lawrence Kohlberg proposed a stage theory of moral reasoning, from a preconventional morality of self-interest, to a conventional morality concerned with upholding laws and social rules, to (in some people) a postconventional morality of universal ethical principles.

- Other researchers believe that morality lies in moral intuition and moral action as well as thinking.
- Some critics argue that Kohlberg's postconventional level represents morality from the perspective of individualist cultures.

Multiple-Choice Questions

- The growth of _____ around axons speeds neurotransmission, enabling better communication between the frontal lobe and other brain regions.
 - neurons
 - the cell body
 - dendrites
 - myelin
 - synapses
- The maturation of the brain's _____ lags behind the development of the limbic system, which may explain the impulsivity of teenagers compared with adults.
 - frontal lobes
 - temporal lobes
 - occipital lobes
 - parietal lobes
 - corpus collosum
- _____ believed that a child's moral judgments build on cognitive development. _____ agreed and sought to describe the development of moral reasoning.
 - Kohlberg; Erikson
 - Erikson; Kohlberg
 - Piaget; Kohlberg
 - Piaget; Erikson
 - Haidt; Hall
- Which level of moral reasoning includes a focus on upholding laws in order to gain social approval?
 - Collectivist
 - Preconventional
 - Conventional
 - Postconventional
 - Formal operational
- What development in adolescents allows for greater impulse control?
 - The hormonal surge of early adolescence
 - Hindbrain changes associated with the onset of puberty
 - Frontal lobe maturation in late adolescence
 - Limbic system development in mid-adolescence
 - A decrease in myelin production throughout adolescence
- Which of Jean Piaget's stages describes typical adolescent thinking?
 - Sensorimotor
 - Preoperational
 - Concrete operational
 - Formal operational
 - Accommodation
- Which of the following correctly describes one of Kohlberg's levels of moral reasoning?
 - Preconventional stage, where one follows moral principles
 - Conventional stage, where individualism is foremost
 - Conventional stage, where it is imperative to uphold the law and follow rules
 - Preconventional stage, where moral judgment depends on rewards and punishments
 - Postconventional stage, where it is imperative to uphold the law and follow rules

Practice FRQs

- Describe how the ideas of Lawrence Kohlberg and Jonathan Haidt differ in regard to the development of morality.
- Name two biological changes related to sexual maturity in adolescence and briefly describe one change in neurological development in adolescence.

(3 points)

Answer

1 point: Lawrence Kohlberg focused on moral reasoning and the way people *think* about moral situations.

1 point: Jonathan Haidt focused on moral intuition and the way people *feel* about moral situations.

Module 52

Adolescence: Social Development and Emerging Adulthood

Module Learning Objectives

- 52-1** Describe the social tasks and challenges of adolescence.
- 52-2** Contrast parental and peer influences during adolescence.
- 52-3** Discuss the characteristics of emerging adulthood.

52-1 What are the social tasks and challenges of adolescence?

Theorist Erik Erikson (1963) contended that each stage of life has its own *psychosocial* task, a crisis that needs resolution. Young children wrestle with issues of *trust*, then *autonomy* (independence), then *initiative*. School-age children strive for *competence*, feeling able and productive. But for people your age, the task is to synthesize past, present, and future possibilities into a clearer sense of self (**TABLE 52.1** on the next page). Adolescents wonder, “Who am I as an individual? What do I want to do with my life? What values should I live by? What do I believe in?” Erikson called this quest the adolescent’s *search for identity*.

As sometimes happens in psychology, Erikson’s interests were bred by his own life experience. As the son of a Jewish mother and a Danish Gentile father, Erikson was “doubly an outsider,” reported Morton Hunt (1993, p. 391). He was “scorned as a Jew in school but mocked as a Gentile in the synagogue because of his blond hair and blue eyes.” Such episodes fueled his interest in the adolescent struggle for identity.

Forming an Identity

To refine their sense of identity, adolescents in individualist cultures usually try out different “selves” in different situations. They may act out one self at home, another with friends, and still another at school or on Facebook. If two situations overlap—as when a teenager brings friends home—the discomfort can be considerable. The teen asks, “Which self should I be? Which is the real me?” The resolution is a self-definition that unifies the various selves into a consistent and comfortable sense of who one is—an **identity**.

For both adolescents and adults, group identities are often formed by how we differ from those around us. When living in Britain, I become conscious of my Americanness. When spending time with my daughter in Africa, I become conscious of my minority (White) race. When surrounded by women, I am mindful of my gender identity. For international students, for those of a minority ethnic group, for people with a disability, for those on a team, a **social identity** often forms around their distinctiveness.

“Somewhere between the ages of 10 and 13 (depending on how hormone-enhanced their beef was), children entered adolescence, a.k.a. ‘the de-cutening.’” -JON STEWART ET AL., *EARTH (THE BOOK)*, 2010

AP® Exam Tip

This is not the only place in the book that the author discusses Erik Erikson’s stage theory. For example, trust was discussed on page 492. Integrity comes up on page 548. Table 52.1 pulls it all together in one place for you.

identity our sense of self; according to Erikson, the adolescent’s task is to solidify a sense of self by testing and integrating various roles.

social identity the “we” aspect of our self-concept; the part of our answer to “Who am I?” that comes from our group memberships.

Table 52.1 Erikson's Stages of Psychosocial Development

Stage (approximate age)	Issue	Description of Task
<i>Infancy</i> (to 1 year)	Trust vs. mistrust	If needs are dependably met, infants develop a sense of basic trust.
<i>Toddlerhood</i> (1 to 3 years)	Autonomy vs. shame and doubt	Toddlers learn to exercise their will and do things for themselves, or they doubt their abilities.
<i>Preschool</i> (3 to 6 years)	Initiative vs. guilt	Preschoolers learn to initiate tasks and carry out plans, or they feel guilty about their efforts to be independent.
<i>Elementary school</i> (6 years to puberty)	Competence vs. inferiority	Children learn the pleasure of applying themselves to tasks, or they feel inferior.
<i>Adolescence</i> (teen years into 20s)	Identity vs. role confusion	Teenagers work at refining a sense of self by testing roles and then integrating them to form a single identity, or they become confused about who they are.
<i>Young adulthood</i> (20s to early 40s)	Intimacy vs. isolation	Young adults struggle to form close relationships and to gain the capacity for intimate love, or they feel socially isolated.
<i>Middle adulthood</i> (40s to 60s)	Generativity vs. stagnation	In middle age, people discover a sense of contributing to the world, usually through family and work, or they may feel a lack of purpose.
<i>Late adulthood</i> (late 60s and up)	Integrity vs. despair	Reflecting on his or her life, an older adult may feel a sense of satisfaction or failure.

Intimacy vs. isolation

"Self-consciousness, the recognition of a creature by itself as a 'self,' [cannot] exist except in contrast with an 'other,' a something which is not the self."
-C. S. LEWIS, *THE PROBLEM OF PAIN*, 1940

But not always. Erikson noticed that some adolescents forge their identity early, simply by adopting their parents' values and expectations. (Traditional, less individualist cultures teach adolescents who they are, rather than encouraging them to decide on their own.) Other adolescents may adopt an identity defined in opposition to parents but in conformity with a particular peer group—jocks, preps, geeks, band kids, debaters.

Most young people do develop a sense of contentment with their lives. When American teens were asked whether a series of statements described them, 81 percent said *Yes* to "I would choose my life the way it is right now." The other 19 percent agreed that "I wish I were somebody else" (Lyons, 2004). Reflecting on their existence, 75 percent of American collegians say they "discuss religion/spirituality" with friends, "pray," and agree that "we are all spiritual beings" and "search for meaning/purpose in life" (Astin et al., 2004; Bryant & Astin, 2008). This would not surprise Stanford psychologist William Damon and his colleagues (2003), who have contended that a key task of adolescence is to achieve a purpose—a desire to accomplish something personally meaningful that makes a difference to the world beyond oneself.

The late teen years, when many people like you in industrialized countries begin attending college or working full time, provide new opportunities for trying out possible roles. Here is something for you to remember: Many college seniors have achieved a clearer identity and a more positive self-concept than they had as first-year students (Waterman, 1988).

Tristan Savatier/Getty Images

Wiklund, Juliana/Getty Images

Who shall I be today? By varying the way they look, adolescents try out different “selves.” Although we eventually form a consistent and stable sense of identity, the self we present may change with the situation.

This could be one of the reasons why the first year of college is such a challenge. Collegians who have achieved a clear sense of identity are less prone to self-destructive behavior such as alcohol misuse (Bishop et al., 2005).

Several nationwide studies indicate that young Americans’ self-esteem falls during the early to midteen years, and, for girls, depression scores often increase. But then self-image rebounds during the late teens and twenties (Robins et al., 2002; Twenge & Campbell, 2001; Twenge & Nolen-Hoeksema, 2002). Late adolescence and early adulthood are also when agreeableness and emotional stability scores increase (Klimstra et al., 2009; Lucas and Donnellan, 2011).

Erikson contended that the adolescent identity stage is followed in young adulthood by a developing capacity for **intimacy**, the ability to form emotionally close relationships. Romantic relationships, which tend to be emotionally intense, are reported by some two in three North American 17-year-olds, but fewer among those in collectivist countries such as China (Collins et al., 2009; Li et al., 2010). Those who enjoy high-quality (intimate, supportive) relationships with family and friends tend also to enjoy similarly high-quality romantic relationships in adolescence, which set the stage for healthy adult relationships. Such relationships are, for most of us, a source of great pleasure. When Mihaly Csikszentmihalyi [chick-SENT-me-hi] and Jeremy Hunter (2003) used a beeper to sample the daily experiences of American teens, they found them unhappiest when alone and happiest when with friends. As Aristotle long ago recognized, we humans are “the social animal.” Relationships matter.

intimacy in Erikson’s theory, the ability to form close, loving relationships; a primary developmental task in late adolescence and early adulthood.

AP® Exam Tip

Careful! In the media, to describe a relationship as intimate usually implies that it is sexual. Erikson means something different. In his theory, an intimate relationship may or may not be sexual (and a sexual relationship may or may not be intimate).

Parent and Peer Relationships

52-2 How do parents and peers influence adolescents?

This next research finding will not surprise you: As adolescents in Western cultures seek to form their own identities, they begin to pull away from their parents (Shanahan et al., 2007). The preschooler who can’t be close enough to her mother, who loves to touch and cling to her, becomes the 14-year-old who wouldn’t be caught dead holding hands with Mom. The transition occurs gradually. By adolescence, arguments occur more often, usually over mundane things—household chores, bedtime, homework (Tesser et al., 1989). Parent-child conflict during the transition to adolescence tends to be greater with first-born than with second-born children, and greater with mothers than with fathers (Burk et al., 2009; Shanahan et al., 2007).

“She says she’s someone from your past who gave birth to you, and raised you, and sacrificed everything so you could have whatever you wanted.”

"It's you who don't understand me—I've been fifteen, but you have never been forty-eight."

For a minority of parents and their adolescents, differences lead to real splits and great stress (Steinberg & Morris, 2001). But most disagreements are at the level of harmless bickering. And most adolescents—6000 of them in 10 countries, from Australia to Bangladesh to Turkey—said they like their parents (Offer et al., 1988). "We usually get along but . . ." adolescents often reported (Galambos, 1992; Steinberg, 1987).

Positive parent-teen relations and positive peer relations often go hand in hand. High school girls who have the most affectionate relationships with their mothers tend also to enjoy the most intimate friendships with girlfriends (Gold & Yanof, 1985). And teens who feel close to their parents tend to be healthy and happy and to do well in school (Resnick et al., 1997). Of course, we can state this correlation the other way: Misbehaving teens are more likely to have tense relationships with parents and other adults.

Adolescence is typically a time of diminishing parental influence and growing peer influence. Asked in a survey if they had "ever had a serious talk" with their child about illegal drugs, 85 percent of American parents answered *Yes*. But if the parents had indeed given this earnest advice, many teens had apparently tuned it out: Only 45 percent could recall such a talk (Morin & Brossard, 1997).

Heredity does much of the heavy lifting in forming individual temperament and personality differences, and peer influences do much of the rest. Most teens are herd animals. They talk, dress, and act more like their peers than their parents. What their friends are, they often become, and what "everybody's doing," they often do. In teen calls to hotline counseling services, peer relationships have been the most discussed topic (Boehm et al., 1999). The average U.S. teen sends 60 text messages per day (Pew, 2012). Many adolescents become absorbed by social networking, sometimes with a compulsive use that produces "Facebook fatigue."

Online communication stimulates intimate self-disclosure—both for better (support groups) and for worse (online predators and extremist groups) (Subrahmanyam & Greenfield, 2008; Valkenburg & Peter, 2009).

For those who feel excluded, the pain is acute. "The social atmosphere in most high schools is poisonously clique-driven and exclusionary," observed social psychologist Elliot Aronson (2001). Most excluded "students suffer in silence. . . . A small number act out in violent ways against their classmates." Those who withdraw are vulnerable to loneliness, low self-esteem, and depression (Steinberg & Morris, 2001). Peer approval matters.

Teens see their parents as having more influence in other areas—for example, in shaping their religious faith and in thinking about college and career choices (*Emerging Trends*, 1997). A Gallup Youth Survey reveals that most share their parents' political views (Lyons, 2005).

Nine times out of ten, it's all about peer pressure.

Emerging Adulthood

52-3 What is emerging adulthood?

In the Western world, adolescence now roughly corresponds to the teen years. At earlier times, and in other parts of the world today, this slice of life has been much smaller (Baumeister & Tice, 1986). Shortly after sexual maturity, young people would assume adult responsibilities and status. The event might be celebrated with an elaborate initiation—a public *rite of passage*. The new adult would then work, marry, and have children.

When schooling became compulsory in many Western countries, independence was put on hold until after graduation. From Europe to Australia, adolescents are now taking more time to establish themselves as adults. In the United States, for example, the average age at first marriage has increased more than 4 years since 1960 (to 28 for men, 26 for women). In 1960, 3 in 4 women and 2 in 3 men had, by age 30, finished school, left home, become financially independent, married, and had a child. Today, fewer than half of 30-year-old women and one-third of men have achieved these five milestones (Henig, 2010). Delayed independence has overlapped with an earlier onset of puberty. Earlier sexual maturity is related both to girls' increased body fat (which can support pregnancy and nursing) and to weakened parent-child bonds, including absent fathers (Ellis, 2004).

Together, later independence and earlier sexual maturity have widened the once-brief interlude between biological maturity and social independence (**FIGURE 52.1**). In prosperous communities, the time from 18 to the mid-twenties is an increasingly not-yet-settled phase of life, which some now call **emerging adulthood** (Arnett, 2006, 2007; Reitzle, 2006). No longer adolescents, these emerging adults, having not yet assumed full adult responsibilities and independence, feel "in between." After high school, those who enter the job market or go to college may be managing their own time and priorities more than ever before. Yet they may be doing so from their parents' home—unable to afford their own place and perhaps still emotionally dependent as well. Recognizing today's more gradually emerging adulthood, the U.S. government now allows dependent children up to age 26 to remain on their parents' health insurance (Cohen, 2010).

"When I was your age, I was an adult."

emerging adulthood for some people in modern cultures, a period from the late teens to mid-twenties, bridging the gap between adolescent dependence and full independence and responsible adulthood.

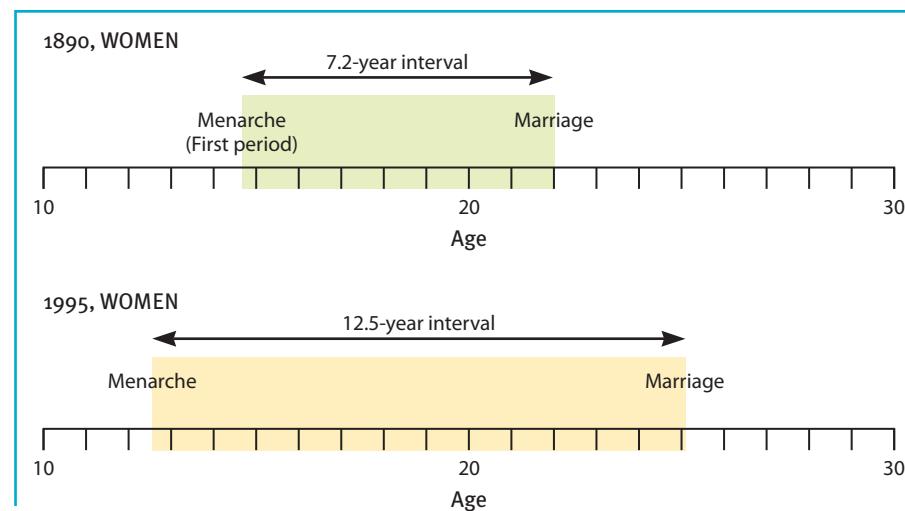

Figure 52.1

The transition to adulthood is being stretched from both ends

In the 1890s, the average interval between a woman's first menstrual period and marriage, which typically marked a transition to adulthood, was about 7 years; in industrialized countries today it is about 12 years (Guttmacher, 1994, 2000). Although many adults are unmarried, later marriage combines with prolonged education and earlier menarche to help stretch out the transition to adulthood.

Before You Move On

▶ ASK YOURSELF

What have been your best and worst experiences during adolescence? How have your experiences been influenced by environmental factors, such as your cultural context, and how have they been influenced by your inborn traits?

▶ TEST YOURSELF

How has the transition from childhood to adulthood changed in Western cultures in the last century or so?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 52 Review

52-1 What are the social tasks and challenges of adolescence?

- Erikson theorized that each life stage has its own psychosocial task, and that a chief task of adolescence is solidifying one's sense of self—one's *identity*. This often means "trying on" a number of different roles.
- *Social identity* is the part of the self-concept that comes from a person's group memberships.

52-2 How do parents and peers influence adolescents?

- During adolescence, parental influence diminishes and peer influence increases.
- Adolescents adopt their peers' ways of dressing, acting, and communicating.
- Parents have more influence in religion, politics, and college and career choices.

52-3 What is emerging adulthood?

- The transition from adolescence to adulthood is now taking longer.
- *Emerging adulthood* is the period from age 18 to the mid-twenties, when many young people are not yet fully independent. But critics note that this stage is found mostly in today's Western cultures.

Multiple-Choice Questions

1. According to Erikson, you develop your _____, a part of who you are, from your group memberships.
 - a. self-interest
 - b. social identity
 - c. social self
 - d. self-esteem
 - e. self-consciousness
2. In many Western societies, it is common for adolescents to graduate high school, go to college, and still live at home with their parents. They have not yet assumed full adult responsibilities and independence. Psychologists have identified this period of time as
 - a. adulthood.
 - b. early adulthood.
 - c. emerging adulthood.
 - d. late adolescence.
 - e. role confusion.
3. Which is true of social relations during the teen years?
 - a. As teens distance themselves from parents, peer relationships become more important.
 - b. High school girls who have the poorest relationships with their mothers have the most intense friendships with peers.
 - c. Parental influence peaks during mid to late adolescence.
 - d. Most adolescents have serious disagreements with parents, leading to great social stress.
 - e. Teens are generally more concerned with family relationships than peer relationships.
4. According to Erikson, what is the primary developmental task for adolescents?
 - a. Trust versus mistrust
 - b. Initiative versus guilt
 - c. Competence versus inferiority
 - d. Identity versus role confusion
 - e. Intimacy versus isolation

5. Compared with the late nineteenth century, what is true about the transition from childhood to adulthood in Western cultures?
 - a. It starts earlier and is completed earlier.
 - b. It starts later and is completed later.
 - c. It starts later and is completed earlier.
 - d. It starts earlier and is completed later.
 - e. It has not changed.
6. Megan, a third grader, is having trouble with math. She is starting to do poorly in other subjects, because she feels she cannot master math. Based on Erikson's stages of psychosocial development, which stage is Megan in?
 - a. Autonomy versus shame and doubt
 - b. Initiative versus guilt
 - c. Competence versus inferiority
 - d. Identity versus role confusion
 - e. Intimacy versus isolation
7. Boez is a 2-year-old boy who is in the process of potty training. When Boez urinates in the potty, he has a sense of pride. If Boez urinates in his pants, he runs and hides. According to Erikson, in which psychosocial stage is Boez?
 - a. Autonomy versus shame and doubt
 - b. Initiative versus guilt
 - c. Competence versus inferiority
 - d. Identity versus role confusion
 - e. Intimacy versus isolation

Practice FRQs

1. What is emerging adulthood? Name two trends that have led to adding this to the stages of life.

Answer

1 point: Emerging adulthood is the period in modern Western cultures during the late teens to the mid-twenties that bridges the gap between adolescent dependence and adult independence.

2 points: Longer years of schooling and later age of marriage and moving out of the family home are the trends that have led to this new stage.

2. Name and describe Erik Erikson's stages of psychosocial development for infancy (first year) and middle adulthood (40s to 60s).

(4 points)

Module 53

Sexual Development

Module Learning Objectives

- 53-1** Explain how biological sex is determined, and describe the role of sex hormones in gender development.
- 53-2** Describe some of the ways that sexual development varies.
- 53-3** Discuss the factors that reduce the risk of sexually transmitted infections.
- 53-4** Discuss the factors that influence teenagers' sexual behaviors and use of contraceptives.
- 53-5** Summarize what research has taught us about sexual orientation.

Image Source/Getty Images

53-1 How is our biological sex determined, and how do sex hormones influence prenatal and adolescent development?

In domains where we face similar challenges—regulating heat with sweat, preferring foods that nourish, growing calluses where the skin meets friction—men and women are similar. Even when describing the ideal mate, both prize traits such as “kind,” “honest,” and “intelligent.” But in mating-related domains, evolutionary psychologists contend, males differ from females whether they are elephants or elephant seals, rural peasants or corporate presidents (Geary, 2010). Our biology may influence our gender differences in two ways: genetically, by our differing *sex chromosomes*, and physiologically, from our differing concentrations of *sex hormones*.

Prenatal Sexual Development

As noted earlier, males and females are variations on a single form—of the 46 chromosomes, 45 are unisex. So great is this similarity that until seven weeks after conception, you were anatomically indistinguishable from someone of the other sex. Then your genes activated your biological sex. Male or female, your sex was determined by your father's contribution to your twenty-third pair of chromosomes, the two sex chromosomes. You received an **X chromosome** from your mother. From your father, you received the one chromosome that is not unisex—either another X chromosome, making you a girl, or a **Y chromosome**, making you a boy.

The Y chromosome includes a single gene which, about seven weeks after conception, throws a master switch triggering the testes to develop and to produce the principal male hormone, **testosterone**. This hormone starts the development of male sex organs. Females also have testosterone, but less of it.

X chromosome the sex chromosome found in both men and women. Females have two X chromosomes; males have one. An X chromosome from each parent produces a female child.

Y chromosome the sex chromosome found only in males. When paired with an X chromosome from the mother, it produces a male child.

testosterone the most important of the male sex hormones. Both males and females have it, but the additional testosterone in males stimulates the growth of the male sex organs in the fetus and the development of the male sex characteristics during puberty.

Another key period for sexual differentiation falls during the fourth and fifth prenatal months. During this period, sex hormones bathe the fetal brain and influence its wiring. Different patterns for males and females develop under the influence of the male's greater testosterone and the female's ovarian hormones (Hines, 2004; Udry, 2000).

Adolescent Sexual Development

Pronounced physical differences emerge during adolescence, when boys and girls enter **puberty** and mature sexually. A surge of hormones triggers a two-year period of rapid physical development, usually beginning at about age 11 in girls and at about age 13 in boys. A year or two before that, however, boys and girls often feel the first stirrings of physical attraction (McClintock & Herdt, 1996).

About the time of puberty, boys' growth propels them to greater height than their female counterparts (**FIGURE 53.1**). During this growth spurt, the **primary sex characteristics**—the reproductive organs and external genitalia—develop dramatically. So do **secondary sex characteristics**, the nonreproductive traits such as breasts and hips in girls, facial hair and deepened voice in boys, and pubic and underarm hair in both sexes (**FIGURE 53.2** on the next page).

In various countries, girls are developing breasts earlier (sometimes before age 10) and reaching puberty earlier than in the past. This phenomenon is variously attributed to increased body fat, increased hormone-mimicking chemicals, and increased stress related to family disruption (Biro et al., 2010).

Puberty's landmarks are the first ejaculation in boys (*spermarche*), usually by about age 14, and the first menstrual period in girls (**menarche**—meh-NAR-key), usually within a year of age 12½ (Anderson et al., 2003). Menarche appears to occur a few months earlier, on average, for girls who have experienced stresses related to father absence, sexual abuse, or insecure attachments (Belsky et al., 2010; Vigil et al., 2005; Zabin et al., 2005). Girls who have

Nick Downes.

puberty the period of sexual maturation, during which a person becomes capable of reproducing.

primary sex characteristics the body structures (ovaries, testes, and external genitalia) that make sexual reproduction possible.

secondary sex characteristics nonreproductive sexual traits, such as female breasts and hips, male voice quality, and body hair.

menarche [meh-NAR-key] the first menstrual period.

Figure 53.1

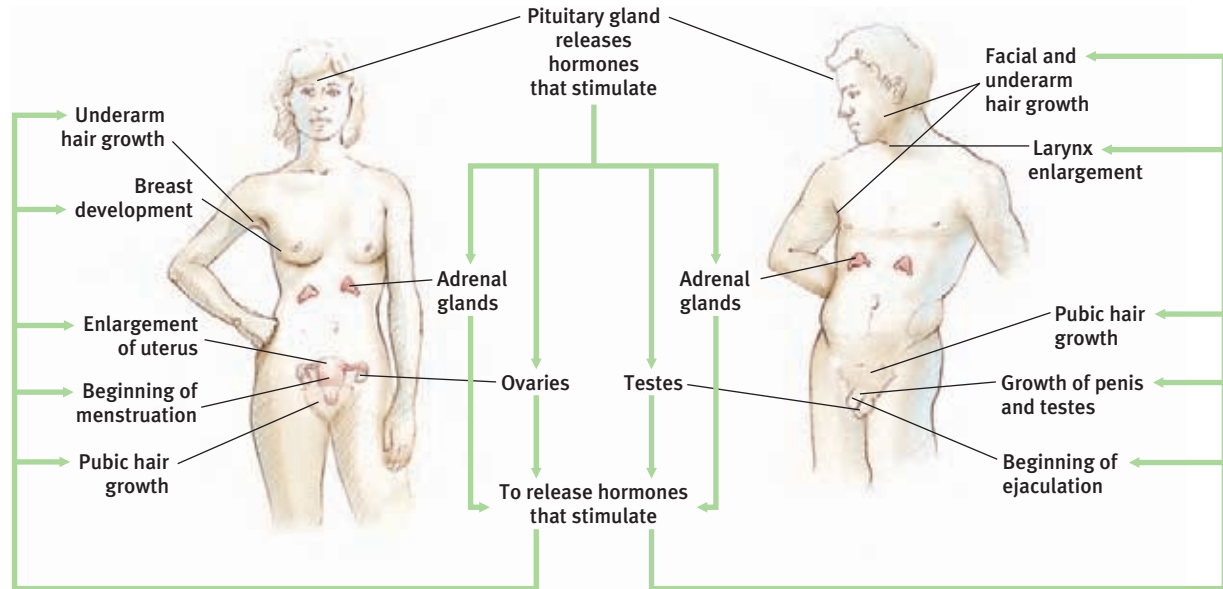

Height differences Throughout childhood, boys and girls are similar in height. At puberty, girls surge ahead briefly, but then boys overtake them at about age 14. (Data from Tanner, 1978.) Studies suggest that sexual development and growth spurts are beginning somewhat earlier than was the case a half-century ago (Herman-Giddens et al., 2001).

Rob Levine/Getty Images

Figure 53.2**Body changes at puberty**

At about age 11 in girls and age 13 in boys, a surge of hormones triggers a variety of physical changes.

been prepared for menarche usually experience it as a positive life transition. Studies have shown that nearly all adult women recall their first menstrual period and remember experiencing a mixture of feelings—pride, excitement, embarrassment, and apprehension (Greif & Ulman, 1982; Woods et al., 1983). Most men have similarly recalled their first ejaculation, which usually occurs as a nocturnal emission (Fuller & Downs, 1990).

Gender in the spotlight Dramatic improvements in South African track star Caster Semenya's race times prompted the International Association of Athletics Federations to undertake sex testing in 2009. Semenya was reported to be intersex—with physical characteristics of both males and females—though she was officially cleared to continue competing as a woman. Semenya declared, "God made me the way I am and I accept myself. I am who I am" (*YOU*, 10 September 2009).

Variations on Sexual Development

53-2 What are some of the ways that sexual development varies?

Sometimes nature blurs the biological line between males and females. Atypical hormone exposure or sensitivity may cause atypical fetal development. *Intersex* individuals are born with intermediate or unusual combinations of male and female physical features. Genetic males, for example, may be born with normal male hormones and testes but without a penis or with a very small one.

Until recently, pediatricians and other medical experts often recommended surgery to create a female identity for these children. One study reviewed 14 cases of boys who had undergone early sex-reassignment surgery and had been raised as girls. Of those cases, 6 had later declared themselves as males, 5 were living as females, and 3 had an unclear gender identity (Reiner & Gearhart, 2004).

Although not born with an intersex condition, a little boy who lost his penis during a botched circumcision became a famous case illustrating the problems involved in sex-reassignment surgery. His parents followed a psychiatrist's advice to raise him as a girl rather than as a damaged boy. Alas, "Brenda" Reimer was not like most other girls. "She" didn't like dolls. She tore her dresses with rough-and-tumble play. At puberty she wanted no part of kissing boys. Finally, Brenda's parents explained what had happened, whereupon "Brenda" immediately rejected the assigned female identity. He cut his hair and chose a male name, David. He eventually married a woman and became a stepfather. And, sadly, he later committed suicide (Colapinto, 2000).

The bottom line: "Sex matters," concluded the National Academy of Sciences (2001). In combination with the environment, sex-related genes and physiology "result in behavioral and cognitive differences between males and females." Nature and nurture work together.

Sexually Transmitted Infections

53-3 How can sexually transmitted infections be prevented?

Rates of *sexually transmitted infections* (STIs; also called *STDs* for *sexually transmitted diseases*) are rising, and two-thirds of the new infections have occurred in people under 25 (CASA, 2004). Teenage girls, because of their not yet fully mature biological development and lower levels of protective antibodies, are especially vulnerable (Dehne & Riedner, 2005; Guttmacher, 1994). A Centers for Disease Control study of sexually experienced 14- to 19-year-old U.S. females found 39.5 percent had STIs (Forhan et al., 2008).

Consider this: If someone uses a birth control method that is 98 percent effective in preventing pregnancy or infection, a 2 percent chance of failure in the first such use accumulates to a risk of nearly 50 percent after 30 such uses. Moreover, when people feel drawn to a partner, they become motivated to underestimate risks (Knäuper et al, 2005).

Condoms offer only limited protection against certain skin-to-skin STIs, such as herpes, but they do reduce other risks (Medical Institute, 1994; NIH, 2001). The effects were clear when Thailand promoted 100 percent condom use by commercial sex workers. Over a 4-year period, as condom use soared from 14 to 94 percent, the annual number of bacterial STIs plummeted from 410,406 to 27,362 (WHO, 2000).

Across the available studies, condoms also have been 80 percent effective in preventing transmission of *HIV* (*human immunodeficiency virus*—the virus that causes **AIDS**) from an infected partner (Weller & Davis-Beaty, 2002; WHO, 2003). Although AIDS can be transmitted by other means, such as needle sharing during drug use, its sexual transmission is most common. Women’s AIDS rates are increasing fastest, partly because the virus is passed from man to woman much more often than from woman to man. A man’s semen can carry more of the virus than can a woman’s vaginal and cervical secretions. The HIV-infected semen can also linger for days in a woman’s vagina and cervix, increasing the time of exposure (Allen & Setlow, 1991; WHO, 2004).

Most people recently diagnosed with AIDS in the United States have been ages 25 to 44 (CDC, 2013a). Given AIDS’ long incubation period, it’s unsurprising that 39 percent of new HIV diagnoses in the United States were among those even younger—13- to 29-year-olds (CDC, 2013b). In 2009, the death of 1.8 million people with AIDS worldwide left behind countless grief-stricken partners and millions of orphaned children (UNAIDS, 2010). Sub-Saharan Africa is home to two-thirds of those infected with HIV, and medical treatment and care for the dying are sapping the region’s social resources.

Many people assume that oral sex falls in the category of “safe sex,” but recent studies show a significant link between oral sex and transmission of STIs, such as the *human papilloma virus* (HPV). Risks rise with the number of sexual partners (Gillison et al., 2012). Most HPV infections can now be prevented with a vaccination administered before sexual contact.

Teen Pregnancy

53-4 What factors influence teenagers’ sexual behaviors and use of contraceptives?

Adolescents’ physical maturation fosters a sexual dimension to their emerging identity. Yet sexual expression varies dramatically with time and culture. Among American women born before 1900, a mere 3 percent had experienced premarital sex by age 18 (Smith, 1998). A century later, about half of U.S. ninth- to twelfth-graders reported having had sexual intercourse (CDC, 2010). Teen intercourse rates are roughly similar in Western Europe and in Latin America, but much lower in Arab and Asian countries and among North Americans of Asian descent (McLaughlin et al., 1997; Wellings et al., 2006). Given the wide variation across time and place, it’s no surprise that twin research has found that environmental factors accounted

AIDS (acquired immune deficiency syndrome) a life-threatening, sexually transmitted infection caused by the *human immunodeficiency virus* (HIV). AIDS depletes the immune system, leaving the person vulnerable to infections.

Thomas Deerbeck, NCMIR/Science Source

An HIV-infected cell

for almost three-fourths of the individual variation in age of sexual initiation (Bricker et al., 2006). Family and cultural values matter.

Compared with European teens, American teens have a higher rate of STIs and also of teen pregnancy (Call et al., 2002; Sullivan/Anderson, 2009). What environmental factors contribute to teen pregnancy?

Minimal communication about birth control Many teenagers are uncomfortable discussing contraception with their parents, partners, and peers. Teens who talk freely with parents, and who are in an exclusive relationship with a partner with whom they communicate openly, are more likely to use contraceptives (Aspy et al., 2007; Milan & Kilmann, 1987).

Guilt related to sexual activity In another survey, 72 percent of sexually active 12- to 17-year-old American girls said they regretted having had sex (Reuters, 2000). Sexual inhibitions or ambivalence can restrain sexual activity, but if passion overwhelms intentions they may also reduce attempts at birth control (Gerrard & Luus, 1995; MacDonald & Hynie, 2008).

Alcohol use Sexually active teens are typically alcohol-using teens (Zimmer-Gembeck & Helfand, 2008), and those who use alcohol prior to sex are less likely to use condoms (Kotchick et al., 2001). By depressing the brain centers that control judgment, inhibition, and self-awareness, alcohol disarms normal restraints, a phenomenon well known to sexually coercive males.

Mass media norms of unprotected promiscuity Media help write the “social scripts” that affect our perceptions and actions. So what sexual scripts do today’s media write on our minds? An average hour of prime-time television on the three major U.S. networks has contained 15 sexual acts, words, and innuendos. The partners were usually unmarried, with no prior romantic relationship, and few communicated any concern for birth control or STIs (Brown et al., 2002; Kunkel, 2001; Sapolsky & Tabarlet, 1991). The more sexual content adolescents view (even when controlling for other predictors of early sexual activity), the more likely they are to perceive their peers as sexually active, to develop sexually permissive attitudes, and to experience early intercourse (Escobar-Chaves et al., 2005; Martino et al., 2005; Ward & Friedman, 2006). (See Close-up: The Sexualization of Girls.)

Recently, there has been a greater emphasis on teen abstinence within some comprehensive sex-education programs. A government-commissioned study of four urban, school-based abstinence programs found that 49 percent of students not participating had sex over the next four to six years. And how many participating in the abstinence programs did so? An identical 49 percent (Trenholm et al., 2007). A National Longitudinal Study of Adolescent Health followed abstinence pledgers and nonpledgers (matched samples of similarly conservative teens who had never had sex). Five years later, the pledgers—82 percent of whom denied having ever pledged—were just as likely to have had premarital sex (Rosenbaum, 2009). However, a more recent experiment offered African-American middle school students an abstinence education program rooted in social psychological theory and research. In the ensuing two years, only 34 percent of those who participated started having sex, compared with 49 percent of those randomly assigned to a health promotion control group (Jemmott et al., 2010).

The National Longitudinal Study of Adolescent Health among 12,000 teens found several factors that predicted sexual restraint:

- **High intelligence** Teens with high rather than average intelligence test scores more often delayed sex, partly because they appreciated possible negative consequences and were more focused on future achievement than on here-and-now pleasures (Halpern et al., 2000).
- **Religious engagement** Actively religious teens have more often reserved sexual activity for adulthood (Lucero et al., 2008).

“All of us who make motion pictures are teachers, teachers with very loud voices.” -FILM PRODUCER GEORGE LUCAS, ACADEMY AWARD CEREMONIES, 1992

Close-up**The Sexualization of Girls**

As you have surely noticed, TV, the Internet, music videos and lyrics, movies, magazines, sports media, and advertising often portray women and even girls as sexual objects. The frequent result, according to both an American Psychological Association task force (2007) and the Scottish Parliament (2010), is harm to their self-image, and unhealthy sexual development.

Sexualization occurs when girls

- are led to value themselves in terms of their sexual appeal.
- compare themselves to narrowly defined beauty standards.
- see themselves as sexual beings for others' use.

© T.Arroyo/JPEGFoto/
PictureGroup via AP IMAGES

In experiments, the APA task force reported, being made self-conscious about one's body, such as by wearing a swimsuit, disrupts thinking when doing math computations or logical reasoning. Sexualization also contributes to eating disorders and depression, and to unrealistic expectations regarding sexuality.

Mindful of today's sexualizing media, the APA has some suggestions for countering these messages. Parents, teachers, and others can teach girls "to value themselves for who they are rather than how they look." They can teach boys "to value girls as friends, sisters, and girlfriends, rather than as sexual objects." And they can help girls and boys develop "media literacy skills" that enable them to recognize and resist the message that women are sexual objects and that a thin, sexy look is all that matters.

- *Father presence* In studies that followed hundreds of New Zealand and U.S. girls from age 5 to 18, a father's absence was linked to sexual activity before age 16 and to teen pregnancy (Ellis et al., 2003). These associations held even after adjusting for other adverse influences, such as poverty. Close family attachments—families that eat together and where parents know their teens' activities and friends—also predicted later sexual initiation (Coley et al., 2008).
- *Participation in service learning programs* Several experiments have found that teens volunteering as tutors or teachers' aides, or participating in community projects, had lower pregnancy rates than were found among comparable teens randomly assigned to control conditions (Kirby, 2002; O'Donnell et al., 2002). Researchers are unsure why. Does service learning promote a sense of personal competence, control, and responsibility? Does it encourage more future-oriented thinking? Or does it simply reduce opportunities for unprotected sex?

Keeping abreast of hypersexuality

An analysis of the 60 top-selling video games found 489 characters, 86 percent of whom were males (like most of the game players). The female characters were much more likely than the male characters to be "hypersexualized"—partially nude or revealingly clothed, with large breasts and tiny waists (Downs & Smith, 2010).

Sexual Orientation**53-5** What has research taught us about sexual orientation?

We express the *direction* of our sexual interest in our **sexual orientation**—our enduring sexual attraction toward members of our own sex (*homosexual orientation*), the other sex (*heterosexual orientation*), or both sexes (*bisexual orientation*). As far as we know, all cultures in all times have been predominantly heterosexual (Bullough, 1990). Some cultures have condemned same-sex relations. (In Kenya and Nigeria, 98 percent have thought homosexuality is "never justified" [Pew, 2006].) Others have accepted same-sex marriage, which by 2013 had become legal in 14 countries. But in both cases, heterosexuality prevails and homosexuality endures.

sexual orientation an enduring sexual attraction toward members of either one's own sex (*homosexual orientation*), the other sex (*heterosexual orientation*), or both sexes (*bisexual orientation*).

FYI

In one British survey, of the 18,876 people contacted, 1 percent were seemingly asexual, having “never felt sexually attracted to anyone at all” (Bogaert, 2004, 2006b).

STAN HONDA/AFP/Getty Images

Driven to suicide In 2010, Rutgers University student Tyler Clementi jumped off this bridge after his intimate encounter with another man reportedly became known. Reports then surfaced of other gay teens who had reacted in a similarly tragic fashion after being taunted. Since 2010, Americans—especially those under 30—have been increasingly supportive of those with same-sex orientations.

FYI

Note that the scientific question is not “What causes homosexuality?” (or “What causes heterosexuality?”) but “What causes differing sexual orientations?” In pursuit of answers, psychological science compares the backgrounds and physiology of people whose sexual orientations *differ*.

How many people are exclusively homosexual? About 10 percent, as the popular press has often assumed? Nearly 25 percent, as average Americans estimated in a 2011 Gallup survey (Morales, 2011)? Not according to more than a dozen national surveys that have explored sexual orientation in Europe and the United States, using methods protecting the respondents’ anonymity. The most accurate figure seems to be about 3 percent of men and 1 or 2 percent of women, or perhaps a tad more if allowing for some underreporting (Chandra et al., 2011; Gates & Newport, 2012; Herbenick et al., 2010a,b). Fewer than 1 percent of survey respondents—for example, only 12 people out of 7076 Dutch adults in one survey (Sandfort et al., 2001)—have reported being actively bisexual. A larger number of adults—13 percent of women and 5 percent of men in a U.S. National Center for Health Statistics survey—report some same-sex sexual contact during their lives (Chandra et al., 2011). And still more have had an occasional homosexual fantasy.

What does it feel like to be the “odd man (or woman) out” in a heterosexual culture? If you are heterosexual, one way to understand is to imagine how you would feel if you were socially isolated for openly admitting or displaying your feelings toward someone of the other sex. How would you react if you overheard people making crude jokes about heterosexual people, or if most movies, TV shows, and advertisements portrayed (or implied) homosexuality? And how would you answer if your family members were pleading with you to change your heterosexual lifestyle and to enter into a homosexual marriage?

Facing such reactions, homosexual people often struggle with their sexual orientation. They may at first try to ignore or deny their desires, hoping they will go away. But they don’t. The feelings typically persist, as do those of heterosexual people—who are similarly incapable of becoming homosexual (Haldeman, 1994, 2002; Myers & Scanzoni, 2005).

Most of today’s psychologists therefore view sexual orientation as neither willfully chosen nor willfully changed. “Efforts to change sexual orientation are unlikely to be successful and involve some risk of harm,” declared a 2009 American Psychological Association report. In 1973, the American Psychiatric Association dropped homosexuality from its list of “mental illnesses.” In 1993, the World Health Organization did the same, as did Japan’s and China’s psychiatric associations in 1995 and 2001. Some have noted that rates of depression and attempted suicide are higher among gays and lesbians. Many psychologists believe, however, that these symptoms may result from experiences with bullying, harassment, and discrimination (Sandfort et al., 2001; Warner et al., 2004). “Homosexuality, in and of itself, is not associated with mental disorders or emotional or social problems,” declared the American Psychological Association (2007).

Thus, sexual orientation in some ways is like handedness: Most people are one way, some the other. A very few are ambidextrous. Regardless, the way one is endures.

This conclusion is most strongly established for men. Compared with men’s sexual orientation, women’s tends to be less strongly felt and may be more variable (Chivers, 2005; Diamond, 2008; Peplau & Garnets, 2000). Men’s lesser *erotic plasticity* (sexual variability) is apparent in many ways (Baumeister, 2000). Adult women’s sexual drive and interests are more flexible and varying than are adult men’s. Women, more than men, for example, prefer to alternate periods of high sexual activity with periods of almost none. They are also more likely than men to feel and act on bisexual attractions (Mosher et al., 2005).

Environment and Sexual Orientation

So, our sexual orientation is something we do not choose and (especially for males) seemingly cannot change. Where then, do these preferences come from? Let’s look first at possible environmental influences on sexual orientation. To see if you can anticipate the conclusions that have emerged from hundreds of studies, try answering *Yes* or *No* to these questions:

1. Is homosexuality linked with problems in a child’s relationships with parents, such as with a domineering mother and an ineffectual father, or a possessive mother and a hostile father?

2. Does homosexuality involve a fear or hatred of people of the other sex, leading individuals to direct their desires toward members of their own sex?
3. Is sexual orientation linked with levels of sex hormones currently in the blood?
4. As children, were most homosexuals molested, seduced, or otherwise sexually victimized by an adult homosexual?

The answer to all these questions has been *No* (Storms, 1983). In a search for possible environmental influences on sexual orientation, Kinsey Institute investigators interviewed nearly 1000 homosexuals and 500 heterosexuals. They assessed nearly every imaginable psychological cause of homosexuality—parental relationships, childhood sexual experiences, peer relationships, and dating experiences (Bell et al., 1981; Hammersmith, 1982). Their findings: Homosexuals were no more likely than heterosexuals to have been smothered by maternal love or neglected by their father. And consider this: If “distant fathers” were more likely to produce homosexual sons, then shouldn’t boys growing up in father-absent homes more often be gay? (They are not.) And shouldn’t the rising number of such homes have led to a noticeable increase in the gay population? (It has not.) Most children raised by gay or lesbian parents grow up straight and well-adjusted (Gartrell & Bos, 2010).

A bottom line has emerged from a half-century’s theory and research: If there are environmental factors that influence sexual orientation, we do not yet know what they are.

Biology and Sexual Orientation

The lack of evidence for environmental causes of homosexuality has motivated researchers to explore possible biological influences. They have considered

- evidence of homosexuality in other species,
- gay-straight brain differences,
- genetics, and
- prenatal hormones.

SAME-SEX ATTRACTION IN OTHER SPECIES

In Boston’s Public Gardens, caretakers have solved the mystery of why a much-loved swan couple’s eggs never hatch. Both swans are female. In New York City’s Central Park Zoo, penguins Silo and Roy spent several years as devoted same-sex partners. At least occasional same-sex relations have been observed in several hundred species (Bagemihl, 1999). Grizzlies, gorillas, monkeys, flamingos, and owls are all on the long list. Among rams, for example, some 7 to 10 percent (to sheep-breeding ranchers, the “duds”) display same-sex attraction by shunning ewes and seeking to mount other males (Perkins & Fitzgerald, 1997). Some degree of homosexual behavior seems a natural part of the animal world.

GAY-STRAIGHT BRAIN DIFFERENCES

Researcher Simon LeVay (1991) studied sections of the hypothalamus (a brain structure linked to emotion) taken from deceased heterosexual and homosexual people. As a gay man, LeVay wanted to do “something connected with my gay identity.” To avoid biasing the results, he did a *blind study*, without knowing which donors were gay or straight. After 9 months of peering through his microscope at a hypothalamus cell cluster that seemed to come in different sizes, he consulted the donor records. The cell cluster was reliably larger in heterosexual men than in women and homosexual men. “I was almost in a state of shock,” LeVay said (1994). “I took a walk by myself on the cliffs over the ocean. I sat for half an hour just thinking what this might mean.”

Stephen J. Carera/AP Photo

Personal values affect sexual orientation less than they affect other forms of sexual behavior

Compared with people who rarely attend religious services, for example, those who attend regularly are one-third as likely to have lived together before marriage, and they report having had many fewer sex partners. But (if male) they are just as likely to be homosexual (Smith, 1998).

Juliet and Juliet Boston’s beloved swan couple, “Romeo and Juliet,” were discovered actually to be, as are many other animal partners, a same-sex pair.

Boston Globe via Getty Images

It should not surprise us that brains differ with sexual orientation. Remember, *everything psychological is simultaneously biological*. But when did the brain difference begin? At conception? During childhood or adolescence? Did experience produce the difference? Or was it genes or prenatal hormones (or genes via prenatal hormones)?

LeVay does not view this cell cluster as an “on-off button” for sexual orientation. Rather, he believes it is an important part of a brain pathway that is active during sexual behavior. He agrees that sexual behavior patterns could influence the brain’s anatomy. (Neural pathways in our brain do grow stronger with use.) In fish, birds, rats, and humans, brain structures vary with experience—including sexual experience (Breedlove, 1997). But LeVay believes it more likely that brain anatomy influences sexual orientation. His hunch seems confirmed by the discovery of a similar difference found between the 7 to 10 percent of male sheep that display same-sex attraction and the 90+ percent attracted to females (Larkin et al., 2002; Roselli et al., 2002, 2004). Moreover, such differences seem to develop soon after birth, perhaps even before birth (Rahman & Wilson, 2003).

Since LeVay’s discovery, other researchers have reported additional gay-straight brain activity differences. One is an area of the hypothalamus that governs sexual arousal (Savic et al., 2005). When straight women were given a whiff of a scent derived from men’s sweat (which contains traces of male hormones), this area became active. Gay men’s brains responded similarly to the men’s scent. Straight men’s brains did not. They showed the arousal response only to a female hormone sample. In a similar study, lesbians’ responses differed from those of straight women (Kranz & Ishai, 2006; Martins et al., 2005).

GENETIC INFLUENCES

Three lines of evidence suggest a genetic influence on sexual orientation.

FAMILY STUDIES Researchers have speculated about possible reasons why “gay genes” might persist in the human gene pool, given that same-sex couples cannot naturally reproduce. One possible answer is kin selection. Recall from Module 15 the evolutionary psychology reminder that many of our genes also reside in our biological relatives. Perhaps, then, gay people’s genes live on through their supporting the survival and reproductive success of their nieces, nephews, and other relatives (who also carry many of the same genes). Gay men make generous uncles, suggests one study of Samoans (Vasey & VanderLaan, 2010).

An alternative “fertile females” theory suggests that maternal genetics may also be at work (Bocklandt et al., 2006). Homosexual men tend to have more homosexual relatives on their mother’s side than on their father’s (Camperio-Ciani et al., 2004, 2009; Zietsch et al., 2008). And the relatives on the mother’s side also produce more offspring than do the maternal relatives of heterosexual men. Perhaps the genes that dispose women to be strongly attracted to men, and therefore to have more children, also dispose some men to be attracted to men (LeVay, 2011).

TWIN STUDIES Twin studies indicate that genes influence sexual orientation. Identical twins (who have identical genes) are somewhat more likely than fraternal twins (whose genes are not identical) to share a homosexual orientation (Alanko et al., 2010; Långström et al., 2008, 2010). However, because sexual orientation differs in many identical twin pairs (especially female twins), other factors must also play a role.

FRUIT FLY STUDIES Laboratory experiments on fruit flies have altered a single gene and changed the flies’ sexual orientation and behavior (Dickson, 2005). During courtship, females acted like males (pursuing other females) and males acted like females (Demir & Dickson, 2005). With humans, it’s likely that multiple genes, possibly in interaction with other influences, shape sexual orientation. In search of such genetic markers, one study financed by the U.S. National Institutes of Health is analyzing the genes of more than 1000 gay brothers.

PRENATAL INFLUENCES

Twins share not only genes, but also a prenatal environment. Two sets of findings indicate that prenatal environment matters.

First, in humans, a critical period for brain development seems to fall between the middle of the second and fifth months after conception (Ellis & Ames, 1987; Gladue, 1990; Meyer-Bahlburg, 1995). Exposure to the hormone levels typically experienced by female fetuses during this period may predispose a person (female or male) to be attracted to males in later life. When pregnant sheep were injected with testosterone during a similar critical period, their female offspring later showed homosexual behavior (Money, 1987).

Second, the mother's immune system may play a role in the development of sexual orientation. Men who have older brothers are somewhat more likely to be gay—about one-third more likely for each additional older brother (Blanchard, 1997, 2008; Bogaert, 2003). If the odds of homosexuality are roughly 2 percent among first sons, they would rise to nearly 3 percent among second sons, 4 percent for third sons, and so on for each additional older brother (see **FIGURE 53.3**). The reason for this curious effect—called the *older-brother* or *fraternal birth-order effect*—is unclear. But the explanation does seem biological. The effect does not occur among adopted brothers (Bogaert, 2006). Researchers suspect the mother's immune system may have a defensive response to substances produced by male fetuses. After each pregnancy with a male fetus, the maternal antibodies may become stronger and may prevent the fetal brain from developing in a typical male pattern.

GAY-STRAIGHT TRAIT DIFFERENCES

On several traits, gays and lesbians appear to fall midway between straight females and males (**TABLE 53.1**; see also LeVay, 2011; Rahman & Koerting, 2008). Gay men tend to

“Modern scientific research indicates that sexual orientation is . . . partly determined by genetics, but more specifically by hormonal activity in the womb.” -GLENN WILSON AND QAZI RAHMAN, *BORN GAY: THE PSYCHOBIOLOGY OF SEX ORIENTATION*, 2005

Figure 53.3

The fraternal birth-order effect

Researcher Ray Blanchard (2008) offered these approximate curves depicting a man's likelihood of homosexuality as a function of his number of older brothers. This correlation has been found in several studies, but only among right-handed men (as about 9 in 10 men are).

Table 53.1 Biological Correlates of Sexual Orientation

Gay-straight trait differences

Sexual orientation is part of a package of traits. Studies—some in need of replication—indicate that homosexuals and heterosexuals differ in the following biological and behavioral traits:

- spatial abilities
- fingerprint ridge counts
- auditory system development
- handedness
- occupational preferences
- relative finger lengths
- gender nonconformity
- age of onset of puberty in males
- male body size
- sleep length
- physical aggression
- walking style

On average (the evidence is strongest for males), results for gays and lesbians fall between those of straight men and straight women. Three biological influences—brain, genetic, and prenatal—may contribute to these differences.

Brain differences

- One hypothalamic cell cluster is smaller in women and gay men than in straight men.
- Gay men's hypothalamus reacts as do straight women's to the smell of sex-related hormones.

Genetic influences

- Shared sexual orientation is higher among identical twins than among fraternal twins.
- Sexual attraction in fruit flies can be genetically manipulated.
- Male homosexuality often appears to be transmitted from the mother's side of the family.

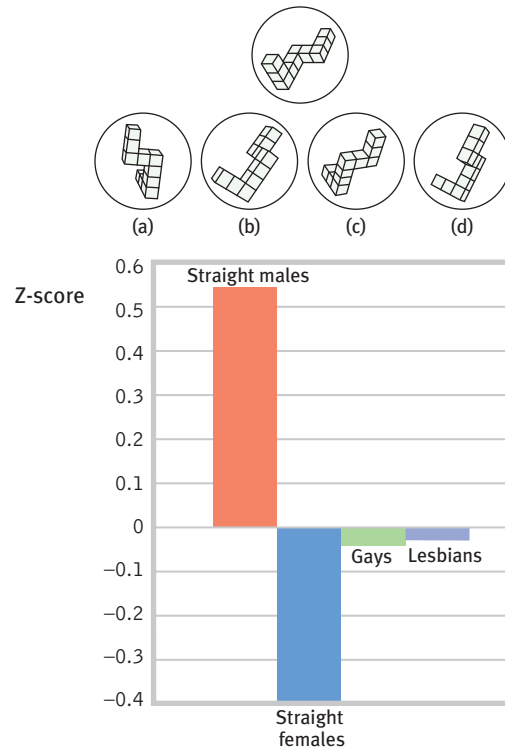

Prenatal influences

- Altered prenatal hormone exposure may lead to homosexuality in humans and other animals.
- Men with several older biological brothers are more likely to be gay, possibly due to a maternal immune-system reaction.

Figure 53.4**Spatial abilities and sexual orientation**

Which of the four figures can be rotated to match the target figure at the top? Straight males tend to find this an easier task than do straight females, with gays and lesbians intermediate. (From Rahman et al., 2003, with 60 people tested in each group.)

Answers: Figures a and d.

be shorter and lighter than straight men—a difference that appears even at birth. Women in same-sex marriages were mostly heavier than average at birth (Bogaert, 2010; Frisch & Zdravkovic, 2010). Data from 20 studies have also revealed handedness differences: Homosexual participants were 39 percent more likely to not be right-handed (Blanchard, 2008; Lalumière et al., 2000).

Gay-straight spatial abilities also differ. On mental rotation tasks such as the one illustrated in **FIGURE 53.4** (Vandenberg & Kuse, 1978), straight men tend to outscore straight women but the scores of gays and lesbians fall between those of straight men and women (Rahman et al., 2003). But straight women and gays both outperform straight men at remembering objects' spatial locations in tasks like those found in memory games (Hassan & Rahman, 2007).

* * *

“There is no sound scientific evidence that sexual orientation can be changed.” -UK ROYAL COLLEGE OF PSYCHIATRISTS, 2009

The consistency of the brain, genetic, and prenatal findings has swung the pendulum toward a biological explanation of sexual orientation (LeVay, 2011; Rahman & Koerting, 2008). Although “much remains to be discovered,” concludes Simon LeVay (2011, p. xvii), “the same processes that are involved in the biological development of our bodies and brains as male or female are also involved in the development of sexual orientation.”

Before You Move On

▶ ASK YOURSELF

What do you think would be an effective strategy for reducing teen pregnancy?

▶ TEST YOURSELF

What factors have been found to predict sexual restraint among teens?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 53 Review

53-1 How is our biological sex determined, and how do sex hormones influence prenatal and adolescent development?

- Both sex chromosomes and sex hormones influence development.
- Biological sex is determined by the father's contribution to the twenty-third pair of chromosomes.
 - The mother always contributes an *X chromosome*.
 - The father may also contribute an X chromosome, producing a female, or a *Y chromosome*, producing a male by triggering additional *testosterone* release and the development of male sex organs.
- During *puberty*, both *primary* and *secondary sex characteristics* develop.
- Sex-related genes and physiology influence behavioral and cognitive gender differences between males and females.

53-2 What are some of the ways that sexual development varies?

- Intersex individuals are born with intermediate or unusual combinations of male and female characteristics.
- Research suggests sex-reassignment surgery can be problematic.

53-3 How can sexually transmitted infections be prevented?

- Safe-sex practices help prevent sexually transmitted infections (STIs).
- Condoms are especially effective in preventing transmission of HIV, the virus that causes *AIDS*.
- A vaccination administered before sexual contact can prevent most human papilloma virus infections.

53-4 What factors influence teenagers' sexual behaviors and use of contraceptives?

- Rates of teen intercourse vary from culture to culture and era to era.
- Factors contributing to teen pregnancy include minimal communication about birth control with parents, partners, and peers; guilt related to sexual activity; alcohol use; and mass media norms of unprotected and impulsive sexuality.
- High intelligence, religious engagement, father presence, and participation in service learning programs have been predictors of teen sexual restraint.

53-5 What has research taught us about sexual orientation?

- *Sexual orientation* is an enduring sexual attraction toward members of one's own sex (homosexual orientation), the other sex (heterosexual orientation), or both sexes (bisexual orientation).
- Sexual orientation is not an indicator of mental health.
- There is no evidence that environmental influences determine sexual orientation.
- Evidence for biological influences includes the presence of same-sex attraction in many animal species; straight-gay differences in body and brain characteristics; higher rates in certain families and in identical twins; exposure to certain hormones during critical periods of prenatal development; and the fraternal birth-order effect.

Multiple-Choice Questions

- Which of the following is an example of a primary sex characteristic?
 - Nonreproductive traits such as breasts and hips in girls
 - Facial hair in boys
 - Deepened voice in boys
 - Pubic and underarm hair in both sexes
 - Reproductive organs in both sexes
- Which of the following is a *primary* sex characteristic that changes at puberty?
 - A growth spurt in height, especially for boys
 - Development of breasts for girls
 - Full development of external genitalia in both sexes
 - Facial hair and deepened voice for boys
 - Appearance of pubic and underarm hair in both sexes
- Which of the following has been shown to be the most effective intervention to reduce teen pregnancies?
 - Abstinence-only sex education in schools
 - Participation in service learning programs
 - Increasing guilt related to sexual activity
 - Taking a pledge to remain abstinent
 - Increased exposure to sexual content in the media

Practice FRQs

- Provide examples of a primary and a secondary sex characteristic for both males and females.
- Explain three examples of evidence that suggests a genetic influence on sexual orientation.

Answer

1 point: Male primary sex characteristics include growth of penis and testes and first ejaculation (spermarche).

1 point: Male secondary sex characteristics include pubic hair, body hair, widening of the shoulders, and lower voice.

1 point: Female primary sex characteristics include menarche and full development of external genitalia.

1 point: Female secondary sex characteristics include pubic hair, body hair, widening of the hips, and growth of breasts.

(3 points)

Module 54

Adulthood: Physical, Cognitive, and Social Development

Module Learning Objectives

- 54-1** Identify the physical changes that occur during middle and late adulthood.
- 54-2** Assess the impact of aging on memory.
- 54-3** Discuss the themes and influences that mark the social journey from early adulthood to death.
- 54-4** Describe trends in people's self-confidence and life satisfaction across the life span.
- 54-5** Describe the range of reactions to the death of a loved one.

The unfolding of people's adult lives continues across the life span. It is, however, more difficult to generalize about adulthood stages than about life's early years. If you know that James is a 1-year-old and Jamal is a 10-year-old, you could say a great deal about each child. Not so with adults who differ by a similar number of years. The boss may be 30 or 60; the marathon runner may be 20 or 50; the 19-year-old may be a parent who supports a child or a child who receives an allowance. Yet our life courses are in some ways similar. Physically, cognitively, and especially socially, we differ at age 50 from our 25-year-old selves. In the discussion that follows, we recognize these differences and use three terms: *early adulthood* (roughly twenties and thirties), *middle adulthood* (to age 65), and *late adulthood* (the years after 65). Within each of these stages, people will vary widely in physical, psychological, and social development.

Physical Development

- 54-1** What physical changes occur during middle and late adulthood?

Like the declining daylight after the summer solstice, our physical abilities—muscular strength, reaction time, sensory keenness, and cardiac output—all begin an almost imperceptible decline in our mid-twenties. Athletes are often the first to notice. World-class sprinters and swimmers peak by their early twenties. Women—who mature earlier than men—also peak earlier. But most of us—especially those of us whose daily lives do not require top physical performance—hardly perceive the early signs of decline.

menopause the time of natural cessation of menstruation; also refers to the biological changes a woman experiences as her ability to reproduce declines.

Adult abilities vary widely

97-year-olds: Don't try this. In 2002, George Blair became the world's oldest barefoot water skier, just days after reaching age 87. And he did it again in 2012, at age 97!

Rick Doyle/Corbis

Physical Changes in Middle Adulthood

Post-40 athletes know all too well that physical decline gradually accelerates. During early and middle adulthood, physical vigor has less to do with age than with a person's health and exercise habits. Many of today's physically fit 50-year-olds run 4 miles with ease, while sedentary 25-year-olds find themselves huffing and puffing up two flights of stairs.

Aging also brings a gradual decline in fertility, especially for women. For a 35- to 39-year-old woman, the chances of getting pregnant after a single act of intercourse are only half those of a woman 19 to 26 (Dunson et al., 2002). Men experience a gradual decline in sperm count, testosterone level, and speed of erection and ejaculation. Women ex-

perience **menopause**, as menstrual cycles end, usually within a few years of age 50. Expectations and attitudes influence the emotional impact of this event. Is it a sign of lost femininity and growing old? Or is it liberation from menstrual periods and fears of pregnancy? For men, too, expectations can influence perceptions. Some experience distress related to a perception of declining virility and physical capacities, but most age without such problems.

With age, sexual activity lessens. Nevertheless, most men and women remain capable of satisfying sexual activity, and most express satisfaction with their sex life. This was true of 70 percent of Canadians surveyed (ages 40 to 64) and 75 percent of Finns (ages 65 to 74) (Kontula & Haavio-Mannila, 2009; Wright, 2006). In another

survey, 75 percent of respondents reported being sexually active into their eighties (Schick et al., 2010). And in an American Association of Retired Persons sexuality survey, it was not until age 75 or older that most women and nearly half of men reported little sexual desire (DeLamater & Sill, 2005). Given good health and a willing partner, the flames of desire, though simmered down, live on. As Alex Comfort (1992, p. 240) jested, "The things that stop you having sex with age are exactly the same as those that stop you riding a bicycle (bad health, thinking it looks silly, no bicycle)."

Physical Changes in Later Life

Is old age "more to be feared than death" (Juvenal, *Satires*)? Or is life "most delightful when it is on the downward slope" (Seneca, *Epistulae ad Lucilium*)? What is it like to grow old?

STRENGTH AND STAMINA

Although physical decline begins in early adulthood, we are not usually acutely aware of it until later life, when the stairs get steeper, the print gets smaller, and other people seem to mumble more. Muscle strength, reaction time, and stamina diminish in late adulthood. As a lifelong basketball player, I find myself increasingly not racing for that loose ball. But even diminished vigor is sufficient for normal activities. Moreover, exercise slows aging. Active older adults tend to be mentally quick older adults. Physical exercise not only enhances muscles, bones, and energy and helps to prevent obesity and heart disease, it also stimulates brain cell development and neural connections, thanks perhaps to increased oxygen and nutrient flow (Erickson et al., 2010; Pereira et al., 2007).

"Happy fortieth. I'll take the muscle tone in your upper arms, the girlish timbre of your voice, your amazing tolerance for caffeine, and your ability to digest french fries. The rest of you can stay."

"For some reason, possibly to save ink, the restaurants had started printing their menus in letters the height of bacteria." -DAVE BARRY, *DAVE BARRY TURNS FIFTY*, 1998

SENSORY ABILITIES

With age, visual sharpness diminishes, and distance perception and adaptation to light-level changes are less acute. The eye’s pupil shrinks and its lens becomes less transparent, reducing the amount of light reaching the retina: A 65-year-old retina receives only about one-third as much light as its 20-year-old counterpart (Kline & Schieber, 1985). Thus, to see as well as a 20-year-old when reading or driving, a 65-year-old needs three times as much light—a reason for buying cars with untinted windshields. This also explains why older people sometimes ask people your age, “Don’t you need better light for reading?”

The senses of smell and hearing also diminish. In Wales, teens’ loitering around a convenience store has been discouraged by a device that emits an aversive high-pitched sound almost no one over 30 can hear (Lyll, 2005).

HEALTH

For those growing older, there is both bad and good news about health. The bad news: The body’s disease-fighting immune system weakens, making older adults more susceptible to life-threatening ailments, such as cancer and pneumonia. The good news: Thanks partly to a lifetime’s accumulation of antibodies, people over 65 suffer fewer short-term ailments, such as common flu and cold viruses. One study found they were half as likely as 20-year-olds and one-fifth as likely as preschoolers to suffer upper respiratory flu each year (National Center for Health Statistics, 1990).

THE AGING BRAIN

Up to the teen years, we process information with greater and greater speed (Fry & Hale, 1996; Kail, 1991). But compared with you, older people take a bit more time to react, to solve perceptual puzzles, even to remember names (Bashore et al., 1997; Verhaeghen & Salthouse, 1997). The neural processing lag is greatest on complex tasks (Cerella, 1985; Poon, 1987). At video games, most 70-year-olds are no match for a 20-year-old.

Slower neural processing combined with diminished sensory abilities can increase accident risks. As **FIGURE 54.1** indicates, fatal accident rates per mile driven increase sharply after age 75. By age 85, they exceed the 16-year-old level. Nevertheless, because older people drive less, they account for fewer than 10 percent of crashes (Coughlin et al., 2004).

Brain regions important to memory begin to atrophy during aging (Schacter, 1996). In early adulthood, a small, gradual net loss of brain cells begins, contributing by age 80 to a brain-weight reduction of 5 percent or so. Earlier, we noted that late-maturing frontal lobes

FYI

Most stairway falls taken by older people occur on the top step, precisely where the person typically descends from a window-lit hallway into the darker stairwell (Fozard & Popkin, 1978). Our knowledge of aging could be used to design environments that would reduce such accidents (National Research Council, 1990).

World record for longevity?

French woman Jeanne Calment, the oldest human in history with authenticated age, died in 1998 at age 122. At age 100, she was still riding a bike. At age 114, she became the oldest film actor ever, by portraying herself in *Vincent and Me*. She is shown at left at age 20 in 1895.

Figure 54.1
Age and driver fatalities Slowing reactions contribute to increased accident risks among those 75 and older, and their greater fragility increases their risk of death when accidents happen (NHTSA, 2000). Would you favor driver exams based on performance, not age, to screen out those whose slow reactions or sensory impairments indicate accident risk?

FYI

How old does a person have to be before you think of him or her as old? Depends on who you ask. For 18- to 29-year-olds, 67 was old. For those 60 and over, old was 76 (Yankelovich, 1995).

"I am still learning." -MICHELANGELO, 1560, AT AGE 85

help account for teen impulsivity. Late in life, atrophy of the inhibition-controlling frontal lobes seemingly explains older people's occasional blunt questions and comments ("Have you put on weight?") (von Hippel, 2007).

As noted earlier, exercise helps counteract some effects of brain aging. It aids memory by stimulating the development of neural connections and by promoting neurogenesis, the birth of new nerve cells, in the hippocampus. Sedentary older adults randomly assigned to aerobic exercise programs exhibit enhanced memory, sharpened judgment, and reduced risk of *neurocognitive disorder* (formerly called "dementia") (Colcombe et al., 2004; Liang et al., 2010; Nazimek, 2009).

Exercise also helps maintain the telomeres, which protect the ends of chromosomes (Cherkas et al., 2008; Erickson, 2009; Pereira et al., 2007). With age, telomeres wear down, much as the tip of a shoelace frays. This wear is accentuated by smoking, obesity, or stress. As telomeres shorten, aging cells may die without being replaced with perfect genetic replicas (Epel, 2009).

The message for seniors is clear: We are more likely to rust from disuse than to wear out from overuse.

Cognitive Development

54-2 How does memory change with age?

AP® Exam Tip

This section is a good example of the complexity of seemingly simple questions. It seems like one should be able to answer a question like "Does memory decline with age?" with a straightforward yes or no. People are complex. Development is complex. We should not be surprised to learn that many factors influence memory in adulthood.

Among the most intriguing developmental psychology questions is whether adult cognitive abilities, such as memory, intelligence, and creativity, parallel the gradually accelerating decline of physical abilities.

As we age, we remember some things well. Looking back in later life, people asked to recall the one or two most important events over the last half-century tend to name events from their teens or twenties (Conway et al., 2005; Rubin et al., 1998). Whatever people experience around this time of life—the election of Barack Obama, the events of 9/11, the civil rights movement—becomes pivotal (Pillemer, 1998; Schuman & Scott, 1989). Our teens and twenties are a time of so many memorable "firsts"—first kiss, first job, first day at college or university, first meeting of in-laws.

Early adulthood is indeed a peak time for some types of learning and remembering. In one test of recall, people (1205 of them) watched videotapes as 14 strangers said their names, using a common format: "Hi, I'm Larry" (Crook & West, 1990). Then those strangers re-

appeared and gave additional details. For example, they said, "I'm from Philadelphia," providing more visual *and* voice cues for remembering the person's name. As **FIGURE 54.2** shows, after a second and third replay of the introductions, everyone remembered more names, but younger adults consistently surpassed older adults.

Perhaps it is not surprising, then, that nearly two-thirds of people over age 40 say their memory is worse than it was 10 years ago (KRC, 2001). In fact, how well older people remember depends on the task. In another experiment (Schonfield & Robertson, 1966), when asked to *recognize* 24 words they had earlier tried to memorize, people showed only a minimal decline in memory. When asked to *recall* that information without clues, the decline was greater (**FIGURE 54.3**).

Figure 54.2

Tests of recall

Recalling new names introduced once, twice, or three times is easier for younger adults than for older ones. (Data from Crook & West, 1990.)

Figure 54.3
Recall and recognition in adulthood In this experiment, the ability to *recall* new information declined during early and middle adulthood, but the ability to *recognize* new information did not. (From Schonfield & Robertson, 1966.)

In our capacity to learn and remember, as in other areas of development, we differ. Younger adults vary in their abilities to learn and remember, but 70-year-olds vary much more. “Differences between the most and least able 70-year-olds become much greater than between the most and least able 50-year-olds,” reports Oxford researcher Patrick Rabbitt (2006). Some 70-year-olds perform below nearly all 20-year-olds; other 70-year-olds match or outdo the average 20-year-old.

No matter how quick or slow we are, remembering seems also to depend on the type of information we are trying to retrieve. If the information is meaningless—nonsense syllables or unimportant events—then the older we are, the more errors we are likely to make. If the information is *meaningful*, older people’s rich web of existing knowledge will help them to hold it. But they may take longer than younger adults to *produce* the words and things they know: Quick-thinking game show winners are usually young or middle-aged adults (Burke & Shafto, 2004). Older people’s capacity to learn and remember *skills* declines less than their verbal recall (Graf, 1990; Labouvie-Vief & Schell, 1982; Perlmutter, 1983).

Module 62 explores another dimension of cognitive development: intelligence. As we will see, **cross-sectional studies** (comparing people of different ages) and **longitudinal studies** (restudying the same people over time) have identified mental abilities that do and do not change as people age. Age is less a predictor of memory and intelligence than is proximity to death. Tell me whether someone is 8 months or 8 years from death and, regardless of age, you’ve given me a clue to that person’s mental ability. Especially in the last three or four years of life, cognitive decline typically accelerates (Wilson et al., 2007). Researchers call this near-death drop *terminal decline* (Backman & MacDonald, 2006).

Social Development

54-3 What themes and influences mark our social journey from early adulthood to death?

Many differences between younger and older adults are created by significant life events. A new job means new relationships, new expectations, and new demands. Marriage brings the joy of intimacy and the stress of merging two lives. The three years surrounding the birth of a child bring increased life satisfaction for most parents (Dyrdal & Lucas, 2011). The death of a loved one creates an irreplaceable loss. Do these adult life events shape a sequence of life changes?

Try This

longitudinal study research in which the same people are restudied and retested over a long period.

Adulthood's Ages and Stages

As people enter their forties, they undergo a transition to middle adulthood, a time when they realize that life will soon be mostly behind instead of ahead of them. Some psychologists have argued that for many the *midlife transition* is a crisis, a time of great struggle, regret, or even feeling struck down by life. The popular image of the midlife crisis is an early-forties man who forsakes his family for a younger girlfriend and a hot sports car. But the fact—reported by large samples of people—is that unhappiness, job dissatisfaction, marital dissatisfaction, divorce, anxiety, and suicide do *not* surge during the early forties (Hunter & Sundel, 1989; Mroczek & Kolarz, 1998). Divorce, for example, is most common among those in their twenties, suicide among those in their seventies and eighties. One study of emotional instability in nearly 10,000 men and women found “not the slightest evidence” that distress peaks anywhere in the midlife age range (McCrae & Costa, 1990).

For the 1 in 4 adults who report experiencing a life crisis, the trigger is not age but a major event, such as illness, divorce, or job loss (Lachman, 2004). Some middle-aged adults describe themselves as a “sandwich generation,” simultaneously supporting their aging parents and their emerging adult children or grandchildren (Riley & Bowen, 2005).

Life events trigger transitions to new life stages at varying ages. The **social clock**—the definition of “the right time” to leave home, get a job, marry, have children, or retire—varies from era to era and culture to culture. The social clock still ticks, but people feel freer about being out of sync with it.

Even *chance events* can have lasting significance, by deflecting us down one road rather than another (Bandura, 1982). Albert Bandura (2005) recalls the ironic true story of a book editor who came to one of Bandura’s lectures on the “Psychology of Chance Encounters and Life Paths”—and ended up marrying the woman who happened to sit next to him. The sequence that led to my authoring this book (which was not my idea) began with my being seated near, and getting to know, a distinguished colleague at an international conference. Chance events can change our lives.

social clock the culturally preferred timing of social events such as marriage, parenthood, and retirement.

“The important events of a person’s life are the products of chains of highly improbable occurrences.” -JOSEPH TRAUB, “TRAUB’S LAW,” 2003

Adulthood's Commitments

Two basic aspects of our lives dominate adulthood. Erik Erikson called them *intimacy* (forming close relationships) and *generativity* (being productive and supporting future generations). Researchers have chosen various terms—*affiliation* and *achievement*, *attachment* and *productivity*, *connectedness* and *competence*. Sigmund Freud (1935) put it most simply: The healthy adult, he said, is one who can *love* and *work*.

LOVE

We typically flirt, fall in love, and commit—one person at a time. “Pair-bonding is a trademark of the human animal,” observed anthropologist Helen Fisher (1993). From an evolutionary perspective, relatively monogamous pairing makes sense: Parents who cooperated

to nurture their children to maturity were more likely to have their genes passed along to posterity than were parents who didn’t.

Adult bonds of love are most satisfying and enduring when marked by a similarity of interests and values, a sharing of emotional and material support, and intimate self-disclosure (see Module 79). Couples who seal their love with commitment—via (in one Vermont study) marriage for heterosexual couples and civil unions for homosexual couples—more often endure (Balsam et al., 2008). Marriage bonds are especially likely to last when couples marry after age 20 and are well educated. Compared with their counterparts of 50 years ago, people in Western countries *are* better educated and marrying later. Yet, ironically, they are nearly twice as likely to divorce. (Both Canada and the United States

now have about one divorce for every two marriages, and in Europe, divorce is only slightly less common.) The divorce rate partly reflects women's lessened economic dependence and men's and women's rising expectations. We now hope not only for an enduring bond, but also for a mate who is a wage earner, caregiver, intimate friend, and warm and responsive lover.

Might test-driving life together in a "trial marriage" minimize divorce risk? In one Gallup survey of American twenty-somethings, 62 percent thought it would (Whitehead & Popenoe, 2001). In reality, in Europe, Canada, and the United States, those who cohabit before marriage have had *higher* rates of divorce and marital dysfunction than those who did not cohabit (Jose et al., 2010). The risk appears greatest for those cohabiting prior to engagement (Goodwin et al., 2010; Rhoades et al., 2009).

American children born to cohabiting parents are about five times more likely to experience their parents' separation than are children born to married parents (Osborne et al., 2007). Two factors contribute. First, cohabiters tend to be initially less committed to the ideal of enduring marriage. Second, they become even less marriage supporting while cohabiting.

Nonetheless, the institution of marriage endures. Worldwide, reports the United Nations, 9 in 10 heterosexual adults marry. And marriage is a predictor of happiness, sexual satisfaction, income, and physical and mental health (Scott et al., 2010). National Opinion Research Center surveys of nearly 50,000 Americans since 1972 reveal that 40 percent of married adults, though only 23 percent of unmarried adults, have reported being "very happy." Lesbian couples, too, report greater well-being than those who are alone (Peplau & Fingerhut, 2007; Wayment & Peplau, 1995). Moreover, neighborhoods with high marriage rates typically have low rates of social pathologies such as crime, delinquency, and emotional disorders among children (Myers & Scanzoni, 2005).

Marriages that last are not always devoid of conflict. Some couples fight but also shower each other with affection. Other couples never raise their voices yet also seldom praise each other or nuzzle. Both styles can last. After observing the interactions of 2000 couples, John Gottman (1994) reported one indicator of marital success: at least a five-to-one ratio of positive to negative interactions. Stable marriages provide five times more instances of smiling, touching, complimenting, and laughing than of sarcasm, criticism, and insults. So, if you want to predict which newlyweds will stay together, don't pay attention to how passionately they are in love. The couples who make it are more often those who refrain from putting down their partners. To prevent a cancerous negativity, successful couples learn to fight fair (to state feelings without insulting) and to steer conflict away from chaos with comments like "I know it's not your fault" or "I'll just be quiet for a moment and listen."

Often, love bears children. For most people, this most enduring of life changes is a happy event. "I feel an overwhelming love for my children unlike anything I feel for anyone else," said 93 percent of American mothers in a national survey (Erickson & Aird, 2005). Many fathers feel the same. A few weeks after the birth of my first child I was suddenly struck by a realization: "So *this* is how my parents felt about me?"

When children begin to absorb time, money, and emotional energy, satisfaction with the marriage itself may decline (Doss et al., 2009). This is especially likely among employed women who, more than they expected, carry the traditional burden of doing the chores at home. Putting effort into creating an equitable relationship can thus pay double dividends: a more satisfying marriage, which breeds better parent-child relations (Erel & Burman, 1995).

Although love bears children, children eventually leave home. This departure is a significant and sometimes difficult event. For most people, however, an empty nest is a happy place (Adelmann et al., 1989; Gorchoff et al., 2008). Many parents experience a "postlaunch honeymoon," especially if they maintain close relationships with their children (White & Edwards, 1990). As Daniel Gilbert (2006) has said, "The only known symptom of 'empty nest syndrome' is increased smiling."

Purestock/Alamy

Love Intimacy, attachment, commitment—love by whatever name—is central to healthy and happy adulthood.

Try This

What do you think? Does marriage correlate with happiness because marital support and intimacy breed happiness, because happy people more often marry and stay married, or both?

"Our love for children is so unlike any other human emotion. I fell in love with my babies so quickly and profoundly, almost completely independently of their particular qualities. And yet 20 years later I was (more or less) happy to see them go—I had to be happy to see them go. We are totally devoted to them when they are little and yet the most we can expect in return when they grow up is that they regard us with bemused and tolerant affection."
—DEVELOPMENTAL PSYCHOLOGIST ALISON GOPNIK, "THE SUPREME INFANT," 2010

WORK

For many adults, the answer to “Who are you?” depends a great deal on the answer to “What do you do?” For women and men, choosing a career path is difficult, especially during bad economic times. Even in the best of times, few students in their first two years of college or university can predict their later careers.

In the end, happiness is about having work that fits your interests and provides you with a sense of competence and accomplishment. It is having a close, supportive companion who cheers your accomplishments (Gable et al., 2006). And for some, it includes having children who love you and whom you love and feel proud of.

Well-Being Across the Life Span

54-4 Do self-confidence and life satisfaction vary with life stages?

“When you were born, you cried and the world rejoiced. Live your life in a manner so that when you die the world cries and you rejoice.” -NATIVE AMERICAN PROVERB

To live is to grow older. This moment marks the oldest you have ever been and the youngest you will henceforth be. That means we all can look back with satisfaction or regret, and forward with hope or dread. When asked what they would have done differently if they could relive their lives, people's most common answer has been “Taken my education more seriously and worked harder at it” (Kinnier & Metha, 1989; Roese & Summerville, 2005). Other regrets—“I should have told my father I loved him,” “I regret that I never went to Europe”—have also focused less on mistakes made than on the things one *failed* to do (Gilovich & Medvec, 1995).

From the teens to midlife, people typically experience a strengthening sense of identity, confidence, and self-esteem (Huang, 2010; Robins & Trzesniewski, 2005). In later life, challenges arise: Income shrinks. Work is often taken away. The body deteriorates. Recall fades. Energy wanes. Family members and friends die or move away. The great enemy, death, looms ever closer. And for those in the terminal decline phase, life satisfaction does decline as death approaches (Gerstorf et al., 2008).

Small wonder that most presume that happiness declines in later life (Lacey et al., 2006). But worldwide, as Gallup researchers discovered, most find that the over-65 years

are not notably unhappy (**FIGURE 54.4**). If anything, positive feelings, supported by enhanced emotional control, grow after midlife, and negative feelings subside (Stone et al., 2010; Urry & Gross, 2010). Older adults increasingly use words that convey positive emotions (Pennebaker & Stone, 2003), and they attend less and less to negative information. Compared with younger adults, for example, they are slower to perceive negative faces and more attentive to positive news (Carstensen & Mikels, 2005; Scheibe & Carstensen, 2010). Older adults also have fewer problems in their social relationships (Fingerman & Charles, 2010), and they experience less intense anger, stress, and worry (Stone et al., 2010).

Figure 54.4

Age and life satisfaction The Gallup Organization asked 142,682 people worldwide to rate their lives on a ladder, from 0 (“the worst possible life”) to 10 (“the best possible life”). Age gave no clue to life satisfaction (Crabtree, 2010).

The aging brain may help nurture these positive feelings. Brain scans of older adults show that the amygdala, a neural processing center for emotions, responds less actively to negative events (but not to positive events), and it interacts less with the hippocampus, a brain memory-processing center (Mather et al., 2004; St. Jacques et al., 2009; Williams et al., 2006). Brain-wave reactions to negative images also diminish with age (Kisley et al., 2007).

Moreover, at all ages, the bad feelings we associate with negative events fade faster than do the good feelings we associate with positive events (Walker et al., 2003). This contributes to most older people’s sense that life, on balance, has been mostly good. Given that growing older is an outcome of living (an outcome most prefer to early dying), the positivity of later life is comforting. Thanks to biological, psychological, and social-cultural influences, more and more people flourish into later life (**FIGURE 54.5**).

“At 20 we worry about what others think of us. At 40 we don’t care what others think of us. At 60 we discover they haven’t been thinking about us at all.”
-ANONYMOUS

“The best thing about being 100 is no peer pressure.” -LEWIS W. KUESTER, 2005, ON TURNING 100

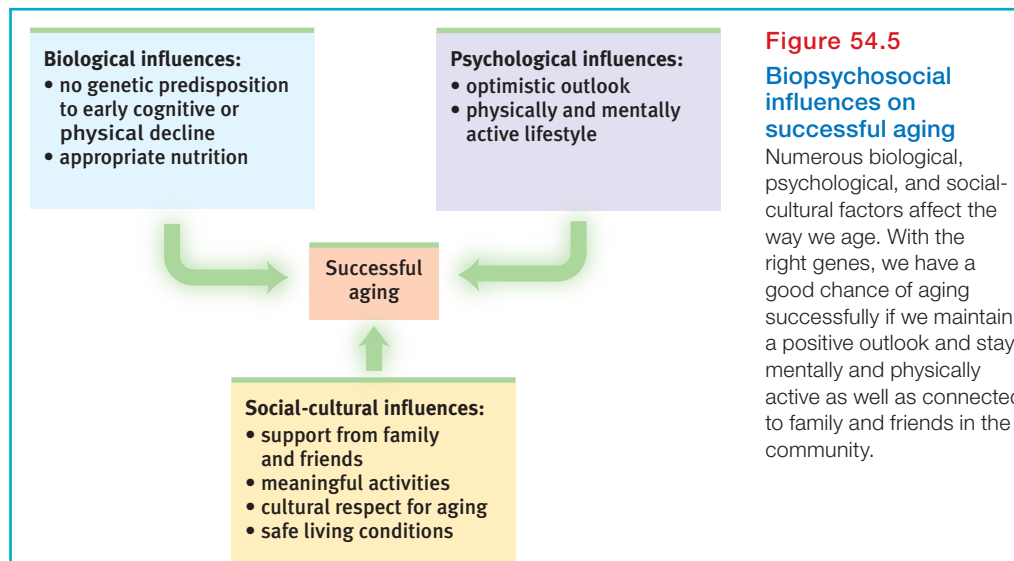

Figure 54.5
Biopsychosocial influences on successful aging
Numerous biological, psychological, and social-cultural factors affect the way we age. With the right genes, we have a good chance of aging successfully if we maintain a positive outlook and stay mentally and physically active as well as connected to family and friends in the community.

Death and Dying

54-5 A loved one’s death triggers what range of reactions?

Warning: If you begin reading the next paragraph, you will die.

But of course, if you hadn’t read this, you would still die in due time. Death is our inevitable end. Most of us will also suffer and cope with the deaths of relatives and friends. Usually, the most difficult separation is from a spouse—a loss suffered by five times more women than men. When, as usually happens, death comes at an expected late-life time, grieving may be relatively short-lived.

Grief is especially severe when a loved one’s death comes suddenly and before its expected time on the social clock. The sudden illness or accident claiming a 45-year-old life partner or a child may trigger a year or more of memory-laden mourning that eventually subsides to a mild depression (Lehman et al., 1987).

For some, however, the loss is unbearable. One Danish long-term study of more than 1 million people found that about 17,000 of them had suffered the death of a child under 18. In the five years following that death, 3 percent of them had a first psychiatric hospitalization. This rate was 67 percent higher than the rate recorded for parents who had not lost a child (Li et al., 2005).

Even so, reactions to a loved one’s death range more widely than most suppose. Some cultures encourage public weeping and wailing; others hide grief. Within any culture,

“Love—why, I’ll tell you what love is: It’s you at 75 and her at 71, each of you listening for the other’s step in the next room, each afraid that a sudden silence, a sudden cry, could mean a lifetime’s talk is over.” -BRIAN MOORE, *THE LUCK OF GINGER COFFEY*, 1960

“Consider, friend, as you pass
by, as you are now, so once was
I. As I am now, you too shall be.
Prepare, therefore, to follow me.”
—SCOTTISH TOMBSTONE EPITAPH

individuals differ. Given similar losses, some people grieve hard and long, others less so (Ott et al., 2007). Contrary to popular misconceptions, however,

- terminally ill and bereaved people do not go through identical predictable stages, such as denial before anger (Friedman & James, 2008; Nolen-Hoeksema & Larson, 1999). A Yale study following 233 bereaved individuals through time did, however, find that yearning for the loved one reached a high point four months after the loss, with anger peaking, on average, about a month later (Maciejewski et al., 2007).
- those who express the strongest grief immediately do not purge their grief more quickly (Bonanno & Kaltman, 1999; Wortman & Silver, 1989).
- bereavement therapy and self-help groups offer support, but there is similar healing power in the passing of time, the support of friends, and the act of giving support and help to others (Baddeley & Singer, 2009; Brown et al., 2008; Neimeyer & Carrier, 2009). Grieving spouses who talk often with others or receive grief counseling adjust about as well as those who grieve more privately (Bonanno, 2004; Stroebe et al., 2005).

We can be grateful for the waning of death-denying attitudes. Facing death with dignity and openness helps people complete the life cycle with a sense of life’s meaningfulness and unity—the sense that their existence has been good and that life and death are parts of an on-going cycle. Although death may be unwelcome, life itself can be affirmed even at death. This is especially so for people who review their lives not with despair but with what Erik Erikson called a sense of *integrity*—a feeling that one’s life has been meaningful and worthwhile.

Before You Move On

▶ ASK YOURSELF

In what ways are you looking forward to adulthood? What concerns do you have about your own transition into adulthood, and how do you think you might address them?

▶ TEST YOURSELF

Research has shown that living together before marriage predicts an increased likelihood of future divorce. Can you imagine two possible explanations for this correlation?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 54 Review

54-1

What physical changes occur during middle and late adulthood?

- Muscular strength, reaction time, sensory abilities, and cardiac output begin to decline in the late twenties and continue to decline throughout middle adulthood (roughly age 40 to 65) and late adulthood (the years after 65).
- Women’s period of fertility ends with *menopause* around age 50; men have no similar age-related sharp drop in hormone levels or fertility.
- In late adulthood, the immune system weakens, increasing susceptibility to life-threatening illnesses.
- Chromosome tips (telomeres) wear down, reducing the chances of normal genetic replication.
- But for some, longevity-supporting genes, low stress, and good health habits enable better health in later life.

54-2 How does memory change with age?

- As the years pass, recall begins to decline, especially for meaningless information, but recognition memory remains strong.
- Developmental researchers study age-related changes (such as memory) with *cross-sectional studies* (comparing people of different ages) and *longitudinal studies* (retesting the same people over a period of years).
- “Terminal decline” describes the cognitive decline in the final few years of life.

54-3 What themes and influences mark our social journey from early adulthood to death?

- Adults do not progress through an orderly sequence of age-related social stages. Chance events can determine life choices.
- The *social clock* is a culture’s preferred timing for social events, such as marriage, parenthood, and retirement.
- Adulthood’s dominant themes are love and work, which Erikson called intimacy and generativity.

54-4 Do self-confidence and life satisfaction vary with life stages?

- Self-confidence tends to strengthen across the life span.
- Surveys show that life satisfaction is unrelated to age. Positive emotions increase after midlife and negative ones decrease.

54-5 A loved one’s death triggers what range of reactions?

- People do not grieve in predictable stages, as was once supposed.
- Strong expressions of emotion may not purge grief, and bereavement therapy is not significantly more effective than grieving without such aid.
- Erikson viewed the late-adulthood psychosocial task as developing a sense of integrity (versus despair).

Multiple-Choice Questions

- Which of the following changes does *not* occur with age?
 - Visual sharpness diminishes.
 - Distance perception is less acute.
 - Adaptation to light-level changes is less rapid.
 - The lens of the eye becomes more transparent.
 - Senses of smell and hearing diminish.
- As telomeres shorten, aging cells may die without being replaced with perfect genetic replicas. This process is slowed by
 - smoking.
 - obesity.
 - stress.
 - aging.
 - exercise.
- According to Erikson, which of the following is a dominant goal of adulthood?
 - Competence
 - Generativity
 - Performance
 - Identity
 - Connectedness
- The aging brain may help nurture positive feelings that are reported by many older adults. Brain scans of older adults show that the _____, a neural processing center for emotions, responds less actively to negative events (but not to positive events), and it interacts less with the hippocampus, a brain memory-processing center.
 - amygdala
 - hypothalamus
 - pineal gland
 - thyroid gland
 - thalamus

5. Which of the following is true of menopause?
- Both men and women experience menopause around the age of 50.
 - Men experience menopause around 50 years of age, but women experience menopause around 65 years of age.
 - Women experience menopause around 50 years of age, but men experience menopause around 65 years of age.
 - Women experience menopause around the age of 50, but men don't experience menopause.
 - Men experience menopause around the age of 65, but women don't experience menopause.
6. Which of the following would be considered an example of Erikson's concept of generativity?
- A 25-year-old meets and marries the love of his life.
 - A 35-year-old earns a lot of money, though she doesn't particularly enjoy her job.
 - An 85-year-old looks back at a life well-lived and feels satisfied.
 - A 40-year-old takes pride in her work and how she has raised her children.
 - A 20-year-old decides to become a physician.
7. The _____ is a culturally determined timetable for certain events, such as having children and retirement.
- critical period
 - menopause
 - intimacy phase
 - attachment stage
 - social clock

Practice FRQs

- Describe two changes in cognitive ability during adulthood. What is one factor that can prevent the steepest decline?
- Numerous biological, psychological, and social-cultural factors affect the way we age. Explain one example for each of the three that contributes to successful aging.

Answer

1 point: There is a decline in recall over the course of adulthood.

1 point: There is a decline in speed of processing over the adult years.

1 point: Exercise can prevent the steepest decline.

(3 points)

AP[®] Exam Practice Questions

Multiple-Choice Questions

- What aspect of development did Jean Piaget's development theory focus on?
 - Social
 - Moral
 - Cognitive
 - Physical
 - Ego
- According to Erikson's psychosocial theory of development, the crisis that needs resolution for adolescents involves the search for what?
 - Trust
 - Identity
 - Autonomy
 - Initiative
 - Worth

3. What is the correct term for a period of time when certain events must take place in order to facilitate proper development?
 - a. Conservation stage
 - b. Preoperational stage
 - c. Attachment period
 - d. Critical period
 - e. Assimilation step
4. Which of the following statements about the impact of aging is *true*?
 - a. During old age, many of the brain's neurons die.
 - b. If we live to be 90 or older, most of us will eventually become senile.
 - c. Older people become less susceptible to short-term illnesses.
 - d. Recognition memory—the ability to identify things previously experienced—declines with age.
 - e. Life satisfaction peaks in the 50s and then gradually declines after age 65.
5. According to Lawrence Kohlberg, what stage of moral development is exhibited when actions are judged “right” because they flow from basic ethical principles?
 - a. Postconventional
 - b. Preconventional
 - c. Conventional
 - d. Preoperational
 - e. Formal operational
6. According to Mary Ainsworth's research on attachment, what would a child need most to become “securely attached”?
 - a. Consistent, responsive caregivers
 - b. The right temperament
 - c. A terry cloth-wrapped “surrogate” mother
 - d. An imprinting experience shortly after birth
 - e. Enriched motor development experiences
7. Temperament refers to what aspect of an infant's development?
 - a. Susceptibility to infection and disease
 - b. Emotional reactivity
 - c. General intelligence
 - d. Level of optimism
 - e. Ability to learn from situations
8. How does fluid intelligence change as we age?
 - a. Decreases slowly with age
 - b. Has not been measured over time
 - c. Increases slowly with age
 - d. Does not change until about age 75
 - e. Remains unchanged if we exercise
9. Once a sperm penetrates the cell wall of an egg and fertilizes it, this structure is known as what?
 - a. An embryo
 - b. A fetus
 - c. Placenta
 - d. A teratogen
 - e. A zygote
10. Social development researchers suggest that infancy's major social achievement is attachment. Childhood's major social achievement is developing which of the following?
 - a. Basic trust
 - b. Into a sexually mature person
 - c. Intimacy
 - d. A positive sense of self
 - e. Object permanence
11. Most adolescents can ponder and debate human nature, good and evil, truth and justice. According to Piaget, this thinking ability is due to the emergence of which stage?
 - a. Concrete operational
 - b. Sensorimotor
 - c. Preoperational
 - d. Formal operational
 - e. Accommodation
12. Cultural norms related to when to leave home, get a job, or marry are referred to as what?
 - a. Social clock
 - b. Midlife crisis
 - c. Critical period
 - d. Life span
 - e. Theory of mind
13. The more often the stimulus is presented, the weaker the response becomes. What do developmental researchers call this decrease in response intensity due to repeated stimulation?
 - a. Stagnation
 - b. Attachment
 - c. Autonomy
 - d. Imprinting
 - e. Habituation
14. Eleanor Maccoby's research found which of the following factors to be the *least* positively correlated with problem behavior in preschool children?
 - a. Parent income
 - b. Parent education level
 - c. Time spent in day care
 - d. Child's temperament
 - e. Parent sensitivity

15. Which of these is an example of a longitudinal study?

- The depth perception of infants is measured once a month for 6 months in a row, starting at six months.
- In the same month, researchers compare the reaction time of 20 sixth graders and 20 first graders.
- The memory of one group of 50-year-old adults is measured and then 20 years later compared to a different group of 70-year-olds.
- A psychologist develops a case study of a woman who is 102 by interviewing her twice a week for 12 weeks.
- Researchers compare curiosity ratings of a group of toddlers with that same group's SAT scores 15 years later.

Free-Response Questions

1. Adolescence has been called a time of “storm and stress.” Describe how each of the following brain areas or psychological concepts might contribute to this storm and stress.

- Limbic system activity
- Frontal lobe development
- Formal operational abilities
- Erikson's identity versus role confusion stage
- Early physical maturation for girls

Rubric for Free Response Question 1

1 point: The limbic system is primed by surges of hormones at puberty, which may lead some adolescents to seek excitement and, possibly, behave impulsively.  Page 514

1 point: Frontal lobes, which are necessary for judgment and planning, continue to develop during adolescence and into the early twenties. Unused pathways are pruned and myelin speeds the connection between the frontal lobes and other areas of the brain. Without completed frontal lobe development, adolescents are often unable to exert adult impulse control. They may be more likely to indulge in risky and/or illegal behaviors despite understanding the possible consequences.  Pages 471, 514

1 point: When adolescents reach the formal operational stage, they have all of the cognitive abilities of earlier stages and can also think abstractly and hypothetically. With the ability to compare reality with a hypothetical ideal, adolescents may be disappointed in what exists, may detect hypocrisy, or may argue with those around them about how to achieve a more just world.  Page 483

1 point: During Erikson's identity versus role confusion stage, teenagers seek a sense of identity. Adolescents typically try out different versions of “self” before adopting a comfortable identity. This process can be difficult and can lead to conflicts with friends and family.  Pages 519–521

1 point: Early maturation puts some girls out of sync with their emotional development and friends' experiences. They may begin associating with older teens or endure teasing or sexual harassment.  Page 514

2. Piaget, Erikson, and Kohlberg described several cognitive, social, and moral reasoning stages of adolescence. Illustrate each of the following stages.

- Concrete operational
- Formal operational
- Identity versus role confusion
- Intimacy versus isolation
- Conventional level
- Postconventional level

(6 points)

3. Cruz and Eva have a 7-year-old son. He is in the second grade and is extremely obedient. He has many friends, most of whom are on a baseball team with him.

What advice might each of the researchers below give to Cruz and Eva about their son's development?

- Jean Piaget (cognitive development)
- Harry and Margaret Harlow (attachment)
- Lawrence Kohlberg (moral levels of thinking)
- Albert Bandura (social learning theory)
- Erik Erikson (psychosocial development)
- Diana Baumrind (parenting styles)
- Lev Vygotsky (scaffolding)

Unit X

Personality

Modules

55 Freud's Psychoanalytic Perspective: Exploring the Unconscious

56 Psychodynamic Theories and Modern Views of the Unconscious

57 Humanistic Theories

58 Trait Theories

59 Social-Cognitive Theories and Exploring the Self

Lord of the Rings hobbit-hero Frodo Baggins knew that throughout his difficult journey there was one who would never fail him—his loyal and ever-cheerful companion, Sam Gamgee. Even before they left their beloved homes in the Shire, Frodo warned Sam that the journey would not be easy.

“It is going to be very dangerous, Sam. It is already dangerous.

Most likely neither of us will come back.”

“If you don’t come back, sir, then I shan’t, that’s certain,” said Sam. “[The Elves told me] ‘Don’t you leave him!’ Leave him! I said. I never mean to. I am going with him, if he climbs to the Moon; and if any of those Black Riders try to stop him, they’ll have Sam Gamgee to reckon with.” (J.R.R. Tolkien, *The Fellowship of the Ring*, 1954, p. 96)

And so they did! Later in the story, when it becomes clear that Frodo’s path will lead him into the dreaded land of Mordor, it is Sam who insists he will be at Frodo’s side, come what may. It is Sam who lifts Frodo’s spirits with songs and stories from their boyhood. And it is Sam whom Frodo leans upon when he can barely take another step. When Frodo is overcome by the evil of the ring he carries, it is Sam who saves him. In the end, it is Sam who helps Frodo successfully

reach the end of his journey. Sam Gamgee—cheerful, optimistic, emotionally stable—never falters in his faithfulness or his belief that they will overcome the threatening darkness.

As he appears and reappears throughout the series, Tolkien’s Sam Gamgee exhibits the distinctive and enduring behaviors that define **personality**—a person’s characteristic pattern of thinking, feeling, and acting. Earlier units have focused on our similar ways of developing, perceiving, learning, remembering, thinking, and feeling. This unit focuses on what makes us each unique.

Much of this book deals with personality. We have considered biological influences on personality, personality development across the life span, and personality-related aspects of learning, motivation, emotion, and health. In later units we will study social influences on personality and disorders of personality.

Two historically significant theories have become part of our cultural legacy. Sigmund Freud’s *psychoanalytic* theory proposed that childhood sexuality and unconscious motivations influence personality. The *humanistic* approach focused on our inner capacities for growth and self-fulfillment. These sweeping perspectives on human nature laid the foundation for later personality theorists and are complemented by what this unit goes on to explore: newer scientific research of specific aspects of personality. Today’s personality researchers study the basic dimensions of personality, the biological roots of these dimensions, and the interaction of persons and environments. They also study self-esteem, self-serving bias, and cultural influences on one’s sense of self. And they study the unconscious mind—with findings that probably would have surprised Freud himself.

personality an individual’s characteristic pattern of thinking, feeling, and acting.

Module 55

Freud's Psychoanalytic Perspective: Exploring the Unconscious

Module Learning Objectives

- 55-1** Explain how Freud's treatment of psychological disorders led to his view of the unconscious mind.
- 55-2** Describe Freud's view of personality.
- 55-3** Identify Freud's developmental stages.
- 55-4** Describe Freud's views on how people defend themselves against anxiety.
- 55-5** Discuss how contemporary psychologists view Freud's psychoanalytic perspective.

Bruce Ayres/Getty Images

Freud's work is so well known that you may assume it's the most important theory in psychology. It's not. However, Freud was the first to focus clinical attention on the unconscious mind, and he is part of psychology's historical development.

Sigmund Freud, 1856–1939

"I was the only worker in a new field."

Psychoanalytic Theory's Core Ideas

- 55-1** How did Sigmund Freud's treatment of psychological disorders lead to his view of the unconscious mind?

Ask 100 people on the street to name a notable deceased psychologist, suggested Keith Stanovich (1996, p. 1), and "Freud would be the winner hands down." In the popular mind, he is to psychology's history what Elvis Presley is to rock music's history. Freud's influence not only lingers in psychiatry and clinical psychology, but also in literary and film interpretation. Almost 9 in 10 American college courses that reference psychoanalysis are outside of psychology departments (Cohen, 2007). His early twentieth-century concepts penetrate our twenty-first-century language. Without realizing their source, we may speak of *ego*, *repression*, *projection*, *sibling rivalry*, *Freudian slips*, and *fixation*. So, who was Freud, and what did he teach?

Like all of us, Sigmund Freud was a product of his times. His Victorian era was a time of tremendous discovery and scientific advancement, but it is also known today as a time of sexual repression and male dominance. Men's and women's roles were clearly defined, with male superiority assumed and only male sexuality generally acknowledged (discreetly).

Long before entering the University of Vienna in 1873, young Freud showed signs of independence and brilliance. He so loved reading plays, poetry, and philosophy that he once ran up a bookstore debt beyond his means. As a teen he often took his evening meal in his tiny bedroom in order to lose no time from his studies. After medical school he set up a private practice specializing in nervous disorders. Before long, however, he faced patients whose disorders made no neurological sense. For example, a patient might have lost all feeling in a hand—yet there is no sensory nerve that, if damaged, would numb the entire hand and nothing else. Freud's search for a cause for such disorders set his mind running in a direction destined to change human self-understanding.

Might some neurological disorders have psychological causes? Observing patients led Freud to his "discovery" of the unconscious. He speculated that lost feeling in one's hand might be caused by a fear of touching one's genitals; that unexplained blindness or deafness might be caused by not wanting to see or hear something that aroused intense anxiety. After some early unsuccessful trials with hypnosis, Freud turned to **free association**, in which he told the patient to relax and say whatever came to mind, no matter how embarrassing or trivial. He assumed that a line of mental dominoes had fallen from his patients' distant past to their troubled present. Free association, he believed, would allow him to retrace that line, following a chain of thought leading into the patient's unconscious, where painful unconscious memories, often from childhood, could be retrieved and released. Freud called his theory of personality and the associated treatment techniques **psychoanalysis**.

Basic to Freud's theory was his belief that the mind is mostly hidden (**FIGURE 55.1**). Our conscious awareness is like the part of an iceberg that floats above the surface. Beneath our awareness is the larger **unconscious** mind with its thoughts, wishes, feelings, and memories. Some of these thoughts we store temporarily in a *preconscious* area, from which we can retrieve them into conscious awareness. Of greater interest to Freud was the mass of unacceptable passions and thoughts that he believed we *repress*, or forcibly block from our consciousness because they would be too unsettling to acknowledge. Freud believed that without our awareness, these troublesome feelings and ideas powerfully influence us, sometimes gaining expression in disguised forms—the work we choose, the beliefs we hold, our daily habits, our troubling symptoms.

AP® Exam Tip

The boldfaced key terms that you read in this module are all quite famous terms. Even though modern psychology rejects many of the specifics of psychoanalysis, the fame of Freud's concepts makes them likely topics for AP® exam questions.

free association in psychoanalysis, a method of exploring the unconscious in which the person relaxes and says whatever comes to mind, no matter how trivial or embarrassing.

psychoanalysis Freud's theory of personality that attributes thoughts and actions to unconscious motives and conflicts; the techniques used in treating psychological disorders by seeking to expose and interpret unconscious tensions.

unconscious according to Freud, a reservoir of mostly unacceptable thoughts, wishes, feelings, and memories. According to contemporary psychologists, information processing of which we are unaware.

Figure 55.1

Freud's idea of the mind's structure

Psychologists have used an iceberg image to illustrate Freud's idea that the mind is mostly hidden beneath the conscious surface. Note that the id is totally unconscious, but ego and superego operate both consciously and unconsciously. Unlike the parts of a frozen iceberg, however, the id, ego, and superego interact.

"Good morning, beheaded—uh, I mean beloved."

"I remember your name perfectly but I just can't think of your face."
—OXFORD PROFESSOR W. A. SPOONER (1844–1930), FAMOUS FOR HIS LINGUISTIC FLIP-FLOPS (SPOONERISMS). SPOONER REBUKED ONE STUDENT FOR "FIGHTING A LIAR IN THE QUADRANGLE" AND ANOTHER WHO "HISSED MY MYSTERY LECTURE," ADDING "YOU HAVE TASTED TWO WORMS."

AP® Exam Tip

Be careful: It's easy to confuse Freud's three layers of the mind (conscious, preconscious, and unconscious) with the three parts of personality (id, ego, superego).

Personality Structure

55-2 What was Freud's view of personality?

In Freud's view, human personality—including its emotions and strivings—arises from a conflict between impulse and restraint—between our aggressive, pleasure-seeking biological urges and our internalized social controls over these urges. Freud believed personality arises from our efforts to resolve this basic conflict—to express these impulses in ways that bring satisfaction without also bringing guilt or punishment. To understand the mind's dynamics during this conflict, Freud proposed three interacting systems: the *id*, *ego*, and *superego* (Figure 55.1).

The **id's** unconscious psychic energy constantly strives to satisfy basic drives to survive, reproduce, and aggress. The id operates on the *pleasure principle*: It seeks immediate gratification. To envision an id-dominated person, think of a newborn infant crying out for satisfaction, caring nothing for the outside world's conditions and demands. Or think of people with a present rather than future time perspective—those who abuse tobacco, alcohol, and other drugs, and would sooner party now than sacrifice today's pleasure for future success and happiness (Keough et al., 1999).

As the **ego** develops, the young child responds to the real world. The ego, operating on the *reality principle*, seeks to gratify the id's impulses in realistic ways that will bring long-term pleasure. (Imagine what would happen if, lacking an ego, we expressed all our unrestrained sexual or aggressive impulses.) The ego contains our partly conscious perceptions, thoughts, judgments, and memories.

Around age 4 or 5, Freud theorized, a child's ego recognizes the demands of the newly emerging **superego**, the voice of our moral compass (conscience) that forces the ego to consider not only the real but the *ideal*. The superego focuses on how we *ought* to behave. It strives for perfection, judging actions and producing positive feelings of pride or negative feelings of guilt. Someone with an exceptionally strong superego may be virtuous yet guilt-ridden; another with a weak superego may be wantonly self-indulgent and remorseless.

Because the superego's demands often oppose the id's, the ego struggles to reconcile the two. It is the personality "executive," mediating among the impulsive demands of the id, the restraining demands of the superego, and the real-life demands of the external world. If chaste Jane feels sexually attracted to John, she may satisfy both id and superego by joining a volunteer organization that John attends regularly.

"Fifty is plenty." "Hundred and fifty."

The ego struggles to reconcile the demands of superego and id, said Freud.

Personality Development

55-3 What developmental stages did Freud propose?

Analysis of his patients' histories convinced Freud that personality forms during life's first few years. He concluded that children pass through a series of **psychosexual stages**, during which the id's pleasure-seeking energies focus on distinct pleasure-sensitive areas of the body called *erogenous zones* (**TABLE 55.1**). Each stage offers its own challenges, which Freud saw as conflicting tendencies.

Table 55.1 Freud's Psychosexual Stages

Stage	Focus
<i>Oral</i> (0–18 months)	Pleasure centers on the mouth—sucking, biting, chewing
<i>Anal</i> (18–36 months)	Pleasure focuses on bowel and bladder elimination; coping with demands for control
<i>Phallic</i> (3–6 years)	Pleasure zone is the genitals; coping with incestuous sexual feelings
<i>Latency</i> (6 to puberty)	A phase of dormant sexual feelings
<i>Genital</i> (puberty on)	Maturation of sexual interests

Freud believed that during the *phallic stage*, for example, boys seek genital stimulation, and they develop both unconscious sexual desires for their mother and jealousy and hatred for their father, whom they consider a rival. Given these feelings, he thought boys also experience guilt and a lurking fear of punishment, perhaps by castration, from their father. Freud called this collection of feelings the **Oedipus complex** after the Greek legend of Oedipus, who unknowingly killed his father and married his mother. Some psychoanalysts in Freud's era believed that girls experienced a parallel *Electra complex*.

Children eventually cope with the threatening feelings, said Freud, by repressing them and by identifying with (trying to become like) the rival parent. It's as though something inside the child decides, "If you can't beat 'em [the parent of the same sex], join 'em." Through this **identification** process, children's superegos gain strength as they incorporate many of their parents' values. Freud believed that identification with the same-sex parent provides what psychologists now call our *gender identity*—our sense of being male or female.

id a reservoir of unconscious psychic energy that, according to Freud, strives to satisfy basic sexual and aggressive drives. The id operates on the *pleasure principle*, demanding immediate gratification.

ego the largely conscious, "executive" part of personality that, according to Freud, mediates among the demands of the id, superego, and reality. The ego operates on the *reality principle*, satisfying the id's desires in ways that will realistically bring pleasure rather than pain.

superego the part of personality that, according to Freud, represents internalized ideals and provides standards for judgment (the conscience) and for future aspirations.

psychosexual stages the childhood stages of development (oral, anal, phallic, latency, genital) during which, according to Freud, the id's pleasure-seeking energies focus on distinct erogenous zones.

Oedipus [ED-uh-puss] complex according to Freud, a boy's sexual desires toward his mother and feelings of jealousy and hatred for the rival father.

identification the process by which, according to Freud, children incorporate their parents' values into their developing superegos.

David Myers

Identification I want to be like Dad.

“Oh, for goodness’ sake! Smoke!”

Freud presumed that our early childhood relations—especially with our parents and caregivers—influence our developing identity, personality, and frailties.

In Freud’s view, conflicts unresolved during earlier psychosexual stages could surface as maladaptive behavior in the adult years. At any point in the oral, anal, or phallic stages, strong conflict could lock, or **fixate**, the person’s pleasure-seeking energies in that stage. A person who had been either orally overindulged or deprived (perhaps by abrupt, early weaning) might fixate at the oral stage. This orally fixated adult could exhibit either passive dependence (like that of a nursing infant) or an exaggerated denial of this dependence (by acting tough or uttering biting sarcasm). Or the person might continue to seek oral gratification by smoking or excessive eating. In such ways, Freud suggested, the twig of personality is bent at an early age.

Freud’s ideas of sexuality were controversial in his own time. “Freud was called a dirty-minded pansexualist and Viennese libertine,” notes historian of psychology Morton Hunt (2007, p. 211). Today his ideas of Oedipal conflict and castration anxiety are disputed even by later *psychodynamic* theorists and therapists (see Module 56) (Shedler, 2010b). Yet we still teach them as part of the history of Western ideas.

Defense Mechanisms

55-4 How did Freud think people defend themselves against anxiety?

fixation according to Freud, a lingering focus of pleasure-seeking energies at an earlier psychosexual stage, in which conflicts were unresolved.

defense mechanisms in psychoanalytic theory, the ego’s protective methods of reducing anxiety by unconsciously distorting reality.

repression in psychoanalytic theory, the basic defense mechanism that banishes from consciousness anxiety-arousing thoughts, feelings, and memories.

Anxiety, said Freud, is the price we pay for civilization. As members of social groups, we must control our sexual and aggressive impulses, not act them out. But sometimes the ego fears losing control of this inner war between the id and superego. The presumed result is a dark cloud of unfocused anxiety that leaves us feeling unsettled but unsure why.

Freud proposed that the ego protects itself with **defense mechanisms**—tactics that reduce or redirect anxiety by distorting reality. Defense mechanisms protect our self-understanding. For Freud, *all defense mechanisms function indirectly and unconsciously*. Just as the body unconsciously defends itself against disease, so also does the ego unconsciously defend itself against anxiety. For example, **repression** banishes anxiety-arousing wishes and feelings from consciousness. According to Freud, *repression underlies all the other defense mechanisms*. However, because repression is often incomplete, repressed urges may appear as symbols in dreams or as slips of the tongue in casual conversation. **TABLE 55.2** describes a sampling of seven other well-known defense mechanisms.

Regression: Faced with a mild stressor, children and young orangutans will seek protection and comfort from their caregivers. Freud might have interpreted these behaviors as regression, a retreat to an earlier developmental stage.

VStock/Alamy

Richard I'Anson/Getty Images

Table 55.2 Seven Defense Mechanisms

Freud believed that *repression*, the basic mechanism that banishes anxiety-arousing impulses, enables other defense mechanisms, seven of which are listed here.

Defense Mechanism	Unconscious Process Employed to Avoid Anxiety-Arousing Thoughts or Feelings	Example
<i>Regression</i>	Retreating to a more infantile psychosexual stage, where some psychic energy remains fixated.	A little boy reverts to the oral comfort of thumb sucking in the car on the way to his first day of school.
<i>Reaction formation</i>	Switching unacceptable impulses into their opposites.	Repressing angry feelings, a person displays exaggerated friendliness.
<i>Projection</i>	Disguising one's own threatening impulses by attributing them to others.	"The thief thinks everyone else is a thief" (an El Salvadoran saying).
<i>Rationalization</i>	Offering self-justifying explanations in place of the real, more threatening unconscious reasons for one's actions.	A habitual drinker says she drinks with her friends "just to be sociable."
<i>Displacement</i>	Shifting sexual or aggressive impulses toward a more acceptable or less threatening object or person.	A little girl kicks the family dog after her mother sends her to her room.
<i>Sublimation</i>	Transferring of unacceptable impulses into socially valued motives.	A man with aggressive urges becomes a surgeon.
<i>Denial</i>	Refusing to believe or even perceive painful realities.	A partner denies evidence of his loved one's affair.

Evaluating Freud's Psychoanalytic Perspective

55-5 How do contemporary psychologists view Freud's psychoanalysis?

Modern Research Contradicts Many of Freud's Ideas

We critique Freud from an early twenty-first-century perspective, a perspective that itself will be subject to revision. Freud did not have access to neurotransmitter or DNA studies, or to all that we have since learned about human development, thinking, and emotion. To criticize his theory by comparing it with today's thinking, some say, is like criticizing Henry Ford's Model T by comparing it with today's hybrid cars. (How tempting it always is to judge people in the past from our perspective in the present.)

But both Freud's admirers and his critics agree that recent research contradicts many of his specific ideas. Today's developmental psychologists see our development as lifelong, not fixed in childhood. They doubt that infants' neural networks are mature enough to sustain as much emotional trauma as Freud assumed. Some think Freud overestimated parental influence and underestimated peer influence. They also doubt that conscience and gender identity form as the child resolves the Oedipus complex at age 5 or 6. We gain our gender identity earlier and become strongly masculine or feminine even without a same-sex parent present. And they note that Freud's ideas about childhood sexuality arose from his skepticism of stories of childhood sexual abuse told by his female patients—stories that some scholars believe he attributed to their own childhood sexual wishes and conflicts (Esterson, 2001; Powell & Boer, 1994).

AP® Exam Tip

The differences between these defense mechanisms aren't always clear. For example, *repression* can be found in almost every example. Focus on the key feature of each given example. If the key feature is seeing your own impulse in someone else, it's projection. If the key feature is shifting your aggression from one target to another, it's displacement.

"Many aspects of Freudian theory are indeed out of date, and they should be: Freud died in 1939, and he has been slow to undertake further revisions."
-PSYCHOLOGIST DREW WESTEN (1998)

ScienceCartoonsPlus.com

"We are arguing like a man who should say, 'If there were an invisible cat in that chair, the chair would look empty; but the chair does look empty; therefore there is an invisible cat in it.'" -C. S. LEWIS, *FOUR LOVES*, 1958

As we saw in Module 24, new ideas about why we dream dispute Freud's belief that dreams disguise and fulfill wishes. And slips of the tongue can be explained as competition between similar verbal choices in our memory network. Someone who says "I don't want to do that—it's a lot of brothel" may simply be blending *bother* and *trouble* (Foss & Hakes, 1978). Researchers find little support for Freud's idea that defense mechanisms disguise sexual and aggressive impulses (though our cognitive gymnastics do indeed work to protect our self-esteem). History also has failed to support another of Freud's ideas—that suppressed sexuality causes psychological disorders. From Freud's time to ours, sexual inhibition has diminished; psychological disorders have not.

Psychologists also criticize Freud's theory for its scientific shortcomings. Recall from Module 5 that good scientific theories explain observations and offer testable hypotheses. Freud's theory rests on few objective observations, and parts of it offer few testable hypotheses. (For Freud, his own recollections and interpretations of patients' free associations, dreams, and slips were evidence enough.)

What is the most serious problem with Freud's theory? It offers after-the-fact explanations of any characteristic (of one person's smoking, another's fear of horses, another's sexual orientation) yet fails to *predict* such behaviors and traits. If you feel angry at your mother's death, you illustrate his theory because "your unresolved childhood dependency needs are threatened." If you do not feel angry, you again illustrate his theory because "you are repressing your anger." That, said Calvin Hall and Gardner Lindzey (1978, p. 68), "is like betting on a horse after the race has been run." A good theory makes testable predictions.

PEANUTS reprinted by permission of UFS, Inc.

So, should psychology post an "Allow Natural Death" order on this old theory? Freud's supporters object. To criticize Freudian theory for not making testable predictions is, they say, like criticizing baseball for not being an aerobic exercise, something it was never intended to be. Freud never claimed that psychoanalysis was predictive science. He merely claimed that, looking back, psychoanalysts could find meaning in their clients' state of mind (Rieff, 1979).

Supporters also note that some of Freud's ideas *are* enduring. It was Freud who drew our attention to the unconscious and the irrational, to our self-protective defenses, to the importance of human sexuality, and to the tension between our biological impulses and our social well-being. It was Freud who challenged our self-righteousness, punctured our pretensions, and reminded us of our potential for evil.

Modern Research Challenges the Idea of Repression

Psychoanalytic theory rests on the assumption that the human mind often *represses* offending wishes, banishing them into the unconscious until they resurface, like long-lost books in a dusty attic. Recover and resolve childhood's conflicted wishes, and emotional healing should follow. Repression became a widely accepted concept, used to explain hypnotic phenomena and psychological disorders. Some of Freud's followers extended repression to explain apparently lost and recovered memories of childhood traumas (Boag, 2006; Cheit, 1998; Erdelyi,

2006). In one survey, 88 percent of university students believed that painful experiences commonly get pushed out of awareness and into the unconscious (Garry et al., 1994).

Today's researchers agree that we sometimes spare our egos by neglecting threatening information (Green et al., 2008). Yet, many contend that repression, if it ever occurs, is a rare mental response to terrible trauma. Even those who have witnessed a parent's murder or survived Nazi death camps retain their unrepressed memories of the horror (Helmreich, 1992, 1994; Malmquist, 1986; Pennebaker, 1990). "Dozens of formal studies have yielded not a single convincing case of repression in the entire literature on trauma," concluded personality researcher John Kihlstrom (2006).

Some researchers do believe that extreme, prolonged stress, such as the stress some severely abused children experience, might disrupt memory by damaging the hippocampus (Schacter, 1996). But the far more common reality is that high stress and associated stress hormones *enhance* memory (see Module 32). Indeed, rape, torture, and other traumatic events haunt survivors, who experience unwanted flashbacks. They are seared onto the soul. "You see the babies," said Holocaust survivor Sally H. (1979). "You see the screaming mothers. You see hanging people. You sit and you see that face there. It's something you don't forget."

"The overall findings . . . seriously challenge the classical psychoanalytic notion of repression." -PSYCHOLOGIST YACOV ROFÉ, "DOES REPRESSION EXIST?" 2008

"During the Holocaust, many children . . . were forced to endure the unendurable. For those who continue to suffer [the] pain is still present, many years later, as real as it was on the day it occurred." -ERIC ZILLMER, MOLLY HARROWER, BARRY FITZLER, AND ROBERT ARCHER, *THE QUEST FOR THE NAZI PERSONALITY*, 1995

Before You Move On

▶ ASK YOURSELF

Which of Freud's presumed defense mechanisms have you found yourself employing?

▶ TEST YOURSELF

How does today's psychological science assess Freud's theory?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 55 Review

- *Personality* is an individual's characteristic pattern of thinking, feeling, and acting.
- Sigmund Freud's theory of *psychoanalysis* is not the most important theory in psychology, but his famous work is historically and culturally significant.

55-1

How did Sigmund Freud's treatment of psychological disorders lead to his view of the unconscious mind?

- In treating patients whose disorders had no clear physical explanation, Freud concluded that these problems reflected unacceptable thoughts and feelings, hidden away in the *unconscious* mind.
- To explore this hidden part of a patient's mind, Freud used *free association* and dream analysis.

55-2

What was Freud's view of personality?

- Freud believed that personality results from conflict arising from the interaction among the mind's three systems: the *id* (pleasure-seeking impulses), *ego* (reality-oriented executive), and *superego* (internalized set of ideals, or conscience).

55-3

What developmental stages did Freud propose?

- Freud believed children pass through five *psychosexual* stages (oral, anal, phallic, latency, and genital).
- Unresolved conflicts at any stage can leave a person's pleasure-seeking impulses *fixated* (stalled) at that stage.

55-4 How did Freud think people defend themselves against anxiety?

- For Freud, anxiety was the product of tensions between the demands of the id and superego. The ego copes by using unconscious *defense mechanisms*, such as *repression*, which he viewed as the basic mechanism underlying and enabling all the others.

55-5 How do contemporary psychologists view Freud's psychoanalysis?

- Today's psychologists give Freud credit for drawing attention to the vast unconscious, to the importance of our sexuality, and to the conflict between biological impulses and social restraints.
- But Freud's concept of repression, and his view of the unconscious as a collection of repressed and unacceptable thoughts, wishes, feelings, and memories, have not survived scientific scrutiny. Freud offered after-the-fact explanations, which are hard to test scientifically.
- Research does not support many of Freud's specific ideas, such as the view that development is fixed in childhood. (We now know it is lifelong.)

Multiple-Choice Questions

- Free association is
 - a method of exploring the unconscious.
 - another name for hypnosis.
 - the major function of the superego.
 - an ego defense mechanism.
 - a method of dream analysis.
- According to Freud, which of the following is true of the ego?
 - It focuses on how we ought to behave.
 - It is the source of guilt.
 - It is the part of the personality present at birth.
 - It strives to satisfy basic drives.
 - It operates under the reality principle.
- Which of the following represents Freud's Oedipus complex?
 - Yutao has begun to suffer from the same recurrent nightmares he had as a child.
 - Madeline manifests repressed anxiety because of guilt she experienced when she disappointed her parents during toilet training.
 - Five-year-old Anagha is taking on many of her mother's values through a process of identification.
 - Four-year-old Carlos is experiencing unconscious sexual desire for his mother and unconscious hatred for his father.
 - Elle has begun to overeat and smoke cigarettes as a college student, indicating a degree of oral fixation.
- According to Freud, which of the following defense mechanisms underlies all of the others?
 - Repression
 - Reaction formation
 - Displacement
 - Projection
 - Regression

Practice FRQs

- Name what Freud believed to be the three parts of the mind and describe the role of each.

Answer

1 point: The conscious mind is what a person is aware of.

1 point: The preconscious mind is a temporary holding place from which memories and feelings can be easily retrieved.

1 point: The unconscious mind is the hidden holding place for unacceptable passions and thoughts.

- Nadina is struggling to decide whether to buy a new sweater that she really cannot afford. What role would each of the three parts of her personality (as theorized by Freud) play in her decision?

(3 points)

Module 56

Psychodynamic Theories and Modern Views of the Unconscious

Module Learning Objectives

- 56-1** Identify which of Freud's ideas were accepted or rejected by his followers.
- 56-2** Describe projective tests and how they are used, and discuss some criticisms of them.
- 56-3** Describe the modern view of the unconscious.

P psychodynamic theories of personality view our behavior as emerging from the interaction between the conscious and unconscious mind, including associated motives and conflicts. These theories are descended from Freud's historical *psychoanalytic theory*, but the modern-day approaches differ in important ways.

psychodynamic theories
modern-day approaches that view personality with a focus on the unconscious and the importance of childhood experiences.

The Neo-Freudian and Psychodynamic Theorists

- 56-1** Which of Freud's ideas did his followers accept or reject?

Freud's writings were controversial, but they soon attracted followers, mostly young, ambitious physicians who formed an inner circle around their strong-minded leader. These pioneering psychoanalysts, whom we often call *neo-Freudians*, accepted Freud's basic ideas: the personality structures of id, ego, and superego; the importance of the unconscious; the shaping of personality in childhood; and the dynamics of anxiety and the defense mechanisms. But they broke off from Freud in two important ways. First, they placed more emphasis on the conscious mind's role in interpreting experience and in coping with the environment. And second, they doubted that sex and aggression were all-consuming motivations. Instead, they tended to emphasize loftier motives and social interactions.

Alfred Adler and Karen Horney [HORN-eye], for example, agreed with Freud that childhood is important. But they believed that childhood *social*, not sexual, tensions are crucial for personality formation (Ferguson, 2003). Adler (who had proposed the still-popular idea of the *inferiority complex*) himself struggled to overcome childhood illnesses and accidents, and he believed that much of our behavior is driven by efforts to conquer childhood inferiority feelings that trigger our strivings for superiority and power. Horney said childhood anxiety triggers our desire for love and security. She also countered Freud's assumptions, arising as they did in his conservative culture, that women have weak superegos and suffer "penis envy," and she attempted to balance the bias she detected in his masculine view of psychology.

Alfred Adler “The individual feels at home in life and feels his existence to be worthwhile just so far as he is useful to others and is overcoming feelings of inferiority” (*Problems of Neurosis*, 1964).

Karen Horney “The view that women are infantile and emotional creatures, and as such, incapable of responsibility and independence is the work of the masculine tendency to lower women’s self-respect” (*Feminine Psychology*, 1932).

Carl Jung “From the living fountain of instinct flows everything that is creative; hence the unconscious is the very source of the creative impulse” (*The Structure and Dynamics of the Psyche*, 1960).

collective unconscious Carl Jung’s concept of a shared, inherited reservoir of memory traces from our species’ history.

Carl Jung—Freud’s disciple-turned-dissenter—placed less emphasis on social factors and agreed with Freud that the unconscious exerts a powerful influence. But to Jung [Yoong], the unconscious contains more than our repressed thoughts and feelings. He believed we also have a **collective unconscious**, a common reservoir of images, or *archetypes*, derived from our species’ universal experiences. Jung said that the collective unconscious explains why, for many people, spiritual concerns are deeply rooted and why people in different cultures share certain myths and images, such as mother as a symbol of nurturance. (Most of today’s psychodynamic psychologists discount the idea of inherited experiences. But many psychodynamic and other psychological theorists do believe that our shared evolutionary history shaped some universal dispositions.)

Some of Freud’s ideas have been incorporated into the diversity of modern perspectives that make up psychodynamic theory. “Most contemporary [psychodynamic] theorists and therapists are not wedded to the idea that sex is the basis of personality,” noted Drew Westen (1996). They “do not talk about ids and egos, and do not go around classifying their patients as oral, anal, or phallic characters.” What they do assume, with Freud and with much support from today’s psychological science, is that much of our mental life is unconscious. With Freud, they also assume that we often struggle with inner conflicts among our wishes, fears, and values, and that childhood shapes our personality and ways of becoming attached to others.

Assessing Unconscious Processes

56-2 What are projective tests, how are they used, and what are some criticisms of them?

Personality assessment tools are useful to those who study personality or provide therapy. Such tools differ because they are tailored to specific theories. How might psychodynamic clinicians attempt to assess personality characteristics?

The first requirement would be some sort of a road into the unconscious, to unearth the residue of early childhood experiences, to move beneath surface pretensions and reveal hidden conflicts and impulses. Objective assessment tools, such as agree-disagree or true-false questionnaires, would be inadequate because they would merely tap the conscious surface.

ScienceCartoonsPlus.com

“The forward thrust of the antlers shows a determined personality, yet the small sun indicates a lack of self-confidence. . . .”

Projective tests aim to provide this “psychological X-ray” by asking test-takers to describe an ambiguous stimulus or tell a story about it. Henry Murray introduced one such test, the **Thematic Apperception Test (TAT)**, in which a person views an ambiguous picture and then makes up a story about it (FIGURE 56.1). The clinician may presume that any hopes, desires, and fears that people see in the ambiguous image are projections of their own inner feelings or conflicts.

The most widely used projective test left some blots on the name of Swiss psychiatrist Hermann Rorschach [ROAR-shock]. He based his famous **Rorschach inkblot test**, in which people describe what they see in a series of inkblots (FIGURE 56.2), on a childhood game. He and his friends would drip ink on a paper, fold it, and then say what they saw in the resulting blot (Sdorow, 2005). Do you see predatory animals or weapons? Perhaps you have aggressive tendencies. But is this a reasonable assumption?

Clinicians’ and critics’ answers differ. Some clinicians cherish the Rorschach, even offering Rorschach-based assessments of criminals’ violence potential to judges. Others view it as a helpful diagnostic tool, a source of suggestive leads, or an icebreaker and a revealing interview technique. The Society for Personality Assessment (2005) commends “its responsible use” (which would *not* include inferring past childhood sexual abuse). And—in response to past criticisms of test scoring and interpretation (Sechrest et al., 1998)—a research-based, computer-aided tool has been designed to improve agreement among raters and enhance the test’s validity (Erdberg, 1990; Exner, 2003).

But the evidence is insufficient to its revilers, who insist the Rorschach is no emotional MRI. They argue that only a few of the many Rorschach-derived scores, such as ones for hostility and anxiety, have demonstrated *validity*—predicting what they are supposed to predict (Wood, 2006). Moreover, they say, these tests do not yield consistent results—they are not *reliable*. Inkblot assessments diagnose many normal adults as pathological (Wood et al., 2003, 2006, 2010). Alternative projective assessment techniques fare little better. “Even seasoned professionals can be fooled by their intuitions and their faith in tools that lack strong evidence of effectiveness,” warned Scott Lilienfeld, James Wood, and Howard Garb (2001). “When a substantial body of research demonstrates that old intuitions are wrong, it is time to adopt new ways of thinking.”

Lewis J. Merrim/Science Source

Figure 56.1

The TAT This clinician presumes that the hopes, fears, and interests expressed in this boy’s descriptions of a series of ambiguous pictures in the Thematic Apperception Test (TAT) are projections of his inner feelings.

“The Rorschach Inkblot Test has been resoundingly discredited. I call it the Dracula of psychological tests, because no one has been able to drive a stake through the cursed thing’s heart.” -CAROL TAVRIS, “MIND GAMES: PSYCHOLOGICAL WARFARE BETWEEN THERAPISTS AND SCIENTISTS,” 2003

“We don’t see things as they are; we see things as we are.” -THE TALMUD

projective test a personality test, such as the Rorschach, that provides ambiguous stimuli designed to trigger projection of one’s inner dynamics.

Thematic Apperception Test (TAT) a projective test in which people express their inner feelings and interests through the stories they make up about ambiguous scenes.

Rorschach inkblot test the most widely used projective test, a set of 10 inkblots, designed by Hermann Rorschach; seeks to identify people’s inner feelings by analyzing their interpretations of the blots.

Stanley Goldblatt/Science Source

Figure 56.2

The Rorschach test In this projective test, people tell what they see in a series of symmetrical inkblots. Some who use this test are confident that the interpretation of ambiguous stimuli will reveal unconscious aspects of the test-taker’s personality.

AP® Exam Tip

It's very important to understand the differences between Freud's view of the unconscious and modern psychology's view of the unconscious. Read this section carefully.

false consensus effect the tendency to overestimate the extent to which others share our beliefs and our behaviors.

terror-management theory a theory of death-related anxiety; explores people's emotional and behavioral responses to reminders of their impending death.

The Modern Unconscious Mind**56-3**

How has modern research developed our understanding of the unconscious?

Freud was right about a big idea that underlies today's psychodynamic thinking: We indeed have limited access to all that goes on in our minds (Erdelyi, 1985, 1988, 2006; Norman, 2010). Our two-track mind has a vast out-of-sight realm.

Nevertheless, many of today's research psychologists now think of the unconscious not as seething passions and repressive censoring but as cooler information processing that occurs without our awareness. To these researchers, the unconscious also involves

- the schemas that automatically control our perceptions and interpretations (Module 17).
- the priming by stimuli to which we have not consciously attended (Modules 16 and 32).
- the right hemisphere brain activity that enables the split-brain patient's left hand to carry out an instruction the patient cannot verbalize (Module 13).
- the implicit memories that operate without conscious recall, even among those with amnesia (Module 33).
- the emotions that activate instantly, before conscious analysis (Module 41).
- the self-concept and stereotypes that automatically and unconsciously influence how we process information about ourselves and others (Module 77).

More than we realize, we fly on autopilot. Our lives are guided by off-screen, out-of-sight, unconscious information processing. The unconscious mind is huge. This understanding of unconscious information processing is more like the pre-Freudian view of an underground, unattended stream of thought from which spontaneous behavior and creative ideas surface (Bargh & Morsella, 2008).

Research has also supported Freud's idea of our unconscious defense mechanisms. For example, Roy Baumeister and his colleagues (1998) found that people tend to see their foibles and attitudes in others, a phenomenon that Freud called projection and that today's researchers call the **false consensus effect**, the tendency to overestimate the extent to which others share our beliefs and behaviors. People who cheat on their taxes or break speed limits tend to think many others do likewise. People who are happy, kind, and trustworthy tend to see others as the same (Wood et al., 2010).

Evidence also confirms the unconscious mechanisms that defend self-esteem, such as reaction formation. Defense mechanisms, Baumeister concluded, are motivated less by the seething impulses that Freud presumed than by our need to protect our self-image.

Finally, recent history has supported Freud's idea that we unconsciously defend ourselves against anxiety. Jeff Greenberg, Sheldon Solomon, and Tom Pyszczynski (1997) proposed that one source of anxiety is "the terror resulting from our awareness of vulnerability and death." Nearly 300 experiments testing their **terror-management theory** show that thinking about one's mortality—for example, by writing a short essay on dying and its associated emotions—provokes various terror-management defenses (Burke et al., 2010). For example, death anxiety increases contempt for others and esteem for oneself (Koole et al., 2006).

Faced with a threatening world, people act not only to enhance their self-esteem but also to adhere more strongly to worldviews that answer questions about life's meaning. The prospect of death promotes religious sentiments, and deep religious convictions enable people to be less defensive—less likely to rise in defense of their worldview—when reminded of death (Jonas & Fischer, 2006; Norenzayan & Hansen, 2006). Moreover, when contemplating death, people cleave to close relationships (Mikulincer et al., 2003). The

"It says, 'Someday you will die.'"

"I don't want to attain immortality through my work; I want to attain immortality by not dying." -FILM DIRECTOR AND ACTOR WOODY ALLEN

events of 9/11—a striking experience of the terror of death—led trapped World Trade Center occupants to spend their last moments calling loved ones, and led most Americans to reach out to family and friends.

“I sought the Lord, and he answered me and delivered me out of all my terror.” -PSALM 34:4

Before You Move On

▶ ASK YOURSELF

What understanding and impressions of Freud did you bring to this unit? Are you surprised to find that some of his ideas (especially the big idea of our unconscious mind) had merit?

▶ TEST YOURSELF

What methods have been used by psychodynamic clinicians to assess unconscious processes?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 56 Review

- *Psychodynamic theories*, which descended from Freud’s historically important work, view personality from the perspective that behavior is a dynamic interaction between the conscious and unconscious mind.

56-1

Which of Freud’s ideas did his followers accept or reject?

- Freud’s early followers, the neo-Freudians, accepted many of his ideas. They differed in placing more emphasis on the conscious mind and in stressing social motives more than sexual or aggression motives.
- Contemporary psychodynamic theorists and therapists reject Freud’s emphasis on sexual motivation. They stress, with support from modern research findings, the view that much of our mental life is unconscious, and they believe that our childhood experiences influence our adult personality and attachment patterns.

56-2

What are projective tests, how are they used, and what are some criticisms of them?

- *Projective tests* attempt to assess personality by showing people vague stimuli with many possible interpretations; answers reveal unconscious motives.
- One such test, the *Rorschach inkblot test*, has low reliability and validity.

56-3

How has modern research developed our understanding of the unconscious?

- Current research confirms that we do not have full access to all that goes on in our mind, but the current view of the unconscious is not that of a hidden storehouse filled with repressed feelings and thoughts.
- Researchers see the unconscious as a separate and parallel track of information processing that occurs outside our awareness, such as schemas that control our perceptions; priming; implicit memories of learned skills; instantly activated emotions; self-concepts and stereotypes that filter information about ourselves and others; and mechanisms that defend our self-esteem and deter anxiety, such as the *false consensus effect/projection* and *terror management*.

Multiple-Choice Questions

1. What did Carl Jung call the shared, inherited reservoir of memory traces from our species' history?
 - a. Neurosis
 - b. Archetypes
 - c. Collective unconscious
 - d. Inferiority complex
 - e. Terror management
2. Scott Lilienfeld, James Wood, and Howard Garb (2001) wrote, "When a substantial body of research demonstrates that old intuitions are wrong, it is time to adopt new ways of thinking." What were they talking about?
 - a. MRI test
 - b. Rorschach inkblot test
 - c. Freud's work on the id and ego
 - d. Psychodynamic theories
 - e. Modern views of the unconscious
3. According to the text, many research psychologists think of _____ as an information processor that works without our awareness.
 - a. the TAT
 - b. the id
 - c. repression
 - d. defense mechanisms
 - e. the unconscious

Practice FRQs

1. Name and accurately describe two projective tests.
2. Explain and give an example of the false consensus effect.

Answer

1 point: Thematic Apperception Test (TAT)

1 point: In the TAT, someone is asked to tell a story about a picture.

1 point: Rorschach Inkblot Test

1 point: In the Rorschach, someone is asked to state what he or she sees in an inkblot.

(2 points)

Module 57

Humanistic Theories

Module Learning Objectives

- 57-1** Describe how humanistic psychologists viewed personality, and explain their goal in studying personality.
- 57-2** Explain how humanistic psychologists assessed a person's sense of self.
- 57-3** Describe how humanistic theories have influenced psychology, and discuss the criticisms they have faced.

- 57-1** How did humanistic psychologists view personality, and what was their goal in studying personality?

By the 1960s, some personality psychologists had become discontented with the sometimes bleak focus on drives and conflicts in psychodynamic theory and the mechanistic psychology of B. F. Skinner's behaviorism (see Modules 27 and 28). In contrast to Freud's study of the base motives of "sick" people, these **humanistic theorists** focused on the ways people strive for self-determination and self-realization. In contrast to behaviorism's scientific objectivity, they studied people through their own self-reported experiences and feelings.

Two pioneering theorists—Abraham Maslow (1908–1970) and Carl Rogers (1902–1987)—offered a "third-force" perspective that emphasized human potential. Like *psychoanalytic theory*, the humanistic theories have been an important part of psychology's history.

humanistic theories view personality with a focus on the potential for healthy personal growth.

self-actualization according to Maslow, one of the ultimate psychological needs that arises after basic physical and psychological needs are met and self-esteem is achieved; the motivation to fulfill one's potential.

Abraham Maslow's Self-Actualizing Person

Maslow proposed that we are motivated by a *hierarchy of needs* (Module 37). If our physiological needs are met, we become concerned with personal safety; if we achieve a sense of security, we then seek to love, to be loved, and to love ourselves; with our love needs satisfied, we seek self-esteem. Having achieved self-esteem, we ultimately seek **self-actualization** (the process of fulfilling our potential) and *self-transcendence* (meaning, purpose, and communion beyond the self).

Maslow (1970) developed his ideas by studying healthy, creative people rather than troubled clinical cases. He based his description of self-actualization on a study of those, such as Abraham Lincoln, who seemed notable for their rich and productive lives. Maslow reported that such people shared certain characteristics: They were self-aware and self-accepting, open and spontaneous, loving and caring, and not paralyzed by others' opinions. Secure in their sense of who they were, their interests were problem-centered rather than self-centered. They focused their energies on a particular task, one they often regarded as their mission in life.

Abraham Maslow (1908–1970)
 "Any theory of motivation that is worthy of attention must deal with the highest capacities of the healthy and strong person as well as with the defensive maneuvers of crippled spirits" (*Motivation and Personality*, 1970, p. 33).

Most enjoyed a few deep relationships rather than many superficial ones. Many had been moved by spiritual or personal *peak experiences* that surpassed ordinary consciousness.

These, said Maslow, are mature adult qualities, ones found in those who have learned enough about life to be compassionate, to have outgrown their mixed feelings toward their parents, to have found their calling, to have “acquired enough courage to be unpopular, to be unashamed about being openly virtuous, etc.” Maslow’s work with college students led him to speculate that those likely to become self-actualizing adults were likable, caring, “privately affectionate to those of their elders who deserve it,” and “secretly uneasy about the cruelty, meanness, and mob spirit so often found in young people.”

Carl Rogers’ Person-Centered Perspective

Fellow humanistic psychologist Carl Rogers agreed with much of Maslow’s thinking. Rogers believed that people are basically good and are endowed with self-actualizing tendencies. Unless thwarted by an environment that inhibits growth, each of us is like an acorn, primed for growth and fulfillment. Rogers’ (1980) *person-centered perspective* (also called *client-centered perspective*) held that a growth-promoting climate required three conditions.

- *Genuineness*: When people are *genuine*, they are open with their own feelings, drop their facades, and are transparent and self-disclosing.
- *Acceptance*: When people are *accepting*, they offer **unconditional positive regard**, an attitude of grace that values us even knowing our failings. It is a profound relief to drop our pretenses, confess our worst feelings, and discover that we are still accepted. In a good marriage, a close family, or an intimate friendship, we are free to be spontaneous without fearing the loss of others’ esteem.
- *Empathy*: When people are *empathic*, they share and mirror other’s feelings and reflect their meanings. “Rarely do we listen with real understanding, true empathy,” said Rogers. “Yet listening, of this very special kind, is one of the most potent forces for change that I know.”

Genuineness, acceptance, and empathy are, Rogers believed, the water, sun, and nutrients that enable people to grow like vigorous oak trees. For “as persons are accepted and prized, they tend to develop a more caring attitude toward themselves” (Rogers, 1980, p. 116). As persons are empathically heard, “it becomes possible for them to listen more accurately to the flow of inner experiencings.”

Writer Calvin Trillin (2006) recalls an example of parental genuineness and acceptance at a camp for children with severe disorders, where his wife, Alice, worked. L., a “magical child,” had genetic diseases that meant she had to be tube-fed and could walk only with difficulty. Alice recalled,

One day, when we were playing duck-duck-goose, I was sitting behind her and she asked me to hold her mail for her while she took her turn to be chased around the circle. It took her a while to make the circuit, and I had time to see that on top of the pile [of mail] was a note from her mom. Then I did something truly awful. . . . I simply had to know what this child’s parents could have done to make her so spectacular, to make her the most optimistic, most enthusiastic, most hopeful human being I had ever encountered. I snuck a quick look at the note, and my eyes fell on this sentence: “If God had given us all of the children in the world to choose from, L., we would only have chosen you.” Before L. got back to her place in the circle, I showed the note to Bud, who was sitting next to me. “Quick. Read this,” I whispered. “It’s the secret of life.”

Maslow and Rogers would have smiled knowingly. For them a central feature of personality is one’s **self-concept**—all the thoughts and feelings we have in response to the question, “Who am I?” If our self-concept is positive, we tend to act and perceive the world

unconditional positive regard according to Rogers, an attitude of total acceptance toward another person.

self-concept all our thoughts and feelings about ourselves, in answer to the question, “Who am I?”

A father *not* offering unconditional positive regard:

“Just remember, son, it doesn’t matter whether you win or lose—unless you want Daddy’s love.”

positively. If it is negative—if in our own eyes we fall far short of our *ideal self*—said Rogers, we feel dissatisfied and unhappy. A worthwhile goal for therapists, parents, teachers, and friends is therefore, he said, to help others know, accept, and be true to themselves.

Assessing the Self

57-2 How did humanistic psychologists assess a person's sense of self?

Humanistic psychologists sometimes assessed personality by asking people to fill out questionnaires that would evaluate their self-concept. One questionnaire, inspired by Carl Rogers, asked people to describe themselves both as they would *ideally* like to be and as they *actually* are. When the ideal and the actual self are nearly alike, said Rogers, the self-concept is positive. Assessing his clients' personal growth during therapy, he looked for successively closer ratings of actual and ideal selves.

Some humanistic psychologists believed that any standardized assessment of personality, even a questionnaire, is depersonalizing. Rather than forcing the person to respond to narrow categories, these humanistic psychologists presumed that interviews and intimate conversation would provide a better understanding of each person's unique experiences.

Evaluating Humanistic Theories

57-3 How have humanistic theories influenced psychology? What criticisms have they faced?

One thing said of Freud can also be said of the humanistic psychologists: Their impact has been pervasive. Maslow's and Rogers' ideas have influenced counseling, education, child raising, and management.

They have also influenced—sometimes in ways they did not intend—much of today's popular psychology. Is a positive self-concept the key to happiness and success? Do acceptance and empathy nurture positive feelings about oneself? Are people basically good and capable of self-improvement? Many people answer *Yes, Yes, and Yes*. Responding to a 1992 *Newsweek* Gallup poll, 9 in 10 people rated self-esteem as very important for “motivating a person to work hard and succeed.” Given a choice, today's North American collegians say they'd rather get a self-esteem boost, such as a compliment or good grade on a paper, than enjoy a favorite food (Bushman et al., 2011). Humanistic psychology's message has been heard.

The prominence of the humanistic perspective set off a backlash of criticism. First, said the critics, its concepts are vague and *subjective*. Consider Maslow's description of self-actualizing people as open, spontaneous, loving, self-accepting, and productive. Is this a scientific description? Isn't it merely a description of the theorist's own values and ideals? Maslow, noted M. Brewster Smith (1978), offered impressions of his own personal heroes. Imagine another theorist who began with a different set of heroes—perhaps Napoleon, John D. Rockefeller, Sr., and Margaret Thatcher. This theorist would likely describe self-actualizing people as “undeterred by others' needs and opinions,” “motivated to achieve,” and “comfortable with power.”

Critics also objected to the idea that, as Rogers put it, “The only question which matters is, ‘Am I living in a way which is deeply satisfying to me, and which truly expresses me?’” (quoted by Wallach & Wallach, 1985). The *individualism* encouraged by humanistic psychology—trusting and acting on one's feelings, being true to oneself, fulfilling oneself—can, the critics have said, lead to self-indulgence, selfishness, and an erosion of moral restraints (Campbell & Specht, 1985; Wallach & Wallach, 1983). Indeed, it is those who focus beyond themselves who are most likely to experience social support, to enjoy life, and to cope effectively with stress (Crandall, 1984).

AP® Exam Tip

Frequently, terms that begin with “self-” (like *self-actualization* or *self-concept*) are terms that are grounded in the humanistic perspective.

© The New Yorker Collection, 1979, Dana Fradon from cartoonbank.com. All Rights Reserved.

"We do pretty well when you stop to think that people are basically good."

Humanistic psychologists reply that a secure, nondefensive self-acceptance is actually the first step toward loving others. Indeed, people who feel intrinsically liked and accepted—for who they are, not just for their achievements—exhibit less-defensive attitudes (Schimmel et al., 2001).

A final accusation leveled against humanistic psychology is that it is *naïve*, that it fails to appreciate the reality of our human capacity for evil. Faced with climate change, overpopulation, terrorism, and the spread of nuclear weapons, we may become apathetic from either of two rationalizations. One is a starry-eyed optimism that denies the threat ("People are basically good; everything will work out"). The other is a dark despair ("It's hopeless; why try?"). Action requires enough realism to fuel concern and enough optimism to provide hope. Humanistic psychology, say the critics, encourages the needed hope but not the equally necessary realism about evil.

Before You Move On

▶ ASK YOURSELF

Have you had someone in your life who accepted you unconditionally? Do you think this person helped you to know yourself better and to develop a better image of yourself?

▶ TEST YOURSELF

What does it mean to be "empathic"? To be "self-actualized"?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 57 Review

57-1

How did humanistic psychologists view personality, and what was their goal in studying personality?

- The *humanistic* psychologists' view of personality focused on the potential for healthy personal growth and people's striving for self-determination and self-realization.
- Abraham Maslow proposed that human motivations form a hierarchy of needs; if basic needs are fulfilled, people will strive toward *self-actualization* and self-transcendence.
- Carl Rogers' person-centered perspective suggested that the ingredients of a growth-promoting environment are genuineness, acceptance (including *unconditional positive regard*), and empathy.
- The *self-concept* was a central feature of personality for both Maslow and Rogers.

57-2

How did humanistic psychologists assess a person's sense of self?

- Some rejected any standardized assessments and relied on interviews and conversations.
- Rogers sometimes used questionnaires in which people described their ideal and actual selves, which he later used to judge progress during therapy.

57-3

How have humanistic theories influenced psychology? What criticisms have they faced?

- Humanistic psychology helped renew interest in the concept of self.
- Critics have said that humanistic psychology's concepts were vague and subjective, its values self-centered, and its assumptions naively optimistic.

Multiple-Choice Questions

- Which of the following theories offers a special focus on the potential for healthy personal growth?
 - Neo-Freudian
 - Psychodynamic
 - Humanistic
 - Behavioral
 - Functionalist
- What do we call the process of fulfilling our potential?
 - Free association
 - Self-transcendence
 - Unconditional positive regard
 - Self-concept
 - Self-actualization
- Humanistic psychologists often prefer to assess personality by
 - having a person write out answers to questions.
 - sitting down and talking to a person.
 - getting a person to describe what he or she sees in ambiguous inkblots.
 - having a person describe their dreams.
 - putting a person in a stressful situation to see how he or she behaves under pressure.
- Which of the following is an example of unconditional positive regard?
 - Mr. and Mrs. Prohaska, who have been married for 37 years, credit the success of their marriage to the fact that each has been able to accept the faults of the other without criticism.
 - Seven-year-old Michaela gets her allowance each week whether she does her chores or not.
 - Ms. Lopez, a second grade teacher, puts a smiley face sticker on her students' papers when they have done a good job.
 - John got a promotion and a raise at work after filling in for a sick manager one day and doing a better job than the manager had done previously.
 - Chen's parents usually praise him when he does well and ignore him when he engages in minor misbehavior.

Practice FRQs

- Describe the three conditions that Carl Rogers believed were necessary for a growth-promoting climate.
- Describe three criticisms that have been made of humanistic psychology.

(3 points)

Answer

1 point: Genuineness, where people are open with their feelings.

1 point: Acceptance, which includes unconditional positive regard, where people are accepted despite their faults and failures.

1 point: Empathy, where the therapist shares and mirrors the feelings of others.

Module 58

Trait Theories

Module Learning Objectives

- 58-1** Explain how psychologists use traits to describe personality.
- 58-2** Describe personality inventories, and discuss their strengths and weaknesses as trait-assessment tools.
- 58-3** Identify the traits that seem to provide the most useful information about personality variation.
- 58-4** Discuss whether research supports the consistency of personality traits over time and across situations.

58-1 How do psychologists use traits to describe personality?

Rather than focusing on unconscious forces and thwarted growth opportunities, some researchers attempt to define personality in terms of stable and enduring behavior patterns, such as Sam Gamgee's loyalty and optimism. This perspective can be traced in part to a remarkable meeting in 1919, when Gordon Allport, a curious 22-year-old psychology student, interviewed Sigmund Freud in Vienna. Allport soon discovered just how preoccupied the founder of psychoanalysis was with finding hidden motives, even in Allport's own behavior during the interview. That experience ultimately led Allport to do what Freud did not do—to describe personality in terms of fundamental **traits**—people's characteristic behaviors and conscious motives (such as the curiosity that actually motivated Allport to see Freud). Meeting Freud, said Allport, "taught me that [psychoanalysis], for all its merits, may plunge too deep, and that psychologists would do well to give full recognition to manifest motives before probing the unconscious." Allport came to define personality in terms of identifiable behavior patterns. He was concerned less with *explaining* individual traits than with *describing* them.

Like Allport, Isabel Briggs Myers (1987) and her mother, Katharine Briggs, wanted to describe important personality differences. They attempted to sort people according to Carl Jung's personality types, based on their responses to 126 questions. The *Myers-Briggs Type Indicator (MBTI)*, available in 21 languages, has been taken by more than 2 million people a year, mostly for counseling, leadership training, and work-team development (CPP, 2008). It offers choices, such as "Do you usually value sentiment more than logic, or value logic more than sentiment?" Then it counts the test-taker's preferences, labels them as indicating, say, a "feeling type" or "thinking type," and feeds them back to the person in complimentary terms. Feeling types, for example, are told they are sensitive to values and are "sympathetic, appreciative, and tactful"; thinking types are told they "prefer an objective standard of truth" and are "good at analyzing." (Every type has its strengths, so everyone is affirmed.)

Most people agree with their announced type profile, which mirrors their declared preferences. They may also accept their label as a basis for being matched with work partners

trait a characteristic pattern of behavior or a disposition to feel and act, as assessed by self-report inventories and peer reports.

and tasks that supposedly suit their temperaments. A National Research Council report noted, however, that despite the test's popularity in business and career counseling, its initial use outran research on its value as a predictor of job performance, and "the popularity of this instrument in the absence of proven scientific worth is troublesome" (Druckman & Bjork, 1991, p. 101; see also Pittenger, 1993). Although research on the MBTI has been accumulating since those cautionary words were expressed, the test remains mostly a counseling and coaching tool, not a research instrument.

Exploring Traits

Classifying people as one or another distinct personality type fails to capture their full individuality. We are each a unique complex of multiple traits. So how else could we describe our personalities? We might describe an apple by placing it along several trait dimensions—relatively large or small, red or green, sweet or sour. By placing people on several trait dimensions simultaneously, psychologists can describe countless individual personality variations. (Remember from Module 18 that variations on just three color dimensions—hue, saturation, and brightness—create many thousands of colors.)

What trait dimensions describe personality? If you had an upcoming blind date, what personality traits might give you an accurate sense of the person? Allport and his associate H. S. Odbert (1936) counted all the words in an unabridged dictionary with which one could describe people. There were almost 18,000! How, then, could psychologists condense the list to a manageable number of basic traits?

Factor Analysis

One technique is *factor analysis*, a statistical procedure used to identify clusters of test items that tap basic components of intelligence (such as spatial ability or verbal skill). Imagine that people who describe themselves as outgoing also tend to say that they like excitement and practical jokes and dislike quiet reading. Such a statistically correlated cluster of behaviors reflects a basic factor, or trait—in this case, *extraversion*.

British psychologists Hans Eysenck and Sybil Eysenck [EYE-zink] believed that we can reduce many of our normal individual variations to two or three dimensions, including *extraversion–introversion* and *emotional stability–instability* (**FIGURE 58.1**). People in 35 countries around the world, from China to Uganda to Russia, have taken the *Eysenck Personality Questionnaire*. When their answers were analyzed, the extraversion and emotionality factors inevitably emerged as basic personality dimensions (Eysenck, 1990, 1992). The Eysencks believed that these factors are genetically influenced, and research supports this belief.

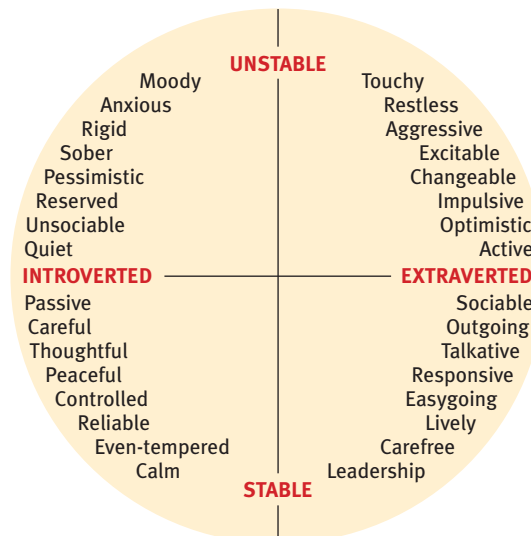

Ida Mae Astute/ABC via Getty Images

Stephen Colbert: The extravert
Trait labels such as *extraversion* can describe our temperament and typical behaviors.

Figure 58.1
Two personality dimensions
Map makers can tell us a lot by using two axes (north–south and east–west). Two primary personality factors (extraversion–introversion and stability–instability) are similarly useful as axes for describing personality variation. Varying combinations define other, more specific traits. (From Eysenck & Eysenck, 1963.) Those who are naturally introverted, such as primatologist Jane Goodall, may be particularly gifted in field studies. Successful entertainers, including recording artist Katy Perry, are often natural extraverts.

AP® Exam Tip

You are not likely to be asked questions about the specific traits in Figure 58.1. Focus instead on the two main dimensions (extraversion–introversion and stability–instability), and use the traits to get a sense of what the main dimensions mean. For example, stable people demonstrate leadership, and they are calm, even-tempered, and carefree.

personality inventory

a questionnaire (often with *true-false* or *agree-disagree* items) on which people respond to items designed to gauge a wide range of feelings and behaviors; used to assess selected personality traits.

Minnesota Multiphasic Personality Inventory (MMPI)

the most widely researched and clinically used of all personality tests. Originally developed to identify emotional disorders (still considered its most appropriate use), this test is now used for many other screening purposes.

empirically derived test a test (such as the MMPI) developed by testing a pool of items and then selecting those that discriminate between groups.

AP® Exam Tip

This is the third time you've encountered the idea of assessing personality. As with the psychodynamic and humanistic theories, psychologists working from the trait perspective have also tried to establish their own unique ways of measuring personality—in this instance by measuring our traits. There are scientifically sound *personality inventories* in use in psychological research, but beware of the hundreds of self-assessments available online that are neither reliable nor valid.

Biology and Personality

Brain-activity scans of extraverts add to the growing list of traits and mental states that have been explored with brain-imaging procedures. (That list includes intelligence, impulsivity, addictive cravings, lying, sexual attraction, aggressiveness, empathy, spiritual experience, and even racial and political attitudes [Olson, 2005].) Such studies indicate that extraverts seek stimulation because their normal *brain arousal* is relatively low. For example, PET scans show that a frontal lobe area involved in behavior inhibition is less active in extraverts than in introverts (Johnson et al., 1999). Dopamine and dopamine-related neural activity tend to be higher in extraverts (Wacker et al., 2006).

Our biology influences our personality in other ways as well. As you may recall from the twin and adoption studies in Module 14, our *genes* have much to say about the behavioral style that helps define our personality. Jerome Kagan, for example, has attributed differences in children's shyness and inhibition to their *autonomic nervous system reactivity*. Given a reactive autonomic nervous system, we respond to stress with greater anxiety and inhibition. The fearless, curious child may become the rock-climbing or fast-driving adult.

Other researchers report that personality differences among dogs (in energy, affection, reactivity, and curious intelligence) are as evident, and as consistently judged, as personality differences among humans (Gosling et al., 2003; Jones & Gosling, 2005). Monkeys, chimpanzees, orangutans, and even birds also have stable personalities (Weiss et al., 2006). Among the Great Tit (a European relative of the American chickadee), bold birds more quickly inspect new objects and explore trees (Groothuis & Carere, 2005; Verbeek et al., 1994). By selective breeding, researchers can produce bold or shy birds. Both have their place in natural history. In lean years, bold birds are more likely to find food; in abundant years, shy birds feed with less risk.

Erik Lam/Shutterstock

Assessing Traits**58-2**

What are personality inventories, and what are their strengths and weaknesses as trait-assessment tools?

If stable and enduring traits guide our actions, can we devise valid and reliable tests of them? Several trait assessment techniques exist—some more valid than others (see Thinking Critically About: How to Be a “Successful” Astrologer or Palm Reader). Some provide quick assessments of a single trait, such as extraversion, anxiety, or self-esteem. **Personality inventories**—longer questionnaires covering a wide range of feelings and behaviors—assess several traits at once.

The classic personality inventory is the **Minnesota Multiphasic Personality Inventory (MMPI)**. Although it assesses “abnormal” personality tendencies rather than normal personality traits, the MMPI illustrates a good way of developing a personality inventory. One of its creators, Starke Hathaway (1960), compared his effort with that of Alfred Binet. Binet, as you will see in Module 61, developed the first intelligence test by selecting items that identified children who would probably have trouble progressing normally in French schools. Like Binet's items, the MMPI items were **empirically derived**. From a large pool of items, Hathaway and his colleagues selected those on which particular diagnostic groups differed. They then grouped the questions into 10 clinical scales, including scales that assess depressive tendencies, masculinity–femininity, and introversion–extraversion.

Hathaway and others initially gave hundreds of true-false statements (“No one seems to understand me”; “I get all the sympathy I should”; “I like poetry”) to groups of psychologically disordered patients and to “normal” people. They retained any statement—no matter how silly it sounded—on which the patient group's answer differed from that of the normal group. “Nothing in the newspaper interests me except the comics” may seem senseless, but it just so happened that depressed people were more likely to answer *True*.

Thinking Critically About

How to Be a “Successful” Astrologer or Palm Reader

“A petite fortune-teller who escapes from prison is a small medium at large.” -ANONYMOUS

Can we discern people's traits from the alignment of the stars and planets at the time of their birth? From their handwriting? From lines on their palms?

Astronomers scoff at the naiveté of astrology—the constellations have shifted in the millennia since astrologers formulated their predictions (Kelly, 1997, 1998). Humorists mock it: “No offense,” writes Dave Barry, “but if you take the horoscope seriously your frontal lobes are the size of Raisinets.” Psychologists instead ask questions: Does it work? Can astrologers surpass chance when given someone's birth date and asked to identify the person from a short lineup of different personality descriptions? Can people pick out their own horoscopes from a lineup of horoscopes? Do people's astrological signs correlate with predicted traits?

The consistent answers have been *No, No, No, and No* (British Psychological Society, 1993; Carlson, 1985; Kelly, 1997; Reichardt, 2010). For example, one researcher examined census data from 20 million married people in England and Wales and found that “astrological sign has no impact on the probability of marrying—and staying married to—someone of any other sign” (Voas, 2008).

Graphologists, who make predictions from handwriting samples, have similarly been found to do no better than chance when trying to discern people's occupations from examining several pages of their handwriting (Beyerstein & Beyerstein, 1992; Dean et al., 1992). Nevertheless, graphologists—and introductory psychology students—will often perceive correlations between personality and handwriting even where there are none (King & Koehler, 2000).

If all these perceived correlations evaporate under close scrutiny, how do astrologers, palm readers, and crystal-ball gazers persuade millions of people worldwide to buy their services? Ray Hyman (1981), palm reader turned research psychologist, has revealed some of their suckering methods.

The first technique, the “stock spiel,” builds on the observation that each of us is in some ways like no one else and in other ways just like everyone. That some things are true of us all enables the “seer” to offer statements that seem impressively accurate: “I sense that you worry about things more than you let on, even to your best friends.” A number of such generally true statements can be combined into a personality description. Imagine that you take a personality test and then receive the following character sketch:

You have a strong need for other people to like and to admire you. You have a tendency to be critical of yourself. . . . You pride yourself on being an independent thinker and do not accept other opinions without satisfactory proof. You have found it unwise to be too frank in revealing yourself to others. At times you are extraverted, affable, sociable; at other times you are introverted, wary, and reserved. Some of your aspirations tend to be pretty unrealistic (Davies, 1997; Forer, 1949).

In experiments, college students have received stock assessments like this one, drawn from statements in a newsstand astrology book. When they thought the bogus, generic feedback was prepared just for them and when it was favorable, they nearly always rated the description as either “good” or “excellent” (Davies, 1997). Even skeptics, given a flattering description attributed to an astrologer, begin to think that “maybe there's something to this astrology stuff after all” (Glick et al., 1989). An astrologer, it has been said, is someone “prepared to tell you what you think of yourself” (Jones, 2000). This acceptance of stock, positive descriptions is called the *Barnum effect*, named in honor of master showman P. T. Barnum's dictum, “We've got something for everyone.”

A second technique used by seers is to “read” our clothing, physical features, gestures, and reactions. An expensive wedding ring and black dress might, for example, suggest a wealthy woman who was recently widowed.

(continued)

Thinking Critically About *(continued)*

You, too, could read such clues, says Hyman. If people seek you out for a reading, start with some safe sympathy: “I sense you’re having some problems lately. You seem unsure what to do. I get the feeling another person is involved.” Then tell them what they want to hear. Memorize some Barnum statements from astrology and fortune-telling manuals and use them liberally. Tell people it is their responsibility to cooperate by relating your message to their specific experiences. Later they will recall that you predicted those specific details. Phrase statements as questions, and when you detect a positive response assert the statement strongly. Finally, be a good listener, and later, in different words, reveal to people what they earlier revealed to you. If you dupe them, they will come.

Better yet, beware of those who, by exploiting people with these techniques, are fortune takers rather than fortune tellers.

“Perhaps you’d like a second opinion?”

© The New Yorker Collection, 2010, Mick Stevens from cartoonbank.com. All Rights Reserved.

(Nevertheless, people have had fun spoofing the MMPI with their own mock items: “Weeping brings tears to my eyes,” “Frantic screams make me nervous,” and “I stay in the bathtub until I look like a raisin” [Frankel et al., 1983].) Today’s MMPI-2 also has scales assessing, for instance, work attitudes, family problems, and anger.

In contrast to the subjectivity of most projective tests, personality inventories are scored objectively—so objectively that a computer can administer and score them. (The computer can also provide descriptions of people who previously responded similarly.) Objectivity does not, however, guarantee validity. For example, individuals taking the MMPI for employment purposes can give socially desirable answers to create a good impression. But in so doing they may also score high on a *lie scale* that assesses faking (as when people respond *false* to a universally true statement such as “I get angry sometimes”). The objectivity of the MMPI has contributed to its popularity and to its translation into more than 100 languages.

The Big Five Factors

58-3 Which traits seem to provide the most useful information about personality variation?

Today’s trait researchers believe that simple trait factors, such as the Eysencks’ introverted–extraverted and unstable–stable dimensions, are important, but they do not tell the whole story. A slightly expanded set of factors—dubbed the *Big Five*—does a better job (Costa & McCrae, 2009). Work by Paul Costa, Robert McCrae, and others shows that where we fall on these five dimensions (conscientiousness, agreeableness, neuroticism, openness, and extraversion; see **TABLE 58.1**), reveals much of what there is to say about our personality. Around the world—across 56 nations and 29 languages in one study (Schmitt et al., 2007)—people describe others in terms roughly consistent with this list. The Big Five may not be the last word. (Some researchers report it takes only two or three factors—such as conscientiousness, agreeableness, and extraversion—to describe the basic personality dimensions [Block, 2010; De Raad et al., 2010].) But for now, at least, five is the winning number in the personality lottery (Heine & Buchtel, 2009; McCrae, 2009). The Big Five—today’s “common currency for personality psychology” (Funder, 2001)—has been the most active personality research topic since the early 1990s and is currently our best approximation of the basic trait dimensions.

Table 58.1 The “Big Five” Personality Factors*(Memory tip: Picturing a CANOE will help you recall these.)*

Disorganized Careless Impulsive	← Conscientiousness →	Organized Careful Disciplined
Ruthless Suspicious Uncooperative	← Agreeableness →	Soft-hearted Trusting Helpful
Calm Secure Self-satisfied	← Neuroticism (emotional stability vs. instability) →	Anxious Insecure Self-pitying
Practical Prefers routine Conforming	← Openness →	Imaginative Prefers variety Independent
Retiring Sober Reserved	← Extraversion →	Sociable Fun-loving Affectionate

Source: Adapted from McCrae & Costa (1986, 2008). Steve Wisbauer/Getty Images

Big Five research has explored various questions:

- **How stable are these traits?** In adulthood, the Big Five traits are quite stable, with some tendencies (emotional instability, extraversion, and openness) waning a bit during early and middle adulthood, and others (agreeableness and conscientiousness) rising (McCrae, 2011; Vaidya et al., 2002). Conscientiousness increases the most during people’s twenties, as people mature and learn to manage their jobs and relationships. Agreeableness increases the most during people’s thirties and continues to increase through their sixties (Srivastava et al., 2003).
- **How heritable are they?** Heritability (the extent to which individual differences are attributable to genes) varies with the diversity of people studied, but it generally runs 50 percent or a tad more for each dimension, and genetic influences are similar in different nations (Loehlin et al., 1998; Yamagata et al., 2006). Many genes, each having small effects, combine to influence our traits (McCrae et al., 2010). Researchers have also identified brain areas associated with the various Big Five traits, such as a frontal lobe area that is sensitive to reward and is larger in extraverts (DeYoung et al., 2010).
- **Do the Big Five traits predict our actual behaviors?** *Yes.* If people report being outgoing, conscientious, and agreeable, “they probably are telling the truth,” reports Big Five researcher Robert McCrae (2011). Here are some examples:
 - Shy introverts are more likely than extraverts to prefer communicating by e-mail rather than face-to-face (Hertel et al., 2008).
 - Highly conscientious people earn better high school and university grades (Poropat, 2009). They also are more likely to be morning types (sometimes called “larks”); evening types (“owls”) are marginally more extraverted (Jackson & Gerard, 1996).
 - If one partner scores lower than the other on agreeableness, stability, and openness, marital and sexual satisfaction may suffer (Botwin et al., 1997; Donnellan et al., 2004).

AP® Exam Tip

Table 58.1 is an excellent summary of the Big Five personality factors and what they mean.

- Our traits infuse our language. In text messaging, extraversion predicts use of personal pronouns, agreeableness predicts positive-emotion words, and neuroticism (emotional instability) predicts negative-emotion words (Holtgraves, 2011).

By exploring such questions, Big Five research has sustained trait psychology and renewed appreciation for the importance of personality. Traits matter.

Evaluating Trait Theories

58-4 Does research support the consistency of personality traits over time and across situations?

Are our personality traits stable and enduring? Or does our behavior depend on where and with whom we find ourselves? J.R.R. Tolkien created characters, like the loyal Sam Gamgee, whose personality traits were consistent across various times and places. The Italian playwright Luigi Pirandello had a different view. For him, personality was ever-changing, tailored to the particular role or situation. In one of Pirandello's plays, Lamberto Laudisi describes himself: "I am really what you take me to be; though, my dear madam, that does not prevent me from also being really what your husband, my sister, my niece, and Signora Cini take me to be—because they also are absolutely right!" To which Signora Sirelli responds, "In other words you are a different person for each of us."

"There is as much difference between us and ourselves, as between us and others." - MICHEL DE MONTAIGNE, *ESSAYS*, 1588

FYI

Roughly speaking, the temporary, external influences on behavior are the focus of social psychology, and the enduring, inner influences are the focus of personality psychology. In actuality, behavior always depends on the interaction of persons with situations.

The Person-Situation Controversy

Who, then, typifies human personality, Tolkien's consistent Sam Gamgee or Pirandello's inconsistent Laudisi? Both. Our behavior is influenced by the interaction of our inner disposition with our environment. Still, the question lingers: Which is more important? Are we *more* as Tolkien or as Pirandello imagined us to be?

When we explore this *person-situation controversy*, we look for genuine personality traits that persist over time *and* across situations. Are some people dependably conscientious and others unreliable, some cheerful and others dour, some friendly and outgoing and others shy? If we are to consider friendliness a trait, friendly people must act friendly at different times and places. Do they?

In earlier chapters, we considered research that has followed lives through time. We noted that some scholars (especially those who study infants) are impressed with personality change; others are struck by personality stability during adulthood. As **FIGURE 58.2** illustrates, data from 152 long-term studies reveal that personality trait scores are positively correlated with scores obtained seven years later, and that as people grow older their personality stabilizes. Interests may change—the avid collector of tropical fish may become an avid gardener. Careers may change—the determined salesperson may become a determined social worker. Relationships may change—the hostile spouse may start over with a

Figure 58.2

Personality stability With age, personality traits become more stable, as reflected in the stronger correlation of trait scores with follow-up scores seven years later. (Data from Roberts & DelVecchio, 2000.)

new partner. But most people recognize their traits as their own, note Robert McCrae and Paul Costa (1994), “and it is well that they do. A person’s recognition of the inevitability of his or her one and only personality is . . . the culminating wisdom of a lifetime.”

So most people—including most psychologists—would probably side with Tolkien’s assumption of stability of personality traits. Moreover, our traits are socially significant. They influence our health, our thinking, and our job performance (Deary & Matthews, 1993; Hogan, 1998). Studies that follow lives through time show that personality traits rival socioeconomic status and cognitive ability as predictors of mortality, divorce, and occupational attainment (Roberts et al., 2007).

Although our personality *traits* may be both stable and potent, the consistency of our specific *behaviors* from one situation to the next is another matter. As Walter Mischel (1968, 2009) has pointed out, people do not act with predictable consistency. Mischel’s studies of college students’ conscientiousness revealed but a modest relationship between a student’s being conscientious on one occasion (say, showing up for class on time) and being similarly conscientious on another occasion (say, turning in assignments on time). Pirandello would not have been surprised. If you’ve noticed how outgoing you are in some situations and how reserved you are in others, perhaps you’re not surprised either (though for certain traits, Mischel reports, you may accurately assess yourself as more consistent).

This inconsistency in behaviors also makes personality test scores weak predictors of behaviors. People’s scores on an extraversion test, for example, do not neatly predict how sociable they actually will be on any given occasion. If we remember such results, says Mischel, we will be more cautious about labeling and pigeonholing individuals. Years in advance, science can tell us the phase of the Moon for any given date. A day in advance, meteorologists can often predict the weather. But we are much further from being able to predict how *you* will feel and act tomorrow.

However, people’s *average* outgoingness, happiness, or carelessness over many situations is predictable (Epstein, 1983a,b). When rating someone’s shyness or agreeableness, this consistency enables people who know someone well to agree on their ratings (Kenrick & Funder, 1988). By collecting snippets of people’s daily experience via body-worn recording devices, Matthias Mehl and his colleagues (2006) confirmed that extraverts really do talk more. (I have repeatedly vowed to cut back on my jabbering and joking during my noontime pickup basketball games with friends. Alas, moments later, the irrepressible chatterbox inevitably reoccupies my body.) As our best friends can verify, we do have genetically influenced personality traits. And those traits even lurk in our

- *music preferences.* Classical, jazz, blues, and folk music lovers tend to be open to experience and verbally intelligent; country, pop, and religious music lovers tend to be cheerful, outgoing, and conscientious (Rentfrow & Gosling, 2003, 2006). On first meeting, students often disclose their music preferences to one another; in doing so, they are swapping information about their personalities.
- *bedrooms and offices.* Our personal spaces display our identity and leave a behavioral residue (in our scattered laundry or neat desktop). And that helps explain why just a few minutes’ inspection of our living and working spaces can enable someone to assess with reasonable accuracy our conscientiousness, our openness to new experiences, and even our emotional stability (Gosling et al., 2002, 2008).

ICP-UK/Alamy

Room with a cue Even at “zero acquaintance,” people can discern something of others’ personality from glimpsing their website, bedroom, or office.

- *personal websites.* Is a personal website or an online profile also a canvas for self-expression? Or is it an opportunity for people to present themselves in false or misleading ways? It’s more the former (Back et al., 2010; Gosling et al., 2007; Marcus et al., 2006). Visitors to personal websites quickly gain important clues to the creator’s extraversion, conscientiousness, and openness to experience. Even mere pictures of people, and their associated clothes, expressions, and postures, can give clues to personality (Naumann et al., 2009).
- *electronic communication.* If you have ever felt you could detect others’ personality from their writing voice, you are right!! (What a cool, exciting finding!!!) People’s ratings of others’ personalities based solely on their e-mails or blogs correlate with actual personality scores on measures such as extraversion and neuroticism (Gill et al., 2006; Oberlander & Gill, 2006; Yarkoni, 2010). Extraverts, for example, use more adjectives.

In unfamiliar, formal situations—perhaps as a guest in the home of a person from another culture—our traits remain hidden as we carefully attend to social cues. In familiar, informal situations—just hanging out with friends—we feel less constrained, allowing our traits to emerge (Buss, 1989). In these informal situations, our expressive styles—our animation, manner of speaking, and gestures—are impressively consistent. That’s why those very thin slices of someone’s behavior—even just three 2-second clips of a teacher—can be revealing (Ambady & Rosenthal, 1992, 1993).

Some people are naturally expressive (and therefore talented at pantomime and charades); others are less expressive (and therefore better poker players). To evaluate people’s voluntary control over their expressiveness, researchers asked people to *act* as expressive or inhibited as possible while stating opinions (DePaulo et al., 1992). The remarkable findings: Inexpressive people, even when feigning expressiveness, were less expressive than expressive people acting naturally. Similarly, expressive people, even when trying to seem inhibited, were less inhibited than inexpressive people acting naturally. It’s hard to be someone you’re not, or not to be who you are.

To sum up, we can say that at any moment the immediate situation powerfully influences a person’s behavior. Social psychologists have assumed, albeit without much evidence, that this is especially so when a “strong situation” makes clear demands (Cooper & Withey, 2009). We can better predict drivers’ behavior at traffic lights from knowing the color of the lights than from knowing the drivers’ personalities. Thus, professors may perceive certain students as subdued (based on their classroom behavior), but friends may perceive them as pretty wild (based on their party behavior). Averaging our behavior across many occasions does, however, reveal distinct personality traits. Traits exist. We differ. And our differences matter.

Before You Move On

▶ ASK YOURSELF

Where would you place yourself on the five personality dimensions—conscientiousness, agreeableness, neuroticism (emotional stability versus instability), openness, and extraversion? Where might your family and friends place you?

▶ TEST YOURSELF

What is the person-situation controversy?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Module 58 Review

58-1 How do psychologists use traits to describe personality?

- *Trait* theorists see personality as a stable and enduring pattern of behavior. They describe our differences rather than trying to explain them.
- Using factor analysis, they identify clusters of behavior tendencies that occur together. Genetic predispositions influence many traits.

58-2 What are personality inventories, and what are their strengths and weaknesses as trait-assessment tools?

- *Personality inventories* (such as the *MMPI*) are questionnaires on which people respond to items designed to gauge a wide range of feelings and behaviors.
- Test items are *empirically derived*, and the tests are objectively scored. But people can fake their answers to create a good impression, and the ease of computerized testing may lead to misuse of the tests.

58-3 Which traits seem to provide the most useful information about personality variation?

- The Big Five personality factors—conscientiousness, agreeableness, neuroticism, openness, and extraversion (CANOE)—currently offer the clearest picture of personality. These factors are stable and appear to be found in all cultures.

58-4 Does research support the consistency of personality traits over time and across situations?

- A person's average traits persist over time and are predictable over many different situations. But traits cannot predict behavior in any one particular situation.

Multiple-Choice Questions

1. Which of the following is the best term or phrase for a characteristic pattern of behavior or a disposition to feel and act?
 - a. Myers-Briggs Indicator
 - b. Factor analysis
 - c. Introversion
 - d. Extroversion
 - e. Trait
2. Which of the following is a "Big Five" personality factor?
 - a. Seriousness
 - b. Neuroticism
 - c. Dutifulness
 - d. Dominance
 - e. Abstractedness
3. Which of the following is best described along a continuum ranging from ruthless and suspicious to helpful and trusting?
 - a. Conscientiousness
 - b. Agreeableness
 - c. Openness
 - d. Extraversion
 - e. Perfectionism
4. Which of the following is true based on "Big Five" personality traits research?
 - a. Highly conscientious people are likely to be evening people or "owls."
 - b. Highly conscientious people get poor grades.
 - c. Married partners scoring the same on agreeableness are more likely to experience marital dissatisfaction.
 - d. Shy introverts are more likely to prefer communicating through e-mail instead of in person.
 - e. Neuroticism predicts the use of positive-emotion words in text messages.

Practice FRQs

1. Explain one weakness and one strength of the Minnesota Multiphasic Personality Inventory (MMPI).

Answer

1 point: One point for any strength (for example, the MMPI is empirically derived, assesses several traits at once, or is easily scored).

1 point: One point for any weakness (for example, the MMPI test-taker might not answer honestly, or validity is not guaranteed).

2. Explain Hans and Sybil Eysenck's personality dimensions.

(4 points)

Module 59

Social-Cognitive Theories and Exploring the Self

Module Learning Objectives

- 59-1** Identify the psychologist who first proposed the social-cognitive perspective, and describe how social-cognitive theorists view personality development.
- 59-2** Describe how social-cognitive researchers explore behavior, and state the criticism they have faced.
- 59-3** Explain why psychology has generated so much research on the self, and discuss the importance of self-esteem to psychology and to human well-being.
- 59-4** Discuss some evidence for self-serving bias, and contrast defensive and secure self-esteem.
- 59-5** Discuss how individualist and collectivist cultures influence people.

Tim Roberts/Getty Images

Social-Cognitive Theories

- 59-1** Who first proposed the social-cognitive perspective, and how do social-cognitive theorists view personality development?

Today's psychological science views individuals as biopsychosocial organisms. The **social-cognitive perspective** on personality proposed by Albert Bandura (1986, 2006, 2008) emphasizes the interaction of our traits with our situations. Much as nature and nurture always work together, so do individuals and their situations.

Those who take the **behavioral approach** to personality development emphasize the effects of learning. We are conditioned to repeat certain behaviors, and we learn by observing and imitating others. For example, a child with a very controlling parent may learn to follow orders rather than think independently, and may exhibit a more timid personality.

Social-cognitive theorists do consider the behavioral perspective, including others' influence. (That's the "social" part.) However, they also emphasize the importance of mental processes: What we *think* about our situations affects our behavior. (That's the "cognitive" part.) Instead of focusing solely on how our environment *controls* us, as behaviorists do, social-cognitive theorists focus on how we and our environment *interact*: How do we interpret and respond to external events? How do our schemas, our memories, and our expectations influence our behavior patterns?

social-cognitive perspective
views behavior as influenced by the interaction between people's traits (including their thinking) and their social context.

behavioral approach
in personality theory, this perspective focuses on the effects of learning on our personality development.

reciprocal determinism

the interacting influences of behavior, internal cognition, and environment.

Reciprocal Influences

Bandura (1986, 2006) views the person-environment interaction as **reciprocal determinism**. “Behavior, internal personal factors, and environmental influences,” he said, “all operate as interlocking determinants of each other” (**FIGURE 59.1**). For example, children’s TV-viewing habits (past behavior) influence their viewing preferences (internal factor), which influence how television (environmental factor) affects their current behavior. The influences are mutual.

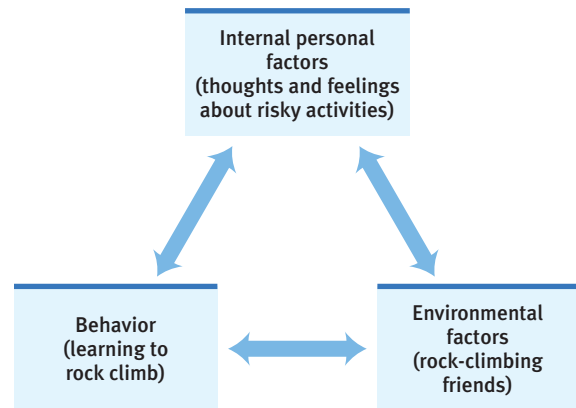

Figure 59.1

Reciprocal determinism

The social-cognitive perspective proposes that our personalities are shaped by the interaction of our personal traits (including our thoughts and feelings), our environment, and our behaviors.

Courtesy of Joslyn Brugh

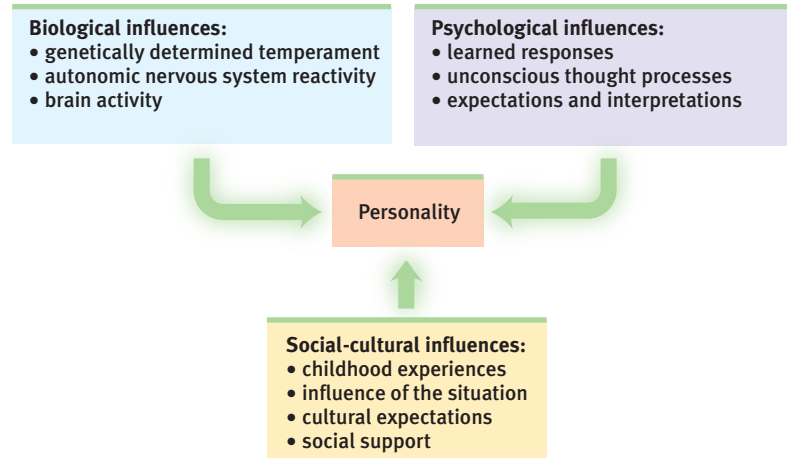

Consider three specific ways in which individuals and environments interact:

1. **Different people choose different environments.** The school you attend, the reading you do, the TV programs you watch, the music you listen to, the friends you associate with—all are part of an environment you participated in choosing, based partly on your dispositions (Funder, 2009; Ickes et al., 1997). You choose your environment and it then shapes you.
2. **Our personalities shape how we interpret and react to events.** Anxious people, for example, are attuned to potentially threatening events (Eysenck et al., 1987). Thus, they perceive the world as threatening, and they react accordingly.
3. **Our personalities help create situations to which we react.** Many experiments reveal that how we view and treat people influences how they in turn treat us. If we expect someone to be angry with us, we may give the person a cold shoulder, touching off the very anger we expect. If we have an easygoing, positive disposition, we will likely enjoy close, supportive friendships (Donnellan et al., 2005; Kendler, 1997).

Figure 59.2

The biopsychosocial approach to the study of personality

As with other psychological phenomena, personality is fruitfully studied at multiple levels.

In such ways, we are both the products and the architects of our environments.

If all this has a familiar ring, it may be because it parallels and reinforces a pervasive theme in psychology and in this book: *Behavior emerges from the interplay of external and internal influences*. Boiling water turns an egg hard and a potato soft. A threatening environment turns one person into a hero, another into a scoundrel. Extraverts enjoy greater well-being in an extraverted culture than an introverted one (Fulmer et al., 2010). *At every moment*, our behavior is influenced by our biology, our social and cultural experiences, and our cognition and dispositions (**FIGURE 59.2**).

Optimism Versus Pessimism

Recall from Module 29 that we learn to cope with life's challenges in various ways. In studying how we interact with our environment, social-cognitive psychologists emphasize our sense of *personal control*—whether we learn to see ourselves as controlling, or as controlled by, our environment. One measure of how helpless or effective you feel is where you stand on optimism-pessimism. How do you characteristically explain negative and positive events? Perhaps you have known students whose *attributional style* is pessimistic—who attribute poor performance to their lack of ability (“I can’t do this”) or to situations enduringly beyond their control (“There is nothing I can do about it”). Such students are more likely to continue getting low grades than are students who adopt the more hopeful attitude that effort, good study habits, and self-discipline can make a difference (Noel et al., 1987; Peterson & Barrett, 1987). Mere fantasies do not fuel motivation and success. Realistic positive expectations do (Oettingen & Mayer, 2002).

Attributional style also matters when dating couples wrestle with conflicts. Optimists and their partners see each other as engaging constructively, and they then tend to feel more supported and satisfied with the resolution and with their relationship (Srivastava et al., 2006). Expect good things from others, and often you will get what you expect. Such studies helped point Martin Seligman toward proposing a more positive psychology (see Close-up: Toward a More Positive Psychology on the next page).

EXCESSIVE OPTIMISM

Positive thinking in the face of adversity can pay dividends, but so, too, can a dash of realism (Schneider, 2001). Realistic anxiety over possible future failures can fuel energetic efforts to avoid the dreaded fate (Goodhart, 1986; Norem, 2001; Showers, 1992). Concerned about failing an upcoming test, students may study thoroughly and outperform their equally able but more confident peers. Asian-American students express somewhat greater pessimism than their European-American counterparts, which Edward Chang (2001) suspects helps explain their often impressive academic achievements. Success requires enough optimism to provide hope and enough pessimism to prevent complacency. We want our airline pilots to be mindful of worst-possible outcomes.

Excessive optimism can blind us to real risks. Neil Weinstein (1980, 1982, 1996) has shown how our natural positive-thinking bias can promote “an unrealistic optimism about future life events.” Most late adolescents see themselves as much less vulnerable than their peers to the HIV virus that causes AIDS (Abrams, 1991). Most college students perceive themselves as less likely than their average classmate to develop drinking problems, drop out of school, have a heart attack by age 40, or go deeply into debt on their high-interest credit cards (Yang et al., 2006). If overconfident of our ability to control an impulse such as the urge to smoke, we are more likely to expose ourselves to temptations—and to fail (Nordgren et al., 2009). Those who optimistically deny the power and effects of smoking or venture into ill-fated relationships remind us that blind optimism can be self-defeating.

People also display illusory optimism about their groups. Throughout a National Football League season, fans of all teams correctly guessed that other teams would win about 50 percent of the games. But they incorrectly guessed, on average (across teams and weeks), that their own team stood about a 2 in 3 chance of winning (Massey et al., 2011). This optimistic and illogical bias persisted despite their team’s experience and monetary incentives for accuracy.

Our natural positive-thinking bias does seem to vanish, however, when we are bracing ourselves for feedback, such as test results (Carroll et al., 2006). (Have you ever noticed that, as a big game nears its end, the outcome seems more in doubt when your team is ahead than when it is behind?) Positive illusions also vanish after a traumatic personal experience—as they did for victims of a catastrophic California earthquake, who had to give up their illusions of being less vulnerable than others to earthquakes (Helweg-Larsen, 1999).

Positive expectations often motivate eventual success.

“We just haven’t been flapping them hard enough.”

Close-up

Toward a More Positive Psychology

During its first century, psychology understandably focused much of its attention on understanding and alleviating negative states. Psychologists have studied abuse and anxiety, depression and disease, prejudice and poverty. Since 1887, articles on selected negative emotions have outnumbered those on positive emotions by 17 to 1.

In ages past, notes American Psychological Association past-president Martin Seligman (2002), times of relative peace and prosperity have enabled cultures to turn their attention from repairing weakness and damage to promoting “the highest qualities of life.” Prosperous fifth-century Athens nurtured philosophy and democracy. Flourishing fifteenth-century Florence nurtured great art. Victorian England, flush with the bounty of the British Empire, nurtured honor, discipline, and duty. In this millennium, Seligman believes, thriving Western cultures have a parallel opportunity to create, as a “humane, scientific monument,” a more **positive psychology**—a psychology concerned not only with weakness and damage but also with strength and virtue. Thanks to his own leadership, the new positive psychology movement has gained strength, with supporters in 77 countries from Croatia to China (IPPA, 2009, 2010; Seligman, 2004, 2011).

Positive psychology shares with humanistic psychology an interest in advancing human fulfillment, but its methodology is scientific. Positive psychology science is exploring

- *positive well-being*—which assesses exercises and interventions aimed at increasing happiness (Schueller, 2010; Sin & Lyubomirsky, 2009),
- *positive health*—which studies how positive emotions enhance and sustain physical well-being (Seligman, 2008; Seligman et al., 2011),
- *positive neuroscience*—which explores the biological foundations of positive emotions, resilience, and social behavior (www.posneuroscience.org), and
- *positive education*—which evaluates educational efforts to increase students’ engagement, resilience, character strengths, optimism, and sense of meaning (Seligman et al., 2009).

“Positive psychology,” say Seligman and colleagues (2005), “is an umbrella term for the study of positive emotions, positive character traits, and enabling institutions.” Taken together, satisfaction with the past, happiness with the present, and optimism about the future define the movement’s first pillar: *positive emotions*. Happiness, Seligman argues, is a by-product of a pleasant, engaged, and meaningful life.

Courtesy of Martin E. P. Seligman

Martin E. P. Seligman “The main purpose of a positive psychology is to measure, understand, and then build the human strengths and the civic virtues.”

Positive psychology is about building not just a pleasant life, says Seligman, but also a good life that engages one’s skills, and a meaningful life that points beyond oneself. Thus, the second pillar, *positive character*, focuses on exploring and enhancing creativity, courage, compassion, integrity, self-control, leadership, wisdom, and spirituality.

The third pillar, *positive groups, communities, and cultures*, seeks to foster a positive social ecology. This includes healthy families, communal neighborhoods, effective schools, socially responsible media, and civil dialogue.

Will psychology have a more positive mission in this century? Without slighting the need to repair damage and cure disease, positive psychology’s proponents hope so. With *American Psychologist* and *British Psychologist* special issues devoted to positive psychology; with many new books; with networked scientists working in worldwide research groups; and with prizes, research awards, summer institutes, and a graduate program promoting positive psychology scholarship, these psychologists have reason to be positive.

positive psychology the scientific study of optimal human functioning; aims to discover and promote strengths and virtues that enable individuals and communities to thrive.

BLINDNESS TO ONE’S OWN INCOMPETENCE

Ironically, people often are most overconfident when most incompetent. That, say some researchers, is because it often takes competence to recognize competence (Kruger & Dunning, 1999). They found that most students scoring at the low end of grammar and logic tests believed they had scored in the top half. If you do not know what good grammar is, you may be unaware that your grammar is poor. This “ignorance of one’s own incompetence” phenomenon has a parallel, as I can confirm, in hard-of-hearing people’s difficulty recognizing their own hearing loss. We’re not so much “in denial” as we are simply unaware of what we don’t hear. If I fail to hear my friend calling my name, the friend notices my inattention. But for me it’s a nonevent. I hear what I hear—which, to me, seems pretty normal.

The difficulty in recognizing one’s own incompetence helps explain why so many low-scoring students are dumbfounded after doing badly on a test. If you don’t know all the Scrabble word possibilities you’ve overlooked, you may feel pretty smart—until someone points them out. As experiments that re-create this phenomenon have demonstrated, our ignorance of what we don’t know helps sustain our confidence in our own abilities (Caputo & Dunning, 2005). Once part of our self-concept, our self-assessments also influence how we perceive our performance. Thinking we’re good at something drives how we perceive ourselves doing (Critcher & Dunning, 2009).

“The living-room [Scrabble] player is lucky. . . . He has no idea how miserably he fails with almost every turn, how many possible words or optimal plays slip by unnoticed.” -STEFAN FATSIS, *WORD FREAK*, 2001

DOONESBURY

© 1986 by G. B. Trudeau. Universal Press Syndicate.

To judge one’s competence and predict one’s future performance, it pays to invite others’ assessments (Dunning, 2006). Based on studies in which both individuals and their acquaintances predict their future, we can hazard some advice: If you’re an AP[®] psychology student preparing for the exam, and you want to predict how well you will do, don’t rate yourself—ask your teacher for a candid evaluation. If you’re a Naval officer and need to assess your leadership ability—don’t rate yourself, ask your fellow officers. And if you’re in love and want to predict whether it will last, don’t listen to your heart—ask your friends.

Assessing Behavior in Situations

59-2 How do social-cognitive researchers explore behavior, and what criticism have they faced?

Social-cognitive psychologists explore how people interact with situations. To predict behavior, they often observe behavior in realistic situations.

Assessing behavior in situations

Reality TV shows, such as Donald Trump's *The Apprentice*, may take "show me" job interviews to the extreme, but they do illustrate a valid point. Seeing how a potential employee behaves in a job-relevant situation helps predict job performance.

AP Photo/Jennifer Szymaszek

One ambitious example was the U.S. Army's World War II strategy for assessing candidates for spy missions. Rather than using paper-and-pencil tests, Army psychologists subjected the candidates to simulated undercover conditions. They tested their ability to handle stress, solve problems, maintain leadership, and withstand intense interrogation without blowing their cover. Although time-consuming and expensive, this assessment of behavior in a realistic situation helped predict later success on actual spy missions (OSS Assessment Staff, 1948). Modern studies indicate that assessment

center exercises are more revealing of visible dimensions, such as communication ability, than others, such as inner achievement drive (Bowler & Woehr, 2006).

Military and educational organizations and many Fortune 500 companies are adopting assessment center strategies (Bray et al., 1991, 1997; Eurich et al., 2009). AT&T has observed prospective managers doing simulated managerial work. Student teachers are observed and evaluated several times during the term they spend in your school. Many colleges assess students' potential via internships and student teaching and assess potential faculty members' teaching abilities by observing them teach. Armies assess their soldiers by observing them during military exercises. Most American cities with populations of 50,000 or more have used assessment centers in evaluating police officers and firefighters (Lowry, 1997).

These procedures exploit the principle that the best means of predicting future behavior is neither a personality test nor an interviewer's intuition. Rather, it is *the person's past behavior patterns in similar situations* (Mischel, 1981; Ouellette & Wood, 1998; Schmidt & Hunter, 1998). As long as the situation and the person remain much the same, the best predictor of future job performance is past job performance; the best predictor of future grades is past grades; the best predictor of future aggressiveness is past aggressiveness; the best predictor of drug use in young adulthood is drug use in high school. If you can't check the person's past behavior, the next-best thing is to create an assessment situation that simulates the task so you can see how the person handles it (Lievens et al., 2009; Meriac et al., 2008).

FYI

A *New York Times* analysis of 100 rampage murders over the last half-century revealed that 55 of the killers had regularly exploded in anger and 63 had threatened violence (Goodstein & Glaberson, 2000). Most didn't, out of the blue, "just snap."

AP® Exam Tip

Tables 59.1 and 59.2 summarize a whole unit's worth of information. Study them well to be clear on the distinctions separating the major approaches to personality.

Evaluating Social-Cognitive Theories

Social-cognitive theories of personality sensitize researchers to how situations affect, and are affected by, individuals. More than other personality theories, they build from psychological research on learning and cognition. (See **TABLE 59.1** for a comparison of personality theories.)

Critics charge that social-cognitive theories focus so much on the situation that they fail to appreciate the person's inner traits. Where is the person in this view of personality, ask the dissenters, and where are human emotions? True, the situation does guide our behavior. But, say the critics, in many instances our unconscious motives, our emotions, and our pervasive traits shine through. Personality traits have been shown to predict behavior at work, love, and play. Our biologically influenced traits really do matter. Consider Percy Ray Pridgen and Charles Gill. Each faced the same situation: They had jointly won a \$90 million lottery jackpot (Harriston, 1993). When Pridgen learned of the winning numbers, he began trembling uncontrollably, huddled with a friend behind a bathroom door while confirming the win, then sobbed. When Gill heard the news, he told his wife and then went to sleep.

* * *

As we have seen, researchers investigate personality using various methods that serve differing purposes. For a synopsis and comparison of these methods, see **TABLE 59.2**.

Table 59.1 Comparing the Major Personality Theories

Personality Theory	Key Proponents	Assumptions	View of Personality
<i>Psychoanalytic</i>	Freud	Emotional disorders spring from unconscious dynamics, such as unresolved sexual and other childhood conflicts, and fixation at various developmental stages. Defense mechanisms fend off anxiety.	Personality consists of pleasure-seeking impulses (the id), a reality-oriented executive (the ego), and an internalized set of ideals (the superego).
<i>Psychodynamic</i>	Adler, Horney, Jung	The unconscious and conscious minds interact. Childhood experiences and defense mechanisms are important.	The dynamic interplay of conscious and unconscious motives and conflicts shape our personality.
<i>Humanistic</i>	Rogers, Maslow	Rather than examining the struggles of sick people, it's better to focus on the ways people strive for self-realization.	If our basic human needs are met, people will strive toward self-actualization. In a climate of unconditional positive regard, we can develop self-awareness and a more realistic and positive self-concept.
<i>Trait</i>	Allport, Eysenck, McCrae, Costa	We have certain stable and enduring characteristics, influenced by genetic predispositions.	Scientific study of traits has isolated important dimensions of personality, such as the Big Five traits (conscientiousness, agreeableness, neuroticism, openness, and extraversion).
<i>Social-Cognitive</i>	Bandura	Our traits and the social context interact to produce our behaviors.	Conditioning and observational learning interact with cognition to create behavior patterns.

Table 59.2 Comparing Research Methods to Investigate Personality

Research Method	Description	Perspectives Incorporating This Method	Benefits	Weaknesses
<i>Case study</i>	In-depth study of one individual.	Psychoanalytic, humanistic	Less expensive than other methods.	May not generalize to the larger population.
<i>Survey</i>	Systematic questioning of a random sample of the population.	Trait, social-cognitive, positive psychology	Results tend to be reliable and can be generalized to the larger population.	May be expensive; correlational findings.
<i>Projective tests</i> (e.g., TAT and Rorschach)	Ambiguous stimuli designed to trigger projection of inner dynamics.	Psychodynamic	Designed to get beneath the conscious surface of a person's self-understanding; may be a good ice-breaker.	Results have weak validity and reliability.
<i>Personality inventories</i> , such as the MMPI (to determine scores on Big Five personality factors)	Objectively scored groups of questions designed to identify personality dispositions.	Trait	Generally reliable and empirically validated.	Explore limited number of traits.
<i>Observation</i>	Studying how individuals react in different situations.	Social-cognitive	Allows researchers to study the effects of environmental factors on the way an individual's personality is expressed.	Results may not apply to the larger population.
<i>Experimentation</i>	Manipulate variables, with random assignment to conditions.	Social-cognitive	Discerns cause and effect.	Some variables cannot feasibly or ethically be manipulated.

Before You Move On

▶ ASK YOURSELF

Are you a pessimist? Do you tend to have low expectations and to attribute bad events to your inability or to circumstances beyond your control? Or are you an optimist, perhaps even being excessively optimistic at times? How has either tendency influenced your choices thus far?

▶ TEST YOURSELF

What do social-cognitive psychologists consider the best way to predict a person's future behavior?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

self in contemporary psychology, assumed to be the center of personality, the organizer of our thoughts, feelings, and actions.

spotlight effect overestimating others' noticing and evaluating our appearance, performance, and blunders (as if we presume a spotlight shines on us).

Exploring the Self

59-3 Why has psychology generated so much research on the self? How important is self-esteem to psychology and to human well-being?

Psychology's concern with people's sense of self dates back at least to William James, who devoted more than 100 pages of his 1890 *Principles of Psychology* to the topic. By 1943, Gordon Allport lamented that the self had become "lost to view." Although humanistic psychology's later emphasis on the self did not instigate much scientific research, it did help renew the concept of self and keep it alive. Now, more than a century after James, the self is one of Western psychology's most vigorously researched topics. Every year, new studies galore appear on self-esteem, self-disclosure, self-awareness, self-schemas, self-monitoring, and so forth. Even neuroscientists have searched for self, by identifying a central frontal lobe region that activates when people respond to self-reflective questions about their traits and dispositions (Damasio, 2010; Mitchell, 2009). Underlying this research is an assumption that the **self**, as organizer of our thoughts, feelings, and actions, is the center of personality.

One example of thinking about self is the concept of possible selves put forth by Hazel Markus and her colleagues (Cross & Markus, 1991; Markus & Nurius, 1986). Your possible selves include your visions of the self you dream of becoming—the rich self, the successful self, the loved and admired self. They also include the self you fear becoming—the unemployed self, the lonely self, the academically failed self. Such possible selves motivate us by laying out specific goals and calling forth the energy to work toward them. University of Michigan students in a combined undergraduate/medical school program earn higher grades if they undergo the program with a clear vision of themselves as successful doctors. Dreams do often give birth to achievements.

Our self-focused perspective may motivate us, but it can also lead us to presume too readily that others are noticing and evaluating us. Thomas Gilovich (1996) demonstrated this **spotlight effect** by having individual Cornell University students don Barry Manilow T-shirts before entering a room with other students. Feeling self-conscious (even in the 1990s, singer Barry Manilow was not cool), the T-shirt wearers guessed that nearly half their peers would take note of the shirt as they walked in. In reality, only 23 percent did. This absence of attention applies not only to our dorky clothes and bad hair but also to our nervousness, irritation, or attraction: Fewer

Neil Collins/Alamy

Possible selves By giving them a chance to try out many possible selves, pretend games offer children important opportunities to develop emotionally, socially, and cognitively. This young girl may or may not grow up to be a physician, but playing adult roles will certainly bear fruit in terms of an expanded vision of what she might become.

"The first step to better times is to imagine them." -CHINESE FORTUNE COOKIE

people notice than we presume (Gilovich & Savitsky, 1999). Others are also less aware than we suppose of the variability—the ups and downs—of our appearance and performance (Gilovich et al., 2002). Even after a blunder (setting off a library alarm, showing up in the wrong clothes), we stick out like a sore thumb less than we imagine (Savitsky et al., 2001). Knowing about the spotlight effect can be empowering. Help public speakers to understand that their natural nervousness is not so apparent to their audience and their speaking performance improves (Savitsky & Gilovich, 2003).

The Benefits of Self-Esteem

How we feel about ourselves is also important. High **self-esteem**—a feeling of self-worth—pays dividends. So does **self-efficacy**, our sense of competence on a task. People who feel good about themselves (who strongly agree with self-affirming questionnaire statements such as, “I am fun to be with”) have fewer sleepless nights. They succumb less easily to pressures to conform. They are more persistent at difficult tasks; they are less shy, anxious, and lonely. And they are just plain happier (Greenberg, 2008; Orth et al., 2008, 2009). If feeling bad, they think they deserve better and thus make more effort to repair their mood (Wood et al., 2009).

But is high self-esteem the horse or the cart? Is it really “the armor that protects kids” from life’s problems (McKay, 2000)? Some psychologists have their doubts (Baumeister, 2006; Dawes, 1994; Leary, 1999; Seligman, 1994, 2002). Children’s academic self-efficacy—their confidence that they can do well in a subject—predicts school achievement. But general self-image does not (Marsh & Craven, 2006; Swann et al., 2007; Trautwein et al., 2006). Maybe self-esteem simply reflects reality. Maybe feeling good *follows* doing well. Maybe it’s a side effect of meeting challenges and surmounting difficulties. Maybe self-esteem is a gauge that reads out the state of our relationships with others. If so, isn’t pushing the gauge artificially higher (“You are special”) akin to forcing a car’s low fuel gauge to display “full”? And if problems and failures cause low self-esteem, won’t the best boost therefore come not from our repeatedly telling children how wonderful they are but from their own effective coping and hard-won achievements?

However, experiments do reveal an *effect* of low self-esteem. Temporarily deflate people’s self-image (say, by telling them they did poorly on an aptitude test or by disparaging their personality) and they will be more likely to disparage others or to express heightened racial prejudice (Ybarra, 1999). Those who are negative about themselves also tend to be oversensitive and judgmental (Baumgardner et al., 1989; Pelham, 1993). In experiments, people made to feel insecure often become excessively critical, as if to impress others with their own brilliance (Amabile, 1983). Such findings are consistent with Maslow’s and Rogers’ presumptions that a healthy self-image pays dividends. Accept yourself and you’ll find it easier to accept others. Disparage yourself and you will be prone to the floccinaucinihilipilification¹ of others. Said more simply, some “love their neighbors as themselves”; others loathe their neighbors as themselves. People who are down on themselves tend to be down on other things and people.

¹ I couldn’t resist throwing that in. But don’t worry, you won’t be tested on floccinaucinihilipilification, which is the act of estimating something as worthless (and was the longest nontechnical word in the first edition of the *Oxford English Dictionary*).

AP® Exam Tip

It’s important to note the difference between *self-esteem* and *self-efficacy*. Although your feeling of self-worth might be related to your beliefs about how competent you are, they are not the same thing.

“When kids increase in self-control, their grades go up later. But when kids increase their self-esteem, there is no effect on their grades.” -ANGELA DUCKWORTH, IN *CHARACTER INTERVIEW*, 2009

self-esteem one’s feelings of high or low self-worth.

self-efficacy one’s sense of competence and effectiveness.

Self-Serving Bias

59-4 What evidence reveals self-serving bias, and how do defensive and secure self-esteem differ?

Carl Rogers (1958) once objected to the religious doctrine that humanity's problems arise from excessive self-love, or pride. He noted that most people he had known "despise themselves, regard themselves as worthless and unlovable." Mark Twain had a similar idea: "No man, deep down in the privacy of his heart, has any considerable respect for himself."

Actually, most of us have a good reputation with ourselves. In studies of self-esteem, even those who score relatively low respond in the midrange of possible scores. (A low-self-esteem person responds to statements such as "I have good ideas" with qualifying adjectives such as *somewhat* or *sometimes*.) Moreover, one of psychology's most provocative and firmly established recent conclusions concerns our potent **self-serving bias**—our readiness to perceive ourselves favorably (Mezulis et al., 2004; Myers, 2008). Consider:

People accept more responsibility for good deeds than for bad, and for successes than for failures. Athletes often privately credit their victories to their own prowess, and their losses to bad breaks, lousy officiating, or the other team's exceptional performance. After receiving poor grades on a test, most students in a half-dozen studies criticized the test, not themselves. On insurance forms, drivers have explained accidents in such words as: "An invisible car came out of nowhere, struck my car, and vanished." "As I reached an intersection, a hedge sprang up, obscuring my vision, and I did not see the other car." "A pedestrian hit me and went under my car." The question "What have I done to deserve this?" is one we usually ask of our troubles, not our successes—those, we assume we deserve.

Most people see themselves as better than average. This is true for nearly any commonplace behavior that is subjectively assessed and socially desirable:

- In national surveys, most business executives say they are more ethical than their average counterpart.
- In several studies, 90 percent of business managers and more than 90 percent of college professors rated their performance as superior to that of their average peer.
- In the National Survey of Families and Households, 49 percent of men said they provided half or more of the child care, though only 31 percent of their wives or partners saw things that way (Galinsky et al., 2008).
- In Australia, 86 percent of people rate their job performance as above average, and only 1 percent as below average.

The phenomenon, which reflects the overestimation of self rather than the underestimation of others (Epley & Dunning, 2000), is less striking in Asia, where people value modesty (Falk et al., 2009; Heine & Hamamura, 2007). Yet self-serving biases have been observed worldwide: among Dutch, Australian, and Chinese students; Japanese drivers; Indian Hindus; and French people of most walks of life. In every one of 53 countries surveyed, people expressed self-esteem above the midpoint of the most widely used scale (Schmitt & Allik, 2005).

Ironically, people even see themselves as more immune than others to self-serving bias (Pronin, 2007). The world, it seems, is Garrison Keillor's fictional Lake Wobegon writ

self-serving bias a readiness to perceive oneself favorably.

"If you are like most people, then like most people, you don't know you're like most people. Science has given us a lot of facts about the average person, and one of the most reliable of these facts is the average person doesn't see herself as average."

-DANIEL GILBERT, *STUMBLING ON HAPPINESS*, 2006

PEANUTS

PEANUTS reprinted by permission of United Feature Syndicate, Inc.

large—a place where “all the women are strong, all the men are good-looking, and all the children are above average.” And so are the pets. Three in four owners believe their pet is smarter than average (Nier, 2004).

Threatened egotism, more than low self-esteem, it seems, predisposes aggression. This is true even in childhood, when the recipe for frequent fighting mixes high self-esteem with social rejection. The most aggressive children tend to have high self-regard that gets punctured by other kids’ dislike (van Boxtel et al., 2004).

An adolescent or adult whose swelled head is deflated by insults is potentially dangerous. Finding their self-esteem threatened, people with large egos may react violently. “Aryan pride” fueled Nazi atrocities. “These biases have the effect of making wars more likely to begin and more difficult to end,” noted Daniel Kahneman and Jonathan Renshon (2007).

Brad Bushman and Roy Baumeister (1998; Bushman et al., 2009) experimented with what they call the “dark side of high self-esteem.” They had 540 undergraduate volunteers write a brief essay, in response to which another supposed student gave them either praise (“Great essay!”) or stinging criticism (“One of the worst essays I have read!”). Then the essay writers played a reaction-time game against the other student. After wins, they could assault their opponent with noise of any intensity for any duration.

Can you anticipate the result? After criticism, those with inflated high self-esteem were “exceptionally aggressive.” They delivered three times the auditory torture of those with normal self-esteem. “Encouraging people to feel good about themselves when they haven’t earned it” poses problems, Baumeister (2001) concluded. “Conceited, self-important individuals turn nasty toward those who puncture their bubbles of self-love.”

Are self-serving perceptions on the rise in North America? Some researchers believe they are. From 1980 to 2007, popular song lyrics became more self-focused (DeWall et al., 2011). From 1988 to 2008, self-esteem scores increased among American collegians, high schoolers, and especially middle school students (Gentile et al., 2010). On one prominent self-esteem inventory on which 40 is the highest possible self-esteem score, 51 percent of 2008 collegians scored 35 or more.

Narcissism—excessive self-love and self-absorption—is also rising, reports psychologist Jean Twenge (2006; Twenge & Foster, 2010). After tracking self-importance across the last several decades, Twenge found that what she calls *Generation Me* (born in the 1980s and 1990s) is expressing more narcissism by agreeing more often with statements such as, “If I ruled the world, it would be a better place,” or “I think I am a special person.” Agreement with such narcissistic statements correlates with materialism, the desire to be famous, inflated expectations, more hookups with fewer committed relationships, more gambling, and more cheating, all of which have been increasing as narcissism has increased.

Some critics of the concept of self-serving bias claim that it overlooks those who feel worthless and unlovable: If self-serving bias prevails, why do so many people disparage themselves? For four reasons:

- Self-directed put-downs can be *subtly strategic*: They elicit reassuring strokes. Saying “No one likes me” may at least elicit “But not everyone has met you!”
- Before an important event, such as a game or a test, self-disparaging comments *prepare us for possible failure*. The coach who extols the superior strength of the upcoming opponent makes a loss understandable, a victory noteworthy.
- A self-disparaging “How could I have been so stupid!” can help us *learn from our mistakes*.

“The enthusiastic claims of the self-esteem movement mostly range from fantasy to hogwash. The effects of self-esteem are small, limited, and not all good.”
—ROY BAUMEISTER (1996)

narcissism excessive self-love and self-absorption.

- Self-disparagement frequently *pertains to one's old self*. Asked to remember their really bad behaviors, people recall things from long ago; good behaviors more easily come to mind from their recent past (Escobedo & Adolphs, 2010). People are much more critical of their distant past selves than of their current selves—even when they have not changed (Wilson & Ross, 2001). “At 18, I was a jerk; today I’m more sensitive.” In their own eyes, chumps yesterday, champs today.

Even so, it’s true: All of us some of the time, and some of us much of the time, do feel inferior—especially when we compare ourselves with those who are a step or two higher on the ladder of status, looks, income, or ability. The deeper and more frequently we have such feelings, the more unhappy, even depressed, we are. But for most people, thinking has a naturally positive bias.

While recognizing the dark side of self-serving bias and self-esteem, some researchers prefer isolating the effects of two types of self-esteem—defensive and secure (Kernis, 2003; Lambird & Mann, 2006; Ryan & Deci, 2004). *Defensive self-esteem* is fragile. It focuses on sustaining itself, which makes failures and criticism feel threatening. Such egotism exposes one to perceived threats, which feed anger and disorder, note Jennifer Crocker and Lora Park (2004).

Secure self-esteem is less fragile, because it is less contingent on external evaluations. To feel accepted for who we are, and not for our looks, wealth, or acclaim, relieves pressures to succeed and enables us to focus beyond ourselves. By losing ourselves in relationships and purposes larger than self, Crocker and Park add, we may achieve a more secure self-esteem and greater quality of life.

“If you compare yourself with others, you may become vain and bitter; for always there will be greater and lesser persons than yourself.” -MAX EHRMANN, “DESIDERATA,” 1927

Before You Move On

▶ ASK YOURSELF

What possible selves do you dream of—or fear—becoming? To what extent do these imagined selves motivate you now?

▶ TEST YOURSELF

In a 1997 Gallup poll, White Americans estimated 44 percent of their fellow White Americans to be high in prejudice (scoring them 5 or higher on a 10-point scale). How many rated themselves similarly high in prejudice? Just 14 percent. What phenomenon does this illustrate?

Answers to the Test Yourself questions can be found in Appendix E at the end of the book.

Culture and the Self

59-5 How do individualist and collectivist cultures influence people?

Imagine that someone were to rip away your social connections, making you a solitary refugee in a foreign land. How much of your identity would remain intact?

If as our solitary traveler you pride yourself on your **individualism**, a great deal of your identity would remain intact—the very core of your being, the sense of “me,” the awareness of your personal convictions and values. Individualists (often people from North America, Western Europe, Australia, or New Zealand) give relatively greater priority to personal goals and define their identity mostly in terms of personal attributes (Schimmack et al., 2005). They strive for personal control and individual achievement. In American culture, with its relatively big *I* and small *we*, 85 percent of people have agreed that it is possible “to pretty much be who you want to be” (Sampson, 2000).

individualism giving priority to one’s own goals over group goals and defining one’s identity in terms of personal attributes rather than group identifications.

Individualists share the human need to belong. They join groups. But they are less focused on group harmony and doing their duty to the group (Brewer & Chen, 2007). And being more self-contained, they more easily move in and out of social groups. They feel relatively free to switch places of worship, switch jobs, or even leave their extended families and migrate to a new place. Marriage is often for as long as they both shall love.

If set adrift in a foreign land as a **collectivist**, you might experience a greater loss of identity. Cut off from family, groups, and loyal friends, you would lose the connections that have defined who you are. In a collectivist culture, group identifications provide a sense of belonging, a set of values, a network of caring individuals, an assurance of security. In return, collectivists have deeper, more stable attachments to their groups—their family, clan, or company. In South Korea, for example, people place less value on expressing a consistent, unique self-concept, and more on tradition and shared practices (Choi & Choi, 2002).

Valuing communal solidarity means placing a premium on preserving group spirit and ensuring that others never lose face. What people say reflects not only what they feel (their inner attitudes) but what they presume others feel (Kashima et al., 1992). Avoiding direct confrontation, blunt honesty, and uncomfortable topics, collectivists often defer to others' wishes and display a polite, self-effacing humility (Markus & Kitayama, 1991). Elders and superiors receive respect, and duty to family may trump personal career and mate preferences (Zhang & Kline, 2009). In new groups, people may be shy and more easily embarrassed than their individualist counterparts (Singelis et al., 1995, 1999). Compared with Westerners, people in Japanese and Chinese cultures, for example, exhibit greater shyness toward strangers and greater concern for social harmony and loyalty (Bond, 1988; Cheek & Melchior, 1990; Triandis, 1994). When the priority is “we,” not “me,” that individualized latte—“decaf, single shot, skinny, extra hot”—that feels so good to a North American in a coffee shop might sound more like a selfish demand in Seoul (Kim & Markus, 1999).

To be sure, there is diversity within cultures. Even in the most individualist countries, some people manifest collectivist values. Within many countries, there are also distinct cultures related to one's religion, economic status, and region (Cohen, 2009). And in collectivist Japan, a spirit of individualism marks the “northern frontier” island of Hokkaido (Kitayama et al., 2006). But in general, people (especially men) in competitive, individualist cultures have more personal freedom, are less geographically bound to their families, enjoy more privacy, and take more pride in personal achievements (**TABLE 59.3** on the next page).

Collectivist culture Although the United States is largely individualist, many cultural subgroups remain collectivist. This is true for many Alaska Natives, who demonstrate respect for tribal elders, and whose identity springs largely from their group affiliations.

“One needs to cultivate the spirit of sacrificing the *little me* to achieve the benefits of the *big me*.” -CHINESE SAYING

Considerate collectivists Japan's collectivist values, including duty to others and social harmony, were on display after the devastating 2011 earthquake and tsunami. Virtually no looting was reported, and residents remained calm and orderly, as shown here while waiting for drinking water.

collectivism giving priority to the goals of one's group (often one's extended family or work group) and defining one's identity accordingly.

Table 59.3 Value Contrasts Between Individualism and Collectivism

Concept	Individualism	Collectivism
<i>Self</i>	Independent (identity from individual traits)	Interdependent (identity from belonging)
<i>Life task</i>	Discover and express one's uniqueness	Maintain connections, fit in, perform role
<i>What matters</i>	Me—personal achievement and fulfillment; rights and liberties; self-esteem	Us—group goals and solidarity; social responsibilities and relationships; family duty
<i>Coping method</i>	Change reality	Accommodate to reality
<i>Morality</i>	Defined by individuals (self-based)	Defined by social networks (duty-based)
<i>Relationships</i>	Many, often temporary or casual; confrontation acceptable	Few, close and enduring; harmony valued
<i>Attributing behavior</i>	Behavior reflects one's personality and attitudes	Behavior reflects social norms and roles
